The trauma patient is initially triaged by EMS along with a physician by protocol or over radio communication, which then alerts the trauma team of the mechanism and suspected injuries. The trauma team prepares accordingly to perform a number of procedures starting always with the ABCs. In hemodynamically unstable patients, focused abdominal sonography for trauma (FAST) is utilized in the trauma bay to detect hemoperitoneum (Fig. 28.1). A positive initial FAST (~80% accuracy) in an unstable patient mandates immediate exploration. Diagnostic peritoneal lavage (DPL) has largely been supplanted by FAST and CT due to its invasive nature and lack of specificity for organ injury. However, DPL is sensitive for hemoperitoneum and may be appropriate in the unstable patient with a negative or nondiagnostic FAST. Depending on the injuries suspected or identified, the disposition of the patient will be to the radiology suite for further imaging, the operating room (OR) for definitive repairs, or the ICU for further resuscitation and monitoring. Many hemodynamically normal patients following substantial blunt injury will complete CT from head to midthigh, including the neck, chest, abdomen, and pelvis, although individual institutions and patient management algorithms exist on imaging strategies. Imaging of the abdominal and pelvic cavities has multiple goals: identify solid organ injury and severity, active arterial extravasation, vascular injury, and the presence of free air or free fluid in the pelvis. For these reasons, CT is obtained in an arterial phase and a venous phase.

Abdominal solid organs include the liver, spleen, pancreas, and kidneys. Over the last two decades, a marked paradigm shift toward nonoperative management of most solid organ injuries in hemodynamically stable patients has occurred (with the pancreas as the major exception).[2] Nonoperative management of solid organ injury at a minimum involves observation with frequent abdominal exams and serial hemoglobin checks. A major reason for the success of nonoperative management of blunt solid organ injury is the infrequent occurrence of hollow viscus injury. The Eastern Association for the Surgery of Trauma (EAST) multicenter study documented small bowel injury in only 0.3% of 275,000 patients.[3,4] On the other hand, the authors also documented that delay of only 8 hours in the treatment of an intestinal perforation increased mortality fourfold (from 2% to 9%).[3,4] Thus, we must be aware of clinical situations in which hollow viscus injury is likely, as its diagnosis remains difficult. Associated injuries on physical exam include seat belt or tire marks across the chest or abdomen, abdominal wall contusion, or truncal degloving injury. A Chance fracture (lumbar flexion/compression fracture) secondary to a lap belt has associated intestinal injury in as many as 25%-30% of patients. CT (with or without oral contrast) is a poor predictor of small bowel injury with a false-negative rate of 15%-30%. Findings suggestive of small bowel injury on CT include free fluid, free air, and bowel wall thickening. Eighty-four percent of patients with free fluid in the abdomen after blunt trauma on CT without solid organ injury have an intestinal injury or mesenteric injury, but only 30% of those have full thickness perforation. Moreover, a negative CT scan does not exclude intestinal perforation. Thus, when there is free fluid in the abdomen without solid organ injury, intestinal/mesenteric injury is present until proven otherwise by surgical exploration. Nance et al.[5] demonstrated that increasing number of
FIGURE 28.1. Focused abdominal sonography for trauma. (Redrawn from Rozycki GS, Ochsner MG, Schmidt JA, et al. A prospective study of surgeon-performed ultrasound as the primary adjuvant modality for injured patient assessment. *J Trauma*. 1995;39:493.)

solid organ injuries increased the likelihood of hollow viscus injury (most commonly small intestine). A single solid organ injury (spleen, liver, pancreas, or kidney) seen on CT had an associated hollow viscus injury in 7.3%, irrespective of the grade of solid organ injury. With additive solid organ injury, the incidence of hollow viscus injury increased; 15.4% with two solid organ injuries and 34.4% with three solid organ injuries. As mentioned, delay to operative intervention for hollow viscus perforation leads to greater mortality, sepsis, and wound dehiscence. Early exploration with control of intestinal contamination reduces morbidity and mortality considerably. The stomach and colon/rectum are injured less commonly than small bowel in blunt trauma, but require prompt diagnosis and exploration as well.

PENETRATING TRAUMA

Penetrating trauma mechanisms include GSWs, knife or SWs, and less commonly, impalement. The likelihood of injury requiring operative repair is higher for abdominal GSW (80%-95%) than for SWs (25%-33%), and the management algorithms differ. Abdominal organs commonly injured with penetrating wounds include the small bowel, liver, stomach, colon, and vascular structures. Any penetrating wound from the nipple line anteriorly (4th intercostal space) or scapular tip posteriorly to the buttocks inferiorly can produce an intraperitoneal injury.

GUNSHOT WOUNDS

In most instances, patients sustaining GSWs to the abdomen require laparotomy as their diagnostic and therapeutic modality, because of the high incidence of injury requiring repair.

PHYSICAL EXAMINATION

Carefully inspect the patient to avoid missing wounds. Bullets that do not strike bone or other solid objects generally travel in a straight line. Trajectory determination is the key to injury identification. Based on your estimate of the path of the bullet(s), determine which body cavities were violated and if so, which structures are at greatest risk of injury. With multiple GSWs, multiple cavity violation, this may be difficult. Nonetheless, hemodynamically unstable patients with abdominal GSWs should not have extensive evaluation before laparotomy. Carefully examine the patient, paying special attention to the body creases, perineum, ears, eyes, and rectum. Bullet wounds should be counted and assessed. An odd number of wounds suggests a retained bullet; elongated wounds without penetration typify graze injuries. Do not describe bullet wounds as entry or exit wounds; physical examination findings are unreliable in this regard. Describe in detail all missile wounds: site, size and configuration, presence of stippling or powder burns. Palpate the abdomen for signs of tenderness. A neurologic examination should be performed to exclude spinal cord injury.

Plain radiographs are essential in the determination of bullet trajectory. This is facilitated by marking cutaneous bullet wounds with radiopaque markers. In addition, pneumoperitoneum, spinal fractures, pneumothorax, or hemothorax may be found. CT has a limited role in the evaluation of patients with abdominal GSW. However, in hemodynamically stable patients in whom peritoneal penetration is questioned, the extraperitoneal path may be documented on CT. On the other hand, high-velocity weapons can produce full-thickness bowel perforation or thrombosis of major vessels without peritoneal penetration. If any doubt exists, laparotomy is mandatory. In addition, selected patients with right upper quadrant GSW isolated to the liver may be candidates for nonoperative management. Similarly, FAST has a limited role in the evaluation of patients with abdominal GSW. It may be useful in operative planning of hypotensive patients with multi-cavity wounds or documenting cardiac effusion/tamponade. Laparoscopy can be useful in the assessment of peritoneal violation or diaphragmatic injury in hemodynamically stable patients with tangential GSW, particularly in the left upper abdomen.

STAB WOUNDS

Indications for immediate exploration of abdominal SWs include hypotension, peritoneal signs, and evisceration. If these signs are not present, a selective management approach is justified. Although several articles have advocated observation of the stable patient with omental evisceration after a SW, we believe the incidence of visceral injury makes routine exploration the safest approach in these patients as well.[6,7] Anterior SWs refer to those in front of the anterior axillary line. One-third of SWs fail to violate the peritoneal cavity. Thus, two-thirds of anterior SWs enter the peritoneal cavity. Of these, less than half produce visceral injury, which requires operative repair. Thus, of patients with anterior SWs, only one-fourth to one-third require laparotomy. The clinical challenge is to safely select patients who require laparotomy and avoid nontherapeutic laparotomy in patients without major injury. Abdominal organs are at risk with thoracic wounds inferior to the nipple line anteriorly (4th intercostal space) and scapular tip posteriorly (Fig. 28.2). Flank SWs lie between the anterior and posterior axillary lines from the scapular tip to the iliac crest (Fig. 28.2b). Back (posterior) SWs are posterior to the posterior axillary line. Flank and posterior SWs have a lower incidence of visceral injury than anterior SWs (Fig. 28.2a).

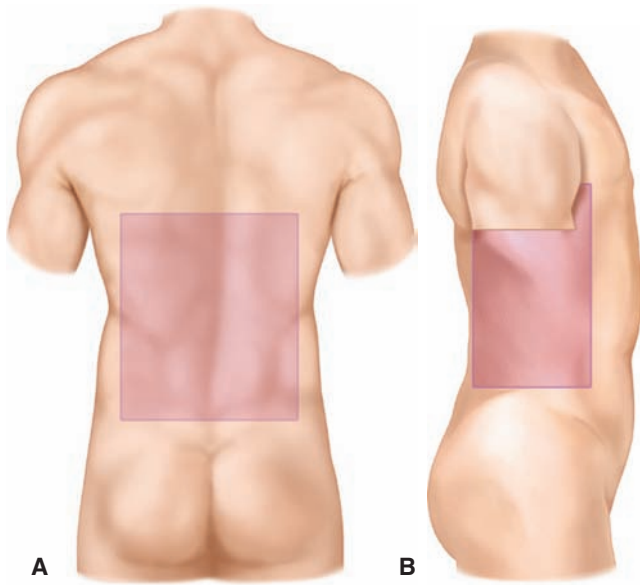
TRAUMA


FIGURE 28.2. **A.** The posterior zone is from scapular tip to iliac crest and between each posterior axillary line. **B.** The flank zone is from 4th intercostal space to iliac crest between anterior and posterior axillary lines. (Redrawn from Boyle EM Jr, Maier RV, Salazar JD, et al. Diagnosis of injuries after stab wounds to the back and flank. *J Trauma*. 1997;42:261.)

Selective management (serial examination) can be used to detect the development of peritoneal signs in a hemodynamically stable patient. The same surgeon should repeat abdominal examinations documenting subtle change in abdominal findings, temperature, pulse rate, and white blood count. With this evaluation method, the delayed laparotomy rate is 40% with <3% mortality.[6-9]

Local wound exploration can be performed in the trauma resuscitation area on patients without indications for operation after anterior abdominal stab. The skin is prepared and anesthetized and the original wound is enlarged. Exploration is considered positive if fascial penetration is found. Most series define this as violation of the anterior fascia, as assessment of posterior fascial penetration is more difficult and less reliable.[8,9] Patients with positive local wound exploration progress to laparotomy.

CT scan with triple contrast (oral, IV, and rectal) can be used to evaluate back and flank SW. Although a popular tool in the past, triple-contrast CT is not often utilized nowadays. CT is not helpful in the evaluation of anterior abdominal SWs, especially in thin patients with slight abdominal musculature.

DPL has been used to evaluate abdominal SWs. The criteria for red blood cell (RBC) counts are generally lower than that for patients with blunt injury, but the range for positive results is from 1,000 to 100,000/mm^3.[10,11] Lower threshold values will improve the sensitivity of the modality, but increase the negative or nontherapeutic laparotomy rate.

Shotgun wounds. Close-range shotgun wounds are high-energy injuries. As such, they can result in blast and penetrating abdominal wounds. Shotgun wounds with peritoneal penetration mandate laparotomy. Those delivered from a distance, and thus lower velocity injury, can be evaluated with CT to determine peritoneal penetration by the pellets. The wider the area of scatter by the pellets, the greater the distance from the shotgun to the victim, with less tissue penetration.

Impalement injury. The impaled object is secured in place and removed in the OR under direct visualization with the abdomen open.

THE EXPLORATORY LAPAROTOMY

Refinements in diagnostic capabilities have allowed a more selective application of laparotomy, reducing the number of nontherapeutic laparotomies.

Indications for Exploratory Laparotomy

Laparotomy for trauma is performed on the basis of physical examination findings alone or on the basis of results of further diagnostic tests. Remember that physical examination alone with blunt injury will miss up to 45% of abdominal injuries, generally in patients with altered mental status or distracting injuries. Indications for laparotomy based on physical finding include obvious peritoneal signs on physical examination, hypotension with a distended abdomen on physical examination, abdominal GSW with peritoneal penetration, or abdominal SW with evisceration, hypotension, or peritonitis.

Findings on diagnostic tests, which mandate laparotomy include positive FAST (in the unstable patient), grossly positive DPL or peritoneal aspiration, or findings with any other diagnostic intervention (e.g., chest x-ray with ruptured diaphragm or pneumoperitoneum, abdominal CT, or laparoscopy suggestive of an intra-abdominal injury requiring repair).

An OR appropriately stocked with appropriate anesthetics and nursing and support should be immediately available 24 hours a day. Once the decision is made to operate, the patient must be rapidly transported directly to the OR with appropriate airway support personnel and the trauma team in attendance. Informed consent is obtained from the patient or relative before laparotomy if possible. This is not always possible or practical, depending on the injuries involved and the clinical state of the patient. In such cases, the operation should proceed without delay to obtain consent.

The patient should already have at least two large-bore intravenous lines placed; other intravenous and arterial access can be placed as necessary in the OR. Control of cavitary bleeding should not be delayed by fluid resuscitation; *the primary goal in the hemorrhaging patient is control of the bleeding*. Administer broad-spectrum, gram-negative, and anaerobic antibiotic coverage (e.g., an extended-spectrum penicillin or a third-generation cephalosporin). Attach chest tubes to underwater seal, do not clamp them, during transport and immediately to suction drainage on arrival in the OR. Make certain that anesthesia and the operating team can visualize the drainage systems of the chest tubes to monitor output during the operation.

Place nasogastric or orogastric tubes and a bladder catheter before laparotomy. However, no procedure should be performed in such a way, which delays control of bleeding and contamination. Sequential compression devices can be used for hemodynamically stable patients. Move the patient onto the operating table with appropriate cervical spine and thoracolumbar spine precautions. If the patient is still immobilized on a backboard, log roll the patient and remove the board before beginning the operation. Occult penetrating wounds must be sought before beginning laparotomy. Be certain to check all creases and folds where penetrating injury is likely to be missed.

Prime the infusion system to infuse blood products and "cell-saved blood" quickly via large-bore lines before the

incision releases the tamponade. Ascertain that packed RBCs are in the OR and plasma and platelets are available for the patient with active hemorrhage. Activate the massive transfusion protocol if indicated.

Preparation of the Patient

The patient is shaved only if time allows. The entire anterolateral neck (remove anterior portion of cervical collar and then sandbag to maintain cervical spine immobilization), chest to the table bilaterally, abdomen, groin, and thigh regions (to the knees bilaterally) are prepared and draped in sterile fashion (Fig. 28.3).

CONDUCT OF THE TRAUMA LAPAROTOMY

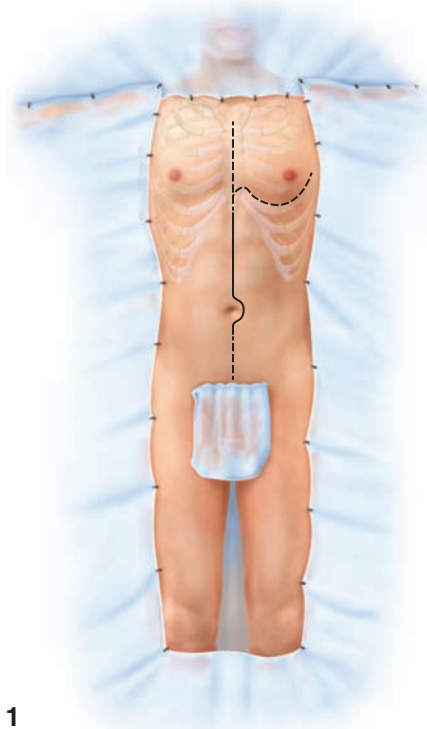
Initial Goals

Stop bleeding and control gastrointestinal contamination. The exploratory laparotomy for trauma is a sequential, consistently conducted, operation. For urgent laparotomy, a generous midline incision is made. Adequate exposure is critical. Self-retaining retractor systems and headlights are useful. Control active bleeding first. Scoop free blood and rapidly pack all four quadrants to control bleeding as a first step. With blunt injury, the likely sources of bleeding are the liver, spleen, and mesentery. Pack the liver and spleen, and quickly clamp the mesenteric bleeders. With penetrating injury, the likely sources of bleeding are the liver, retroperitoneal vascular

1

FIGURE 28.3. Full prep of the trauma patient for laparotomy. (Redrawn from Champion HR, Robbs JV, Trunkey DD. Trauma surgery. In: Dudley H, Carter D, Russell RCG, eds. *Rob and Smith's Operative Surgery*. Boston, MA: Butterworth; 1989:540, Figure 1).

structures, and mesentery. Pack the liver and retroperitoneum, and quickly clamp bleeding mesenteric vessels. If packing does not control a bleeding site, this source of hemorrhage must be controlled as the first priority.

Once active bleeding is stopped, control of gastrointestinal contamination must be achieved next. Quickly control bowel content spillage using Babcock clamps, Allis clamps, a stapler, rapid temporary sutures, or ligatures. Only when hemorrhage and GI contamination are controlled, should the surgeon proceed to full exploration of the abdomen. Systematically explore the entire abdomen, giving priority to areas of ongoing hemorrhage to definitively control bleeding: liver, spleen, stomach, right colon, transverse colon, descending colon, sigmoid colon, rectum, and small bowel, from ligament of Treitz to terminal ileum, carefully inspecting the entire bowel wall and the mesentery. Next, open the lesser sac and explore the pancreas (visualize and palpate). A Kocher maneuver may be needed to visualize the duodenum, with evidence of possible injury. Finally, inspect the left and right hemidiaphragms and retroperitoneum, pelvic structures, including the bladder and rectum. Note the size of any retroperitoneal hematoma. With penetrating injury, exploration should focus on following the path of the weapon or missile. Retroperitoneal violation by a penetrating wound requires exploration of the retroperitoneum. The abdomen may be closed with running nonabsorbable or absorbable monofilament suture (e.g., No. 1 nylon or No. 1 looped slowly absorbable suture). Leave skin open with delayed secondary closure if there is contamination or prolonged hypoperfusion. If gross edema of abdominal contents precludes closure, absorbable mesh, sterile intravenous bags (Bogota bag), or intestinal bags can be used with moist gauze and an impermeable dressing, or a vacuum-assisted closure (VAC) dressing to prevent possible abdominal compartment syndrome (ACS) (see Chapter 6). Recognize the combination of complex injuries and physiologic signs (hypothermia, acidosis, and coagulopathy) that dictate abbreviated laparotomy (damage control).


SPECIFIC ORGAN INJURY

Diaphragmatic Injury

Anatomy and Physiology. The diaphragm is an arched muscular tendinous structure that separates the thorax from the abdomen. It is formed of a central tendon, which receives muscle fibers in a radial fashion. These fibers originate from the xiphoid and sternum anteriorly, the inferior border of the cartilage of the 9th-10th rib, and portions of the tips of the 11th and 12th ribs. Posteriorly, the diaphragm originates from the first and second lumbar vertebrae.

The aorta, thoracic duct, and azygos vein course through the aortic hiatus at the level of the 12th thoracic vertebra. The esophagus and the vagus nerves course through the esophageal hiatus at the level of the tenth thoracic vertebra and the vena cava is the only anatomic structure coursing through the caval hiatus, at the level of the eighth thoracic vertebra (Fig. 28.4).

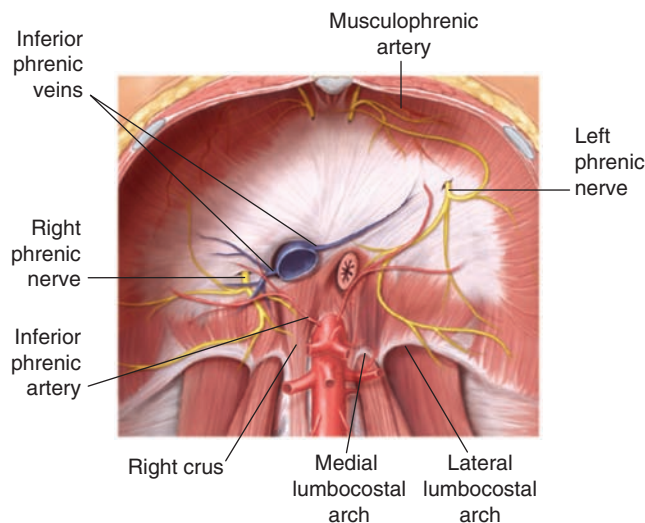
The diaphragm has a fundamental function in the respiratory process, when it flattens, increasing the size of the thoracic cavity, thus creating a tidal volume. To accomplish this function, the diaphragm moves 3–5 cm in either direction. The simultaneous contraction of the abdominal muscles creates a gradient between the abdominal and thoracic cavity. When the patient is in the supine position, the gradient between the abdominal and thoracic pleural cavity fluctuates from 7 to 20 cm of water. During maximal inspiration, this gradient can be higher than 100 cm of water. It has been postulated, that


FIGURE 28.4. The origins and neurovascular supply of the diaphragm. (From Valentine RJ, Wind SS. Anatomic exposures in vascular surgery. Philadelphia, PA: Lippincott Williams and Wilkins; 2003:236, Figure 9-7).
FIGURE 28.5. Chest radiograph of a patient with a ruptured left hemidiaphragm following a motor vehicle crash. A hemothorax is present and a hollow viscus as a result of the diaphragmatic tear is clearly seen in the chest.

the sudden increase of the intra-abdominal pressure (IAP), as in the case of blunt compressive mechanisms, elevates the gradient to levels responsible for the disruption of the diaphragm. Furthermore, this increase in the thoracoabdominal gradient may facilitate the migration of abdominal organs into the thoracic cavity.

Incidence. From the National Trauma Data Base, the incidence of diaphragmatic injury is 35% for blunt trauma and 65% for penetrating injury.[12] The most common location of diaphragmatic injury is the left side; in blunt trauma, 80% on the left and 20% on the right.[13] In penetrating trauma, diaphragmatic injury is more common on the left due to the preponderance of right hand-handed assailants and the fact that the liver protects the right hemidiaphragm, preventing abdominal viscera from herniation into the thoracic cavity. The organs more frequently involved in herniation in order of frequency are the stomach, colon, spleen, and small bowel.

Diagnosis. The high incidence of associated injuries can overshadow the diagnosis of diaphragmatic injury in the acute phase. High index of suspicion should be exercised when a penetrating wound of the left chest occurs below the 4th interspace and in blunt trauma when there is a simultaneous hemoperitoneum and left hemopneumothorax. The clinician should also be cognizant of the location and trajectory of the penetrating object and the possibility of diaphragmatic involvement. Most diaphragmatic injuries from penetrating trauma are diagnosed intraoperatively. Blunt diaphragmatic injury is generally a larger tear. During the laparotomy, the diaphragm should be inspected carefully with the help of a good headlamp illumination and an extension of your hand using a sponge stick, which allows spreading this floppy muscular organ, to avoid missing other rents. Injury to the diaphragm may be missed at laparotomy (5%), usually a posterior laceration.

The symptoms and signs of diaphragmatic injury range from minimal dyspnea, chest pain, shoulder pain, bowel sounds in the chest, to severe respiratory distress and shock, when associated with massive viscus herniation or associated thoracoabdominal injuries. On occasion, a scaphoid abdomen is seen on physical examination, with extensive herniation of abdominal contents into the chest.

The chest radiograph is the best screening modality in the diagnosis of diaphragmatic rupture, and any lack of delineation of this organ, particularly if it is associated with pleural effusion, should raise the suspicion of diaphragmatic injury. The chest radiograph will be diagnostic for diaphragmatic rupture in 25% of cases with abdominal viscera (usually stomach or small bowel) seen in the chest and normal in 25% of cases of blunt diaphragmatic injury. In 50% of cases, the chest radiograph is abnormal but not diagnostic (Fig. 28.5). Findings include elevation of a hemidiaphragm, obscuring of the diaphragmatic border, loss of the costophrenic angles, or lower lobe collapse.

Both DPL and FAST (focused assessment sonographic for trauma) will miss diaphragmatic injury.[13] CT has become the most used tool in the evaluation of abdominal injury in the last two decades. Initially, CT reported a sensitivity of 14%-–61% and a specificity of 76%-99% in the diagnosis of diaphragmatic rupture. More modern CT technology has improved the accuracy to 80%-–100%.[14,15] Magnetic resonance imaging may also be useful, particularly in cases of questionable CT or delayed diagnosis of diaphragmatic injury.[16]

Laparoscopy and thoracoscopy have become useful adjuncts in the diagnosis of diaphragmatic rupture.[17] Laparoscopy perhaps is more useful in patients without other indication for laparotomy, and thoracoscopy in a subacute situation of diagnostic dilemma. Laparoscopy is ideal with penetrating thoracoabdominal wounds on the left side, where the presence of diaphragmatic or abdominal injury is unclear. Laparoscopy may be used as a therapeutic tool in this setting, allowing repair of the diaphragm.

Surgical Management of Acute Diaphragmatic Rupture. The surgical management of acute diaphragmatic rupture, once the abdominal cavity is open, should not preclude the meticulous inspection of the entire abdominal cavity and its contents (Table 28.1). Once other priorities such as control of bleeding and contamination are accomplished, the attention should be focused on the diaphragm. With herniation of abdominal structures, these organs should be carefully retracted back to the abdomen. Good illumination with head lamps, and good exposure, with the transection of the triangular and falciform ligaments if necessary, will provide excellent

TABLE 28.1

DIAPHRAGM INJURY SCALE

■ GRADE[a]	■ DESCRIPTION OF INJURY	■ AIS-90
I	Contusion	2
II	Laceration <2 cm	3
III	Laceration 2–10 cm	3
IV	Laceration >10 cm with tissue loss ≤25 cm^2	3
V	Laceration with tissue loss >25 cm^2	3

visualization of the area. Careful downward traction of the spleen and stomach on the left side and the liver on the right will allow inspection of the diaphragms.

The edges of the diaphragmatic tear should be grasped with long Allis clamps and then proceed with a careful inspection of any lesion in the intrathoracic organs, if the rent is big enough. If there is evidence of contamination of the pleural cavity, with gastroenteric contamination, extensive irrigation of the thoracic cavity should be performed at this time. If the irrigation of the thoracic cavity is considered inadequate, a subsequent thoracotomy, according to some authors,[18] or a video-assisted thoracoscopy are options after completion of the laparotomy. In either case, large chest tubes should be placed as part of the procedure.

Multiple techniques are appropriate to suture the torn diaphragm. The diaphragm should be repaired with monofilament 0 or 1 (polypropylene) nonabsorbable material, with a one-layer or two-layer closure. Horizontal mattress sutures may serve as definitive closure or as the first of two layers of closure. This may be followed by a second layer of a running interlocking suture of the same material, superficial to the first layer. The function of this layer is, in theory, to prevent postoperative bleeding from the edges of this extremely vascularized structure. Central/pericardial tears occur in 5% of cases. The heart must be carefully inspected as well. With lacerations that extend to the esophageal hiatus, be certain not to compromise the orifice when closing; a large bougie may be helpful in this setting. On rare occasion, a detachment of lower insertion of the diaphragmatic fibers with reattachment of the diaphragm in a more cephalad manner is necessary. Mesh is rarely necessary in the acute phase. Diaphragmatic rupture has also been repaired successfully laparoscopically and thoracoscopically.

As a principle, an acute diaphragmatic disruption should be repaired through the abdomen, to address other intra-abdominal injury, which will be present in the majority of patients. In cases of subacute or delayed diagnosis of diaphragmatic injury, a thoracic approach may be easier, avoiding adhesions within the abdomen.

Stomach and Small Bowel Injury

Injury to the stomach or small intestine is more common after penetrating than blunt abdominal trauma. GSWs that violate the peritoneal cavity have a higher incidence of hollow viscus injury (70%) compared to SWs (30%). Thus, we have different strategies for the management of GSW versus SW of the abdomen; mandatory surgery for the GSWs and the possibility of a selective approach for the SWs. Blunt injuries of the

stomach and small bowel are uncommon. The incidence found in a multicenter study of 275,000 blunt trauma victims by the EAST was 0.3%.[3,4] In patients with any blunt abdominal injury, 4%–7% will have hollow viscus injury. The finding of solid organ injuries increases the likelihood of hollow viscus injury.[5]

Anatomy. The empty stomach is essentially intrathoracic and protected by the ribcage. When distended, the stomach is at risk for rupture because of direct compression or acute increase in intraluminal pressure. The arterial blood supply of the stomach is the left gastric artery, right gastric artery, left and right gastroepiploic arteries, and the short gastric arteries.

The small intestine distal to the ligament of Treitz is 5–6 m. The small intestine is suspended on its mesentery, with its blood supply originating from the superior mesenteric artery (SMA). The arterial supply to the small intestine has multiple arcades and thus is a well-vascularized structure.

Pathophysiology. Blunt trauma usually produces contusions and intramural hematomas on the stomach and small bowel; more serious injuries such as perforations and mesenteric avulsions are less common.[19-21] Localized blows to the abdomen, by farm animals or handlebar injuries have been replaced by automobile crashes and sports injuries such as lacrosse sticks slashes to the abdomen, or football helmet collisions against the unprotected torso. Furthermore, the mandatory use of the seat belt has saved many lives but has increased the incidence of small bowel injury. The incidence of injury to the small intestine with the use of the three-point lap and shoulder restrain is increased 4.3-fold and increased 10-fold with the lap belt-only restraint, compared to the unrestrained victim.[3] The association of small bowel perforation or mesenteric injury with Chance fractures of the lumbar spine, associated with the seat belt, has been emphasized earlier.

Blast injury presents different complexes of injury from contusions to perforation, depending whether from primary blast effect and depending on proximity of the patient to the center of the explosion. Secondary blast effect is caused by projectiles from the explosion, with a penetrating component. Tertiary and quaternary injuries are caused by the generation of "blast winds" and fire, respectively. The more serious concern with blast injuries is the possibility of delayed clinical presentation with serious adverse consequences.

Diagnosis. An accurate history of the mechanism of injury, penetrating or blunt, is essential. The location of entrance and trajectory of the penetrating weapons: thoracic–abdominal wall or anterior abdomen should raise the suspicion of gastric or small bowel injury.

The initial laboratory studies: hemoglobin, hematocrit, serum amylase, and white blood cell count are of little value in the initial diagnosis of gastric or small bowel injury. However, fever, leukocytosis, increase in the serum amylase, and metabolic acidosis in the next 24 hours postadmission may be the first sign of a missed hollow viscus injury

DPL has been supplanted by FAST and CT. However, DPL has its value in the detection of hemoperitoneum. In addition, when the white cell count in the DPL effluent is more than 500 per mm^3, it may be considered positive for bowel injury. Nevertheless, Jacobs et al.[22] demonstrated that even using an elevation of over 500 per mm^3 white cells in the lavage, it should not be used a sole criterion in the diagnosis of bowel perforation. Elevation of the alkaline phosphatase >10 units in the DPL effluent or an elevation of the amylase >20 IU/L suggests bowel injury. More recently, authors[23] have used ratios of red cells/white cells in the DPL effluent to make a more accurate diagnosis of bowel lesions, avoiding the "lag period" of appearance of the white cells after the injury occurs.

TRAUMA

Despite its sensitivity of 84% and the specificity of 99% for detection of hemoperitoneum, Focused assessment by sonography for trauma (FAST) is unreliable in the diagnosis of bowel injury. CT findings of free intraperitoneal air, free peritoneal fluid, thickening of the bowel wall, and mesenteric fat streaking are important predictors of injury. The Elvis Presley trauma center[23] found that the overall sensitivity and specificity of CT for bowel injury was 88.3% and 99.4%, respectively. The authors go further to recommend DPL if a single abnormal finding is found at CT and laparotomy or if several signs are found in the same diagnostic modality. The presence of intraperitoneal fluid on CT has different discriminatory values for different studies. Fakhry directed a multi-institutional study for EAST in 95 trauma centers and found that only 29% of patients with free fluid had full-thickness bowel injury. In the same series, 38% of patients with free fluid without solid viscus injury had bowel injury.[3,4] Despite a plethora of publications on the subject, there is no consensus in regard to the best management of the patient with free abdominal fluid in the absence of solid viscus injury; DPL, serial abdominal physical examinations; "diet trials" in the absence of abdominal pain or diagnostic laparoscopy have been proposed. The EAST trial noted that 12% of patients with normal CT had bowel injury.[3,4] Therefore, a prudent decision could be to keep the patient for observation.

Laparoscopy has been used for diagnosis and treatment of penetrating injury to the thoracoabdominal torso, to exclude penetration of the peritoneum and to assist in the diagnosis of diaphragmatic injuries. Its use in the diagnosis of gastric or small bowel lesions is limited at this point in time. However, it may have a role in the patient about whom there is a low level of suspicion to exclude bowel injury in the presence of fluid without a solid viscus injury.

Management of Gastric Injuries. Gastric injuries are managed with the help of a good illumination (head lights) and good exposure (Table 28.2). The gastroesophageal junction may be difficult to visualize. This area can be exposed better with the division of the left triangular ligament of the left lobe of the liver and reverse Trendelenburg maneuver. The posterior wall of the stomach should always be inspected, particularly in the presence of penetrating injuries of this organ, which have involved the anterior wall. The gastrocolic ligament should be opened carefully, trying to avoid injury to the middle colic artery.

The surgical repair of the stomach wall is according the grade of severity.[19] Most grade I injuries, such as gastric wall hematomas, can be treated with evacuation of the hematoma if considered necessary, and the use of interrupted Lembert sutures. Small perforations can be treated with one- or two-layer closure. Larger perforations should be closed in two layers: a running suture of absorbable material is used for the inner layer and interrupted seromuscular silk stitches for the outer layer. Grade III gastric injury with major involvement of the greater curvature can be repaired with the assistance of GIA stapler, being certain to avoid unacceptable narrowing of the stomach lumen. The management of grade IV stomach injuries may require the use of a Bilroth 1 or a Bilroth 2 anastomosis for the repair. Grade V gastric injuries are rare; massive destruction of the organ, which could require a total gastrectomy and the use of a Roux-en-Y, with an esophagojejunostomy.

Surgical Management of Injuries of the Small Bowel. The evaluation of the bowel at the beginning of the laparotomy is fundamental. Systematic inspection of every loop of small bowel, starting from the ligament of Treitz, is better performed with the attentive help of the assistant surgeon for visualization of the bowel (Table 28.3). It is preferable

■ GRADE[a]	■ DESCRIPTION OF INJURY	■ AIS-90
I	Contusion or hematoma	2

to initially control a bowel injury, secondary to a penetrating injury and continue the "running of the bowel" to make a total assessment of the injuries and plan the surgical therapy. Grade I bowel injury can be treated by inversion with seromuscular sutures. Grade II bowel injury can be treated with debridement if necessary and with single- or double-layer closure, using absorbable and nonabsorbable material. Grade III or IV injury, more likely, will require bowel resection and anastomosis, unless the transverse closure will not produce a narrowing of the lumen of more than 30%.[20]

The anastomoses can be handsewn in one or two layers, or stapled. However, remember that the stapling devices are designed for normal thickness intestine. Stapled anastomosis should be avoided if possible, in the presence of edematous bowel, unless a new type of staplers with longer staple length can be obtained. Although the literature is inconclusive, several studies have suggested higher leak rates for stapled anastomoses versus handsewn anastomoses in the trauma patient.[24,25] Grade V bowel injury is associated with devascularization of the intestine requiring resection. In the presence of doubt regarding bowel viability, a 24-hour "second look" reexploration is necessary.

Colon and Rectal Injury. Management of colorectal injury has evolved over the past 40 years with the acceptance of evidence-based guidelines generated by civilian trauma centers, overriding the prior approach championed by military surgeons based on the application of lessons learned from battlefield injuries.[26-28] During the World War II, influenced by Ogilvie,[27] the Office of the Surgeon General of the United States mandated colostomy for all colonic injuries. This declaration made colostomy or exteriorization the standard of care for injury of the large bowel for 40 years. Woodhall and Oschner in 1951 pioneered the use of primary repair in the civilian injuries.[28] However, it was not until 1979 when Stone

and Fabian[29] in the United States and Demetriades[30] in South Africa produced seminal reports, confronting the dogma of "mandatory colostomy." Nevertheless, this was a select population of patients, without hypotension or associated injuries. Chaping et al.[31] in a prospective, randomized study of 59 patients concluded that irrespective of risk factors, primary repair does not increase the incidence of complications and should be recommended for any type of colonic lesion. A meta-analysis of five prospective studies[32] showed no difference in mortality between primary repair and colostomy for colonic injury. Blunt trauma is responsible for only 5% of the colonic injuries, and in nonurban settings, is most often caused by motor vehicle accidents, and results in sheering damage, due to acute increase in intraluminal pressure causing blowout, or avulsion/crush injury to the mesocolon. The colon is injured in 25% of GSW and 5% of SWs. Other injuries to the colon can be caused iatrogenically during colonoscopy, or can be the result of swallowed objects or objects inserted rectally. Injuries to the rectum are most often caused by penetrating objects, either to the abdomen or to the buttocks.

Anatomy. The colon begins at the ileocecal valve and ends at the rectosigmoid junction at the sacral promontory where the three taenia coli begin to diverge, and the epiploic appendages and mesentery stop. The rectum continues from the rectosigmoid junction and remains intraperitoneal for approximately 8 cm to the middle transverse fold, at which point the peritoneal reflection ends and the rectum becomes extraperitoneal. It extends for an additional 8 cm until the anorectal ring, demarcated by the dentate line.

The ascending colon is supplied by the ileocolic and right colic arteries from the SMA. The splenic flexure and proximal transverse colon are supplied by the middle colic artery, also from the SMA. The hepatic flexure is supplied by the marginal artery, formed by the anastomosis of the arcades from the middle colic and left colic arteries. The descending colon is supplied by the left colic artery from the inferior mesenteric artery (IMA). The sigmoid colon is supplied by the sigmoid artery, also from the IMA. The proximal rectum is supplied by the terminal branch of the IMA, the superior rectal artery. Finally, the distal two-thirds of the rectum is supplied by the middle and inferior rectal arteries from the internal iliac and internal pudendal arteries.

Diagnosis. The single most important method for diagnosis of colonic injury is serial examinations by a single examiner to allow assessment of the relative stability of the patient and subtle changes in physical examination. In trauma patients with obvious peritoneal signs (rebound, distension, guarding), an exploratory laparotomy is warranted without the need for further evaluation. Several studies[33] have shown that selective management, based on serial physical examinations of the patient, is safe, cost-effective, and avoids unnecessary laparotomy.

The presence of extraluminal air, contrast extravasation, colonic wall thickness, and stranding of the mesentery are suggestive of colon injury on CT or plain radiograph. Even though many trauma centers perform triple contrast CT (oral, IV, and rectal contrast) in the presence of penetrating trauma of the flank or back to exclude colonic injury, others believe that is unnecessary[34] in the diagnosis and management of colon injury.

Patients who have a penetrating injury to the abdomen, disruption of the bony pelvis, history of anal trauma, or pain in the buttock region should be suspected of harboring rectal injury. Any patient with suspected rectal injury must undergo rigid sigmoidoscopy, even if an exploratory laparotomy is already planned. Hematoma, perforation, and intraluminal blood are indicators of rectal injury. Transabdominal examination of the lower rectum is not recommended and provides no diagnostic benefit while subjecting the patient to increased risk of iatrogenic injury (Tables 28.4 and 28.5).

Management. When the decision is made to take a patient to the OR, a preoperative dose of broad spectrum antibiotics that cover aerobes and anaerobes, especially gram-negative rods should be given. Second-generation cephalosporin, ampicillin/sulbactan, or piperacillin is as effective as multiple antibiotics.[35] In addition, several studies have demonstrated the value of only 24 hours antibiotic coverage versus 5 days.[36]

Most colonic injuries are identified as part of a trauma laparotomy for penetrating abdominal trauma. Once bleeding and active GI soilage are controlled, the colon is mobilized by incising the white line of Toldt, the avascular plane between the omentum and transverse colon, and the splenocolic ligament. As mentioned above, operative management of colon injury has undergone a major shift toward primary repair and avoidance of colostomy.[37] The guidelines for primary repair,

even including colon injury which requires resection, include minimal stool contamination, no hypotension/shock, <1 L blood loss, <8 hour delay to operation, and minimal associated intra-abdominal injury. If primary repair cannot be safely performed due to patient instability or edematous or ischemic intestine, colostomy may be a safer option.

Areas of controversy include the use of GI staplers versus hand-sewn anastomoses and the use of one versus two layers of repair. Either technique can be used[37-39] and the decision should be guided by the surgeon experience and preference. If the patient is hemodynamically unstable, a damage control approach is necessary. Bleeding cessation and fecal contamination control should be the priority.

Inappropriately worn lap belts can cause a deserosalization type injury to the colon. This results in an intact mucosal tube exposed by a 360-degree tear of the muscular and serosal layers and tear of the mesentery. This injury is repaired by telescoping the mucosa on itself and suturing the muscular and serosal layers.

Proximal rectal injuries (intraperitoneal) are treated with a similar approach to colon injuries. The extraperitoneal colon injuries, if they are located distally near the anus, at times can be repaired transanally. However, in general, the rectal injury per se, is not repaired. More generally, middle and lower third rectal injuries are managed primarily by proximal diversion. Currently, there is no role for rectal washout.[40] The use of presacral drainage is also controversial, due to the complications and discomfort for the patient.[41] Presacral drainage should be considered only for lower one-third injury, essentially anal canal.

Special Considerations. For patients who undergo a colostomy, the timing of the takedown is still debated.[42] Current recommendations vary from performing the takedown within 14 days of the placement to waiting 9 months. Since most injuries heal within 10 days, there is no necessity to delay the takedown beyond 2 weeks in the patient who is stable and fully recovered otherwise.

Duodenal Injury

Anatomy. The anatomy of the structures in the right upper quadrant of the abdomen is complex. The duodenum constitutes the beginning of the small bowel and measures approximately 21 cm.[43] It is divided into four portions: the first (superior), second (descending), third (transverse), and fourth (ascending) portions. The first portion of the duodenum ranges from the pyloric muscle to the common bile duct superiorly and the gastroduodenal artery inferiorly. Its origin is marked by the pyloric vein of Mayo. The second portion extends from the common bile duct and the gastroduodenal artery to the ampulla of Vater. The third portion extends from the ampulla of Vater to the mesenteric vessels (SMA and vein), which cross anteriorly over the junction of the third and fourth portions as they emerge from the inferior border of the neck of the pancreas. The fourth portion extends from these vessels to the point at which the duodenum emerges from the retroperitoneum to join the jejunum just to the left of the second lumbar vertebra. The entry to the duodenum is closed by the pyloric sphincter, and its exit is suspended by the fibromuscular ligament of Treitz. The duodenum is mobile at the pylorus and its fourth portion but remains fixed at other points.[44,45]

The duodenum is, for all practical purposes, a retroperitoneal organ, except for the anterior half of the circumference of its first portion. The first portion, the distal half of the third portion, and the fourth portion in its entirety lie directly over the vertebral column, which, coupled with the psoas muscles, aorta, IVC, and right kidney, form its posterior boundaries.

The duodenum shares its blood supply with the pancreas (Fig. 28.6). Vessels, which supply the duodenum include the gastroduodenal artery and its branches, the retroduodenal artery, the supraduodenal artery of Wilkie, the superior pancreaticoduodenal artery, and the SMA and its first branch, the inferior pancreaticoduodenal artery. The gastroduodenal artery courses from its hepatic origin at the superior surface of the duodenum under its second portion and enters the pancreas just below and opposite the common bile duct above the duodenum. The dorsal and ventral pancreaticoduodenal arcades are formed by the anastomosis of the superior and inferior pancreatic duodenal arteries and supply numerous branches to the pancreas and the duodenum.[46-50] The common bile duct enters the posterior substance of the head of the pancreas in 83% of patients after it passes under the duodenum.[51,52]

After piercing the capsule of the pancreas posteriorly, the duct courses down within the pancreatic substance a few centimeters from the curve of the duodenum, entering the duodenal lumen at the junction between the second and third portion of the duodenum approximately 2.0–2.5 cm from the pylorus.[53] Three main variations exist with regard to how both the common bile duct and pancreatic duct enter the duodenum. In 85% of individuals, both ducts enter through a common channel at the ampulla of Vater; in 5% both ducts enter the duodenum on the same ampulla but through separate channels.[47] In the remaining 10% of individuals, each duct enters the duodenum separately.

The duodenum serves as the mixing point for the partially digested chyle from the stomach and the proteolytic and lipolytic secretions of the biliary tract and pancreas. As such, it commonly contains not only food but powerful activated digestive enzymes, including lipase, trypsin, amylase, elastase, and peptidases, among others.[54]
FIGURE 28.6. Relationship and shared vascular supply of the duodenum and pancreas. (Redrawn from Zollinger RM Jr, Ellison EC. *Zollinger's Atlas of Surgical Operations*. New York: McGraw Hill;2011: 19, Plate 1.)

Mechanism of Injury. The true incidence of duodenal injury is difficult to determine.[48,55-69] As best estimated, duodenal injuries occur in approximately 4.3% of patients with abdominal injuries. The anatomic location of the duodenum protects it from injury. Overall, penetrating injury is the most common cause of duodenal trauma. In a review of the literature encompassing 17 series published during the last 22 years, 1,513 cases of duodenal injuries were identified; 77.7% occurred as the result of penetrating trauma, whereas 22.3% occurred as the result of blunt trauma.[67-159] Blunt injury may cause wall disruption from crushing, shearing, or bursting. A good example of crush injury occurs when the steering wheel impacts on the midepigastrium.

Associated Injuries. The duodenum, by virtue of its anatomic proximity to other important organs, is rarely injured alone; multiple associated injuries are the rule rather than the exception. This is particularly true with penetrating trauma, but it also occurs with blunt trauma. Isolated duodenal injury usually occurs in the form of duodenal hematoma. In the study by Stone and Fabian,[75] of the 321 patients reviewed, 91.5% had associated injuries, with a total of 1,143 associated injuries in these patients. The liver was the most commonly injured organ (16.9%). Other commonly injured organs included the pancreas (11.6%); small bowel (11.6%); colon (11.5%); and genitourinary in 6.6%.[68-79] Major abdominal venous injuries occurred in 9.8%; the IVC accounted for most of these injuries. Arterial injuries occurred in 6.6%, with the aorta most commonly. Miscellaneous injuries, mostly extra-abdominal, accounted for 253 injuries (8.3%). The lung was the most frequently injured extra-abdominal organ.[75]

Anatomic Location of Injury. The most frequent site of duodenal injury was the second portion, 33.0% in review of 1,033 cases.[67,71,72,75-80] The third and fourth portions sustained injury in 19.4% and 19.0%, respectively. The least frequently injured portion of the duodenum was the first (14.4%). However, with penetrating trauma, injuries were distributed throughout the anatomic course of the duodenum, whereas in blunt trauma most injuries remained confined to the second portion of the duodenum, usually its posterior surface.[76]

Diagnosis. Delay in the diagnosis and management of duodenal injury results in significant morbidity and mortality. Patients involved in head-on collision or force impacts from the right, who have struck the steering wheel, or required extrication should be suspected as harboring duodenal injuries. Patients who have sustained blows to the midepigastrium must always be evaluated thoroughly. Finally, patients who have fallen from great heights are subject to deceleration injuries of the duodenum.

When examining the patient, remember that the retroperitoneal location of the duodenum may preclude early manifestation of injury on physical examination. Abdominal discomfort may be out of proportion to the physical findings, and peritoneal irritation may occur late and become apparent only when blood, enteric contents, or enzymes that were initially contained retroperitoneally enter the peritoneal cavity. Physical examination may be characterized by minimal findings. Any tenderness over the right upper quadrant or midepigastrium must raise the suspicion of duodenal injury. Signs of rebound tenderness, abdominal rigidity, or absence of bowel sounds indicate intra-abdominal injury and should prompt early surgical intervention. Laboratory tests are of little help in the early diagnosis of duodenal injury.

Plain films of the abdomen are useful only if they are positive. Positive findings include the presence of air collections outlining the right kidney with extraperitoneal rupture of the duodenum, presence of gas around the right psoas muscle and in the retrocecal region, but these findings are rare.

CT with oral and intravenous contrast is the diagnostic method of choice in hemodynamically stable patients with suspected duodenal injury who have sustained blunt abdominal trauma.[84-90] If the CT identifies extravasation of oral contrast from the duodenum associated with a retroperitoneal hematoma, no further studies are needed. However, if the CT scan is inconclusive, we recommend an upper gastrointestinal series with Gastrografin and fluoroscopic visualization of duodenal peristalsis to confirm extravasation of contrast from the duodenum. If no extravasation is identified, thin barium is then administered, which can provide better delineation of duodenal anatomy and thus establish the presence of duodenal hematoma. Additionally, in patients with high concern for duodenal injury in whom no conclusion could be reached from both the contrast and the CT scan studies, exploratory laparotomy and retroperitoneal exploration of the duodenum should be considered to exclude duodenal injury. DPL may be unreliable in evaluation of injury to the retroperitoneal organs.[69,73,91]

Surgical Management of Duodenal Injury. Proven or suspected duodenal injury, coupled with the classic findings of intra-abdominal injury (i.e., abdominal tenderness, guarding, rebound tenderness, or decreased bowel sounds), mandates immediate exploratory laparotomy. Broad-spectrum antibiotics are administered before the abdominal incision.[92,93]

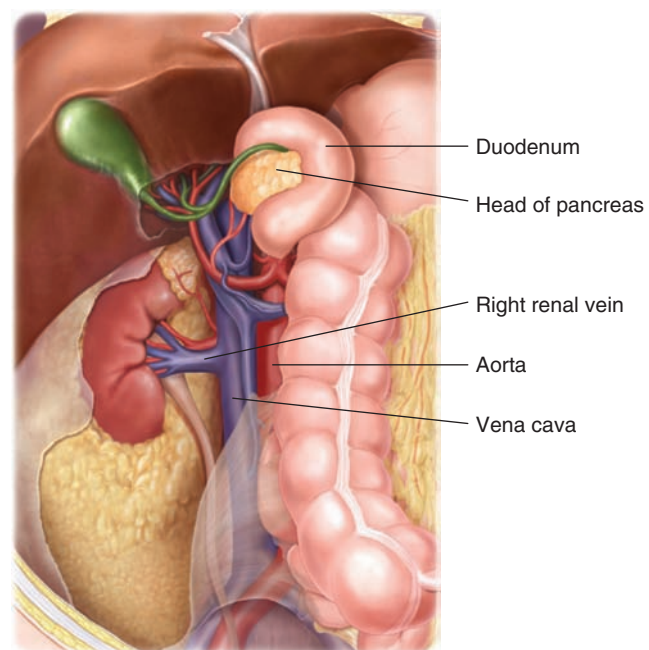
The duodenum must be thoroughly explored with all four portions visualized directly. Findings that should increase suspicion of a duodenal injury include crepitation along the duodenal sweep, bile staining of paraduodenal tissue or a documented bile leak, or the presence of a right-sided retroperitoneal hematoma or perirenal hematoma. The duodenum should then be mobilized by a Kocher maneuver, a Cattell and Braasch maneuver, or both[94] (Fig. 28.7). These maneuvers should provide full visualization of the anterior and posterior walls of all portions of the duodenum. The nasogastric tube should be advanced through the pylorus and palpated digitally while the surgeon performs the dissection. This provides a guide to identify the duodenum in the midst of a large retroperitoneal hematoma and will thus avoid iatrogenic laceration


FIGURE 28.7. Right medial visceral rotation. (Redrawn from Singh N. Major abdominal vascular trauma. In: Martin MJ, Beekley AC, eds. *Front Line Surgery*. New York: Springer, 2010:148, Figure 11.4.)

to the duodenal wall during dissection. Inspection of the third portion of the duodenum requires mobilization of the hepatic flexure of the colon according to the method described by Cattell and Braasch.[94] The retroperitoneal attachments of the small bowel are incised sharply from the right lower quadrant to the duodenojejunal junction, and the small bowel is reflected in its entirety out of the abdominal cavity. This maneuver is often unnecessary, and its performance in the presence of a large retroperitoneal hematoma, especially those caused by pelvic fractures, may lead to exsanguination. The fourth portion of the duodenum can be visualized by transecting the ligament of Treitz while avoiding injury to the inferior mesenteric vein or, again, by performing the Cattell and Braasch maneuver.[94]

Duodenal injury can easily be missed, with disastrous consequences. Massive injury, such as may occur with associated vascular injuries to the aorta or vena cava, may divert the surgeon's attention from the duodenum. If findings such as minimal hematoma or insignificant edema are deemed trivial and disregarded, a duodenal injury may be missed.

After a duodenal injury is identified, its extent should be defined. Factors which have a role in its management include the number of associated injuries, especially to the pancreas and biliary tree, and the period of time which has elapsed from identification to treatment. Snyder et al.[77] identified several important factors of value in evaluation of the severity of duodenal injury; agent of entry, the size and site of injury, the interval from injury to repair (in hours), and an associated injury to the common bile duct. Injuries were classified as mild on the basis of the following: (1) the agent of entry consisted of a SW; (2) the size of injury encompassed <75% of the duodenal wall; (3) the site of injury was located in the third or fourth portion of the duodenum; (4) the injury repair interval was <24 hours; and (5) no associated injury to the common bile duct. Injuries were classified as severe on the basis of the following: (1) the agent of entry was blunt trauma or a missile; (2) the size of injury encompassed more than 75% of the duodenal wall; (3) the site of injury was located in the first or second portion of the duodenum; (4) the repair interval was >24 hours; and (5) an associated injury to the common bile duct. Most authors have reported the presence of associated pancreatic injury to be predictive of increased morbidity and mortality.[21,73,95,96]

Cogbill et al.[82] used American Association for the Surgery of Trauma organ injury scale (AAST-OIS) for duodenum in a cooperative multicenter trial in which they graded 164 duodenal injuries (Table 28.6). Mortality rates for grade I-V duodenal injuries were 8%, 19%, 21%, 75%, and 25%, respectively. The authors found that mortality did not correlate well with the severity of duodenal injury and concluded that anatomic features of duodenal injury represent only a part of the risk of morbidity and mortality.

Approximately 75%-85% of all duodenal injuries can be repaired safely using simple surgical techniques. Basic surgical principles, such as debridement of the duodenal injuries to viable tissues and a meticulous double-layer technique for closure, approximating the inner layer using fine absorbable sutures and a seromuscular closure of interrupted nonabsorbable Lembert sutures, should be used. Duodenorrhaphy alone carries a small risk of narrowing the duodenal lumen. Several technical points must be kept in mind to avoid this problem when closing duodenal lacerations. These technical points were outlined by Kraus and Condon[97] on the basis of the results of an animal model in which they established that longitudinal duodenotomies can be closed transversely if the length of the duodenotomy does not exceed one half of the circumference of the duodenum. These investigators recommended that longitudinal closures be performed if the duodenotomy exceeds one-half of the circumference of the duodenum. In neither of these closures was the duodenal lumen narrowed.

We recommend that drains be used routinely, but emphasize that this drain system should be of the closed-suction type and should not be placed directly against the suture line to avoid duodenal fistula formation. Other points to be considered for penetrating injuries include the potential for blast effect. For blunt injuries, the degree of associated retroperitoneal and

TABLE 28.6

DUODENUM INJURY SCALE

GRADE[a]	TYPE OF INJURY	DESCRIPTION OF INJURY	AIS-90

TRAUMA

periduodenal inflammatory processes resulting from extruded duodenal contents should be assessed. After evaluation of these factors, the surgeon can choose the procedures that are needed to repair or decompress the duodenum, resect devitalized areas, buttress the repair, or exclude the duodenum from the passage of gastric contents.

In the past, adjunct maneuvers were used to safeguard the duodenal closure. One of these maneuvers is tube duodenostomy, of which the following three types exist: (1) primary, in which the tube is placed through a separate SW in the duodenum (the authors do not support this method); (2) antegrade, in which the duodenum is decompressed by way of the passage of a tube through the pylorus; or (3) retrograde, in which the tube is passed through a jejunostomy site. However, these techniques now are used much less commonly.

The addition of tube decompression for duodenal repair is controversial; opinions are strongly divided between those who staunchly support its routine use, such as Corley et al.,[72] Stone and Fabian,[75] and Hasson et al.,[99] and those who advocate against its use, including Ivatury et al.[80] and Kashuk et al.[101] Stone and Fabian[75] reported a high rate of duodenal complications in 8 of 44 duodenal wounds closed without tube decompression, with three subsequent deaths attributed to duodenal complications before the routine use of decompressive techniques. These investigators reported only one duodenal fistula in 237 patients after the routine use of decompression began.

Hasson et al.[99] reviewed several series of duodenal injuries and found a 2.3% rate of fistula formation in decompressed repairs versus an 11.8% rate in patients without decompression. Contrasting data are presented by Ivatury[80,100] in two separate studies in which they evaluated patients who sustained duodenal injuries and associated injuries of comparable severity. These investigators found consistently higher duodenal morbidity rates in the form of duodenal fistulas and abdominal sepsis as well as higher mortality rates in the group treated with duodenal repair and decompression. Most other series in the literature advocate the use of decompression in a selective fashion.[69,76-78] We advocate individualization of treatment with regard to decompressive techniques and agree with Kelly that "treatment of duodenal injuries, perhaps more than any other bowel trauma, must be individualized."[68]

In some cases, either the injury itself or debridement necessary to remove devitalized tissue may leave a defect in the duodenal wall that, if repaired primarily, might narrow the duodenal lumen or subject the suture line to undue tension and possible breakdown. The reasons cited for disruption of duodenal closures after tissue loss are high intraluminal pressure, tendency of duodenal mucosa to extrude through closure leading to the leakage, and breakdown from autodigestive enzymes of the pancreas and bile. In these cases, a jejunal serosal patch may be used to effect a safe closure.[102-106] An on-lay Roux en Y duodenojejunostomy may be utilized to close large duodenal defects. For larger defects, the ingenious techniques of a jejunal mucosal patch were described by Jones and Joergenson[106] and later modified to include a fairly large pedicle graft by DeShazo et al.[107] This patch can be constructed by using a proximal segment of jejunum, which can be carried up in a retrocolic location on its vascular pedicle. The antimesenteric border of the jejunum can then be split longitudinally and anastomosed using a double-layer technique to the duodenum to close the defect. This technique has also been used successfully by others.[102,108]

If the entire circumference of the duodenum has been devitalized, a segmental resection and end-to-end duodenoduodenostomy may be performed. Resections of segments of the first, third, and fourth portions of the duodenum, although technically challenging, are not associated with the high risk of vascular compromise during mobilization of the second portion. The rate-limiting step in mobilization of the second portion of the duodenum is the shared blood supply with the pancreas. Nevertheless, segmental resection and primary end-to-end duodenoduodenostomy are possible in the second portion. In cases where the duodenal wound is immediately adjacent to the ampulla of Vater, extreme caution must be exercised to preserve the integrity of this structure. In such cases, a choledochostomy may be necessary, with the passage of a probe to identify the ampulla and keep it in view during the creation of the anastomosis. Avulsions of the ampulla of Vater have been treated successfully by duodenorrhaphy and implantation of the ampulla into a Roux-en-Y limb of jejunum.[109] Similarly, avulsions of the common bile duct resulting from lacerations of the second portion of the duodenum have been repaired successfully with common bile duct reimplantation.[103] If an end-to-end anastomosis of the duodenum cannot be performed without tension, a Roux-en-Y duodenojejunostomy may be performed and the distal portion of the duodenum oversewn.

Patients sustaining severe duodenal injury may be considered as candidates for more complex duodenal repairs such as pyloric exclusion.[109,110] Such injuries include those caused by blunt trauma or missiles, those involving more than 75% of the wall, those involving the first and second portions of the duodenum, those associated with a delay in repair of more than 24 hours, and those with associated injuries to the pancreas, common bile duct, or both. Injuries described as grades III and IV of the AAST-OIS duodenum organ injury scale[20] can also be considered for these repairs (see Table 28.6). Other criteria that may lead the surgeon to consider these more complex surgical procedures include compromised blood supply to the duodenum and associated injury to the head of the pancreas without disruption of the main pancreatic duct. We consider injuries involving more than 50% of the circumference of the duodenal wall, whether associated with pancreatic injuries or not, to be high-risk. The main purpose of these procedures is to exclude the duodenum from the passage of gastric contents to allow time for the duodenal repair to heal and to prevent suture line dehiscence.

Pyloric exclusion entails duodenorrhaphy plus a gastrotomy in the most dependent portion of the greater curvature of the stomach. The pylorus is identified through the gastrotomy and occluded using a running suture of nonabsorbable monofilament polypropylene sutures or absorbable polyglycolic acid sutures. Care must be taken to avoid exclusion of antral tissue from the gastric lumen. A gastrojejunostomy is then performed through the previously created gastrotomy to achieve complete pyloric occlusion and diversion of gastric contents. Vagotomy is not a part of this surgical procedure. Gastrojejunostomy without a vagotomy is suspected as being an ulcerogenic procedure by many surgeons. Patients in whom the pyloric exclusion procedure was performed by upper gastrointestinal studies after periods ranging from 2 months to 3 years after the operations demonstrated a functioning pylorus with passage of contents into the duodenum (Fig. 28.8).

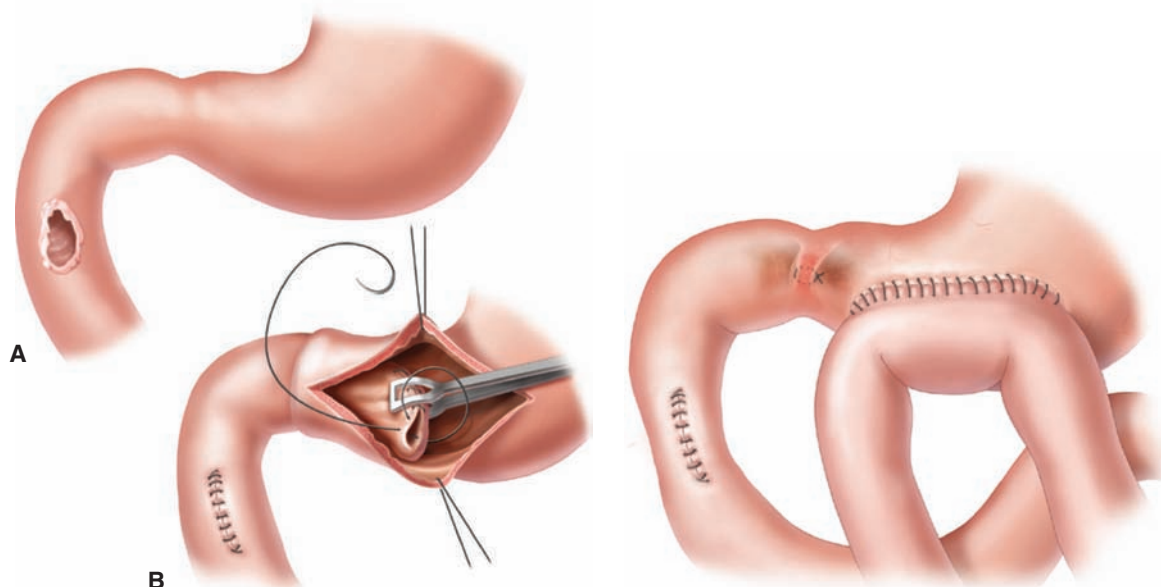
An alternate method for achieving pyloric exclusion is using a stapling device placed across the pylorus. This procedure was popularized by Kelly et al.[68]; however, it should not be employed and has been largely abandoned as it generally fails to reopen. Martin[112] reported a follow-up study describing an expanded experience with pyloric exclusion in which 128 of 313 patients (41%) who sustained duodenal injuries were treated with this procedure; a 5.5% duodenal fistula rate was seen. In this study, 42 patients underwent upper gastrointestinal tract examination after their operations. In patients examined 21 days or more after their operations, 94% had a patent pylorus. Marginal ulceration was infrequent and reported in only four of these patients, thus confirming the efficacy of this surgical procedure.


FIGURE 28.8. A: Pyloric exclusion. The duodenal injury is repaired. A gastrotomy is made on a dependent portion of the stomach and the pylorus oversewn from within using a nylon suture. (Redrawn from Frey C, Araida T. Trauma to the pancreas and duodenum. In: Blaisdell FW, Trunkey DD, eds. *Abdominal Trauma.* New York: Thieme; 1993:145, Figure 9–10A,B.) B: Pyloric exclusion. The pyloric exclusion is completed with the gastrojejunostomy. (Redrawn from Frey C, Araida T. Trauma to the pancreas and duodenum. In: Blaisdell FW, Trunkey DD, eds. *Abdominal Trauma.* New York,: Thieme; 1993:146, Figure 9–10C.)

Monsour et al.[113] and Flynn et al.[114] reported their experiences in the management of pancreaticoduodenal injuries. These investigators concluded that well-defined protocols, with careful selection of surgical procedures according to the grade of injury, yield better outcomes. They also concluded that techniques such as pyloric exclusion should be reserved for the infrequent complex injuries that involve both the pancreas and duodenum.[111] As previously shown, between 75% and 85% of duodenal injuries are amenable to repair by duodenorrhaphy. Pyloric exclusion should be performed for complex duodenal injuries AAST-OIS grades III-IV, which are amenable to primary repair and associated with a pancreatic injury AAST-OIS grades II-III. A variation of the duodenal diverticularization procedure as originally described by Berne should be employed when there are destructive injuries of the first portion of the duodenum with associated antral injuries requiring resection and reconstruction with a gastrojejunostomy also in the presence of a pancreatic injury.[115]

Pancreaticoduodenectomy is a formidable procedure in critically ill patients. Combined destructive injury to both the head of the pancreas and the duodenum is the major indication. In essence, pancreaticoduodenectomy is indicated when the injury has necessitated the operation, which then is completing the resection. A review of 70 series[69,70,116-155] reported in the literature from 1964 to 2008 yielded a total of 255 patients who underwent pancreaticoduodenectomy. The tabulated mortality rate for all the series reviewed was 31%.

Mortality. Duodenal injuries, as a whole, carry a considerable mortality rate ranging from 5.3% to 30%; with calculated average mortality rate of 17%.[67-83] Several authors reported early mortality rates associated with shock, prolonged bleeding, and the sequelae of massive blood replacement ranging from 35.7% to 73%, with an average of 52.9%.[55,67,76] The figures on late mortality can be attributed exclusively to the end results of the duodenal injury and associated complications which include sepsis, duodenal fistula formation, and multiple organ failure. Thus, early deaths are from hemorrhage due to associated vascular injury and late deaths are attributable to sepsis from the duodenal injury.

Factors known to increase mortality rates include the presence of associated pancreatic[67,68,70,75] and common bile duct injury.[77] Perhaps, the most important associated factor in determination of the mortality associated with duodenal injury is the delay in time from recognition to definitive repair.

Morbidity. Duodenal injuries are associated with high rates of morbidity, averaging 63.7%. Duodenal morbidity is represented primarily by duodenal fistula formation resulting from failure of surgical repair because of suture line dehiscence and is represented occasionally by duodenal obstruction. Duodenal fistula rates ranged from 0% to 16.2%, with an average of 6.6%.[65,69,72,75-77] Other important complications caused by associated injuries include intra-abdominal abscess, 10.9%-18.4%; recurrent pancreatitis, 2.5%-14.9%; and bile duct fistula, 1.3%.[65,69,75,77]

Blunt Duodenal Rupture. Diagnosis of blunt injury of the duodenum is difficult. All sizable series of blunt duodenal injuries include multiple instances in which this diagnosis was delayed.[44,69,73-83] Delay in diagnosis and treatment of blunt duodenal rupture more than 24 hours increases mortality several-fold. These findings support the concept that early surgical intervention improves outcome and demonstrates that the critical delay period is less than the classically reported 24 hours. The frequent difficulty with diagnosis of blunt rupture of the duodenum and the danger posed by the delayed recognition merit special discussions of the diagnostic features of these injuries. The most common cause of blunt rupture of the duodenum is impact of the epigastrium of an unrestrained driver against the steering wheel of an automobile. A variety of other blows to the abdomen may also cause this injury; it has occurred as a result of punches, kicks, falls, deceleration, and handlebar injuries. With the advent of high-resolution

multi-slice CT, the delayed detection of blunt duodenal injuries has been reduced.

The ultimate diagnostic test in blunt abdominal trauma remains the exploratory laparotomy. Because no noninvasive test is completely accurate, patients having met the clinical profile described previously and who have persistent or increasing abdominal pain 6 hours after injury, especially if accompanied by increased abdominal tenderness or rising white blood cell count or serum amylase level, should be considered candidates for exploratory laparotomy.

The devastating consequences of duodenal rupture, coupled with mortality rates ranging from 40% to 71%[44,69,75,77] and the high incidence of fistula formation in survivors as high as 50%,[44] warrant an aggressive diagnostic approach in establishment of this diagnosis and institution of early surgical treatment. The surgeon must also be aware that retroperitoneal rupture of the duodenum may be overlooked at operation.[67,70]

Intramural Duodenal Hematoma. The management of intramural duodenal hematoma remains controversial. Intramural duodenal hematomas are usually caused by blunt abdominal trauma and can occur in any part of the duodenum. Although most cases have been documented in normal persons (including many children), their occurrence has been associated with clotting disorders, anticoagulant therapy, and alcoholism.[160-173] Intramural hematomas of the duodenum are believed to be the result of shearing forces that rupture vessels within the duodenal wall.[161-165] They are most often submucosal, but subserosal and intramuscular hematomas have also been reported. Duodenal hematomas are usually manifested by signs of upper gastrointestinal obstruction after trauma. Copious bilious vomiting after blunt abdominal trauma should raise the suspicion of the evaluating physician. Often, a symptom-free interval of several hours is described. Physical examination usually discloses mild epigastric tenderness. A history of trauma may not be obtainable. An abdominal mass is rarely palpable. Laboratory values may show a mild elevation in the white blood cell count and, occasionally, an elevation of the serum bilirubin or amylase level. Profound fluid and electrolyte disturbances may be present if the obstruction has been long-standing, but this is rare. The basic findings on plain films of the abdomen are gastric distention, sometimes dilation of the proximal duodenum, an air fluid level in the duodenum, and absence of the right psoas shadow. The diagnostic test of choice has been an upper gastrointestinal series using water-soluble contrast material. This technique may demonstrate the classic "coiled spring" deformity of the duodenal mucosa known as Felson's sign[166] or the "stacked coin" sign. This radiographic finding reflects mucosal dissection of the hematoma. The obstruction is usually partial. If no duodenal perforation is observed, superior detail may be seen by repeating the upper gastrointestinal series using thin barium. Evidence of duodenal perforation must be sought diligently. If the serum amylase level is elevated, it is wise to obtain an abdominal CT to look for an associated pancreatic injury. The CT scan may also detect peritoneal air or extravasated contrast material in occult perforations.

Although some authors recommend operative intervention for duodenal hematoma,[161-168] consensus generally is to avoid surgical intervention, as most patients can be treated successfully without operation.[169-172] Nasogastric suction and parenteral feeding or hyperalimentation should be instituted. Careful attention should be paid to fluid and electrolyte balance. If the patient exhibits no sign of increase in abdominal pain or tenderness, then nonoperative management should be continued until the obstruction resolves. In most cases, this resolution occurs within 1 week; however, duodenal obstruction has persisted up to 38 days.[172] Patients with a diagnosis of duodenal hematoma must be observed carefully as a small number may harbor an occult duodenal perforation. The appearance of increased abdominal pain or tenderness on clinical examination, or retroperitoneal air on follow-up of plain abdominal films, mandates immediate surgical intervention. Approximately 3% of the patients with duodenal hematoma have occult duodenal perforations.[160] Some authors have recommended that an obstructing duodenal hematoma be evacuated through a seromuscular incision if discovered at the time of laparotomy for trauma.[161-168] If this evacuation cannot be accomplished, performance of a gastrojejunostomy has been recommended.[14] However, most authors would leave the duodenal hematoma undisturbed and allow 2–4 weeks for its resolution.[169-172] After this time has elapsed, and if the duodenal hematoma is not resolved, surgical intervention is then recommended for evacuation. Evacuation after this time may be technically easier. The evacuation is carried out by way of a seromuscular incision, avoiding penetration into the duodenal lumen. The seromuscular layer is then approximated with Lembert sutures of nonabsorbable materials.

Jewett et al.[173] recommended conservative management as the treatment of choice in the uncomplicated case in the pediatric population because obstruction is relieved in almost all patients. In contrast, the surgical approach carries a higher complication rate and results in an appreciably longer hospital stay. These authors recommended that surgery should be reserved for those cases complicated by perforation or a severely damaged duodenum. They also recommended hematoma evacuation, rather than bypass operations, for those few cases in which perforation or severe injury to the duodenum occurred.

PANCREATIC INJURY

Anatomy. The pancreas lies transversely in the retroperitoneal sac across the upper abdomen. It measures 15–20 cm in length, 3 cm in width, and 1–1.5 cm in thickness. Its average weight is approximately 90 g, ranging from 40 to 180 g. It is almost triangular in shape and is related to the omental bursa superiorly, the transverse mesocolon anteriorly, and the greater abdominal cavity inferiorly. Its motion is relatively limited, and for all practical purposes it is a fixed organ. The SMA and vein course posterior to the neck of the pancreas and are closely attached to the uncinate process, with this process wrapping around the posterolateral aspect of the vein (see Fig. 28.6).

The head of the pancreas lies within the concave sweep of the duodenum with the body crossing the spine and angled superiorly and toward the left shoulder, and the tail is in close proximity to the hilum of the spleen. Because of these relationships, the potential for associated injuries with injury to the pancreas is obvious; pancreatic injuries are uncommonly isolated.

The pancreas is arbitrarily divided into five parts: the head, uncinate process, neck, body, and tail. The head of the pancreas is defined as the portion lying to the right of the SMA and vein. It is located at the level of the second lumbar vertebra in the midline or slightly to the right of it. The head of the pancreas, which lies nestled in the C-loop of the duodenum and in conjunction with it, is suspended from the liver by the hepatoduodenal ligament. The head is firmly fixed to the medial aspect of the second and third portions of the duodenum. The division between the head and the neck is marked anteriorly by a line originating from the portal vein (PV) superiorly to the superior mesenteric vein (SMV) inferiorly.

The anterior pancreaticoduodenal arcade parallels the duodenal curvature but is related to the anterior pancreatic surface rather than to the duodenum. Similarly, the posterior surface of the head of the pancreas is related to the hilum and medial

border of the right kidney, the right renovascular pedicle, the IVC, and ostium of the left renal vein (RV), the right crus of the diaphragm, the posterior pancreaticoduodenal arcade, and the right gonadal vein.

The uncinate process is an extension of the lower left part of the posterior surface of the head, usually passing behind the PV and the superior mesenteric vessels just anterior to the aorta and IVC. The morphologic features of the uncinate process are variable. It may be entirely absent, or it may completely encircle the superior mesenteric vessels. In the presence of an uncinate process, 65% of the pancreas lies to the left of the superior mesenteric vessels. However, in its absence, 80% of the mass of the gland lies to the left of the superior mesenteric vessels. This is an important surgical consideration when planning distal pancreatectomy.

The neck of the pancreas measures approximately 1.5–2 cm in length and lies at the level of the first lumbar vertebra. It is defined as the portion that overlies the superior mesenteric vessels and is fixed between the celiac trunk superiorly and the superior mesenteric vessels inferiorly. Anteriorly, the neck is partially covered by the pylorus. To the right, the gastroduodenal artery gives rise to the superior pancreaticoduodenal artery. Posteriorly, the PV is formed by the union of the superior mesenteric and splenic veins (SV). In general, there are no anterior tributaries to these vessels. On occasion, however, one or two small veins may enter the PV and four to five may enter the SMV. Making contributions to the PV from the right are a few short lateral veins, and entering the PV from the left are both the left gastric and SV and, rarely, the inferior mesenteric vein.

The body of the pancreas lies at the level of the first lumbar vertebra and is technically defined as that portion of the pancreas that lies to the left of the superior mesenteric vessels. It is triangularly shaped and is related to the fourth portion of the duodenum and the ligament of Treitz. Both superior mesenteric vessels emerge from under the inferior border of the body and pass over the uncinate process of the head of the pancreas.

The splenic artery and vein course along the superior border of the pancreas. The anterior surface of the body of the pancreas is covered by the posterior wall of the omental bursa that separates the pancreas from the stomach. The pancreas is also related to the transverse mesocolon, which separates into two layers, one leaf covering the anterior and one leaf covering the inferior surface of the pancreas. The middle colic artery emerges from beneath the inferior border of the pancreas to course between the two leaves of the mesocolon. The inferior mesenteric vein passes posterior to the pancreas at the distal inferior margin of the body.

The tail of the pancreas rises to the level of the 12th thoracic vertebra. It is more mobile than the proximal pancreas. The tip is closely related to the hilum of the spleen and, along with the splenic vessels, is covered by the two leaves of the splenorenal ligament. There is no true anatomic division between the body and the tail of the pancreas.

The main pancreatic duct of Wirsung originates in the tail of the pancreas. According to Anacker,[174] two small ducts arise infrequently to form the main duct. Throughout its course in the tail and body, the duct lies midway between the superior and inferior margins and slightly more posterior than anterior. The duct of Wirsung and the accessory duct of Santorini lie anterior to the major pancreatic vessels.

The duct of Wirsung crosses the spinal column between the 12th thoracic and the 2nd lumbar vertebra.[175,176] In the body and tail, 15–20 short tributaries enter the duct at almost right angles.[174]. The superior and inferior tributaries tend to alternate with one another. In addition, the duct of Wirsung may receive a longer tributary draining the uncinate process. In some patients, the duct of Santorini in the head empties into the main duct. Multiple small tributary ducts in the head

may open directly into the intrapancreatic portion of the common bile duct or empty directly into the duodenum.[177] This is often cited as the reason for draining all pancreatic injuries postoperatively.

The arterial blood supply of the pancreas originates from both the celiac trunk and the SMA. Anatomic proximity and shared blood supply commonly result in both pancreatic and duodenal injuries. The duodenum and head of the pancreas are supplied by paired pancreaticoduodenal arterial arcades that are always present. They are formed by a pair of superior and inferior pancreaticoduodenal arteries, each bifurcating into anterior and posterior branches to form these arcades. These arcades lie within the pancreas and also supply the duodenum. They constitute the chief obstacles to complete pancreatectomy. All major arteries lie posterior to the ducts.

The gastroduodenal artery arises as the first major branch from the common hepatic artery approximately 1 cm after the common hepatic originates from the celiac trunk. It gives off the right gastroepiploic and, subsequently, the superior pancreaticoduodenal artery, which bifurcates into the anterior superior and posterior superior pancreaticoduodenal arteries. The anterior superior pancreaticoduodenal artery lies on the surface of the pancreas and gives off 8–10 branches to the anterior surface of the duodenum, 1–3 branches to the proximal jejunum, and numerous branches to the pancreas. During pancreatic resection, the duodenal branches may be ligated, but the jejunal branches must be preserved. The anterior superior pancreaticoduodenal artery enters the substance of the pancreas and passes posteroinferiorly to anastomose with the anterior inferior pancreaticoduodenal artery, a branch of the inferior pancreaticoduodenal artery arising from the SMA. The posterior superior pancreaticoduodenal artery can only be seen when the pancreas is mobilized in a cephalad direction to expose its posterior surface. The posterior superior pancreaticoduodenal artery then joins the posterior inferior pancreaticoduodenal artery from the inferior pancreaticoduodenal artery to form the posterior arcade. The dorsal pancreatic artery lies posterior to the neck of the pancreas and the SV and measures 1.5 mm in diameter.

The splenic artery is located on the posterosuperior aspect of the body and tail of the pancreas and follows a tortuous course along the superior margin of the pancreas. There are 2–10 branches of the splenic artery that supply the body and tail of the pancreas. Many of these branches anastomose with the transverse pancreatic artery. There are three possible configurations of the blood supply to the body and tail of the pancreas: type 1, the blood supply is from the splenic artery alone (22%); type 2, the blood supply is from the splenic and transverse pancreatic arteries with anastomosis in the tail of the pancreas (53%); and type 3, the blood supply is from the splenic and transverse pancreatic arteries without distal anastomosis (25%).

The pancreatica magna arises from the distal one-third of the splenic artery and quickly gives off numerous branches to the tail of the pancreas, several of which anastomose with the transverse pancreatic artery. The final contribution to pancreatic perfusion is the caudal pancreatic artery, which arises from the left gastroepiploic artery or from a splenic hilar branch. It anastomoses with branches of the pancreatica magna. The venous drainage of the pancreas in general parallels the arteries and lies superficial to them. Similar to the arteries, the veins are posterior to the ducts. The venous drainage of the pancreas is to the PV, the SV, and the superior and inferior mesenteric veins. Four pancreaticoduodenal veins form venous arcades that drain the head of the pancreas and the duodenum. The SV receives 3–13 short pancreatic tributaries.

The PV arises from the confluence of the superior mesenteric and SV behind the neck of the pancreas. Rarely, the inferior mesenteric vein can also enter at this junction. The PV

lies behind the pancreas and in front of the IVC and can be separated easily from the posterior surface of the pancreas.

Physiology. The pancreas is a compound tubuloalveolar gland with both endocrine and exocrine cells. The endocrine cells are separated histologically into nests of cells known as the islets of Langerhans. The proportion of the islet population in the tail is considerably greater than in the body and head.[178] There are three dominant types of islet cells: the alpha cells produce glucagon, the beta cells produce insulin, and the delta cells produce somatostatin. Insulin and glucagon secretion are both strictly regulated by blood sugar levels. A decrease in blood sugar triggers glucagon secretion, and the subsequent increase in blood sugar fosters insulin secretion.

The high concentration of islet cells in the tail of the pancreas suggests that distal pancreatectomy would be tolerated poorly in terms of the endocrine secretion of the gland. However, excision of more than 90% of the substance of the pancreas is required to produce endocrine deficiency, provided that the pancreas is otherwise normal. Partial resection induces hypertrophy and an increase in the physiologic activity of the remaining islets as a compensatory mechanism. A 90%-95% pancreatic resection performed for trauma will produce diabetes, but the digestion and absorption of food may not be disturbed. However, after total pancreatectomy, both enzymatic and hormonal replacement must be administered.

The exocrine secretion of the pancreas contains two components. The first component is an aqueous secretion of variable volume that is remarkable for its high concentration of bicarbonate. The other component is a solution of small volume containing digestive enzyme precursors that are synthesized and secreted by the acinar cells of the pancreas. A leak of pancreatic secretions from a duodenal repair or from a pancreaticojejunostomy will easily digest any suture line in close proximity, whether gastrointestinal or vascular.

Mechanism of Injury. Pancreatic injury is uncommon, 3.8% of all patients sustaining abdominal injuries.[179-184] The retroperitoneal location of the pancreas protects it from injury. Penetrating injuries include GSWs, SWs, shotgun wounds, and, during wartime, fragment injuries from grenades or shrapnel. Most blunt injuries occur as a result of motor vehicular crashes or assaults.

Penetrating injury is the most common cause of pancreatic trauma. In a review of the literature encompassing 76 series published during the last 44 years, 4,982 cases of pancreatic injury were identified. Seventy percent occurred as a result of penetrating trauma; 30% as a result of blunt trauma. Among the penetrating injuries 72.3% were by gunshots; 23.1% were stabbings, and 4.3% were shotgun blasts. Among blunt injuries, 85.5% were caused by motor vehicular crashes and 14.5% were caused by assault or miscellaneous injuries.[185-206]

The pancreas is a retroperitoneal organ that lies against a rigid vertebral column. Unlike the somewhat mobile duodenum, the pancreas is fixed in position and therefore prone to crush injury. Crushing injuries usually occur when a direct force is applied to the abdominal wall and transmitted to the pancreas, which is then compressed posteriorly against the rigid, unyielding vertebral column. A classic example of crush injury occurs when the steering wheel or bicycle handbar impacts the midepigastrium. Forces applied to the right upper quadrant can be expected to cause injuries to the head of the pancreas, whereas direct impacts on the midepigastrium usually fracture the neck of the pancreas. Forces applied to the left upper quadrant often cause injury to the tail of the pancreas.

Associated Injuries. The pancreas, by virtue of its anatomic proximity to other important organs, is rarely injured alone; multiple associated injuries are the rule. Isolated pancreatic injury is usually seen in the form of blunt pancreatic transection, generally at the neck of the gland. A review of 50 series published during the last 45 years identified a total of 3,465 cases of pancreatic injury. These patients sustained a total of 7,526 associated injuries. The liver was the most commonly injured organ (19.3%). Other commonly injured organs included the stomach (16%); spleen (11%); colon (8%); and duodenum (7.8%).

Major abdominal venous injuries occurred in 5.5%; IVC, PV, and SMV most commonly. Arterial injuries occurred in 4.5%, with the aorta and SMA most frequently. Two hundred sixty-eight unspecified major vascular injuries could not be classified; thus, major vascular injuries in 13.7% overall. Vascular injuries were therefore the third most frequent injuries encountered with pancreatic injury.

Anatomic Location of Injury. To identify the anatomic location of pancreatic injuries, we reviewed 12 series published during the last 40 years. The most frequent site of injury was the pancreatic head and neck (37%). The pancreatic body was injured in 36%, and the pancreatic tail in 26%. Multiple sites of injury occurred in 3%. The distribution of injuries differs for penetrating and blunt trauma. Whereas penetrating trauma injuries are distributed throughout the anatomic course of the pancreas, in blunt trauma most injuries occur at the neck of the gland.

Diagnosis. The diagnosis of pancreatic injury requires a high index of suspicion. Delay in diagnosis and management of pancreatic injury will be accompanied by substantially increased morbidity and mortality rates. For example, patients involved in head-on collisions and patients who have sustained steering wheel damage or required extrication, particularly when they have been trapped against the steering wheel, may harbor pancreatic injury. Patients who have sustained blows to the midepigastrium should also be evaluated carefully.

Retroperitoneal location of the pancreas usually precludes early detection of injury by physical examination. Abdominal discomfort and pain may be out of proportion to the physical examination findings because peritoneal irritation may occur late and become apparent only when blood or pancreatic enzymes, initially contained within the retroperitoneum, extravasate into the peritoneal cavity. The physical examination is usually characterized by few, if any, findings. Any tenderness over the right upper quadrant or midepigastrium should always be evaluated with a suspicion for an underlying pancreatic injury. Obviously, signs of rebound tenderness, abdominal rigidity, or the absence of bowel sounds indicate intra-abdominal injury; although nonspecific findings, they should prompt immediate surgical intervention.

Laboratory tests provide little help in the early diagnosis of pancreatic injuries. The serum amylase level has long been considered as a diagnostic test for pancreatic injury. However, a wide range of elevations in the serum amylase level has been reported in 10%-91% of patients who had serum amylase determinations obtained preoperatively.[186-189] Amylase determinations are neither sensitive nor specific for pancreatic injury.[186-206] Serum amylase isoenzymes are not considerably more accurate than conventional serum amylase levels.[192-196]

Currently, CT is the imaging method of choice for the diagnosis of acute pancreatic injury. On the other hand, the findings of pancreatic injury may be subtle, especially soon after injury. Unexplained thickening of the anterior renal fascia suggests pancreatic injury and should prompt further evaluation of the pancreas by other methods.[194-213] Recently, Lane et al.[211] summarized the positive CT findings in pancreatic injury, including "direct visualization of a parenchymal fracture or hematoma, intraperitoneal and extraperitoneal fluid, fluid separating the SV and pancreatic body, thickened left anterior

renal fascia, focal fluid at the sight of fracture, and retroperitoneal hematoma." A recent multicenter from AAST comparing 16-slice to 64-slice CT demonstrated that even new technology CT commonly misses pancreatic injury.[214] The sensitivity for diagnosis of any pancreatic injury was 60% for 16-slice CT and 47% for 64-slice CT. The sensitivity for diagnosis of pancreatic duct injury was 54% for 16-slice CT and 52% for 64-slice CT.

Hayward et al.[215] in 1989 proposed the routine use of ERCP preoperatively as a valuable tool for excluding pancreatic injury. Whittwell et al.[216] further validated the role of early ERCP in the evaluation of patients with blunt pancreatic trauma.

In addition to diagnosis, ERCP has been used as an interventional modality for ductal disruptions.[217,218] Duchesne used ERCP to stage patients in the initial evaluation of possible pancreatic injury. This preoperative evaluation confirmed ductal injury in patients who then underwent laparotomy and avoided operation in those patients with an intact pancreatic duct. He also cited the opportunity to intervene with ERCP, with placement of a stent.[219]

Surgical Management of Pancreatic Injury. Proven or suspected pancreatic injury, coupled with the classic findings of intra-abdominal injury (i.e., abdominal tenderness, guarding, or rebound tenderness), mandates immediate exploratory laparotomy. Broad-spectrum antibiotics are administered before the abdominal incision. We prefer the use of a second-generation cephalosporin and agree with Jones[220] and Nichols et al.[221] that cefoxitin provides ample coverage initially.

Abdominal injuries should be explored through a midline incision extending from xiphoid to pubis. The goals in the operative management of pancreatic injury have changed little since Stone's classic report in 1981. "Proper management of pancreatic wounds is based on three essentials: (1) arrest of hemorrhage, (2) selective debridement, and (3) control of pancreatic secretions. Failure to satisfy these tenets routinely leads to the development of serious and often lethal complications."[189] Immediate control of life-threatening hemorrhage from vascular or solid organs such as the liver or spleen should be the first goal of the operation, followed by immediate control of any sources of gastrointestinal spillage. The next step in the management of abdominal trauma should consist of a thorough exploration of the abdominal cavity. The pancreas should be explored carefully, and the pancreatic head, neck, body, and tail should be visualized directly. Intraoperative findings that should increase the suspicion of a pancreatic injury include the presence of a central retroperitoneal hematoma, proximity injuries, bile staining of the retroperitoneum, and edema surrounding the pancreas and lesser sac.

Exsanguinating injuries posing an immediate threat to life may divert the trauma surgeon's attention from detection of a pancreatic injury. The goal of a thorough and meticulous exploration of all pancreatic injuries is to establish the presence or absence of a major pancreatic ductal injury. The presence of ductal disruption is the "sine qua non" of a major pancreatic injury, and a major determinant in morbidity. A complete exploration and visualization of the entire pancreas and duodenum requires multiple approaches, including a thorough and extensive retroperitoneal exploration with the use of several maneuvers.

Recently, Asensio et al.[222] described a unified approach for the surgical exposure of pancreatic injuries. These maneuvers provide full visualization of the anterior and posterior walls of the entire pancreatic gland. A Kocher maneuver should first be performed by incising the lateral peritoneal attachments of the duodenum and sweeping the second and third portions medially with the use of a combination of sharp and blunt

dissection. When a large retroperitoneal hematoma is encountered, the nasogastric tube should be advanced through the pylorus and palpated digitally to serve as a guide and to avoid iatrogenic laceration of the duodenal wall during dissection. This mobilization should be extensive enough that the surgeon can palpate the entire head of the pancreas to the level of the superior mesenteric vessels. This maneuver will allow the surgeon to visualize the anterior and posterior aspects of the second and third portions of the duodenum and will also permit exposure of the head and uncinate process of the pancreas and IVC. If the pericaval tissues are dissected cephalad, the suprarenal IVC can also be exposed. The uncinate process is absent in 15% of patients. When the trauma surgeon considers performing a distal pancreatectomy, the determination should be whether the patient possesses an uncinate process. Normally, a resection to the left of the superior mesenteric vessels extirpates approximately 65% of the gland. Although this is an extensive resection, pancreatic exocrine or endocrine insufficiency generally does not result. However, when the uncinate process is absent, a resection to the left of the superior mesenteric vessels may result in pancreatic insufficiency and the need for insulin replacement.

The next maneuver to be performed in the exposure of the pancreas consists of division of the gastrohepatic ligament to gain access to the lesser sac. This facilitates inspection of the superior border of the pancreas including the head and body and the splenic artery and vein as they course along the superior border of the pancreas. Division of the gastrocolic ligament permits full inspection of the anterior aspect and inferior border of the gland along its entire length.

On occasion, an associated splenic injury is found with a hematoma that obscures the splenic hilum and tail of the pancreas. Aird and Helman[223] described a maneuver to expose the splenic hilum by mobilizing the splenic flexure of the colon and the lienosplenic, splenocolic, and splenorenal ligaments to mobilize the spleen from a lateral to medial position. In addition to excellent exposure of the spleen and its vascular supply, this allows visualization of the posterior aspect of the tail of the pancreas.

When an injury penetrates the anterior surface of the pancreas, the surgeon must ascertain whether the integrity of the main pancreatic duct has been violated. This requires exposure of the posterior aspect of the body and tail of the pancreas. This may be accomplished by transecting the retroperitoneal attachments of the inferior border of the pancreas while elevating the pancreas cephalad to allow inspection of the posterior surface of the gland followed by bimanual palpation. This maneuver is technically challenging and should be performed with meticulous precision to prevent iatrogenic injury to the superior mesenteric vessels. These maneuvers provide accurate intraoperative assessment of both glandular and ductal integrity. Thus, thorough assessment of the pancreas intraoperatively requires both **visual inspection** of the entire gland and **bimanual palpation** of the pancreas.

In the assessment of pancreatic injuries, it is important to recognize any major ductal injury. The use of intraoperative observations such as direct visualization of ductal violation, complete transection of the pancreas, free escape of pancreatic fluid, laceration of more than one-half of the diameter of the gland, central perforation, and severe laceration with or without massive tissue disruption predict the presence of a major ductal injury with a high degree of accuracy. However, there are circumstances in which the assessment of ductal integrity cannot be made. In these uncommon cases, intraoperative pancreatography has been recommended as a technique for the visualization of the main pancreatic duct. In our opinion, intraoperative pancreatography has a limited role and should be reserved for the assessment of ductal integrity when injuries have occurred at the head of the pancreas and when the

trauma surgeon considers vital the determination of whether there is extensive damage to the major duct in the head (i.e., as a criterion for selection of a complex procedure such as pancreaticoduodenectomy).

After a pancreatic injury is identified, its extent should be defined. Factors that play a role in its management include the number of associated injuries and their acuity. Risk factors defined by Asensio et al.[224] known to increase mortality rates in patients with pancreatic injury include the presence of associated duodenal and common bile duct injuries because their management must be taken into account in the operative procedure selected to treat the pancreatic injury. We recommend that all pancreatic injuries be staged according to the AAST-OIS for duodenum[20] (Table 28.7).

Many different surgical techniques for the treatment of pancreatic injuries have been described. Approximately 60% of all pancreatic injuries can be treated by external drainage alone. Closed-suction systems with wide drainage of the pancreas are critical in the management. Fabian[119] reported the superiority of closed-suction drainage for pancreatic trauma in a randomized prospective study, with septic complications after pancreatic injury considerably reduced by closed-suction drainage. The authors postulated that bacterial contamination through sump catheters is a major source for intra-abdominal infections after pancreatic trauma. There is no consensus about the length of time that drains must remain in place. We recommend leaving the drains in place for a minimum of 10–14 days and certainly until after the patient resumes oral intake.

The trauma surgeon should decide early whether damage control is needed according to the patient's physiologic state. Subsequently, the trauma surgeon can choose the procedures that are needed to repair the pancreatic injury definitively. Grade I and grade II injuries occur with a frequency of 60% and 20%, respectively.[11] Grade III injuries represent 15% of all pancreatic injuries, whereas grades IV and V injuries are uncommon, occurring with a frequency of only 5%. It is for this higher grade of injury that the more complex surgical techniques should be reserved.

We advocate that all pancreatic contusions and shallow capsular tears or lacerations be managed by simple external drainage with closed-suction systems. The capsule of the pancreas should not be closed by itself, because this has been known to lead to the formation of pancreatic pseudocyst. Any injury that violates the pancreatic parenchyma should be examined meticulously to determine whether there is ductal involvement.

At times it may be quite difficult for the surgeon to establish the involvement of the major ductal system. This presents a dilemma for the trauma surgeon. Performing a pancreatorrhaphy in this scenario will not only miss, but undertreat a major ductal injury, thereby increasing the possibility for the development of severe postoperative complications. In this situation, we assume a ductal injury and upgrade the injury to select a more appropriate treatment, which, in this case, would be pancreatic resection. This decision is straightforward if the injury lies to the left of the superior mesenteric vessels where distal resection, although challenging, does not approach the degree of complexity of a resection to the right of the superior mesenteric vessels. If the injury is to the right of the superior mesenteric vessels, the surgeon must consider either draining extensively and accepting the potential development of a pancreatic fistula with its attendant morbidity or performing an extended resection to the right of the superior mesenteric vessels.[225-229] Patton et al.[230] addressed intraoperative assessment and management of pancreatic injury in 134 patients. Thirty percent of injuries were to the right of the superior mesenteric vessels (proximal) and 70% were distal. All proximal pancreatic injuries were managed by drainage without resection. Two-thirds of distal pancreatic injuries underwent distal pancreatectomy based on high suspicion of ductal injury. In the subgroup of patients with distal pancreatic injury and indeterminate ductal integrity, the complication rate was similar whether managed by drainage alone (27%) or distal resection (33%). The incidence of pancreatic fistula in this series of pancreatic injuries was 15%, nearly all of which closed spontaneously. Thus, this paper suggests that the vast majority of proximal pancreatic injuries can be treated by drainage alone. The rare, devastating combined pancreatic and duodenal injury may require pancreaticoduodenectomy.

In 1961, Fogelman[231] reported the first series of many from Parkland Memorial Hospital in Dallas. The author clearly outlined some of the basic surgical principles in use today for the management of pancreatic injuries. He recommended the use of pancreatorrhaphy with nonabsorbable suture to repair pancreatic parenchymal lacerations, adding the caveat that the

pancreatorrhaphy should not be performed until the continuity of the main pancreatic duct has been evaluated. He recommended obligatory drainage of pancreatic injuries and outlined reasons such as the technical impossibility of completely closing disrupted pancreatic tissue and the high frequency of secondary pancreatic breakdown resulting in enzyme spillage and lesser sac chemical and bacterial phlegmon formation. He also strongly advocated pancreatic resection as the most reliable method for treating pancreatic injuries.

Kerry and Glass[232] in 1962 were the first to report pancreaticoduodenal injuries as an entity and described an approach to their management that included resection of the traumatized pancreas whenever possible, wide debridement of the duodenum, and diversion of gastrointestinal secretions from the injured area. They recommended early diagnosis and prompt, aggressive surgical management. This publication set in motion the ideas that would later crystallize with the development of duodenal diverticularization and pyloric exclusion procedures.

Stone et al.[233] in 1962 outlined the evolution of principles for the care of pancreatic injuries. Reporting his own experience with 62 cases of pancreatic injuries, the author recommended a step-by-step approach to management consisting of hemostasis, conservative debridement, and control of pancreatic secretions. He condemned reanastomosis of the ductal system of the pancreas and advocated ligation of the end of the severed major duct and proposed pancreatectomy as the mainstay of management of pancreatic injury. Similarly, he recommended that pancreaticojejunostomy should be used infrequently and only when conservation of pancreatic tissue is of the utmost necessity.

Pancreaticoduodenectomy was suggested by Thal and Wilson[234] in 1964 as a treatment for patients who sustained severe blunt trauma to the head of the pancreas. Thal and others have recommended that pancreaticoduodenectomy should be limited to patients with massive pancreaticoduodenal injuries.[222,234-237]

In 1979, Pachter et al.[238] reported the use of a stapling device to perform distal pancreatectomy. In 1982, Robey et al.[239] reported four cases of distal pancreatectomy with splenic salvage for blunt traumatic injuries. In 1989, Pachter et al.[240] reported the nine patients treated with distal pancreatectomy with splenic preservation, and refuted the surgical dogma that splenic preservation is more time-consuming than distal pancreatectomy and splenectomy.

In 1991, Gentilello et al.[241] reported pancreatic ductal ligation as a safe alternative to pancreaticojejunostomy after pancreaticoduodenectomy in hemodynamically unstable patients. When comparing pancreatic duct ligation to pancreaticojejunostomy, he found no statistical difference in either the mortality rate or pancreatic morbidity rate.

We reviewed 62 series that outlined the surgical methods used to treat pancreatic injury. Fifty-nine percent of the patients were treated with external drainage, and 28% were treated with distal pancreatectomy. A combination of distal pancreatectomy and pancreaticojejunostomy was used in only 2.5% of the cases. Pancreaticoduodenectomy is a formidable procedure in critically ill patients. A review of 80 series reported in the literature from 1964 to 2008 yielded a total of 255 patients who underwent pancreaticoduodenectomy. The tabulated mortality rate for all series reviewed was 31%, essentially unchanged for decades.[232-245]

Pancreaticoduodenal Injury. Severe pancreaticoduodenal injury is fortunately rare. The vast majority of these injuries are commonly caused by penetrating trauma and frequently associated with multiple injuries. Patients with higher pancreatic injury severity who have associated duodenal injuries should be considered candidates for more complex pancreaticoduodenal repairs such as pyloric exclusion. Candidates include patients with pancreatic injury grade II or above in association with injury to the common bile duct, involving more than 75% of the duodenal wall and involving the first and second portions of the duodenum or associated with delay in repair of more than 24 hours. Other criteria that may lead the surgeon to consider diverticularization or pyloric exclusion include compromised blood supply to the duodenum and associated injury to the head of the pancreas without disruption of the main pancreatic duct or pancreatic injury associated with a duodenal injury involving more than 50% of the circumference of the duodenum. The main purpose of these procedures is to exclude the duodenum from the passage of gastric contents and a suitable period of time for the duodenal repair to heal. In the presence of a pancreatic injury, these procedures can only be used if the duodenal injury is amenable to primary repair.

The original duodenal diverticularization was described by Berne et al.[115]; its main purpose was to decrease the high rate of morbidity and mortality in patients who incurred combined pancreaticoduodenal injuries. The original diverticularization procedure included antrectomy, debridement, and closure of the duodenum, tube duodenostomy, vagotomy, biliary tract drainage, and feeding jejunostomy. The classical duodenal diverticularization is a time-consuming and complicated surgical procedure that many critically injured patients can hardly withstand and has thus been abandoned.

An alternative method to achieve exclusion of the duodenal suture line and diversion of the gastric contents was devised by Vaughan et al.[245] This procedure entailed duodenorrhaphy plus a gastrotomy in the most dependent portion of the greater curvature of the stomach through which the pylorus is identified and occluded with a large, running, nonabsorbable suture. Care must be taken to avoid exclusion of antral tissue from the gastric lumen. A gastrojejunostomy is then performed through the previously created gastrotomy to achieve complete pyloric occlusion and diversion of the gastric contents, plus any pancreatic repair or resection, and external drainage (see Fig. 28.8). Graham et al.[246] reported 68 patients who sustained combined pancreaticoduodenal injuries, 32 of whom required pyloric exclusion (30 temporarily and 2 permanently) resulting from gastric antral wounds. No deaths occurred, and only two duodenal fistulas developed, for an incidence rate of 6.9%. Both fistulas healed successfully.

Mortality. Pancreatic injury carries a considerable mortality rate. A review of a total of 4,134 patients in the literature reveals a mean mortality of 19.1% (range 5%-54%). Associated injuries are responsible for the majority of the deaths in patients with pancreatic injury. Early deaths are from hemorrhage due to associated vascular, splenic, or hepatic injury. Shock is a strong predictor of mortality in the patient with pancreatic injury. Late deaths are due to infection, associated with pancreatic or hollow viscus injury.

The number of associated injuries is also an important determinant of the mortality rate, with increasing mortality as the number of associated injuries rises. In series totaling 712 patients, reported the mortality rate for patients with 0–1, 2–3, and 4 or more associated injuries was 2.5%, 13.6%, and 29.6%, respectively.[200,190,248]

The mechanism of injury is an important determinant of the mortality rate, with the highest mortality associated with close range shotgun injury (54%). Nineteen series presented a breakdown of mortality rates according to the mechanism of injury. The mean mortality rate for penetrating injury was 20% versus 19% for blunt trauma. Proximal pancreatic injuries are also related to increases in mortality rates.

Morbidity. Forty series in the literature encompassing 3,898 patients with pancreatic injury were reviewed, reporting an average morbidity of 36.6% (range 11%-62%).[102-150]

Pancreatic morbidity is represented primarily by fistulas, with an incidence of 14%. Pancreatic abscess was the second most frequent complication (8%), followed by posttraumatic pancreatitis (4%), pseudocyst (3%), and late hemorrhage (1%). Collected under the category of other complications that occurred in 4% is exocrine and endocrine insufficiency. Exocrine or endocrine insufficiency is unusual after pancreatic injuries. Distal pancreatectomy to the left of the superior mesenteric vessels should leave adequate functioning pancreatic tissue.[88,246,247,249]

The literature shows no uniformity in the definition of what constitutes a pancreatic fistula. In fact, prolonged pancreatic drainage is considered the rule with these injuries. Furthermore, a controlled pancreatic fistula may be simply an expected result of appropriate therapy. Our definition of a fistula is any drainage of >50 mL that persists longer than 2 weeks with objectively measured and elevated amylase and lipase levels. The majority of pancreatic fistulae will ultimately close without further operative intervention.

Fistulas may rarely result in death if they are associated with pancreatic abscess. Aggressive parenteral nutrition with absolute gastrointestinal tract rest is the standard method for the treatment of these fistulas. Enteral nutrition with an elemental diet provided with a distal feeding jejunostomy has been tried as an alternative, but the authors have observed in some cases that the fistula output has increased considerably in some patients whereas others tolerate enteral nutrition well and without any concomitant increase in the output.

More recently, the long-acting somatostatin analog, octreotide acetate, has been used to inhibit pancreatic exocrine secretion. This treatment was originally reported as a helpful adjunct in the management of postoperative complications after elective pancreatic procedures.[250] Good results were noted, with decreased time to closure of the postoperative fistula. The use of this synthetic analog has been extended to the treatment of posttraumatic pancreatic fistulas, but there are few data in the literature documenting its efficacy.

It is difficult to establish definitive guidelines for when operative intervention or ERCP with stent placement is required in the management of fistulae. However, reintervention should be considered for fistulae of >2 months duration with unrelenting production of high volumes. These fistulas can be managed either by pancreatic resection or resection with internal drainage.

Pancreatic abscess as a specific infectious complication of pancreatic injury is difficult to define, given the large number of associated injuries in pancreatic trauma. The association with either a colon or duodenal injury is known to result in a 60% rate of abscess formation versus a much lower rate of 10%-15% in patients without colonic or duodenal injuries. Similarly, Jones[247] reported that 60% of patients with colon injuries in his series experienced the development of intra-abdominal abscess, but few were related to the pancreatic injury.

Cogbill et al.[225] reported intra-abdominal abscess formation in 24 of 71 surviving patients, for an incidence of 34%. He established a correlation between abscess formation and large requirements for blood transfusions during the first 24 hours and also reported that these abscesses were found much more frequently in patients with associated hollow viscus injuries. Left upper quadrant abscesses are much more common after distal pancreatectomy than after distal pancreatectomy with splenic preservation. The mainstay of management consists of percutaneous CT-guided drainage. Cogbill et al.[225] reported a 79% success rate with this approach.

True pancreatic complex abscesses associated with pancreatic necrosis and infected peripancreatic fluid collections are generally not amenable to percutaneous CT-guided drainage. These abscesses often require surgical reintervention to debride necrotic pancreatic tissue and to establish generous drainage.

Posttraumatic pancreatitis has been defined by Cogbill et al.[225] as persistent serum amylase elevations persisting for more than 3 days. The vast majority of posttraumatic pancreatitis results from blunt abdominal trauma. A complication of posttraumatic pancreatitis is its evolution into hemorrhagic pancreatitis. This is usually manifested by bloody pancreatic drainage. This condition carries a high mortality rate.

Pancreatic pseudocysts generally result from overlooked blunt pancreatic injuries treated nonoperatively. In addition, pseudocyst formation is regarded as failure to establish adequate postoperative drainage for pancreatic secretions. The presence of a pseudocyst should be considered if there is prolonged elevation of the serum amylase postoperatively and should be pursued aggressively.

Posttraumatic pseudocysts should be investigated with ERCP, which will delineate the status of the pancreatic duct. This is important for selection of the method of treatment. If the ductal system is found to be intact, the pseudocyst can be managed with percutaneous drainage. If the pseudocyst is a result of a missed ductal injury, percutaneous drainage will not provide definitive therapy, and these patients are best treated by reexploration and pancreatectomy or internal drainage by a Roux-en-Y jejunal limb. In rare circumstances, endoscopic transpancreatic stenting of the pancreatic duct has been tried successfully.

Posttraumatic hemorrhage can be a lethal complication. Erosion of the vessels surrounding the pancreas may occur when there has been an inadequate debridement or external drainage and is unpredictable. The management consists of urgent return to the OR, but this carries a high mortality rate. Angiographic embolization has been used as a temporizing measure before return to the OR, or for definitive control.

Liver Injury

The liver is the most commonly injured intra-abdominal organ; injury occurs more often with penetrating trauma than in blunt trauma. The mortality rate for liver injury is 10%, higher for blunt than penetrating injury. Richardson[251,252] has documented this decrease in mortality from liver injury over the past several decades. As he outlined, the reasons for improved outcome include damage control and packing of liver injury, improved operative techniques, arteriography and embolization, and the nonoperative management of the majority of hepatic injuries.

Anatomy. An understanding of hepatic anatomy is essential to manage complex liver injuries.[253-255] A sagittal plane from the IVC to the gallbladder fossa separates the right and left lobes of the liver (Cantlie's line). The segmental anatomy of the liver is shown in Figure 28.9. The right and left hepatic veins have a short extrahepatic course before they empty directly into the IVC (Fig. 28.10).[253] The middle hepatic vein usually joins the left hepatic vein within the liver parenchyma. The retrohepatic IVC (8–10 cm in length) has multiple, small hepatic veins which enter the IVC directly; this area is difficult to access and control. The PV delivers 75% of the hepatic blood flow and 50% of the oxygenated blood. The right and left hepatic arteries generally arise from the common hepatic artery. Anomalies are frequent and include the right hepatic artery originating from the SMA (15%) and the left hepatic artery originating from the left gastric artery (12%).

Adequate mobilization of the liver requires division of the ligamentous attachments. The falciform ligament divides the left lateral segment of the liver from the medial segment of the left lobe. The coronary ligaments are the diaphragmatic attachments to the liver (anterior and posterior leaflets); they do not meet on the posterior surface of the liver (the bare area). The triangular ligaments (left and right) are the more
FIGURE 28.9. Hepatic anatomy. The liver is separated into nine anatomic segments. (Redrawn from Burlew CC, Moore EE. Injuries to the liver, biliary tract, spleen, and diaphragm. In: ACS Surgery: Principles and Practice. 2010 Decker Intellectual Properties. http://74.205.62.209/bcdecker/pdf/acs/part7_ch07.pdf., page 4, Figure 6.)

lateral extensions of the coronary ligaments. Injury to the diaphragm, phrenic veins, and hepatic veins must be avoided during mobilization of the liver.

Diagnosis. The appropriate diagnostic modality depends on the hemodynamic status of the patient on arrival in the trauma resuscitation area. If the patient is hemodynamically unstable due to liver injury, immediate laparotomy is required;
FIGURE 28.10. Anatomy of the retrohepatic IVC. (Redrawn from Buckman RF Jr, Miraliakbari R, Badellino MM. Juxtahepatic venous injuries: a critical review of reported management strategies. *J Trauma* 2000;48:979, Figure 1.)

these patients generally have grade IV or V hepatic injury. If the patient is hemodynamically stable with a blunt mechanism of injury, CT is the diagnostic test of choice. The key decision point in the management of the patient with liver injury is whether he/she is stable and can undergo CT. In essence, hemodynamically stable patients with liver injuries can be treated nonoperatively. FAST and DPL will document hemoperitoneum, but are not specific for liver injury. Of liver injuries, 70% are no longer bleeding at the time of laparotomy for a positive DPL.

Treatment. The management of blunt hepatic injury has evolved substantially in the past several years. The hemodynamically stable patient with blunt injury of the liver, without other intra-abdominal injury requiring laparotomy, can be treated nonoperatively, regardless of the grade of the liver injury.[252,253,255-260] This represents 60%-85% of patients with liver injury. The presence of hemoperitoneum on CT does not mandate laparotomy. Arterial blush or pooling of contrast on CT and high-grade (grade IV and V) hepatic injuries is most likely to fail nonoperative management. Nonetheless, embolization can circumvent the need for laparotomy; angioembolization has assumed an increasing role in the treatment of liver injury, both in nonoperative management and postoperatively after laparotomy.[261-264] If arterial bleeding is suspected intraoperatively, postoperative angiography/embolization may be necessary. Liver necrosis is not unexpected after substantial embolization. This may be complicated by abscess formation.

The criteria for nonoperative management of blunt liver injuries include hemodynamic stability, absence of peritoneal signs, lack of continued need for transfusion for the hepatic injury. Posterior right lobe injuries (even if extensive) and the split-liver type of injuries (extensive injury along the relatively avascular plane between the left and right lobes) can generally be managed successfully nonoperatively. The details of nonoperative management are institution-specific and provider-specific. Remember that as many as 26% of patients managed nonoperatively will require an intervention for a complication; only 15% will require an operation. Ninety percent of the patients with a complication requiring treatment have grade IV or V liver injury.[262] The complications generally are managed by ERCP and stent for bile duct leak, percutaneous drainage of an abscess or biloma, or arteriography/embolization for bleeding. Similarly, the need to re-image asymptomatic hepatic injuries by CT scan is not documented. Follow-up CT can be deferred, except to document healing (at ~8 weeks) in physically active patients (e.g., athletes) before resumption of normal activities.

Immediate laparotomy or angiographic intervention is required for those patients with hemodynamic instability, continued blood product requirement (<10%), or who fail nonoperative therapy by demonstrating enlarging lesions on CT scan.[258,265-268] The majority of patients requiring laparotomy for hepatic injury are hemodynamically unstable on arrival and have grade IV or V liver injury. The hemodynamically unstable patient requires immediate operative management. Management principles include availability of blood and a rapid infusion system through upper torso access. Exploration is through a long midline incision. In the past, extension to a median sternotomy or right thoracotomy was advocated for exposure of the liver injury. A right subcostal extension, (left or even bilateral subcostal extension) gives good exposure and nearly always avoids the thoracotomy or sternotomy (Fig. 28.11).[269] Use of a self-retaining retractor (Rochard, Thompson, or Upper Hand) to lift the upper edges of the wound cephalad and anteriorly facilitates exposure of the liver. Complete mobilization of the liver is performed, including division of the ligaments.[265-279]

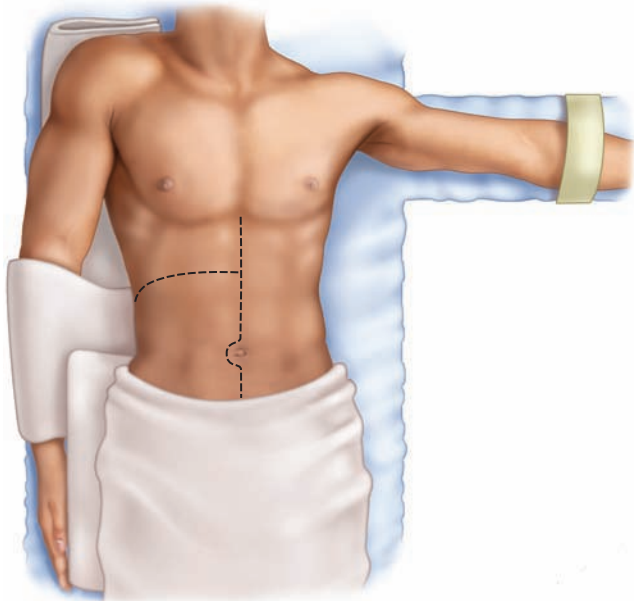
TRAUMA


FIGURE 28.11. Combined midline–transverse incision for major hepatic injury. The patient is in the supine position with the right flank and shoulder slightly elevated. (Redrawn from Berney T, Morel P, Huber O, et al. Combined midline–transverse surgical approach for severe blunt injuries to the right liver. *J Trauma* 2000;48: 350, Figure 1.)

Most blunt and penetrating hepatic injuries are grades I-III (85%) and can be managed with simple techniques (e.g., electrocautery, simple suture, or hemostatic agents) (Table 28.8). Complex liver injuries can produce exsanguinating hemorrhage. Rapid, temporary tamponade of the bleeding by manual compression of the liver injury immediately after entering the abdomen allows the anesthesiologist to resuscitate the patient (Fig. 28.12A). After resuscitation, the liver injury can be repaired. Attempts to identify major hepatic injury prior to effective resuscitation will generally exacerbate the patient's bleeding and coagulopathy (Fig. 28.12B).

For complex hepatic injuries, occlude the portal triad with an atraumatic clamp or vessel loops (Pringle maneuver). This should reduce bleeding from the liver, except in the setting of retrohepatic venous injuries. Studies suggest that 60 minutes of warm hepatic ischemia can be tolerated. Especially in the hypotensive patient, we intermittently release the clamp to perfuse the liver, rather than allow continuous ischemia. Hepatorrhaphy with individual vessel ligation is recommended instead of large ischemia-producing mass parenchymal suturing. Glisson's capsule is incised with the electrocautery. The injury within the liver is approached by the finger fracture technique (Fig. 28.13) or by division of the liver tissue over a right-angled clamp with ligation of the hepatic tissue with 2-0 silk sutures, or more recently with the stapler. Use of the stapling devices has greatly facilitated management of elective and urgent liver surgery because of the speed added to the operation. With gentle traction on the liver edges, expose the injury site. Blood vessels and bile ducts are directly visualized and ligated or repaired. Nonviable liver tissue should be debrided. The defect in the liver can be packed with viable omentum. Use closed-suction drainage of grade III-V injuries. Drains are not necessary for grade I and II injuries if bleeding and bile leakage are controlled. Perform resectional debridement of nonviable tissue rather than formal anatomic resection. Perform perihepatic packing in cases of hemorrhage, hypothermia, and coagulopathy. Approximately 5% of patients with hepatic injury require perihepatic packing (damage control laparotomy).[253,265,266,272-282] Indications include coagulopathy, subcapsular hematomas, bilobar injuries, and hypothermia, or to allow transfer of the patient to a higher level of care.

Anatomic hepatic resection (segment or lobe) is not often required for liver injury; resectional debridement and direct suture control of the vessels and ducts can generally accomplish the same objectives, with lower mortality. Indications for formal hepatic resection include total destruction of a segment or lobe, an extensive injury that cannot be controlled with perihepatic packing and control of bleeding that can be achieved only by anatomic resection. Planned, delayed anatomic resection is also an approach for major hepatic injury, if packing sufficiently controls hemorrhage during the initial laparotomy.[265,272,275,278,281]

TABLE 28.8

LIVER INJURY SCALE (1994 REVISION)

■ GRADE[a]	■ TYPE OF INJURY	■ DESCRIPTION OF INJURY	■ AIS-90
I	Hematoma	Subcapsular, <10% surface area	2
	Laceration	Capsular tear, <1 cm parenchymal depth	2
II	Hematoma	Subcapsular, 10%-50% surface area; intraparenchymal <10 cm in diameter	2
	Laceration	Capsular tear 1–3 cm parenchymal depth, <10 cm in length	2
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma >10 cm or expanding	3
	Laceration	Parenchymal depth >3 cm	3
IV	Laceration	Parenchymal disruption involving 25%-75% hepatic lobe or 1–3 Couinaud's segments	4
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud's segments within a single lobe	5
	Vascular	Juxtahepatic venous injuries (i.e., retrohepatic vena cava/central major hepatic veins)	5
VI	Vascular	Hepatic avulsion	6

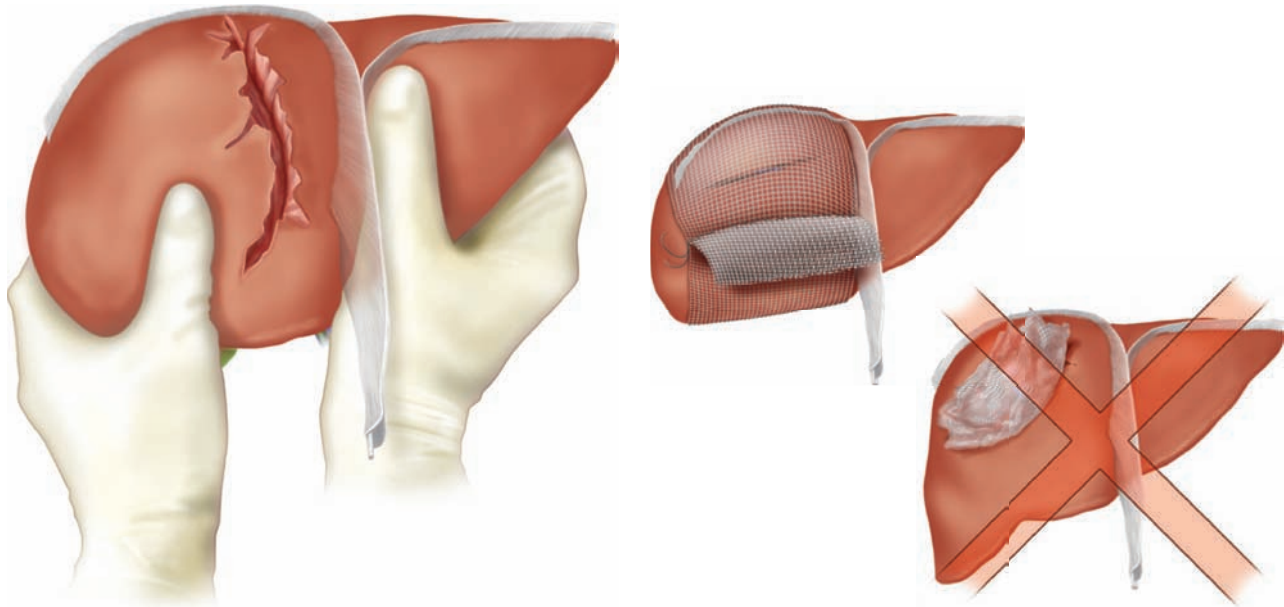
[a]Advance one grade for multiple injuries up to grade III.
AIS, abbreviated injury score.
From Moore EE, Shackford SR, Pachter HL. Organ injury scaling: spleen, liver and kidney. *J Trauma*. 1995;38:323–324.


FIGURE 28.12. **A:** When compressing the liver to achieve tamponade, it is critical to realign the liver parenchyma back to its normal anatomic position. When compressing the left and right lobes back together, gently push the liver posteriorly and superiorly to compress any venous bleeding from behind the liver. (Redrawn from Badger SA, Barclay R, Campbell P, et al. Management of liver trauma. *World J Surg.* 2009;33:2528, Figure 5). **B:** The same principles of normal anatomic restorations are essential when packing the liver. Do so with the intent of realigning the liver to normal position. Forcing packs in a crack within the liver will worsen the injury and bleeding. (From Badger SA, Barclay R, Campbell P, et al. Management of liver trauma. *World J Surg* 2009;33:2529, Figure 7.)

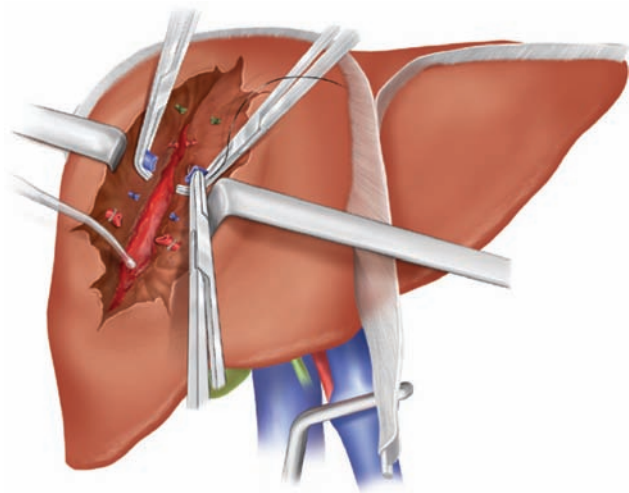
Selective hepatic artery ligation has been reported in 1%-2% of hepatic injury cases. (We rarely use this technique.) The liver will generally tolerate this because of the oxygen content of portal blood. Direct suture control of bleeding within the liver is preferable to hepatic artery ligation. Nonetheless, patients with considerable central hepatic laceration who had damage control laparotomy may be candidates for arteriography with possible embolization postoperatively.


FIGURE 28.13. To gain control of bleeding from the liver, the liver injury is enlarged by hepatotomy and bleeding controlled by direct suture or ligation. Rapid access may be obtained by finger-fracture technique or the stapling devices. (Redrawn from Badger SA, Barclay R, Campbell P, et al. Management of liver trauma. *World J Surg.* 2009;33:2530, Figure 8.)

Cholecystectomy may be required secondary to ischemic complications from interruption of the right hepatic artery.

Hepatic vascular isolation with occlusion of the suprahepatic and infrahepatic venae cavae, as well as application of the Pringle maneuver, may be required for major retrohepatic venous injury. Atrial-caval shunts have been recommended by some for retrohepatic caval injury (not the authors). A 36F chest tube or 9-mm endotracheal tube, each with extra side holes, is inserted through the right atrial appendage. The side holes allow flow from the shunt into the right atrium. The distal end of the tube is at the level of the RV. Survival with this technique is dismal. Alternatively, complex retrohepatic vascular injury in which tamponade does not achieve hemostasis can be repaired in an avascular field on venovenous bypass with total hepatic vascular isolation. The hypovolemic trauma patient may not tolerate suprahepatic caval clamping for any period of time. Survival depends on prompt recognition of this anatomic site of injury. Our approach to retrohepatic venous injuries includes experienced help at the OR table, self-retaining retractors with anterior and cephalad pull on the costal margin for exposure, rapid and full mobilization of the liver, extension of the midline incision as discussed above, and direct exposure and repair of the venous injury.

Bleeding from penetrating wounds of the liver that are not easily accessed, at times, can be controlled with internal tamponade (Fig. 28.14). This is accomplished by using Penrose drains tied at each end (as a balloon) over a red rubber catheter. The end of the Penrose drain is brought through the skin.[279] Finally, in wounds where tamponade does not achieve hemostasis, consider repair under vascular isolation by experienced personnel.

Outcome. Mortality correlates with the degree of injury. Because most hepatic injuries are grades I-II, the overall mortality for liver injuries is 10%. However, the mortality for more severe liver injury is grade III, 25%; grade IV, 46%; and grade
FIGURE 28.14. Balloon tamponade to control bleeding from a bullet tract through the liver, using a foley within a penrose drain. (Redrawn from Burlew CC, Moore EE. Injuries to the liver, biliary tract, spleen, and diaphragm. In: ACS Surgery: Principles and Practice. Decker Intellectual Properties; 2010. http://74.205.62.209/bcdecker/pdf/acs/part7_ch07.pdf., page 10, Figure 10.)

V, 50%-80%, in many series. Notably, Polanco et al. recently reported a liver-related mortality of 9% for high-grade liver injury.[259,267,271]

Complications. With recurrent bleeding (occurs in 2%-7% of patients), return the patient to the OR or, in selected patients, obtain an angiogram and perform embolization. Recurrent bleeding is generally caused by inadequate initial hemostasis. Hypothermia and coagulopathy must be corrected. Preparations to control retrohepatic hemorrhage (i.e., vascular bypass) should be made. Hemobilia is a rare complication of liver injury. The classic presentation is right upper quadrant pain, jaundice, and hemorrhage; one-third of patients have all three components of the triad. The patient may present with hemobilia days or weeks after injury. Treatment is angiogram and embolization.

Intrahepatic or perihepatic abscess or biloma (occurs in 7%-40% of patients) can generally be drained percutaneously. Meticulous control of bleeding and repair of bile ducts, adequate debridement, and closed-suction drainage are essential to avoid abscess formation. Biliary fistulas (>50 mL per day for >2 weeks) usually resolve nonoperatively if external drainage of the leak is adequate and distal obstruction is not present. If >300 mL of bile drains each day, further evaluation with a radionuclide scan, a fistulogram, ERCP, or a transhepatic cholangiogram may be necessary. Major ductal injury can be stented to facilitate healing of the injury or as a guide if operative repair is required. Endoscopic sphincterotomy or transampullary stenting may facilitate resolution of the biliary leak. *Extrahepatic biliary tract injury* is uncommon. The gallbladder is the most common site; cholecystectomy is the usual treatment. Injury to the extrahepatic bile ducts can be missed at laparotomy unless careful operative inspection of the porta hepatis is performed. A cholangiogram through the gallbladder or cystic duct stump defines the injury. The location and severity of the injury will dictate the appropriate treatment. Simple bile duct injury (<50% of the circumference) can be repaired with primary suture repair. Complex bile duct injury (>50% of the circumference) may require Roux-en-Y choledochojejunostomy or hepaticojejunostomy. Primary end-to-end

anastomosis of the bile duct is not advised; the stricture rate approaches 50%.

Splenic Injury

The paradigm shift toward nonoperative management of blunt abdominal injury has been dramatic with injury to the spleen.[252,283-292] Several decades ago, the only therapy for blunt injury of the spleen, irrespective of magnitude, was splenectomy. Led by the pediatric surgeons who demonstrated that splenic injury could be observed and the awareness of overwhelming post-splenectomy infection (OPSI), the majority of blunt splenic injuries are observed currently.[285,293-303] Blunt splenic injury is produced by compression or deceleration force (e.g., from motor vehicle crashes, falls, or direct blows to the abdomen). Penetrating injury to the spleen is far less common.

Anatomy and Function. The spleen is bounded by the stomach, left hemidiaphragm, left kidney and adrenal gland, colon, and chest wall.[304] These relationships define the attachment of the spleen: gastrosplenic ligament, splenorenal ligament, splenophrenic ligament, splenocolic ligament, and pancreaticosplenic attachments. The spleen receives 5% of the cardiac output, primarily through the splenic artery. The splenic artery usually bifurcates into superior and inferior polar arteries. Further division of the blood supply is along transverse planes. The spleen has an open microcirculation without endothelium. The white pulp comprises 25% of splenic volume and is the lymphoid component of the spleen. The red blood is 75% of splenic volume and contains the splenic cords and sinuses. It filters blood-borne bacteria, particulate matter, and aged cells. The spleen produces antibodies, properdin, and tuftsin. In addition, the spleen comprises 25% of the lymphoid mass in humans.

Diagnosis. The patient may have signs of hypovolemia with tachycardia or hypotension, or complain of left upper quadrant tenderness or referred pain to the left shoulder (Kehr's sign). Physical examination is insensitive and nonspecific in the diagnosis of splenic injury. The patient may have signs of generalized peritoneal irritation or left upper quadrant tenderness or fullness. Twenty-five percent of patients with left lower rib fractures (ribs 9 through 12) will have splenic injury. In the unstable trauma patient, ultrasound or DPL provides the most rapid diagnosis of hemoperitoneum, the source of which is commonly the spleen. In the stable patient with blunt injury, CT of the abdomen provides delineation and grading of the splenic injury (Table 28.9).[260] The most common finding on CT in association with a splenic injury is hemoperitoneum. Interestingly, hemoperitoneum in children with blunt injury to the spleen is uncommon, thus making FAST unreliable in the pediatric population. The need and timing of follow-up CT remain controversial. Our practice is to obtain follow-up CT of blunt splenic injury at 48 hours. This is based on the data of Fabian's group,[305-307] demonstrating that serial CT documented early splenic artery pseudoaneurysms in 4% of patients and another 3% of splenic artery pseudoaneurysms were found only on the follow-up CT.

Angiography has been used as an adjunct in the management of splenic injury in highly selected patients, with therapeutic embolization of arterial bleeding. The role of angiography/embolization for splenic injury is still evolving and highly variable between hospitals.[305-323] The majority of the studies advocating liberal use of angiography/embolization utilize historical controls.[308-316] With the rapid evolution toward nonoperative management of blunt splenic injury, such comparisons are difficult to interpret. We use angiography/

TABLE 28.9

SPLEEN INJURY SCALE (1994 REVISION)

GRADE[a]	INJURY TYPE	DESCRIPTION OF INJURY	AIS-90
I	Hematoma	Subcapsular, <10% surface area	2
	Laceration	Capsular tear, <1 cm parenchymal depth	2
II	Hematoma	Subcapsular, 10%-50% surface area; intraparenchymal, <5 cm in diameter	2
	Laceration	Capsular tear, 1–3 cm parenchymal depth that does not involve a trabecular vessel	2
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma ≥5 cm or expanding	3
	Laceration	Parenchymal depth >3 cm or involving trabecular vessels	3
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)	4
V	Laceration	Completely shattered spleen	5
	Vascular	Hilar vascular injury that devascularizes spleen	5

[a]Advance one grade for multiple injuries up to grade III.
AIS, abbreviated injury score.

TRAUMA

embolization of splenic injury in the stable patient with an arterial blush.

The time course for healing of blunt splenic injuries treated nonoperatively has not been clearly delineated. What seems defined is that the higher the grade splenic injury, the longer the spleen takes to heal; time to radiographic evidence of healing of the spleen correlates with the grade of splenic injury. Second, more than 80% of splenic injuries will heal by 2–2½ months postinjury.[324,325]

Treatment. The availability of abdominal CT and an understanding of the importance of splenic function have resulted in the preservation of the majority of injured spleens, by nonoperative management. Safe management of splenic injury depends primarily on the hemodynamic stability of the patient on presentation. Unstable patients due to splenic injury, irrespective of the grade, should be in the OR. Other factors include the age of the patient, associated injuries (which are the rule in adults), and the grade of the splenic injury. Nonoperative management of splenic injury is successful in >90% of children, irrespective of the grade of splenic injury. Nonoperative management of blunt splenic injury in adults has become more routine; 65%-80% of adults ultimately managed nonoperatively for blunt injury to the spleen.[288,326] If hemodynamically stable, adult patients with grade I or II injury can generally be treated nonoperatively. Patients with grade IV or V splenic injuries are most often unstable. Grade III splenic injuries (certainly in children, and in selected adults) can be treated nonoperatively based on stability and reliable physical examination. The failure rate of nonoperative management of splenic injuries in adults is 5%-10% and increases with grade of splenic injury: grade I, 5%; grade II, 10%; grade III, 20%; grade IV, 33%; and grade V, 75%.[286,327,328] In two recent studies from the National Trauma Data Bank, failure rates for high-grade splenic injuries (grades IV and V) were 53% and 55%.[290,319] In the study by Watson et al., 60% of 3,085 adults with grade IV and V splenic injuries went directly to the OR. Of the 40% of high-grade splenic injuries which were admitted for observation, 55% failed. Thus, the majority (80%) of grade IV and V splenic injuries in adults ultimately underwent laparotomy. As mortality for failed nonoperative management increased from 0% to 15.7% over the period of the study, it suggests that many of these patients may have been better served by early splenectomy. The EAST multicenter study of failure of nonoperative management of blunt splenic injury corroborates the hypothesis that high-grade splenic injuries and hypotensive patients need to be in the OR.[327] The potential consequences of observation of the adult with blunt splenic injury, especially high-grade injuries or patients with hypotension, are that preventable deaths will occur. Fastidious judgment and patient selection are critical for safe nonoperative management of blunt splenic injury. In adults (but not in children), risk of failure of nonoperative management of blunt splenic injury correlates with grade of splenic injury and quantity of hemoperitoneum.

Sixty percent of failures occur within 24 hours of injury; 90% of failures occur within 72 hours of injury.[325-327] Patients with substantial splenic injuries managed nonoperatively should be observed in a monitored unit and have immediate access to CT, a surgeon, and an OR. Changes in physical examination, hemodynamic stability, ongoing blood or fluid requirements indicate the need for laparotomy.

If the patient is not hemodynamically stable, operative treatment is required. The operative therapy of choice is splenic conservation where possible to avoid the risk of death from OPSI. However, in the presence of multiple injuries or critical instability, splenectomy is most appropriate.

Exploration is through a long midline incision. The abdomen is packed and explored. Exsanguinating hemorrhage and gastrointestinal soilage are controlled first.

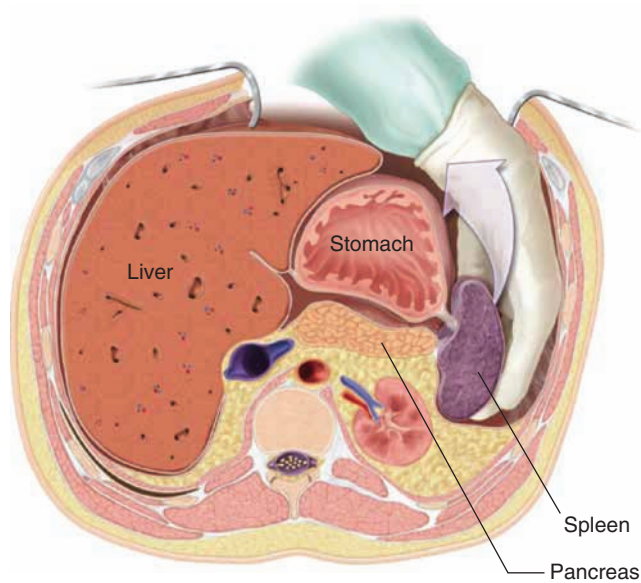
Mobilize the spleen to visualize the injury. The operator's nondominant hand will provide medial traction on the spleen to facilitate the operation. The splenocolic ligament can be vascular and require ligation. The splenorenal and splenophrenic ligaments are avascular and should be divided sharply; avoid injury to the splenic capsule as this is performed (Fig. 28.15). Further mobilize the spleen by bluntly freeing it from the retroperitoneum. It is important to stay in the plane posterior to the pancreas as the spleen and pancreas are mobilized. The hilum of the spleen can then be controlled with manual compression. The gastrosplenic ligament with the short gastric vessels is divided and ligated near the spleen to avoid injury or late necrosis of the gastric wall. Fully mobilize the spleen into the operative field. Splenectomy should be performed in unstable patients, and in those with associated life-threatening injury, or multiple sources for postoperative blood loss (pelvic fracture, multiple long bone fractures), and complex


FIGURE 28.15. Mobilization of the spleen from the left upper quadrant to the midline. (Redrawn from Trunkey DD. Spleen. In: Blaisdell FW, Trunkey DD, eds. *Trauma Management: Abdominal Trauma*. New York, NY: Thime-Stratton; 1982:190, Figure 10.3.)
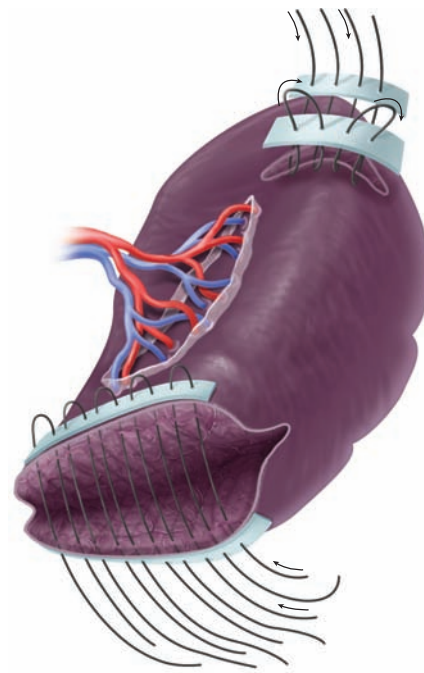

FIGURE 28.16. Splenic repair using pledgets after splenic resection. (Redrawn from Moore EE. Splenic injury. In: Dudley H, Carter D, Russell RCG, eds. *Rob and Smith's Operative Surgery*. Boston, MA: Butterworth; 1989:370, Figure 9.)

splenic injuries. Splenorrhaphy should be considered when circumstances permit. Because of the increased reliance on nonoperative management of splenic injury, the opportunity to attempt splenorrhaphy is uncommon. The technique is dictated by the magnitude of the splenic injury and the patient's hemodynamic status. Nonbleeding grade I splenic injury may require no treatment. Topical hemostatic agents, an argon beam coagulator, or electrocautery may suffice. Grade II-III splenic injuries may require the aforementioned interventions, suture repair, or mesh wrap of capsular defects. Suture repair in adults often requires Teflon pledgets to avoid tearing of the splenic capsule (Fig. 28.16). Grade IV and V splenic injuries may require anatomic resection, including ligation of the lobar artery. A small rim of capsule at the resection line may help reinforce the resection line. Pledgeted horizontal mattress sutures may also be necessary. Grade V splenic injury usually requires splenectomy. One-third of the splenic mass must be functional to maintain immunocompetence.[328] Thus, at least one-half of the spleen must be preserved to justify splenorrhaphy. Drainage of the splenic fossa is associated with an increased incidence of subphrenic abscess and should be avoided. The exception is when concern exists about injury to the tail of the pancreas.

Outcome. The outcome is generally good; rebleeding rates as low as 1% have been reported with splenorrhaphy. The failure rate of nonoperative therapy is 2% in children and generally 5%-10% in adults. It had been reported previously that adults >55 years of age are especially susceptible to failure of nonoperative therapy[329,330]; current data do not support this contention.[331,332] Although the failure of nonoperative management of blunt splenic injury is higher in the very old (>75 years), age alone does not mandate operation.[332]

Pulmonary complications, which are common in patients treated operatively and nonoperatively, include atelectasis, left pleural effusion, and pneumonia. Left subphrenic abscess occurs in 3%-13% of postoperative patients and may be more common with the use of drains or with concomitant bowel injury.

Thrombocytosis occurs in as many as 50% of patients after splenectomy; the platelet count usually peaks 2–10 days postoperatively. The elevated platelet count generally abates in several weeks. Treatment is usually not required.

The risk of OPSI is greater in children than in adults; the overall risk is <0.5%.[293,300-304] The mortality rate for OPSI approaches 50%. The common organisms are encapsulated organisms: meningococcus, *Haemophilus influenzae*, and *Streptococcus pneumoniae*, as well as *Staphylococcus aureus* and *Escherichia coli*. After splenectomy, pneumococcal (Pneumovax), *H. influenzae*, and meningococcal vaccines should be administered.[293-296,317,334] The timing of injection of the vaccine is controversial. Some authors recommend giving the vaccine 3–4 weeks postoperatively because the patient may be too immunosuppressed in the immediate postinjury period. We vaccinate the patient prior to discharge from the initial hospitalization. Current recommendation is to repeat the pneumococcal vaccination at 5 years. The patient should be discharged from the hospital with a clear understanding of the concerns about OPSI, should wear a tag alerting health care providers of his or her asplenic state, and should begin penicillin therapy with the development of even mild infections.

Abdominal Vascular Injury

Abdominal vascular injuries are among the most lethal injuries sustained by trauma patients. Similarly, these injuries are also among the most difficult and challenging injuries encountered by trauma surgeons. Generally, these patients arrive at trauma centers in profound shock secondary to massive blood loss, which is often unrelenting. Patients sustaining abdominal vascular injuries best exemplify the lethal vicious cycle of

shock, acidosis, hypothermia, coagulopathy, and cardiac dys-rhythmias.[335-340] Many of these patients present in cardiopul-monary arrest and require drastic life-saving measures, such as emergency department thoracotomy, aortic cross-clamping, and open cardiopulmonary resuscitation for any opportunity to reach the OR alive. To compound the problem, exposure of bleeding retroperitoneal vessels is difficult and requires exten-sive dissection and mobilization of intra-abdominal organs. These maneuvers are time-consuming and fraught with pit-falls, as rapid dissection through large retroperitoneal hemato-mas can lead to iatrogenic injury in patients who can ill afford further injury.[335-340]

Abdominal vascular injury rarely occurs as an isolated entity. In fact, multiple associated injuries are the rule rather than the exception, thus increasing not only injury severity but the time needed to repair many critical associated injuries. Abdominal vascular injuries are also characterized by massive blood losses requiring large quantities of crystalloid solution, blood and blood products for intravascular volume replace-ment. Coupled with the frequent need to cross-clamp the aorta or other major intra-abdominal vessels, this scenario predis-poses these patients to the development of reperfusion injuries and if they survive, their sequelae.[6]

The concept of "bail out" later renamed as "damage control" is usually applied in patients sustaining abdominal vascular injuries. Similarly, these patients often demand tem-porary abdominal wall closure with prosthetic materials, which initiates a cycle of frequent surgical reinterventions, producing additive physiologic and immunologic insults to an already compromised patient.[338]

The classical dilemma encountered by trauma surgeons of how to repair vascular injuries in the midst of massive contamination while avoiding graft infections and vessel blowout remains a difficult problem. Septic processes and multiple system organ failure (MSOF) are frequent compli-cations encountered by these patients, as profound shock, tissue hypoperfusion, massive blood volume replacement, generalized edema, and prolonged contamination places these patients at risk for these complications. All of these factors clearly conspire to produce high morbidity rates for patients sustaining these injuries. Improved outcomes are generally the result of expedient and precise surgical interventions by trauma surgeons with experience in the management of these injuries along with the vast surgical armamentarium needed to effectively deal with them.[339-342]

Anatomic Location of Injury. Abdominal vascular injury associated with blunt trauma most commonly occurs in upper abdominal vessels (Table 28.10).[335] However, penetrating inju-ries may occur in any of the retroperitoneal zones, as missile

TABLE 28.10

ABDOMINAL VASCULAR INJURY SCALE

■ GRADE[a]	■ DESCRIPTION OF INJURY	■ AIS-90
I	Non-named SMA or SMV branches	NS
	Non-named IMA or inferior mesenteric vein branches	NS
	Phrenic artery or vein	NS
	Lumbar artery or vein	NS
	Gonadal artery or vein	NS
	Ovarian artery or vein	NS
II	Right, left, or common hepatic artery	3
	Splenic artery or vein	3
	Right or left gastric arteries	3
	Gastroduodenal artery	3
	IMA, or inferior mesenteric vein, trunk	3
	Primary named branches of mesenteric artery (e.g., ileocolic artery) or mesenteric vein	3
	Other named abdominal vessels requiring ligation or repair	3
III	SMV, trunk	3
	Renal artery or vein	3
	Iliac artery or vein	3
	Hypogastric artery or vein	3
	Vena cava, infrarenal	3
IV	SMA, trunk	3
	Celiac axis proper	3
	Vena cava, suprarenal and infrahepatic	3
	Aorta, infrarenal	4
V	Portal vein	3
	Extraparenchymal hepatic vein	3/5
	Vena cava, retrohepatic or suprahepatic	5
	Aorta suprarenal, subdiaphragmatic	4

[a]This classification system is applicable to extraparenchymal vascular injuries. If the vessel injury is within 2 cm of the organ parenchyma, refer to specific organ injury scale. Increase one grade for multiple grade III or IV injuries involving >50% vessel circumference. Downgrade one grade if <25% vessel circumfer-ence laceration for grade IV or V.
NS, not scored; AIS, abbreviated injury score.
From Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scales III: chest wall, abdominal vascular, ureter, bladder and urethra. *J Trauma.* 1992;33:337–339.

trajectories are unpredictable, frequently injuring more than one vessel. The cumulative effect on mortality rises as multiple vessels are injured. Because of close proximity between abdominal arteries and veins, the potential for the development of arteriovenous fistulas exists either acutely or chronically; however, they are uncommon.[343-344]

The abdominal aorta may be injured at its suprarenal or infrarenal portions. The IVC may be injured at its suprarenal or infrarenal portions or its retrohepatic location, one of the most lethal injuries. The SMA may be injured in any of its four zones, just as the SMV may be injured at its infrapancreatic or retropancreatic location. The PV may be injured either at its origin at the confluence of the superior mesenteric and SV or it may be injured alone within the confines of the portal triad. The renal artery (RA) may be injured in one of its three portions whereas the RVs may be injured either at their confluence with the IVC or at the renal hilum.[343-344]

Operative Intervention. In the OR, the patient's entire torso from the neck to mid-thighs and table to table laterally is prepared and draped. The area to the mid-thighs is important should the necessity arise to obtain autogenous saphenous vein graft. The trauma surgeon must confirm that there are sufficient units of blood in the OR for immediate transfusion via rapid infusion technology. Maneuvers to prevent hypothermia include placement of a warming blanket on the operating table, covering the patient's lower extremities with a circulating warm air mattress, covering the head to prevent heat loss, increasing the ventilator cascade temperature to 42°C, and an ample supply of heated irrigation fluids. In addition, the availability of autotransfusion apparatus and cell-saving technology is of great value. Appropriate instruments and shunts must be available, including the Argon beam coagulator and newer hemostatic agents.[335,343]

Exposure and Incisions. Abdominal injuries should be explored through a midline incision extending from xiphoid to pubis. Immediate control of life-threatening hemorrhage followed by immediate control of sources of gastrointestinal spillage are early goals. The next step in the management of abdominal injuries consists of a thorough exploration of the abdominal cavity. Since the abdominal vasculature resides in the retroperitoneum, a thorough exploration of these structures must be performed utilizing a systematic approach of the anatomic zones of the retroperitoneum.

Surgical Technique. The first and most important goal in the management of abdominal vascular injuries is hemorrhage control. As in all vascular injuries, proximal and distal control of the bleeding vessel is required. However, in exsanguinating abdominal vascular injury, achieving this rapidly may be difficult. Unfortunately, a notable number of patients succumb without vascular control.[335-341,343,345]

Frequently, these patients experience severe and profound hypotension, therefore cross-clamping of the aorta is the first maneuver instituted to stop life-threatening hemorrhage. If the patient arrives profoundly hypotensive or experiences cardiopulmonary arrest in the OR, an immediate left anterolateral thoracotomy with aortic cross-clamping and open cardiopulmonary resuscitation should be performed prior to proceeding with the laparotomy.[335,336-340,343,345]

For patients who arrive with hemodynamic stability, but decompensate during laparotomy, the abdominal aorta can be controlled at the aortic hiatus, either digitally or by the use of an abdominal aortic root compressor, or by cross-clamping with a Crawford-DeBakey or other aortic clamps. Placement of a cross-clamp in this location is difficult, as the abdominal aorta is surrounded by the crura of the diaphragm, which often requires transection of the crus to reach

a portion of the infradiaphragmatic aorta to place the aortic crossclamp.

Once the exsanguinating hemorrhage has been controlled, the trauma surgeon should classify the hemorrhage or hematoma into one of the three zones of the retroperitoneum. Zone I begins at the aortic hiatus and ends at the sacral promontory; it is located at the midline with the spinal column posteriorly. This zone is divided into supramesocolic and inframesocolic compartments. Zone II, right and left are located at the pericolic gutters. Zone III begins at the sacral promontory and contains the major pelvic blood vessels (Fig. 28.17).

Zone I supramesocolic contains the suprarenal abdominal aorta, the celiac axis (Tripod of Haller), and the first two parts of the SMA. The SMA is divided into four parts. Part 1 has its origin at the aorta and ends at the point where the inferior pancreaticoduodenal artery emerges; Part 2 from the origin of the inferior pancreaticoduodenal to the origin of the middle colic artery; Part 3 is the trunk distal to the middle colic artery; and Part 4 encompasses the origins of the segmental jejunal, ileal, or colic branches. Zone I supramesocolic also contains the infrahepatic suprarenal IVC, the infrarenal IVC as well as the proximal portion of the SMV.[345-349]

Zone I inframesocolic contains the last two portions of the SMA, the IMA, the infrarenal aorta and vena cava, as well as the distal SMV. Zone II is divided into right and left, each containing the renal vascular pedicle. Zone III contains the bifurcation of the aorta into the common iliac arteries and veins which further bifurcate into the internal and external iliac vessels. It also contains the retroperitoneal venous plexus of the Batson. The portal–retrohepatic area contains the PV, hepatic artery, and retrohepatic vena cava.[345-350]

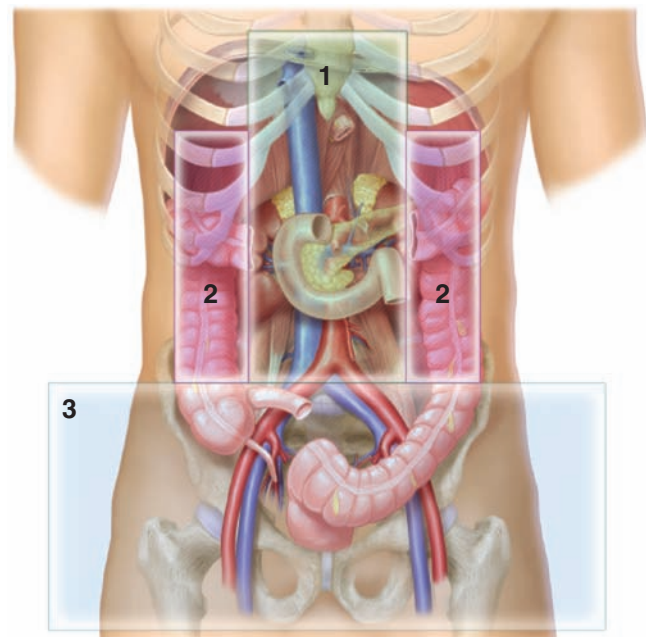
Thus, the trauma surgeon first identifies the location of the hemorrhage or hematoma into one of the zones of the retroperitoneum. The surgeon must then approach this zone to obtain vascular control, expose the injured blood vessel, and attempt definitive repair and/or ligation. Each zone requires different and complex maneuvers for exposure of these vessels.


FIGURE 28.17. Retroperitoneal zones. (Redrawn from Kudsk KA, Sheldon GF. Retroperitoneal hematoma. In: Blaisdell FW, Trunkey DD, eds. *Trauma Management: Abdominal Trauma.* New York: Thime-Stratton; 1982:281, Figure 14-2.)

Zone I supramesocolic is generally approached utilizing a maneuver that rotates the left-sided viscera medially (left medial visceral rotation) (Fig. 28.18). This approach requires transection of the avascular line of Toldt of the left colon, along with incision of the lienosplenic ligament and rotation of the left colon, spleen, tail, and body of the pancreas as well as the stomach medially. This exposes the aorta from its entrance into the abdominal cavity via the aortic hiatus and includes exposure of the origin of the celiac axis,[348] the first two zones of SMA and the left renal vascular pedicle.[345-351] The left kidney can be mobilized medially, although this is generally not done.[351]

An alternative maneuver includes performing an extended Kocher maneuver along with transection of the avascular line of Toldt of the right colon, mobilizing medially the right colon, hepatic flexure, duodenum, and head of the pancreas to the level of the superior mesenteric vessels; elevating these structures in a cephalad direction and incising the loose retroperitoneal tissue to the left of the IVC (right medial visceral rotation) (see Fig. 28.7). This maneuver exposes the suprarenal abdominal aorta between the celiac axis and the SMA. This maneuver has a disadvantage in that the exposure obtained is below the level of any injury to the supraceliac aorta and the aorta at the hiatus.[335-341]

Maneuvers used to expose injuries in zone I inframesocolic include displacing the transverse colon and mesocolon cephalad, eviscerating the small bowel to the right, locating the ligament of Treitz, transecting it along with the loose retroperitoneal tissue alongside the left of the abdominal aorta until left RV is located. This exposes the infrarenal aorta. Meticulous attention must be directed to avoid iatrogenic injury to the IMV. To expose the infrarenal IVC, the avascular line of Toldt of the right colon is transected while performing an extensive Kocher maneuver sweeping the pancreas and duodenum to the left and incising the retroperitoneal tissues covering the IVC.

Exposure to right and left zone II depends as to whether the perirenal hematoma is actively bleeding and whether it is located laterally or medially. If active bleeding is found medially or if there is an expanding hematoma, vascular control of the RA and vein is required. Vessel loops should be used for control; alternatively, a Henley subclavian/renal clamp may also be used. On the right, this is achieved by mobilizing the

FIGURE 28.18. Left medial visceral rotation. (Redrawn from Singh N. Major abdominal vascular trauma. In: Martin MJ, Beekley Ac, eds. *Front Line Surgery*. New York, NY: Springer; 2010:145, Figure 11.2.)

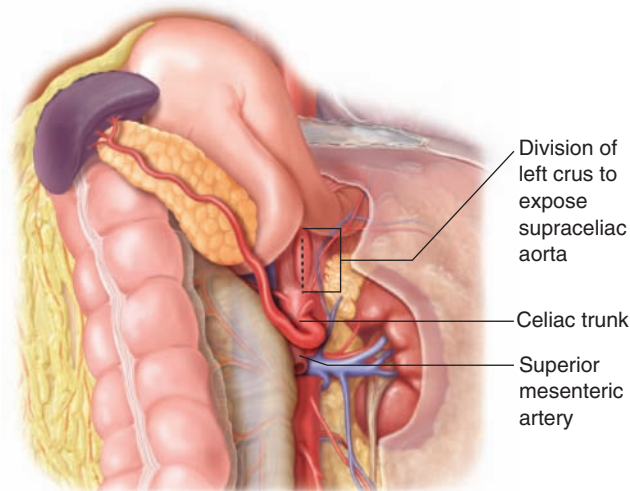
right colon and hepatic flexure as well as performing a Kocher maneuver, exposing the IVC infrarenally and continuing the dissection cephalad by incising the tissues directly over the suprarenal infrahepatic IVC. This is continued until the right RV is encountered. Further dissection superiorly and posteriorly to the right RV will locate the right RA.[351]

On the left side, the left colon and splenic flexure are mobilized. The small bowel is then eviscerated to the right. The ligament of Treitz is located, and the transverse colon and mesocolon are displaced cephalad. This should expose the intrarenal abdominal aorta. Cephalad dissection will locate the left RV as it crosses over the abdominal aorta. The left RA will also be found superiorly and posteriorly to the left RV. Once mobilized and controlled and if uninjured, the renal vessels may be retracted with a vein retractor Alternatively, if a perirenal hematoma or active bleeding is found laterally with no extension into the hilum of the kidney, the lateral aspects of Gerota's fascia can be incised and the kidney elevated and displaced medially to locate the hemorrhage.

Exposure of the vessels in zone III can be achieved by transection of the avascular line of Toldt of both the right and left colons and displacing them medially. Utilizing a combination of blunt and sharp dissection, the common iliac vessels are located. Meticulous attention must be paid to locate and preserve the ureter as it crosses the common iliac artery. Avoid devascularization of the ureter's blood supply. A vessel loop should be passed around the ureter to retract it. Dissection is then extended in a caudad direction, opening the retroperitoneum over the vessels.[351]

Structures in the portal–retrohepatic area are difficult to expose and require extensive dissection. The PV is formed by the confluence of the SMV and the slightly smaller SV posterior to the neck of the pancreas.[349] This confluence is located just to the right of the body of the second lumbar vertebra (L2) and immediately anterior to the left border of the IVC. The inferior mesenteric vein (IMV) is the third major tributary to the IVC contributing its flow to the PV, by entering either the SV generally, or SMV in the immediate vicinity of the major confluence rarely. In as many as 30% of cases, the IMV enters at the angle of the major confluence. In contrast to the suprapancreatic PV, the retropancreatic confluence zone is not intimately related to the bile duct or hepatic artery.

Sound knowledge of the anatomy of the portal confluence is of utmost importance to trauma surgeons. From its origin, the valveless PV passes cephalad, inclining slightly rightward over its course of 7.5–10 cm to reach the hilum of the liver, where it divides extrahepatically into right and left branches. During its course, it passes in succession behind the upper pancreatic neck and the first portion of the duodenum. Then, upon entering the hepatoduodenal ligament, it forms a relationship with the hepatic artery and bile duct, lying behind these structures and forming the anterior border of the foramen of Winslow. Throughout its length, the PV lies immediately anterior to the suprarenal segment of the IVC. The PV receives, in addition to its main tributaries, the pyloric vein from the pancreas and duodenum, left gastric (coronary) vein, and the superior pancreaticoduodenal vein. A cystic vein, if present, also drains into the PV.

Wounds of the suprapancreatic PV can be exposed by an extensive Kocher maneuver, with mobilization and rotation of the hepatic flexure of the colon. Preliminary hepatic inflow occlusion and the division of the cystic duct facilitate the exposure. Retropancreatic wounds involving the portal confluence or its major tributaries and suprapancreatic wounds with suspected additional injury of the IVC or other vessels are exposed by a combination of an extensive Kocher maneuver and mobilization of the entire right colon and mesenteric base, from the cecum to the duodenojejunal flexure. This maneuver, when combined with leftward mobilization of hepatic flexure,


TRAUMA

provides access to the entire PV and the proximal portions of its major tributaries. It also exposes the entire infrahepatic vena cava and the aorta up to the origin of the SMA.[335-339,345-347]

Surgical transection of the neck of the pancreas can also be utilized to expose the retropancreatic PV. An avascular plane exists between the neck of the pancreas and the anterior surface of the PV, as there are no venous tributaries draining into the anterior surface of the PV. Transection of the neck of the pancreas can be achieved either with a GIA or TIA stapler. This maneuver is recommended when there is an associated pancreatic injury, which will mandate distal pancreatectomy, or as completion pancreatectomy for an almost totally transected pancreas at its neck. It may be utilized as the last ditch effort, if hemorrhage containment cannot be accomplished in any other way. All of these maneuvers as well as direct dissection of the portal triad will also expose the hepatic artery and its branches.

One of the most difficult vascular structures to expose is the retrohepatic vena cava. This segment of the IVC has unique anatomic features such as multiple tributaries draining anteriorly at the level of the caudate lobe. This portion of the vena cava measures approximately 7–12 cm in length and lies in a groove on the posterior aspect of the liver. The retrohepatic cava is joined by the major hepatic veins: the right, middle, and left hepatic veins. Frequently, the left and the middle hepatic veins join in a short 1–2 cm common trunk prior to entering the retrohepatic IVC. Similarly, other major accessory hepatic veins of different sizes may also drain into the retrohepatic IVC.[353-355]

Exposure of the retrohepatic IVC and the major hepatic veins is both difficult and fraught with pitfalls. Prior to any direct attempts at exposure, a wide right-sided visceral rotation is undertaken by transecting the avascular line of Toldt of the right colon and performing an extensive Kocher maneuver, thus exposing both infrarenal as well as the suprarenal infrahepatic IVC. Similarly, the falciform ligament is sharply transected toward its origin at the bare area of the liver where meticulous transection of the coronary ligaments will expose 1–2 cm of the retrohepatic IVC.

One of the ways to expose the retrohepatic IVC is by directly approaching it via an extensive hepatotomy through the interlobar plane at Cantlie's line; frequently, this is done as completion of a massive fracture. Alternatively, sharp transection of the right triangular ligament with extensive right to left mobilization of the right lobe of the liver will expose the right hepatic vein as well as the retrohepatic IVC. The left hepatic vein can be exposed by transecting the left triangular ligament and rotating laterally the lateral segment of the left lobe of the liver. Uncommonly, a median sternotomy is necessary to control the intrapericardial portion of the IVC.

Once exposure and proximal and distal control have been obtained, all abdominal vascular injuries should be graded utilizing the AAST-OIS for vascular injuries (Table 28.10).[335] Routine principles of vascular surgery apply to the management of abdominal vascular injuries. Adequate exposure, proximal and distal control, debridement of injured vessel wall, prevention of embolization of clot, debris or plaque, irrigation with heparinized saline, judicious use of Fogarty catheters, meticulous arteriorrhaphy or venorrhaphy with monofilament vascular sutures, avoidance of narrowing of the vessel during repair, insertion of an autogenous or prosthetic graft when applicable, and, rarely, intraoperative angiography when feasible are the mainstays of successful repair. Occasionally, the use of temporary vascular shunts as part of damage control may be required.

The management of vascular injuries in zone I supramesocolic will consist of primary arteriorrhaphy of the suprarenal abdominal aorta when feasible, and in rare occasions, the insertion of a Dacron or PTFE graft. Injuries to the celiac axis usually undergo primary repair if simple, or ligation if destructive. Management of injuries to the first two parts of the SMA should be dealt with by primary repair whenever possible. Intense vasoconstriction makes this difficult. These injuries can also be ligated, as theoretically there are sufficient collaterals to preserve the viability of the small and large bowel; however, profound vasospasm may lead to intense ischemia and bowel necrosis. The first two zones of the SMA can also be repaired either with an autogenous or prosthetic graft. Insertion of a shunt may be utilized as a temporary measure.

The management of injuries in zone I inframesocolic employs the same techniques as in zone I supramesocolic. Parts 3 and 4 of the SMA should also be repaired, although the main jejunal, ileal, and colic branches of Part 4 may be ligated.[12,13] The management of IMA injury is usually by ligation; it rarely requires reconstruction.[335,337-340,345-347] The management of injury to infrahepatic suprarenal IVC, as well as the infrarenal IVC will consist of lateral venorrhaphy whenever feasible. If through-and-through injuries are found in these vessels, both anterior and posterior aspects of the vessel must be repaired. This can prove quite challenging. Complex infrarenal IVC injuries not amenable to repair will require ligation.

Although the infrahepatic suprarenal IVC has no venous tributaries, it is very difficult to mobilize. In general, these repairs are accomplished by extension of the injury in the anterior wall and repair of the posterior wall from within.

With massive destruction of the infrahepatic suprarenal IVC, ligation can be considered; however, survival rates are low. Rarely, prosthetic grafts have been utilized in this position. The management of injuries to the infrarenal IVC generally consists of lateral venorrhaphy after placement of a partially occluding Satinsky or Derra vascular clamp. In the presence of through-and-through injuries, primary repair can be accomplished either by extending the laceration or rotating the vessel. However, this involves ligation of many of its lumbar veins which are quite fragile. We recommend performing the repair from within the vessel. The infrarenal IVC can be ligated in cases of massive destruction. Ligation is generally well tolerated. Injuries to the SMV should be primarily repaired although they can also be ligated; serious sequelae to the circulation of the small and large bowel may result.[349]

Injuries to either right or left zone II can be challenging. Injury to the RA can be either primarily repaired or resected and grafted utilizing either an autogenous or prosthetic graft.[351] Rarely, an aortorenal bypass can be performed utilizing a distal site in the anterior wall of the abdominal aorta. Primary repair of the renal arteries is difficult. Generally, ligation of the RA is performed with subsequent nephrectomy. Injury to the RVs can also be repaired with primary venorrhaphy or ligation. An injury to the right RV that cannot be successfully repaired requires ligation and will demand that a nephrectomy be performed secondary to the lack of venous collaterals. Ligation of the left RV is generally well tolerated provided that it is performed proximally and close to the IVC as the venous collaterals such as the gonadal, adrenal, and renolumbar veins handle the venous outflow.

Injury to zone III can also be challenging, often with associated colonic and genitourinary injuries resulting in considerable contamination. Injury to the common iliac arteries can be primarily repaired via arteriorrhaphy. Occasionally, resection and primary anastomosis can be performed. Prosthetic and rarely autogenous grafts can also be utilized to repair common iliac arteries. Internal iliac artery injuries are generally treated by ligation. Injury to the external iliac artery can be primarily repaired via arteriorrhaphy and occasionally by resection and primary anastomosis. Iliofemoral bypasses can be performed

usually with prosthetic and rarely with autogenous grafts, as it is uncommon to find a saphenous vein of adequate size to perform an iliofemoral repair. In the presence of massive contamination, it is strongly recommended that all grafts, whether autogenous or prosthetic, be covered by reperitonealization with autogenous tissues to avoid grafts blowouts. Insertion of shunts may be utilized as a temporary measure in either the iliac artery or vein.

When there has been massive destruction of either the common or internal iliac artery, ligation may be needed. Arterial flow can be restored utilizing a crossover femoro-femoral or axillo-femoral bypass. These bypasses have the disadvantages of involving uninjured vessels and have a high incidence of thrombosis. Injury to the iliac veins, either common, external, or internal, can be dealt with by ligation, as this is frequently well tolerated, although they can also be dealt with by lateral venorrhaphy.

Injury to the PV should be primarily repaired whenever possible. Lateral venorrhaphy, although technically difficult, should be attempted even if the repair narrows the PV. Alternatively, if the patient is acidotic, hypothermic, and coagulopathic, the PV can be ligated. This frequently results in the splanchnic hypervolemia and systemic hypovolemia syndrome.[353-355] Other techniques that have been employed with rare success include resection of the damaged segment and primary end-to-end anastomosis, autogenous and prosthetic grafts, end-to-side portacaval shunts, and transposition of the SV to the SMV. Injury to the hepatic artery can be primarily repaired or ligated.

The management of injury to the retrohepatic IVC consists of primary venorrhaphy, as this represents the only chance for survival in these patients. Ligation is not an option as patients will not survive. In a few reported cases in the literature, the entire liver has been extirpated and a number 36 or 40 Fr chest tube has been placed in the retrohepatic IVC as a shunt in anticipation of a hepatic transplant. Injury to the hepatic veins should be primarily repaired; ligation will most often result in hepatic necrosis as there are no collateral venous channels between the hepatic lobes.

Whenever a trauma surgeon performs an abdominal vascular repair, serious consideration must be given to "second look" operation to assess for bowel viability. This is particularly important after repair of any part of the SMA and should be considered after repair or ligation of the PV or SMV. Contamination from gastrointestinal or genitourinary injuries pose great risks for the development of infection in prosthetic grafts inserted to bypass injured vessels. Whenever possible, all grafts, either autogenous or prosthetic, should be reperitonealized. Similarly, for all vascular repairs adjacent to gastrointestinal suture lines, an effort should be made to interpose viable tissue, generally omentum between the suture lines to prevent vascular-enteric fistula or anastomotic dehiscence.

Abdominal Compartment Syndrome

The World Society of the ACS has developed consensus definitions, diagnostic criteria, and treatment algorithms for intra-abdominal hypertension and ACS.[355-358] Normal IAP pressure represents pressure within the abdominal cavity (normal IAP is 5–7 mm Hg in the ICU population); intra-abdominal hypertension (IAH) is defined as IAP ≥ 12 mm Hg. ACS is sustained IAP > 20 mm Hg associated with new organ dysfunction/failure secondary to decreased end-organ perfusion. Intra-abdominal hypertension affects multiple systems in a vicious cycle, which will culminate in multiple system organ dysfunction if untreated.

ACS has been classified as primary, secondary, or recurrent.[355-357] *Primary ACS* is associated with injury or pathology within the abdominal cavity: intra-abdominal hemorrhage, intra-abdominal sepsis, ischemic bowel, ileus, or severe pancreatitis. *Secondary ACS* is associated with conditions which do not originate in the abdominal cavity such as massive fluid resuscitation with the burn patient. *Recurrent ACS* occurs after surgical decompression, prior to or after definitive closure.

The common etiologies for ACS include major abdominal trauma, massive fluid resuscitation, burns, ruptured abdominal aortic aneurysm, intraperitoneal or retroperitoneal hemorrhage, pancreatitis, intestinal obstruction or ileus, and abdominal surgery. Risk factors for the development of ACS include abdominal surgery/trauma, fluid resuscitation >5 L per 24 hours, ileus, pulmonary/renal/liver dysfunction, hypothermia, acidosis, and anemia.

Clinical manifestations of ACS are seen in multiple organ systems. Direct end-organ compression combined with decreased cardiac output from ACS has a mortality >40% when diagnosed; 100% if left untreated. Physical examination of the abdomen is not sensitive in the diagnosis of IAH. Neurologic findings in IAH include potential increase in intracranial pressure secondary to decreased internal jugular venous drainage, important with closed head injury patients. Abdominal decompression has been reported as therapeutic treatment for elevated intracranial pressure.[358] Pulmonary effects include high peak airway pressures (>40 cm H_2O) and decreased functional residual capacity secondary to the elevated diaphragm with poor excursion. If untreated, ACS ultimately results in hypoxia, hypercapnia, and respiratory acidosis. Cardiovascular effects may be difficult to delineate as decreased venous return and falsely elevated filling pressures from abdominal hypertension and elevated intrathoracic pressure lead to decreased cardiac output and end-organ perfusion. These effects are exacerbated if the patient is hypovolemic. The kidney and intestine are most sensitive to IAH. IAH leads to splanchnic hypoperfusion, bowel ischemia, and potential bacterial translocation. Oliguria and decreased GFR secondary to renal compression and decreased cardiac output occur with minimal elevation in IAP (as low as 15–20 mm Hg); oliguria is one of the earliest signs of ACS.

Diagnosis. The standard method for diagnosis of IAH is the measurement of bladder pressure via an arterial line transducer. If IAH is suspected, serial bladder pressures are recommended. Bladder pressures >20–25 mm Hg, with the appropriate clinical signs, suggest ACS.[356-358]

Multiple strategies to decrease IAP involve medical and surgical approaches. Abdominal decompression is the only treatment for ACS once end-organ dysfunction is present. The intra-abdominal organs are allowed to eviscerate and a temporary closure device is placed on the abdomen (VAC, Bogota bag). *Reperfusion syndrome* is a postoperative complication with its effects ranging from hemodynamic instability to cardiac arrest. The administration of mannitol and bicarbonate prior to decompression may be of benefit. In extreme situations when patients cannot tolerate transport to the OR, the abdomen may be opened at the bedside in the ICU. Avoid doing this in cases where ACS is secondary to intra-abdominal hemorrhage. Keep in mind that as fluid resuscitation continues, recurrent ACS may occur even with temporary abdominal closure, or after definitive closure. Preemptive "open abdomen" is usually exercised in patients undergoing damage control surgery or in those at high risk for ACS at time of surgical exploration.

Aggressive intravenous resuscitation with isotonic fluids is a major cause of secondary ACS as a result of third-spacing

and visceral edema. Restrictive fluid administration should be practiced in patients with IAH or at risk for ACS. Excess fluid removal is the key in the medical management of oliguric/anuric patients who may respond to diuretic therapy or continuous venovenous hemofiltration/ultrafiltration.

Additional medical management of IAH includes sedation, analgesia, pharmacologic paralysis, body positioning, intestinal decompression, and percutaneous decompression of the abdomen. Judicious use of neuromuscular blockade in conjunction with adequate sedation and analgesia may help IAH; however, the benefits must outweigh the risks. Ileus or bowel obstruction is not an uncommon occurrence in ICU patients at risk for ACS. Decompression of intraluminal intestinal contents via nasogastric or rectal tubes can also reduce IAP. Percutaneous drainage of intra-abdominal fluid may reduce IAP. Close monitoring of urine output and serial (q4–6h) bladder pressures along with these medical strategies may help prevent the transition from IAH without end-organ damage to ACS with renal dysfunction and intestinal ischemia.

Damage Control

Damage control is the global approach taken toward the patient in extremis (see Chapter 6). Life-threatening injuries are addressed first as dictated by the patient's physiologic reserve. Any operative procedure adds physiologic stress to an injured patient; the magnitude and duration of the operation dictate degree of additional physiologic insult. Damage control is not specific to abdominal catastrophe; it applies to the critically injured multitrauma patient. Injuries are prioritized and treatment is staged as dictated by physiologic state. Indications for a damage control approach include the multiply injured patient with intra-abdominal injury along with hemodynamic instability, acidosis, hypothermia, or nonsurgical bleeding (coagulopathy). It is critical that major bleeding (surgical bleeding) be controlled at the index operation. Common abdominal injuries where damage control is applied include vascular, major hepatic, or pelvic injury. The major goals of the trauma laparotomy are control of hemorrhage and contamination (intestinal contents, pus) by packing, temporary shunting of vessels, or bowel resection without anastomosis. The abdomen is left open for a second look in 24–48 hours or to prevent ACS in at-risk patients (e.g., >10 units PRBCs or 5 L crystalloid). Additional criteria which suggest the need for damage control include arterial pH ≤ 7.1, temperature < 35°C, or coagulopathy.

The laparotomy is then truncated and the patient transferred to the ICU. Aggressive resuscitation in ICU, correction of coagulopathy and acidosis and core rewarming. Most importantly in the ICU, is the prompt management of hypothermia, coagulopathy, and metabolic acidosis. Particularly in polytrauma patients with substantial hemorrhage, it is not uncommon to see continuous oozing from wounds or line sites. Nonsurgical bleeding (coagulopathy) must be addressed aggressively. Ongoing bleeding and failure to correct coagulopathy indicate need for return to the operating; 20% of damage control patients will require early return to the OR. With planned return to the OR, perform reexploration with more detailed look at injuries, definitive or partial repair of injuries (i.e., bowel anastomosis, pack removal, ligation/bypass), depending upon the patient's reserve, may take more than one trip to the OR. The abdomen may be left open or closed, depending upon the patient's status at the completion of definitive repair and degree of bowel edema.

Damage control decreases mortality in these severely injured patients, but adds real morbidity. The complications of damage control surgery include intra-abdominal abscess, anastomotic leak, an open abdomen, and gastrointestinal fistula.

The open abdomen is the by-product of damage control surgery and ACS. It refers to a patient whose abdominal fascia is left temporarily in discontinuity for the purpose of reexploration, prevention of ACS in patients who will require massive resuscitation, or as treatment of ACS. Temporary closure techniques aim to control third-spaced fluid and allow swelling of intestines during resuscitation. These devices usually consist of a nonadhesive barrier that covers the intestines while allowing excess fluid to be suctioned via superficial drains. Currently, the most common device is the VAC, which uses a sponge as means of suction to collect fluid and pull fascia and skin edges together. If tolerated, judicious fluid removal may decrease visceral edema and increase the likelihood of primary closure of the abdomen. If fascial closure is not possible, skin-only closure with future plans to repair ventral hernia is the next best option. Skin grafting and biologic meshes can be used for closure when fascial or skin-only closure is no longer an option. Subsequent fascial closure can be accomplished when the patient is completely recovered, months later.

Retroperitoneal Hematoma

Prior to widespread use of abdominal CT, preoperative diagnosis of retroperitoneal hematoma was an uncommon diagnosis. Its presence is usually associated with multiple injuries and consequently, with an increase in morbidity and mortality. The retroperitoneum is a protected space, located behind the posterior parietal peritoneum and anterior to the spine and associated muscles. This large and potentially expandable space may hold more than 3,000 mL of blood and be responsible for the presence of severe hemodynamic instability.

Mechanism of Injury and Clinical Presentation. Retroperitoneal hematoma is present in 15%-40% of patients admitted with blunt trauma.[360-362] The most common etiology of this injury is motor vehicle crash (32%-73%) followed by pedestrian struck by a car (12%-42%). We reported a mean Trauma Score and injury severity score of 10.6 and 40, respectively, in patients with retroperitoneal hematoma.[360] Furthermore, 20%-40% of patients with traumatic retroperitoneal hematoma arrive to the hospital in hypovolemic shock. In our series, transfusions during the first 24 hours postinjury were 3,532 mL. The association of extra-abdominal injuries is significant, as high as 74%.[360] Penetrating retroperitoneal hematoma is generally associated with multiple injuries and is more likely diagnosed intraoperatively.

Diagnosis. Prior to availability of CT, traumatic retroperitoneal hematomas were diagnosed at the time of laparotomy in 60%-70% of cases.[362-365] The introduction of CT has revolutionized the evaluation of the patient with abdominal trauma, including the patient with retroperitoneal hematoma. With the introduction of the DPL, a negative result was considered reliable to exclude significant intra-abdominal injury. In the presence of pelvic fractures, the DPL should be performed with a supra-umbilical technique to avoid false-positive results.

Retroperitoneal hematoma has been classified by Kudsk and Sheldon[363] (see Fig. 28.17), dividing the abdomen into three zones: zone 1 (central or medial hematoma), zone 2 (perirenal, flank hematoma), and zone 3 (pelvic hematoma). Henao and Aldrete added zone 4 for hematoma occupying two or more zones.[361] The most common location of the retroperitoneal hematoma is localized in zones 2 and 3.

Management of Traumatic Retroperitoneal Hematoma. Preoperative CT of the abdomen in the hemodynamically stable patient allows evaluation of solid and hollow organs and vessels of the retroperitoneal space, facilitating not only the decision-making processes but also the surgical strategy. On the other hand, intraoperative management of the retroperitoneal hematoma continues with few modifications for the last few decades.

Zone 1 (central hematoma) following blunt trauma[5] should be explored to exclude bleeding from a major vessel or branch thereof (aorta or vena cava) and allow inspection of the pancreas and duodenum; visceral injuries are found in two-thirds.[362] The IVC is the most common organ affected with an associated mortality of 43%. Pancreatic injury due to blunt trauma occurs in 1%-27% with a mortality of 17%-27%.[363-367] It is imperative to recognize these injuries at the time of laparotomy or with interpretation of preoperative CT.

The decision to explore zone 2 retroperitoneal hematomas from blunt injury is more complex. The indications for exploration are the presence of pulsatile or expanding hematoma, large extravasation of urine, or clinical or radiographic evidence of renovascular injury. In our series of blunt traumatic retroperitoneal hematomas, 41% of hematomas located in zone 2 were explored and in 49% of the cases, an organ injury was identified.[360] The kidney is the most common organ injured in this location; management of kidney injuries is discussed in Chapter 29.

Zone 3 (pelvic hematoma) blunt injury should not be explored routinely, unless in the presence of exsanguination, generally due to injury of the main iliac artery or vein which needs to be emergently controlled. Many of these hematomas in a hemodynamically stable patient can be controlled by angiographic embolization, or packing with some type of external abdominal compression.

The mortality of patients explored with hematomas in zone 3 ranges from 63% to 83%. Flint et al.[365] reported 66% mortality with hypogastric artery ligation, today rarely performed, and 50% with packing, today successful in penetrating trauma and damage control of this area. In our series, 12% of patients with blunt retroperitoneal hematoma were explored and 38% had iliac vein injury. The majority of zone 3 blunt retroperitoneal hematomas are associated with bony pelvic disruption.[361]

The management of retroperitoneal hemorrhage in zone 3 associated with pelvic fracture has evolved. In the past, the sequence was as follows: Resuscitation, DPL, external fixation, followed by angiographic embolization if more than six units of blood were required to keep the patient hemodynamically stable. Currently, the modern management scheme is resuscitation, temporary pelvic stabilization, with sheets or pelvic corset devices, FAST, less commonly DPL, followed by CT, and finally, angiographic embolization, if evidence of active bleeding (blush) in the CT or continued requirement of blood transfusions. The indications to go to the OR, at times for pelvic packing are presence of another organ injury requiring laparotomy or inability to control the bleeding angiographically.

The management of a retroperitoneal hematoma secondary to penetrating mechanism is more straightforward. Retroperitoneal hematomas secondary to penetrating trauma should all be explored, regardless of the location.

Morbidity and Mortality. The patients who survive more than 24 hours develop complications in 50%, generally associated with MSOF. Respiratory failure occurred in over 40%. Intra-abdominal abscesses occur with the similar frequency of 4.3% to that of blunt abdominal trauma more generally. The mortality from a traumatic retroperitoneal hematoma ranges from 18% to 40%.[360] The management of the patient with traumatic retroperitoneal hematoma should be multidisciplinary, often involving interventional radiology, orthopedic surgery, urology, in addition to the acute care surgeon.

CHAPTER 29 ■ GENITOURINARY TRAUMA

BRADLEY A. ERICKSON AND JACK W. MCANINCH

RENAL TRAUMA

Epidemiology

Trauma patients suffer renal injury at rates of 1.4%-3.25% with proportionally higher rates seen in younger patients and in men (3:1 male to female).[1–3] Most renal trauma in the United States and Europe is blunt (95%-97%),[2,4] but there are major worldwide differences in the mechanism of renal injury (i.e., Turkey 31% blunt).[5,6] The most common blunt mechanism is motor vehicle accident and the most common penetrating injuries are from stab and gunshot wounds, with penetrating traumas having a proportionally higher rate of severe injury.[2] With the advent of sophisticated renal trauma imaging and grading systems, the majority of contemporary renal traumas can be managed nonoperatively.[7]

Pathophysiology

Blunt Renal Trauma. The kidneys are relatively protected organs, surrounded by the abdominal viscera anteriorly, the diaphragm and liver superiorly, and the back muscles and spine anteriormedially. This degree of protection means that only major blunt forces to the body lead to renal trauma, explaining the high rate of associated injuries to surrounding viscera (20%-94%).[8,9]

Motor vehicle accidents and falls are the most common mechanism for blunt renal trauma, with injuries coming both from direct impact of the abdominal wall and ribs with the kidney and from secondary impacts during the acute deceleration. The renal pedicle is especially prone to deceleration injuries. Because the renal vein and artery are the kidney's most secure attachments, they absorb the majority of the force during deceleration, leading to both tears and thrombosis of the renal vasculature. Parenchymal injuries of the kidney can result from both direct and secondary impacts with the surrounding musculature, the 11th and 12th ribs and the spinous processes[8,10] (Fig. 29.1).

Penetrating Renal Trauma. Penetrating trauma tends to be more severe and more unpredictable than blunt trauma. Gunshot injuries can damage the kidney from both direct impact of the bullet (permanent cavity) and from the bullets blast effect (temporary cavity), with high-velocity bullets leading to relatively more damage.[6] With stab wounds, the path of the injury can sometimes provide insight into the severity of injury. Wounds posterior to the anterior axillary line will more often lead to parenchymal injury only, most of which can be managed nonoperatively. Conversely, anterior renal injuries are more likely to injure the hilar strictures, which tend to be more life threatening in nature and require operative management, though use of these anatomical landmarks should never supplant appropriate imaging when possible.[11]

Initial Evaluation

Physical Exam. Historical and clinical findings suggestive of blunt renal trauma include hematuria, flank pain, flank ecchymoses, fractured ribs, and abdominal distention, with hematuria being the most common finding (80%-94%)[12] (Fig. 29.2).

Laboratory. An evaluation of the urine should be done in all trauma patients, including both gross evaluation and either dipstick or microscopic analysis. Hematuria should alert one to genitourinary injury, though the degree of hematuria does not always correlate well with the severity of renal injury, especially with penetrating and hilar injuries.[13] Serum creatinine at the time of trauma is rarely helpful as it generally reflects serum creatinine before injury. However, elevated creatinine may indicate preexisting renal pathology which has been cited as a risk factor for renal injury in the event of trauma.[14]

Imaging. The gold-standard imaging modality for genitourinary trauma in the hemodynamically stable patient is an IV contrast CT scan with both arterial and excretory phases (10 minutes after initial injection) (Fig. 29.3).[15] The excretory phase can be eliminated if no renal pathology is seen on the arterial phase, but is helpful in diagnosing the collecting system and ureteral injuries. Understanding which patients should undergo imaging is critical in the proper management of renal trauma and in general, all trauma patients with gross hematuria should be imaged with a CT scan. In blunt trauma patients with microscopic hematuria (>3RBCs/hpf) only, imaging can be reserved for adults who are unstable (systolic BP < 90) and in children with >50 RBCs/hpf, as major genitourinary injury has been found in only 0.2% and 2% of these patients, respectively.[16]

There are other less ideal imaging modalities including ultrasound, which in skilled hands can diagnose perinephric fluid collections but generally not the severity of renal injury.[17] Renal angiography is unnecessarily invasive to diagnose renal trauma in the era of CT scan, but can be used in conjunction with angioembolization when used to treat hemorrhage.[18] IVP can be especially useful in the setting of unstable patients, where renal injury is suspected, but imaging is not obtained prior to laparotomy. A single, on-table abdominal plain-film 10 minutes after a rapid bolus of contrast (2 mL/kg) can rule out most major renal injuries if found to be normal.[19]

Injury Classification. The American Association for the Surgery of Trauma (AAST) grading system for renal trauma, which has been recently modified (Table 29.1; Fig. 29.4), has been validated as a predictor of both injury severity and negative patient outcomes in large retrospective studies.[4,20] It relies on a properly performed CT scan for accurate grading and staging. Most grade I-III injuries can be managed conservatively. With the new grading modifications, many grade IV injuries can also be initially managed nonoperatively, whereas, nearly all grade V injuries will require intervention.[4,20,21]

Management

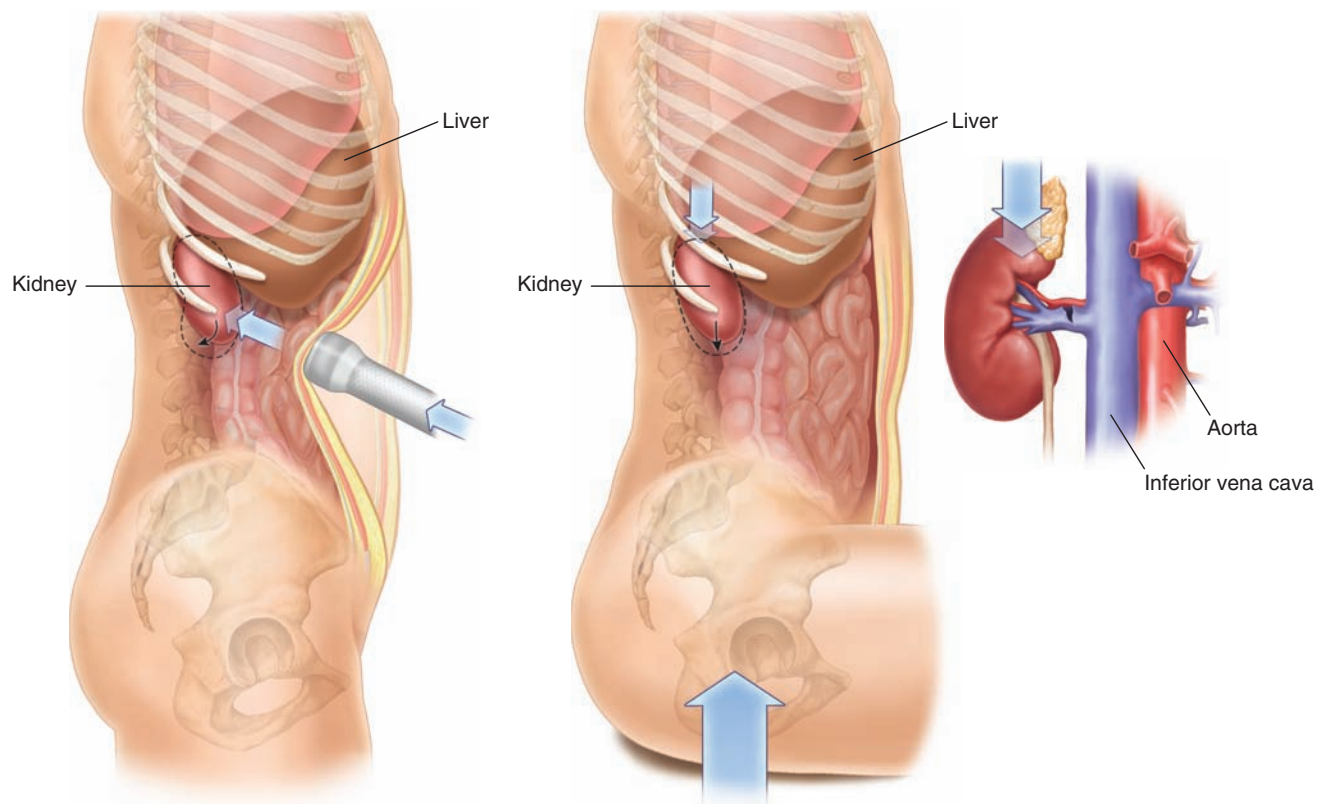
Conservative Renal Management. Directed conservative management is the mainstay of most contemporary renal trauma management algorithms (Algorithms. 29.1 and 29.2). While historically penetrating trauma to the kidney from


FIGURE 29.1. Mechanisms for blunt injury of the renal parenchyma.

gunshot and stab wounds resulted in renal exploration, it is no longer an absolute indicator for surgery with the advent of modern imaging techniques allowing for more accurate staging.[2] The protected retroperitoneal location of the kidney and its enveloping by Gerota's fascia will often be sufficient to tamponade renal bleeding.[8] Many conservative protocols include serial hematocrit concentration and bed rest for 24–48 hours, though these have never been rigorously validated.[16] Repeat imaging is also recommended for conservatively managed

grade III-V injuries and for those patients with worsening clinical findings and/or Hct concentration as late bleeds can occur in up to 25% of patients.[22]

Surgical Management. Absolute indications for surgical management are few (Table 29.2), but prompt recognition is important as renal hemorrhage can be life threatening. The surgical approach to the damaged kidney is complicated and controversial. We have found that control of the renal vasculature prior to opening Gerota's fascia can decrease the likelihood of nephrectomy and make any subsequent renal surgery more controlled as bleeding can be managed prospectively, though others have disagreed with these findings.[2,23–25]

The initial surgical approach after laparotomy when vascular control is obtained, begins with identification of the aorta, where an incision of the posterior peritoneum is then made superior to the inferior mesenteric artery, gaining access to the retroperitoneum. Extension of the incision superiorly will lead to the left renal vein, which is the key anatomical landmark. The right renal artery can be found superior and medial to the left renal vein, often located with cephalad retraction of the vein and dissection between the aorta and inferior vena cava. The left renal artery lies just posterior and superior to the left renal vein. The right renal vein can be found on the opposite the left renal vein on the contralateral side of the IVC. Once the vessels are isolated, vessels loops are placed,

but not occluded. The colon ipsilateral to the injury is then retracted medially and Gerota's fascia is opened. If uncontrollable bleeding is encountered, the vessels are then occluded by the vessel loops, starting with the respective renal artery and followed by the renal vein if necessary[23] (Fig. 29.5).

Renorrhaphy should be attempted for renal parenchymal injuries if possible (Fig. 29.6). All nonviable tissue should first be removed sharply. If greater than two-third of the kidney is nonviable, a nephrectomy should be strongly considered. Any bleeding parenchymal vessels should then be suture ligated with 4-0 chromic suture and any collecting system lacerations with a watertight running 4-0 chromic. Adequate collecting system closure can be confirmed by injection of methylene blue into the renal pelvis.[26]

Coverage of the repaired parenchymal bed is essential. If the renal capsule is still present, it can be used for coverage. Alternatively, coverage with off-the-shelf agents, such as Gelfoam, has been shown to assist with both parenchymal hemostasis and wound compression.[27,28] Bolsters made from these materials are secured to the remaining capsule with carefully placed 3-0 monofilament sutures. Additional coverage can be achieved with omentum, perinephric fat, and peritoneal flaps as needed.

TRAUMA

ALGORITHM 29.2 Penetrating Renal Trauma algorithm. (From Santucci R, Wessels H, Bartsch G, et al. Evaluation and management of renal injuries: consensus statement of the renal trauma subcommittee. *BJU Int.* 2004;93(7):937–954.)

Renal vascular injuries that require surgical intervention can be managed with the same initial operative approach. Incomplete renal arterial injuries can be repaired primarily with fine interrupted monofilament suture. Complete disruptions will often require nephrectomy, but if it's clinically necessary to attempt repair, arterial debridement and thrombectomy are usually required before the reanastomosis is attempted. In cases where a tension-free anastomosis is not possible, interposition with the hypogastric artery is preferred over the saphenous vein.[23,29]

Renal vein injuries are often more difficult to diagnose and to treat. Venous tears can be repaired primarily, but complete disruptions generally lead to nephrectomy. With left renal vein injuries near the IVC, ligation of the vein does not necessitate nephrectomy if collateral venous drainage provided by the adrenal, gonadal, and lumbar veins remains intact.[30]

Relative indications for surgical exploration of the kidney are shown in Table 29.2. If the retroperitoneum is incompletely staged and a large hematoma is noted at the time of surgery, an IVP should be obtained with abnormalities dictating exploration.[31] Repairing the kidney when concomitant abdominal visceral injuries are present can minimize complications such as postoperative infection and fistula.[32,33] With large devitalized segments present, exploration and removal of the segments may minimize postoperative abscesses, urinomas, and late hemorrhage.[34] Late or persistent bleeds may also require renal exploration, though angioembolization is being utilized at trauma centers more often with initial outcomes comparable to surgery.[18] Urinomas seen on CT scan will generally resolve spontaneously, but may require late percutaneous or endoscopic procedures, and rarely open surgery.[35]

Interventional Radiology. In patients with major renal injuries who are not undergoing laparotomy for other concomitant injuries, persistent renal bleeding that has failed conservative management (persistent bleeding requiring transfusion) may be managed with angioembolization of the kidney.[36] Early outcomes with this approach have been favorable, but failures do occur and open surgical management must always be considered if embolization fails to control bleeding.

Complications of Renal Injury and Management. Secondary hemorrhage and arteriovenous fistula formation in

TABLE 29.2

INDICATIONS FOR RENAL EXPLORATION

■ INDICATION	■ DESCRIPTION	■ TYPE
Absolute	Persistent, life-threatening hemorrhage believed to stem from renal injury	Acute
	Renal pedicle avulsion	Acute
	Expanding, pulsatile or uncontained retroperitoneal hematoma	Acute
Relative	A large laceration of renal pelvis or avulsion of the UPJ with major urinary leak	Acute/delayed
	Coexisting abdominal visceral injuries	Acute/delayed
	Persistent urinary leakage or abscess after failed percutaneous or endoscopic management	Delayed
	Abnormal intraoperative IVP in setting of suspected renal injury	Acute
	Large devitalized parenchymal segment with urinary leak after failed endoscopic management	Delayed
	Complete renal artery thrombosis of both kidneys, or of a solitary kidney with preserved renal perfusion	Acute
	Renovascular hypertension	Delayed

conservatively managed renal injuries is more common with deeper and higher-grade lesions, with rates of late bleeds in grade III and IV lesions between 13% and 25%.[37] Most of these bleeds can be managed successfully with angiographic embolization. Late bleeds have been reported up to 1 month after the initial injury which may correspond to the timing of retroperitoneal hematoma resolution, exposing a previously tamponaded artery.[38] Presentation is generally flank pain and/or hematuria or in the setting of an arteriovenous fistula, new onset hypertension.

Urinary extravasation from UPJ injury or from calyceal injury from a devitalized segment can successfully be managed with ureteral stent and/or percutaneous drain placement in >90% of cases, but may require open repair if a large devitalized renal segment is preventing healing or if leakage persists.[35] Abscesses associated with these leaks can be usually managed with percutaneous drainage alone.

New onset hypertension is noted in 5% of patients with conservatively managed renal trauma, with higher rates (40%-50%) in individuals with severe renal arterial injuries.[39] The mechanism is thought to be from renal ischemia and inappropriate renin release. Nephrectomy is the most common and most effective treatment. Renal insufficiency after conservative management has not been well studied, but angioembolization of renal hemorrhage leads to a 10% ipsilateral renal function and it is thought that some loss of function should be expected, especially with severe injury.[40]

Summary. With the advent of improved imaging techniques, outcomes data and grading criteria, the contemporary management of renal trauma has become mostly nonoperative. Grade V injuries and unstable patients will require surgery most often and in instances where the kidney must be explored, appropriate surgical techniques can lead to preservation of renal parenchyma in many cases. Prompt recognition of potential renal injuries followed by appropriate laboratory studies and imaging techniques can decrease renal trauma morbidity and mortality considerably.

URETERAL TRAUMA

Epidemiology

Ureteral injuries from external trauma are rare, accounting for <1% of urologic trauma, likely due to their small size, mobility, and relatively protected location in the retroperitoneum.[41] They are infrequently subject to injury from external blunt trauma, with the exception of UPJ deceleration injuries, which are more common in children.[42] When the ureter is injured from penetrating trauma, it is frequently associated with other abdominal injuries which can make them difficult to diagnose since the other injuries will often take diagnostic and management precedent.[43]

Most ureteral trauma experience comes from iatrogenic injury, usually encountered during difficult pelvic or ureteroscopic stone surgery, occurring at rates of 0.05%-30% depending on the type and difficulty of surgery being performed.[44] The most common types of iatrogenic injury are suture ligation, crush injury, and ureteral devascularization from aggressive ureteral skeletonization. Gynecologic surgery accounts for over half of injuries, with the remainder occurring during urologic, colorectal, general, and vascular surgery. Iatrogenic injuries can be prevented with good exposure and a thorough understanding of surgical anatomy. Preoperative imaging[45] and ureteral stenting have not been shown to decrease injury rate, but may make identification of the injury and subsequent repair easier.[46]

Diagnosis

Presentation. Early signs and symptoms of ureteral trauma are generally vague and nonspecific and include flank pain and hematuria. However, hematuria can be absent in up to 30% of cases and therefore, a high index of suspicion must be present whenever there is concern for a ureteral injury if an accurate diagnosis is to be made.[41] The surgical field/anatomy,
FIGURE 29.5. Surgical Approach to obtaining Hilar Control.

mechanism of injury, and path of the external trauma must be scrutinized with a low threshold to image and/or explore the ureter if injury is suspected.

Unfortunately, many ureteral injuries will present in a delayed fashion (65%-93%), often with symptoms such as prolonged ileus, low urine output, flank/abdominal pain, acute renal failure, or high drain output.[47] Morbidity from ureteral trauma is significantly higher when the diagnosis is delayed, resulting in higher rates of urinoma, infection, and renal unit loss.[48]

Imaging. With penetrating trauma, the best imaging modality to diagnose ureteral injury is a CT scan with delayed images obtained 10 minute after injection of IV contrast dye (Fig. 29.7). Delayed extravasation of contrast medial to the kidney is common for UPJ injuries and more distal extravasation for ureteral injuries. Ureteral injuries may also show hydronephrosis, delayed nephrograms, and contrast absent in the distal ureter. A complete IVP will also accurately diagnose most injuries, though this is rarely used anymore in the acute setting.[49] When a laparotomy is being performed without preoperative imaging and ureteral injury is suspected, a one-shot IVP can be utilized, which has high test specificity. However, the sensitivity is unacceptably low to rule out injury (20%-30%) and in these cases surgical exploration is probably the best way to diagnose injury, which can be improved by injection of intravenous methylene blue and inspection of the surgical field for dye extravasation. Retrograde pyelograms are both sensitive and specific but are logistically difficult to

perform in the trauma setting and best used for diagnosing iatrogenic or delayed ureteral injuries or in the setting where IVP or CT scan results are equivocal.

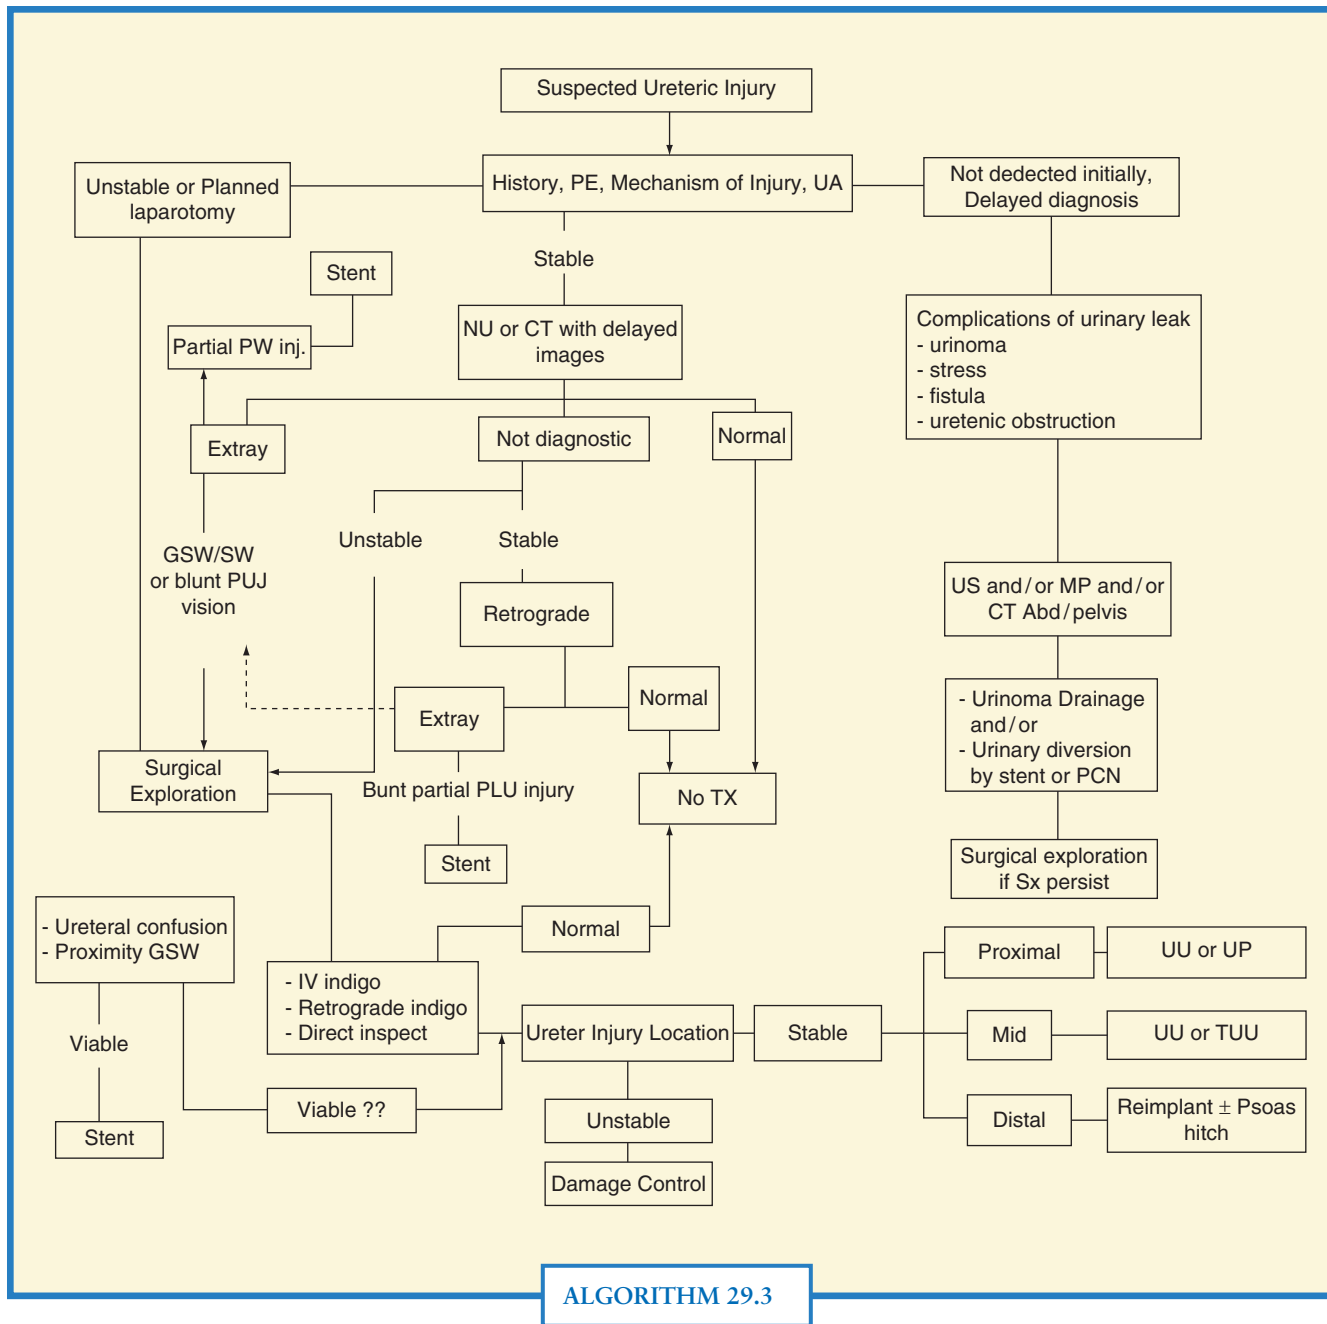
Treatment (Algorithm. 29.3)
ENDOSCOPIC MANAGEMENT
Endoscopic management with a ureteral stent can be utilized in patients with incomplete injuries, including those in the UPJ, that are not otherwise undergoing surgical exploration. In patients with delayed presentation of iatrogenic injuries after surgery, placing a ureteral stent is a reasonable first option as

FIGURE 29.7. CT scan showing ureteral trauma on excretory images.

these injuries are often caused by inadvertent stitch placement that may dissolve with time relieving the obstruction.[43] Outcomes of partial ureteral and UPJ injuries managed with stenting alone are excellent, with open intervention required rarely.

SURGICAL MANAGEMENT
Most penetrating injuries will be diagnosed during surgical exploration. Repair options are generally dictated by the patient's overall clinical picture, but in general, the ureter should be repaired in the same operative setting. The type of repair is dependent on both the mechanism and location of the injury. Gunshot injuries will often be associated with other abdominal injuries, but these should never preclude ureteral repair in the stable patient. Careful attention must be paid to the path of the bullet and any concern for injury to the ureter warrants exploration of the retroperitoneum with careful attention to the blast cavity. Any discoloration of the ureter may indicate devascularization injury and would warrant surgical repair as late leaks are common.[44]

Principles of a good ureteral repair are the same regardless of location and include careful mobilization of the ureter with adventia sparing so not to devascularize the segment, aggressive debridement of the damaged ureter until healthy, bleeding ends are encountered, and, finally, a stented, tension-free watertight anastomosis.

Proximal ureteral injuries are best managed with excision of the injured segment and reanastomosis with either the healthy proximal ureter (ipsilateral ureteroureterostomy, IUU) or the renal pelvis. Mid-ureteral injuries can be managed with an IUU if the distal segment is healthy. However, in cases where the distal segment is unreliable or damaged, the ureter can be anastomosed to the contralateral ureter (transureteroureterostomy) or a Boari flap (tabularized bladder flap) can be created. Distal ureteral injuries should be managed with reimplantation since the distal blood supply is less reliable after injury. If the distance from the injury to the bladder cannot be bridged without tension, a psoas hitch can be utilized. Additional options for longer-segment injuries include ileal interposition and autotransplantation, though these are seldom utilized in the acute traumatic setting. Outcomes for ureteral injuries of


ALGORITHM 29.3

ALGORITHM 29.3 Ureteral Trauma algorithm. (From Brandes S, Chelsky M, Armenakas N, McAninch J. Diagnosis and management of ureteric injury: an evidence based analysis. *BJU Int*. 2004;94(3):277–289.)

all kinds are excellent if the above-mentioned principles are followed, though comparison outcomes studies are lacking.

With ureteral injuries in traumatic situations, a damage control approach to the injury should always be considered. Suture ligation of the ureter proximal to the injury with subsequent percutaneous nephrostomy tube is a reasonable option in the unstable patient and is much preferable to leaving the ureter drain into the surgical cavity. If the patient stabilizes, delayed repair can then be performed with improved outcomes.

Conclusion. Ureteral trauma is rare and will most often be encountered after iatrogenic injury. Early diagnosis is key to successful management, though this can often be difficult in a traumatic situation. Maintaining a high index of suspicion followed by appropriate imaging and intraoperative techniques can minimize morbidity from injury. Surgical repair of ureteral injuries is generally straightforward and often successful if proper repair principles are followed.

BLADDER TRAUMA

Epidemiology

Traumatic bladder injury is a result of blunt trauma 65%-85% of the time.[50] Nearly 2% of blunt abdominal trauma will injure the bladder, with 80% of these a result of pelvic fracture.[51] Of all pelvic fractures, 5%-10% will suffer a major bladder injury.[50,52]

Penetrating trauma is less common, with bladder injuries reported in 3.6% of abdominal gunshot wounds. Iatrogenic injury to the bladder occurs in 0.1%-10% of all pelvic cases, with increasing complexity of cases leading to higher rates of injury.[53]

Pathophysiology

The most common cause of blunt bladder trauma is motor vehicle accident (90%), either from a direct blow to the bladder, most commonly by the steering wheel or lap belt, or in the setting of a pelvic fracture.[53] Driving while intoxicated is an independent risk factor for bladder injury, as it predisposes to both MVAs and full bladders.[54]

When pelvic fractures lead to bladder injury, they are generally located at the fascial attachments of the bladder to pelvis, with pubic symphysis diastasis (RR 9.8) and obturator ring fractures (RR 3.2) being the most predictive fracture patterns for bladder injury.[55] Fractures in other locations can lead to bladder injury when fragments secondarily penetrate the bladder.[56] Bladder injuries from pelvic fracture are associated with urethral disruption in up to 15% of cases.[57] Direct blows to the bladder from external trauma lead to high intravesical pressures and ruptures are generally found at the dome of the bladder, generally the weakest location.

Penetrating trauma to the bladder is most often a result of gunshot or stab wounds. These will rarely be isolated injuries and will many times lead to multiple vesicotomies.[58]

Initial Evaluation

Physical Exam. The most common signs and symptoms of bladder trauma are hematuria (80%-100%) and abdominal pain (62%).[53] With direct trauma, bruising may be seen on the anterior abdominal wall, and urine extravasation may also be noted as perineal, scrotal, thigh, and abdominal wall edema and swelling.[58] In patients with a delayed diagnosis, symptoms may include low urine output or prolonged ileus.

Laboratory. A urinalysis should be obtained in all trauma patients, and hematuria should alert one to the possibility of genitourinary injury. Gross hematuria in the setting of pelvic fracture should always raise the suspicion of bladder and/or urethral injury. Bladder injuries that are recognized in a delayed fashion may present with elevated Cr levels secondary to systemic absorption of urine or prolonged ileus after injury.

Imaging. Correct imaging is the single most important factor in guiding appropriate management of bladder injury. If blood is seen at the urethral meatus, begin with a retrograde urethrogram to rule out concomitant urethral injury. A catheter should then be placed when appropriate and used to perform either a static or CT cystogram. If a CT scan is already being performed, CT cystogram is usually the most appropriate study. Distention of the bladder with contrast is important, and a minimum of 350 mL of contrast should be instilled to improve diagnostic sensitivity, which when performed appropriately, is over 95%.[59] Clamping the catheter during CT scan with IV contrast is not an appropriate alternative and if <350 mL is used, clot or peritoneal contents, which nearly always initially fill the cystotomy, may not be sufficiently displaced and injuries will be missed.[58] Static cystograms will always require AP, lateral and excretory images. CT cystograms will require only pelvic imaging after the bladder is filled, though excretory images may help delineate the location of injury.[60]

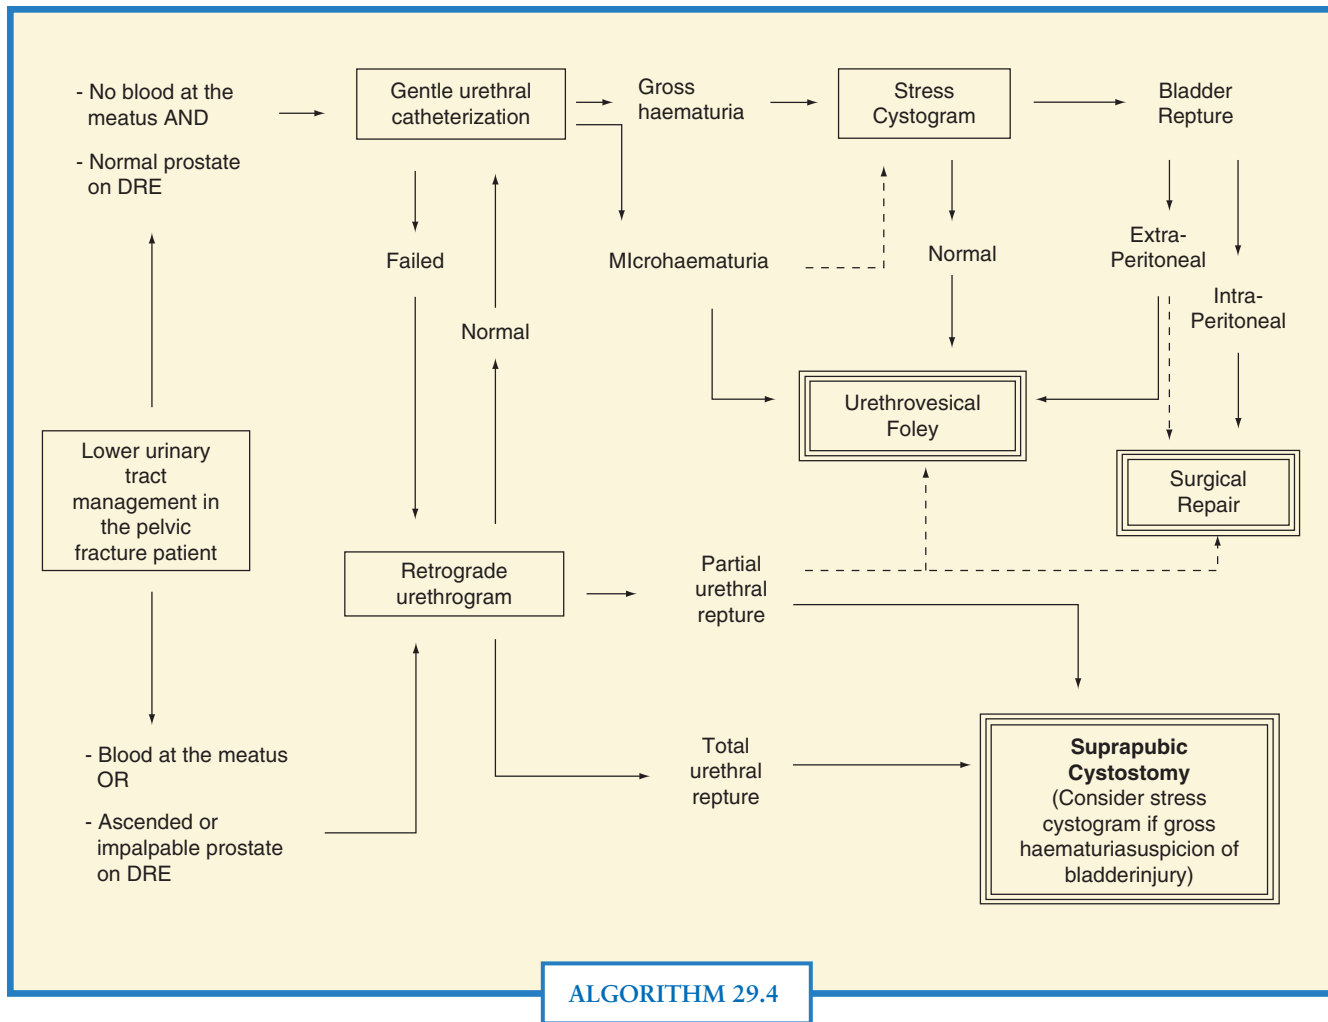
Injury Classification. Injuries are most commonly separated into extra- and intraperitoneal, with combined injuries

FIGURE 29.8. CT scan showing extraperitoneal bladder injury.

present in up to 5%.[53] Extraperitoneal ruptures will show contrast extravasation generally confined to perivesical soft tissues, often in a "flare" pattern (Fig. 29.8). Intraperitoneal ruptures will show contrast extravasating into the cul-de-sac, outlining loops of bowel and if large enough, extend to other abdominal viscera such as the spleen (Fig. 29.9). Of blunt injuries, approximately 40% will be intraperitoneal and 60% extraperitoneal. Most penetrating injuries to the bladder will have an intraperitoneal component and concomitant abdominal visceral injuries.[61] Bladder neck injuries, which are most often associated with pelvic fractures and extraperitoneal injuries, should be carefully looked for as well as these can dramatically change management and outcomes.[62] Medial and inferior contrast extravasation is commonly seen with injuries of the bladder neck.

Management (Algorithm. 29.4)

Extraperitoneal. Conservative management with Foley catheter drainage is appropriate in most cases of extraperitoneal injury.[63] Foley drainage is usually maintained for 10–14 days after which time, a cystogram should be obtained demonstrating no leak before removal. Notable exceptions to conservative management include insufficient bladder drainage with the catheter, generally as a result of gross hematuria and clots, concomitant vaginal or rectal injury, bony fragments

FIGURE 29.9. CT scan showing intraperitoneal bladder injury.


ALGORITHM 29.4

ALGORITHM 29.4 Urethral trauma management algorithm.

within the bladder, and bladder neck injury. Poor drainage from hematuria/clots or bony fragments can prevent coaptation of the bladder injury and impair healing. Concomitant vaginal and rectal injuries can lead to vagino- or rectovesical fistulas, which can be extremely difficult to manage and can be prevented with early bladder closure. Bladder neck injuries will generally not heal with catheter drainage alone since the injury involves sphincteric tissue, which will effectively hold the defect open, preventing healing and complicating catheter drainage. Additionally, if the patient is being explored surgically for other abdominal or orthopedic injuries, it is also generally felt that repair of the bladder should be performed concomitantly, since conservative management has a complication rate of up to 25%, including fistula formation, bladder calculi, delayed healing, and sepsis.[63]

Intraperitoneal. All intraperitoneal injuries should be repaired surgically, with the lone exception being small, iatrogenic injuries secondary to transurethral bladder tumor resection.[50] Most of these injuries will be a result of large external forces, which will often lead to large defects, most often at the dome, that are unlikely to heal spontaneously (Fig. 29.10). Given the extreme external force needed to rupture the bladder, concomitant injuries are common and overall mortality is high (20%-40%).[64] Gunshot and stab wounds will
FIGURE 29.10. Mechanism of blunt bladder injuries.

often have multiple cystotomies (entry/exit wound), and these should always be anticipated and carefully looked for.

Surgical Technique. The bladder should be approached surgically in a uniform fashion, regardless of the size and location of the bladder injury, by making an anterior midline cystotomy, which allows for complete visualization of bladder mucosa and ureters.[50] Bladder injuries should be repaired intravesically with a single layer of 3-0 chromic suture to ensure the mucosa is adequately coapted. If the extravesical component of the injury can also be located with minimal dissection and difficulty, an additional muscle layer closure can be performed using Vicryl suture on the outside of the bladder. If ureteral integrity is questioned, methylene blue can be given intravenously, or alternatively, ureteral catheterization can be performed with the bladder open. The surgical cystotomy should be closed in two layers, and a catheter and suprapubic tube should be left in place for at least 10 days, at which time a cystogram should be performed which will dictate catheter removal.[58]

Summary

Bladder injuries are rare and are most commonly secondary to blunt trauma associate with pelvic fractures. A properly performed cystogram has high diagnostic sensitivity and can help direct proper management. Most extraperitoneal injuries can be managed conservatively, but exceptions to this rule should always be considered. Intraperitoneal injuries should always be repaired surgically. Regardless of location or mechanism of bladder injury, with prompt injury recognition outcomes are excellent.

URETHRAL TRAUMA

Anatomy/Epidemiology

A thorough understanding of the urethral anatomy is important when discussing urethral trauma, since gender and age variations of the urethra as well as the specific trauma location will have important management implications. The male urethra is nearly 18–20 cm in length and is separated into two distinct anterior and posterior parts, both of which are relatively vulnerable to trauma, though from different mechanisms.[65] Conversely, the female urethra is only 4–6 cm in length, is well protected, and is rarely injured. The gender differences are especially evident when comparing posterior urethral injuries from pelvic fractures, which result in injury in up to 10% of male pelvic fractures but in only 1%-2% of similar fractures in females.[66] The anterior urethra, which is absent in females, is 14–16 cm in length in males and spans from the bulbar urethra to the urethral meatus, all of which is vulnerable to blunt injury.

Pathophysiology

Posterior Urethra. The majority (90%) of traumatic posterior urethral injuries in males will occur as a result of blunt trauma and pelvic fractures.[67] The prostatic and the membranous urethra have ligamentous attachments to the bony pelvis and shearing of these attachments from fractures can lead to tearing of urethral segments. Fracture patterns most predictive of urethral trauma include Malgaigne's fractures (anterior fracture through both rami of the symphysis pubis with posterior pelvic disruption either from facture of the sacrum or sacroiliac joint; OR 3.4), straddle fractures (fracture of

all four pubic rami; OR 3.85), and straddle + sacroiliac fractures (OR 24.02).[67] The most common location for injury is at the prostatomembranous junction, which is relatively unsupported and therefore subject to the most shearing force (Fig. 29.11). Concomitant injury to the bladder (10%) and/or other abdominal organs (27%) is common, which can be attributed to the massive trauma generally required for a pelvic fracture to occur.[68] Penetrating trauma is rare but is usually from gunshot wounds. Other mechanisms of injury include iatrogenic injury from urethral instrumentation and from surgical removal of the prostate, both of which are usually ischemic injuries.

Anterior Urethra. Most injuries to the anterior urethra are a result of blunt trauma. The bulbar urethra is particularly vulnerable to straddle injury since it is relatively immobile and can be compressed by direct force against the underlying symphysis pubis (Fig. 29.12). Common culprits are bicycle handlebars and the tops of fences and not surprisingly, they are more common in younger males.[69] The penile urethra is much more mobile and less commonly injured. However, in nearly 20% of patients with penile fractures, a concomitant urethral injury will be noted, usually presenting as immediate detumescence with blood at the urethral meatus.[70] Gunshot wounds and stabbings more often involve the penile urethra with concomitant penile, testicular and rectal injuries happening frequently.[71]

Initial Evaluation

Presentation. Hematuria, and, more specifically, blood at the urethral meatus, is the most common sign of urethral injury, though it can be absent in up to 50% of posterior and 25% of anterior urethral injuries.[72] However, clinical suspicion should always dictate workup for urethral injury. For posterior urethral injuries, any type of pelvic fracture should alert one to the possibility of urethral injury. For anterior injuries, any type of straddle mechanism, especially when bruising is seen on physical exam, should alert one to injury. Frequently, patients will also present with painful urination or the inability to urinate. A high-riding prostate on digital rectal exam has often been implemented as a way to diagnose posterior
FIGURE 29.11. Posterior urethral disruption.
FIGURE 29.12. Anterior urethral trauma.

urethral injury, but has been shown to have both poor sensitivity and specificity, especially in young patients.[73]

Diagnosis. If blood is seen at the urethral meatus or if a urethral injury is suspected, a retrograde urethrogram should be performed before attempt at catheterization is made. These studies are best performed with the patient in a 30-degree oblique position, though this may not be possible in patients with a pelvic fracture. A 12–14F Foley catheter is then inserted into the tip of the penis and 1–2 mL is placed into the balloon to seed the catheter in the fossa navicularis. Retrograde injection through the catheter of full-strength contrast medium is then performed. This should be done under fluoroscopy if possible, but otherwise, radiographs should be obtained after at least 10 mL has been injected. Grading systems for urethral injuries vary, but in general, anterior injuries are classified as either partial or complete disruptions. In the posterior urethra, they are classified as partial, complete, or complex, with the latter pertaining to a complete injury that also involves the bladder neck.[65] Cystourethrography should not be used as a diagnostic tool for urethral injuries, except in females, but can later be utilized to help with catheter placement in certain injuries. Other imaging modalities such as ultrasound, CT, and MRI have little utility in the acute setting.

Management

Anterior Urethral Injury. With partial and complete disruptions from blunt trauma in males, injuries can be managed with either a Foley catheter or a suprapubic tube. A suprapubic tube has advantages over urethral catheterization in that it diverts the urine but also avoids urethral manipulation, which has been theorized to possibly worsen the injury and increase the need for subsequent complex urethral reconstruction.[74] Many penetrating injuries and all injuries that are the result of penile fractures should be explored in the acute setting. If a small segment is injured, it can be excised and the urethra can be repaired primarily. With larger injuries, the urethra should be marsupialized and delayed urethroplasty can be performed, usually at 3 months.[65]

Many traumas to the anterior urethra will result in urethral stricture disease. These injuries are best repaired at least 3 months after the initial trauma to allow for resolution of the hematoma and stabilization of the scar tissue. Repair

technique is dependent on the length and location of stricture. Some strictures will be amenable to endoscopic stricture incision, but many perineal straddle injuries will be associated with important spongiofibrosis and will require open urethroplasty, many of which can be repaired with excision of the scar with primary anastomosis.[75]

Posterior Urethral Injury.
URINARY DIVERSION
Many posterior urethral injuries, especially those from with pelvic fractures, will be associated with other abdominal and orthopedic traumas that will often take management precedent to the urethral injury. Because of this, suprapubic tube placement is often the best initial management for posterior urethral injuries as it is a simple procedure that safely diverts the urine away from the injury. Suprapubic tubes be placed percutaneously or in an open fashion, often during abdominal exploration for other injury.[76]

IMMEDIATE PRIMARY REPAIR
Immediate repair of posterior urethral injuries has been associated with higher rates of impotence, incontinence, and stricture rates as compared with either delayed repair or primary endoscopic realignment and is not advised in most situations.[65] Exceptions to this rule include those injuries associated with bladder neck injuries, since the urine will preferentially drain through the bladder neck injury despite diversion, and rectal injuries, with the goal of preventing devastating rectoprostatic fistulas.[77]

IMMEDIATE PRIMARY REALIGNMENT
Primary realignment can be attempted in the stable patient either using purely endoscopic techniques or in an open fashion. Realignment differs from repair in that no attempt is made to secure the ends of the urethral segments to one another, and is simply to bring the transected ends in line with one another and achieve bladder drainage via a urethral catheter. Traction should not be placed on the catheter as bladder neck injury can ensue.[75] Aligning the urethral ends may decrease the need for subsequent urethroplasty versus suprapubic tube alone (62% vs. 100%) and likely makes delayed urethroplasty technically easier.[76]

DELAYED RECONSTRUCTION
Many posterior urethral injuries will result in subsequent stricture formation. Repair of these distraction injuries can be extremely challenging, with the difficulty directly correlating

with the distance between the transected ends. Repair should be performed only by experienced surgeons, at least 3 months after the injury,[65] with restricture rates of <10%. Impotence (40%) and incontinence (5%) rates probably reflect damage done at the time of initial injury and are not from the surgery itself.

FEMALE URETHRAL INJURY

Injuries to the female urethra are rare. Distal injuries can be repaired primarily, generally through a vaginal approach. Proximal injuries are often associated with bladder injuries and are best repaired transvesically or retropubically. Long injuries with intact bladder necks may be best managed with initial suprapubic tube diversion with delayed repair to reduce the risk of urethral loss and incontinence.[78]

PEDIATRIC URETHRAL INJURY

The prostate is less developed in the pediatric male and the bladder neck becomes the most vulnerable segment of urethra to injury. If a bladder neck injury is suspected, immediate repair is advised. Injuries to more distal segments should follow management principles similar those of the adult male.[69]

Summary

Urethral injuries are rare and can often be challenging to manage in the acute trauma setting. In general, supraprostatic diversion is an acceptable option for the initial management of all injuries to the urethra. Delayed repair of any resulting urethral injury can then be performed by experienced hands after other injuries have been resolved and the patient is stable. However, no two urethral injuries are alike and each patient should be assessed and managed according to their initial clinical situations.

EXTERNAL GENITALIA TRAUMA

Epidemiology

Injuries to the male genitalia are rarely life threatening, but without prompt intervention, long-term sexual and psychological effects may result. Over one-third of all urologic trauma in the United States involves the genitalia.[79] In modern warfare, the genitalia are particularly vulnerable to injury, present in over 50% of unique urologic traumas.[80]

Scrotal/Testicular Trauma

Etiology. Nearly 85% of scrotal trauma is blunt, with the most common mechanisms being assault (33%), MVA (22%), and athletic activity (10%).[81] Penetrating trauma can be a result of knife, gunshot, bite, and blast injuries. Self-mutilation can also occur, usually during acute psychotic episodes.[82]

Diagnosis. Most scrotal injuries will be diagnosed by physical examination alone. However, when the integrity of the underlying testicular tissue is questioned, ultrasound is the imaging modality of choice. A high-frequency transducer (10 MHz) will give the best resolution of the testicular parenchyma, but may not always provide enough tissue penetration if a large scrotal hematoma is present, in which case lower frequencies (5 MHz) may be required. Change in the normal homogeneous pattern of the testicle is suggestive of injury (Fig. 29.13). Ultrasound is specific but not sensitive (<50%) for tunica albuginea ruptures, and ultrasound findings should
FIGURE 29.13. Ultrasound (10 MHz) imaging of testicle suggestive of injury.

never preclude surgical exploration if the suspicion is high for testicular rupture.[83]

Management. All testicular rupture injuries should be explored surgically, with prompt (<72 hours after injury) intervention leading to a decreased risk of testicular loss, infection, infertility, and pain.[81,84] Scrotal hematomas and hematoceles can be managed nonoperatively, but if testicular integrity is at all questioned, exploration is advised. A scrotal incision is made over the testicle, which is then delivered into the field. The hematoma is evacuated and the tunica vaginalis is opened, exposing the underlying tunica albuginea and testicle. All nonviable tissue should be excised and the tunical injury should then be repaired using absorbable sutures over all viable seminiferous tubules. In cases where tunica is unavailable or insufficient for coverage, use of autologous tunica vaginalis or Gore-Tex graft can be substituted.[85] A penrose drain is placed postoperatively.

Penile Trauma

Etiology. The majority of penile injuries will be penile fractures, or, more specifically, rupture of the fascial covering of the corpus cavernosum. These are nearly always the result of injury during sexual activity when an erect penis slips out of the vagina during intercourse and thrusts against the perineum or symphisis pubis. The relatively inelastic tunica albuginea will then absorb the majority of the bending force and subsequently tear. Nearly 10% of all penile fractures will also involve the urethra. Other mechanisms of injury include self-mutilation (including penile amputation), gunshot injury, and crush injury.

DIAGNOSIS

Diagnosing a penile injury is usually done by physical exam alone. When a tunical injury occurs, the patient will often hear a loud snapping noise, with resulting detumesence. Blood that had once filled the cavernosal bodies can now escape through the tunical injury, often quickly filling the space between the tunica albuginea and the skin. When Buck's fascia remains intact, the classic "eggplant" deformity ensues (Fig. 29.14). If Buck's fascia is compromised, the blood can also travel within the fascial planes to the scrotum and anterior abdominal wall. If blood is seen at the urethral meatus after injury or if the patient has hematuria, a concomitant urethral injury should be suspected. The tunical injuries are nearly always distal to the penile suspensory ligaments and unilateral,[86] ranging from 0.5 to 4 cm in length. The location of the injury can often be palpated and may cause point tenderness. If the diagnosis of
FIGURE 29.14. Penile fracture with classic "eggplant" deformity.

fracture is in question, ultrasound, cavernosometry, and MRI have been reported to be of some use.[86]

MANAGEMENT

All penile fractures should be explored surgically since reports comparing operative versus conservative nonoperative management show decreased rates of penile curvature, erectile dysfunction, and abscess formation in the surgical group.[87] Exploration is likely beneficial up to 1 week after the injury.[88] The penis can be explored either by degloving the penis via a circumcision incision or by a single linear incision over the injury if it can be easily localized. Any hematoma is evacuated and the tear is closed with interrupted 2-0 absorbable (polydioxanone) suture, with care to avoid the dorsal neurovascular bundles. The urethra should be thoroughly inspected through the same incision and repaired in a tension-free fashion over a urethral catheter if injured.

All deep-penetrating trauma to the penis and genitalia should be explored to assess the extent of damage with the goal of preserving reproductive organ function.[89] Penetrating injuries of the cavernosal bodies should be repaired as described above with the goal to preserve function and avoid penile curvature. When the spermatic cord is injured, ligation of vessels is often necessary but this does not mandate orchiectomy if collateral circulation from the cremasteric and/or vasal blood supply remains intact.[86] Vas deferens injuries should usually be ligated and then formally repaired using the microscope in a delayed fashion.

Penile amputation is a rare event and is usually the result of an acute psychotic episode or severe gender dysphoria.[90] Preservation of the penis can and should be sought whenever possible. The amputated penis should initially be wrapped in a saline-soaked gauze, put in a sealed sterile bag and then placed on ice, with care to avoid direct contact of the ice with the penis. The repair should begin with a spatulated urethral anastomosis over a catheter, followed by reattachment of the corporeal bodies with absorbable sutures. A microscopic reconstruction of the dorsal nerves, arteries, and veins should

then ensue whenever possible, to improve penile sensation and decrease the risk of skin loss.[91] Erectile function can generally be preserved if the repair occurs <24 hours after amputation.

Genital Skin Loss

Etiology. The most common etiology for genital skin loss is infectious, usually the result of Fournier's gangrene (75%).[92] Traumatic avulsion of skin from accidents (farm machinery and motorcycle) and bite wounds can also occur. Avulsion injuries usually result when the genital skin becomes entangled in clothing that is traumatically ripped from the individual's body.

Management. Gangrenous skin should be immediately and aggressively excised. Secondary debridements are often necessary and should be planned in most cases. Reconstruction should take place only after the disease and the patient have fully stabilized.[93] A myriad of techniques are often necessary including primary closure, skin grafting, local tissue/ thigh flaps, and combinations thereof. When the scrotal skin is involved and the testicles are left uncovered, scrotal pouches can be created or saline-soaked gauze can be used for protection in anticipation of eventual reconstruction.

Minor avulsion injuries can generally be repaired primarily after copious irrigation. Complete, circumferential avulsion injuries of the penis will usually require a more aggressive debridement because blood supply to the distal penile skin is often unrecoverable.[94] In these situations, observation after debridement followed by either primary repair (once skin integrity has declared itself) or skin grafting is recommended. Animal bite wounds can usually be closed primarily after irrigation and debridement.[95] Human bite wounds to the penis, which are more likely to present late and therefore, more likely to be grossly contaminated at presentation, should generally be left open and allowed to heal by secondary intention.[95] Most injuries to the scrotal skin can be repaired primarily if <70% of the skin has been lost.

CONCLUSION

Injuries to the external genitalia are rare, but can have lasting sexual and psychological sequelae if not managed in a timely and appropriate fashion. Goals of all management should be to first preserve sexual and urodynamic function, followed by cosmetic appearance if possible.

TRAUMA

ACUTE CARE SURGERY: SKELETAL AND SOFT-TISSUE INJURY

GUSTAVO X. CORDERO, GARY S. GRUEN, PETER A. SISKA, AND IVAN S. TARKIN

Expert care of musculoskeletal injury in the polytrauma patient will lead to optimized long-term clinical outcomes. After the initial assessment and stabilization of the patient, the orthopedic trauma surgeon has the responsibility of thoroughly evaluating the pelvis and extremities for both bone and soft-tissue injury during the secondary survey. A collaborative effort, however, between the general trauma surgeon and the orthopedic surgeon is required to coordinate care and promote safe and efficacious treatment of the multiply injured patient.[1]

GENERAL PRINCIPLES

The evaluation of the trauma patient with musculoskeletal injury includes a complete history and physical with an extensive neurologic and vascular examination. Specific fractures and dislocations will pose a greater risk to surrounding neurovascular structures, and the status of these structures should be noted (Table 30.1). The soft tissue surrounding the fracture site needs to be scrutinized for any defects to determine if the fracture is open or closed. Musculoskeletal emergencies such as compartment syndrome or vascular injury need to be promptly identified.

Further, a tertiary survey is of the utmost importance considering that 15–20% of musculoskeletal injuries are initially missed in the polytrauma patient.[2] This should be performed after the initial 24–48 hours. At this point of time in the patient's treatment course, distracting injuries would have been stabilized and the patient can sometimes assist with localizing further sites of musculoskeletal trauma.

Beyond physical examination, imaging is a critical aspect of the orthopedic workup. At least two orthogonal radiographs that include the proximal and distal joints of the injured extremity should be obtained. Further dedicated radiographs and imaging modalities (computed tomography and magnet resonance imaging) should be ordered by the consulting orthopedist.

Initial Care: Realignment and Reduction

After achieving the diagnosis of fracture or dislocation, prompt delivery of orthopedic care is essential to stop the cycle of injury. Prompt reduction/relocation and splinting protects the soft-tissue envelope, including nerves and vasculature from further traumatic insult. Reductions and relocations should be performed after completion of the secondary survey. Fractures can be immobilized with a well-padded, plaster splint spanning the joint proximal and distal to the fracture site.

Open Fractures

Open fractures in a trauma patient are a site for bacterial proliferation and need to be treated with debridement of debris and necrotic tissue followed by irrigation to decrease bacterial loads. The energy imparted to produce an open fracture causes major stripping of muscle and periosteum with considerable devascularization to the bone. Inadequate debridement increases the risk of developing osteomyelitis, nonunion, and potential loss of limb. Antibiotics are an adjunct treatment to a thorough debridement of an open wound and cannot be used independently.

The Gustilo and Anderson classification continues to be the most commonly used system to describe and guide treatment of open fractures.[3] The grade of the fracture is determined by the extent of soft-tissue disruption, degree of contamination of the wound, and severity of the fracture. In applying the classification system, the extent of soft-tissue disruption can only be determined after a thorough debridement has been performed. A grade I fracture is the result of low-energy trauma with a wound that is <1 cm that was caused by protrusion of the bone through the skin or a low-velocity bullet. A wound >1 cm with minimal devitalized soft tissue and contamination that was caused by moderate energy is classified as a grade II fracture. Grade III fractures are caused by high-energy trauma and have extensive soft-tissue injury, gross contamination, a laceration >10 cm, or a segmental fracture. High-power rifles and close-range shotgun blasts impact substantial soft-tissue injury and should be treated as grade III fractures. The presence of adequate soft-tissue coverage with intact periosteum, substantial soft-tissue loss with exposed bone that will require tissue transfer for coverage, and the presence of a vascular injury requiring repair for limb preservation subdivide grade III fractures into grade IIIa, IIIb, and IIIc, respectively.

The initial management of open fractures begins in the trauma resuscitation area. Gross contamination should be removed from the wound. Following the application of a dressing and fracture reduction, fractures should be splinted to decrease pain, reduce hemorrhage, and prevent further soft-tissue injury. Patients with open wounds need antibiotic prophylaxis with tetanus toxoid and a first-generation cephalosporin. Grade III fractures and contaminated wounds also receive an aminoglycoside to prevent gram-negative infection. Barnyard injuries warrant prophylaxis against anaerobes, such as clostridium, with penicillin. In the operating room, it is recommended to debride tissue that lacks contractility, consistency, and the ability to bleed.[4] Loose, devitalized bone should be removed regardless of whether or not it is crucial to stabilization. It has been shown that delays of up to 24 hours do not influence infection rates; however, it is recommended to not delay surgical care of open fractures in a stable patient and perform the initial debridement within 6 hours.[5] The combination of low-pressure irrigation with mechanical scrubbing is effective in reducing bacterial loads.[6] There is no consensus regarding the use of additives in the irrigation fluid. Bacitracin has been shown to not degrade in irrigation solutions; it interferes in the cell wall synthesis of microbes without the risk of cell necrosis and delayed wound healing seen with povidone–iodine and chlorhexidine.[7] Definitive fixation can be performed with an infection rate of <2% following debridement and irrigation in grade I fractures and grade II fractures with minimal soft-tissue loss.[3] Grade III fractures and wounds with severe soft-tissue damage are treated in a staged fashion with temporary immobilization with an external fixator.

TABLE 30.1

NEUROVASCULAR INJURIES ASSOCIATED WITH ORTHOPEDIC TRAUMA

■ ORTHOPEDIC INJURY	■ NEUROVASCULAR INJURY
Anterior shoulder dislocation	Axillary nerve injury, axillary artery injury
Humeral shaft fracture	Radial nerve injury
Supracondylar humeral fracture	Brachial artery
Distal radius fracture	Median nerve injury
Perilunate dislocation	Median nerve injury
Posterior hip dislocation	Sciatic nerve injury
Supracondylar femoral fracture/knee dislocation	Popliteal artery injury/ thrombosis
Proximal fibular fracture	Peroneal nerve injury
Mangled extremity/tibial fracture	All neurovascular structures of the lower leg

Following a thorough debridement, soft-tissue defects can be temporarily covered with an antibiotic bead pouch or a vacuum-assisted wound closure. High concentrations of antibiotics can be delivered to a wound through the use of antibiotic cement. Traditionally, tobramycin or vancomycin have been combined with one package of bone cement. The antibiotic cement can then be formed into beads on a stainless-steel wire and placed within a soft-tissue defect at an open fracture. If there is inadequate tissue to close the wound, a bead pouch can be formed by sealing the wound with an adhesive drape (i.e., Ioban and Tegaderm).[8] The use of vacuum-assisted wound closure (VAC) has gained popularity in the treatment of traumatic wounds. Vacuum-assisted wound dressing devices have been shown to dramatically increase the formation of granulation tissue, decrease the wound bacterial count, and decrease edema following fasciotomies.[9,10] The rate of deep infections following open tibial fractures has been shown to decrease fivefold when using VAC dressings rather than standard wound care.[11] External fixators can be used to span fracture sites and maintain immobilization while allowing for monitoring of soft tissues. By restoring limb length and alignment, improved circulation promotes healing, reduces inflammation, and increases revascularization of devitalized tissue.

Wounds should continue to be taken to the operating room for repeat irrigation and debridement every 48–72 hours. Debridements need to be thorough with early removal of nonviable tissue to allow for timely preparation of the wound for soft-tissue coverage. Decreased infection and flap complication rates occur when flap coverage is performed within 7 days of injury.[12] The early involvement of a plastic surgeon will aid in the planning of reconstructive options.

Compartment Syndrome

Compartment syndrome is a surgical emergency. The diagnosis of compartment syndrome can be challenging, especially in a trauma patient who is sedated or intubated. The devastating outcomes associated with a missed compartment syndrome stress the importance of early diagnosis and fasciotomies (Fig. 30.1A). Compartment syndrome is the result of an elevated pressure within a closed myofascial compartment that results in microcirculatory failure and tissue ischemia. Fifty percent of compartment syndromes are associated with a fracture and are caused by hemorrhage and edema in the injured soft tissue around the fracture. Other etiologies include vascular injuries with reperfusion injury and crush injuries. A constrictive dressing or splint can cause circumferential constriction of an extremity with resulting compartment syndrome that generally resolves with loosening of the dressings. The leg and the forearm are the most common sites for compartment syndrome secondary to tighter, more robust fascial boundaries. Compartment syndrome can also occur in the hand or foot, and rarely does it occur in the deltoid, arm, buttock, or thigh.[13] The presence of an open fracture does not exclude the possibility of a concurrent compartment syndrome. Compartment syndrome has been noted to be present in 9% of open tibial fractures.[14]

The diagnosis is based on clinical examination findings. Compartment pressure measurements are reserved for uncooperative, intoxicated, sedated, or obtunded patients. The classic signs of compartment syndrome are the five Ps: pressure, paresthesia, pain, paralysis, and pulselessness. The presence of tense, noncompressible compartments is generally the presenting sign that will initiate evaluation for compartment syndrome. Pain that is out of proportion to what would be expected for a particular injury and pain with passive stretch of muscles are key signs that confirm the diagnosis. Increasing demands for pain medication are also indicative of a developing compartment syndrome. Pulselessness, paralysis, and paresthesias are late signs that indicate a missed compartment syndrome. The presence of pulses and a normal neurologic examination should not be used to exclude a compartment syndrome.

Invasive compartment measurements can be used to assist in making the diagnosis when clinical findings are questionable. The delta P can be calculated by the difference between the diastolic blood pressure and compartment pressure. Values of <30 mm Hg are associated with inadequate oxygen delivery to tissues and require fasciotomies for treatment of compartment syndrome.[15] The use of continuous monitoring of compartment pressures has been advocated for the obtunded patient.[16] In general, compartment pressures of >20 mm Hg should raise suspicion for the development of a compartment syndrome. If suspicion of a compartment syndrome is high, it is better to perform a preemptive fasciotomy rather than miss a compartment syndrome and face potential limb loss.

The treatment of compartment syndrome is emergent decompressive fasciotomies. In compartment syndromes involving the leg, the anterior, lateral, and deep posterior compartments are the most frequently involved. The two-incision technique provides a reliable method for decompressing all four compartments. A lateral incision is made between the tibial crest and the fibula to release the anterior and lateral compartments. Longitudinal fasciotomies are made over both compartments until the muscles are soft (Figs. 30.1B and 30.2). Care should be taken to protect the superficial peroneal nerve as it courses posterior to the lateral intermuscular septum (Fig. 30.1C). A medial incision is then made 2 cm posterior to the posterior boarder of the tibia. The proximal aspect of the soleus is released from the tibia to allow access to the deep posterior compartment. Longitudinal fasciotomies are then made through the deep and superficial posterior compartments.

Compartment syndrome in the forearm also requires decompressive fasciotomies with two incisions. A curvilinear incision is made over the volar aspect of the forearm from the antecubital fossa to the palm (Figs. 30.3 and 30.4). The superficial fascia, deep intramuscular fascia, and carpal tunnel should be released. If the dorsal compartments remain tense

FIGURE 30.1. A: Necrotic muscle (anterior compartment) identified at the time of fasciotomy after delayed presentation of a compartment syndrome that resulted in permanent foot drop. B: Lateral-based longitudinal incision for release of both the anterior and lateral compartments of the leg in a patient with a segmental tibial shaft fracture. The fracture was provisionally stabilized with a spanning external fixation and a VAC was utilized to help decreased edema.
FIGURE 30.1. *(Continued)* C: The forceps marks the superficial peroneal nerve as it pierces through the fascia of the lateral compartment.

following volar fasciotomies, a longitudinal incision is made over the dorsal aspect of the forearm. Fasciotomies are then performed over the extensor compartment and mobile wad.

Vacuum-assisted dressing application following fasciotomies has been shown to significantly decrease the time to definitive wound closure (delayed primary closure or skin grafting) when compared to not using a VAC, 6.7 days and 16.1 days, respectively.[17] Irrigation and debridement of fasciotomy sites should be performed every 48–72 hours until delayed closure or skin grafting is performed.

Vascular Injury

A vascular consultation should be obtained if distal pulses are not equal to the contralateral extremity after reduction. In a patient in shock, pulses may be difficult to palpate and further evaluation with an ankle–brachial index (ABI) or an arteriogram can identify a vascular injury. If revascularization is deemed necessary, it should be emergently performed within 6 hours. Temporary or definitive fracture-dislocation stabilization needs to be performed prior to vascular repair to prevent reinjury or inappropriate tensioning of the vessel. An external fixator provides immediate, portable stabilization and can be applied quickly. The external fixator restores length and stability to facilitate vascular repair. Prophylactic fasciotomies should be performed to prevent reperfusion compartment syndromes.

Deep Vein Thrombosis and Pulmonary Embolism Prevention

The risk factors associated with the development of deep venous thrombosis (DVT) and pulmonary embolism (PE) are surgery, immobilization, fractures, and coagulopathy.[18] All of these risk factors are present in a multiply injured patient. The mortality rate for an untreated PE is 30%.[18] There continues to be controversy regarding the best prophylaxis for DVT. No significant decrease in the occurrence of DVT has been noted with the use of low-dose heparin, pneumatic compression devices, or arteriovenous foot pumps in the trauma patient.[19] Low-molecular-weight heparin has been indicated for DVT prevention in patients with pelvic fractures, complex lower extremity fractures that require surgical fixation, prolonged bed rest, and spinal cord injuries with complete or incomplete paralysis.[19] The use of vena cava filters has been recommended in patients who cannot receive anticoagulation secondary to ongoing bleeding or severe head injuries.[20]

MANAGEMENT OF INJURIES

Extremity Fractures

Fractures that involve the extremities can result in significant morbidity, decreased mobility, and post-traumatic arthritis.

FIGURE 30.2. **A:** A lateral fasciotomy of the leg is performed by making a longitudinal incision from the proximal end of the fibula to the lateral malleolus and decompresses the anterior and lateral compartments. **B:** A medial incision situated between the anterior and posterior crests of the tibia provides a decompressive fasciotomy for the deep and superficial posterior compartments of the leg.

Extremity fractures can be seen in young patients who sustain high-energy trauma as well as elderly patients who sustain insufficiency fractures from low-energy mechanisms. The treatment modality and timing of surgical intervention for these injuries varies depending on the physiologic status of the multiply injured patient.

Damage Control Orthopedics

Early total care is the concept of stabilizing long-bone fractures acutely, especially for polytrauma patients. By stabilizing long-bone fractures, there is a subsequent decrease in fat emboli syndrome, mortality rate, and length of hospital stay. Over time, it was noted that some patients did not tolerate early total care and worsened with immediate definitive fracture treatments. This has led to the emergence of damage control orthopedics (DCO), with patients at risk of developing complications with acute fracture management being initially stabilized with provisional external fixation and less evasive procedures. However, it is still unclear what parameters can be used to identify at-risk patients who will benefit from DCO rather than early total care.

Patients with multiple trauma who survive the initial insult and the acute resuscitation period are subsequently faced with a 50% mortality rate from infection, acute respiratory distress syndrome (ARDS), and multiple organ failure.[21,22] Early total care is the preferred treatment in most polytrauma patients; however, an unfavorable immunologic response will be seen in a rare subset of these patients following acute definitive fracture fixation within the first 24 hours after injury.[23] The initial trauma has been referred to as the "first-hit" and the impact of the subsequent surgical burden as the "second-hit" phenomenon. To reduce the negative impact of the second hit, the principles of DCO were introduced.[24,25] The "second-hit" phenomenon may impact in particular those patients with more severe injury and initial physiologic derangement.[24] It appears the timing of secondary-hit phenomena may be most evident between days 3 and 5 following injury.[26]

FIGURE 30.3. A: A patient with compartment syndrome of the forearm that was treated with complete release of the superficial fascia, deep intramuscular fascia, and carpal tunnel.

B

C

FIGURE 30.3. *(Continued)* B: Only the carpal tunnel portion could be reapproximated. C: A Jacob's ladder, utilizing vessel loop and staples, was used to approximate the tissues and minimize the area that would ultimately require a skin graft.

Diaphyseal Fractures

Diaphyseal fractures are frequently associated with high-energy traumas and many have associated injuries. Surgical goals are to restore limb length, alignment, and rotation while allowing for early mobilization of the patient. The use of provisional external fixation with delayed definitive treatment has been recommended to limit adverse surgical insult in unstable polytrauma patients. In the absence of pin-site infections, provisional fracture fixation with an external fixator for <2 weeks does not adversely affect definitive treatment with IMN.[27,28]

Initial imaging modalities of a grossly deformed lower extremity include orthogonal radiographs of the diaphysis and the proximal and distal joints. Fractures involving the articular margins are frequently seen with diaphyseal fractures. A computed tomography scan should be obtained prior to proceeding with surgical intervention if there is any concern for an articular fracture that would alter management. Femoral neck fractures are associated with 10% of femoral shaft fractures and approximately 30% are missed on initial evaluation.[29] A protocol with a dedicated internal rotation AP radiograph of the hip, fine-cut CT scan through the femoral neck, intraoperative fluoroscopic lateral radiograph of the hip, and postoperative AP and lateral radiographs of the proximal femur has been recommended to better detect and treat associated femoral neck fractures.[30]

Acute intramedullary nailing is the treatment choice for most diaphyseal fractures. Fat embolism syndrome occurs when marrow fat macroglobules are released from the intramedullary canal following a long-bone fracture, especially

FIGURE 30.4. A: A curvilinear incision spanning over the volar aspect of the forearm from the antecubital fossa to the palm is used to decompress the superficial and deep compartments of the volar forearm. **B:** The dorsal compartments are released by performing a longitudinal incision over the dorsal aspect of the forearm.

in the femoral shaft. The lack of venous valves in the femur allows canal contents to drain into the bloodstream. After the fat emboli are released to the bloodstream, the emboli are surrounded by activated platelets that together cause an intense inflammatory response in the lung. The inflammatory response results in increased vasoconstriction and increased pulmonary artery pressures that can exacerbate pulmonary problems in a multiply injured patient.[31] Urgent stabilization of long-bone fractures has been recommended to decrease fat embolization, which is primarily accomplished with intramedullary nailing. The use of early external fixation followed by delayed intramedullary nailing has been shown to have decreased systemic inflammation when compared to early intramedullary nailing.[32] The degree of fat embolization has been shown to be greatest during nailing insertion with only minor differences during reaming.[27]

Open reduction and internal fixation (ORIF) with plates and screws is infrequently used to treat diaphyseal fractures since IMN minimizes soft-tissue stripping, devascularization of bone fragments, and infection rates. ORIF does have a role in the treatment of proximal and distal metadiaphyseal fractures with articular extension, ipsilateral femoral neck fracture, the presence of a total joint arthroplasty, extremely small intramedullary canals, and when there is a preexisting deformity that prevents the use of IMN.

Periarticular Fractures

The treatment of periarticular fractures varies from the management of diaphyseal fractures in that the articular surface must be anatomically reduced in addition to restoring alignment, length, and rotation. Inadequate restoration of the

articular surface predisposes the patient to post-traumatic arthritis. Surgery must frequently be delayed to allow for soft-tissue swelling to decrease as well fracture blisters to resolve prior to definitive treatment. This is most evident in the treatment of tibial plateau and distal tibial pilon fractures.[33,34] The extensive surgical approaches that must be made to reduce and stabilize periarticular fractures may lead to further soft-tissue insult and failure to allow for the resolution of the initial swelling can result in postoperative wound complications. Patients must be closely monitored for signs of compartment syndrome and if fasciotomies are performed, the incisions must be placed to allow for subsequent surgical approaches to be made during definitive fixation.

A two-staged approach is frequently utilized in treating tibial plateau and pilon fractures when significant soft-tissue injury is present.[33] Initial management requires reduction of the fracture with realignment of the articular segment through ligamentotaxis. Acute application of a spanning external fixator allows for realignment of the joint, restoration of length, and immobilization to facilitate soft-tissue healing. In pilon fractures, the fibula can be acutely plated to assist in restoration of length and to maintain the talus reduced in the mortise if, soft tissues allow. Plain radiographs and CT scans are required to adequately visualize the fracture. CT scans should be obtained after the fracture has been reduced and length restored. CT scans allow for evaluation of intra-articular depression that must be addressed during definitive fixation.

When soft-tissue swelling has decreased, fracture blisters have reepithelialized, and skin wrinkles have returned definitive fixation can be performed. The surgical principles of ORIF of periarticular fractures are restoration of length, anatomic reduction of the articular surface, and bone grafting of metaphyseal defects. Nonsurgical management of periarticular fractures is generally reserved for patients that are nonambulatory, a poor surgical candidate secondary to comorbidities, or significant soft-tissue injury that precludes surgery.[35]

PELVIC FRACTURES

Incidence, Mechanism, and Associated Injuries

Pelvic fractures can result from low-energy trauma, such as a ground-level fall in the elderly, or from high-energy trauma, such as motor vehicle and motorcycles crashes, pedestrians struck by motor vehicles, and falls from heights. Stable fracture patterns generally result from low-energy trauma and can be managed nonoperatively. Surgery is generally required for the treatment of the unstable fractures that are caused by high-energy trauma.

Between 3% and 5% of traffic accidents are associated with pelvic injuries and account for 74% of unstable pelvic ring disruptions.[36,37] Among the unstable pelvic ring disruptions, more than 88% are associated with injuries to the head, chest, abdomen, spine, or long bones.[38] Urogenital injury (bladder disruption, urethra disruption, and vaginal tear), vascular injury, or bowel injury are the most commonly associated intrapelvic injury.[36] The mortality rate may be as high as 50% in complex pelvic ring disruptions.[39]

Clinical Evaluation

A trauma patient should be evaluated for a pelvic injury concurrently with resuscitation, especially in the setting of hypotension. The evaluation begins with obtaining a history and

clinical examination. The involvement of the orthopedic team should occur as soon as a pelvic disruption is suspected. A communicative patient with a pelvic fracture may complain of pelvic pain and the inability to void if there is a urethral disruption.[37]

During the physical examination, it is critical to thoroughly examine the soft tissue around the pelvis for a laceration or degloving injury. While maintaining spine precautions, a patient can be logrolled to allow adequate evaluation of the posterior pelvis for lacerations or hematomas. The early identification of an open pelvic injury can facilitate an urgent exploratory laparotomy and a diverting colostomy. Approximately 4% of pelvic fractures are open and have a 50% mortality rate.[37,40] Active bleeding through a soft-tissue defect in an open pelvic fracture poses a major challenge. The patient can rapidly exsanguinate since the fracture is no longer contained. Early blood transfusions, pressure tamponade of soft-tissue bleeding in the trauma room, urgent laparotomy for control of bleeding from extrapelvic sources, pelvic packing, and an arteriogram with embolization can assist with management of this problem.[40,41] Only 1% of pelvic fractures have a major vascular disruption; however, these disruptions result in a 75% mortality rate.[42]

In males, the scrotum should be examined for testicular displacement and the urethral meatus for blood. A urethral injury cannot be excluded by the absence of blood at the urethral meatus and can be further evaluated with a retrograde urethrogram or cystogram. The pubic symphysis should be palpated for diastasis and the rami for crepitus. A visual and bimanual pelvic examination should be conducted in females to evaluate for lacerations of the urethra, vagina, or rectum. Vaginal lacerations with healthy tissue should be irrigated and closed, whereas perineal lacerations are generally managed with serial debridements and delayed closure.

Urethral injuries should be evaluated with a rectal examination before inserting a Foley catheter. Urethral disruptions are more common in males and commonly occur below the urogenital diaphragm. A displaced prostate is indicative of a urethral disruption. The presence of blood with a digital rectal examination requires further evaluation with anoscopy and proctoscopy. A rectal tear with a pelvic fracture warrants irrigation of the wound and a diverting colostomy. Proctoscopy should also be considered for all patients with significantly displaced pelvic fractures, which can perforate the rectum.

Pelvic instability can be difficult to assess manually. Rotational stability can be evaluated with direct pelvic compression and vertical stability with the push–pull maneuver of the lower leg. Once pelvic instability has been identified, further stressing should be avoided to prevent excessive bleeding and patient discomfort. A detailed motor and sensory examination of the lower extremities should also be performed to assess for a neurologic injury.

Radiographic Evaluation

An anteroposterior pelvis radiograph should be obtained on all patients involved in a high-energy trauma and those with pelvic pain following a low-energy trauma. Pelvic inlet and outlet views should be obtained to evaluate anteroposterior and vertical displacement of the hemipelvis, respectively. It is important to remember that the displacement observed on radiographs is a static representation of a dynamic process that could have recoiled following the initial injury.

A computed tomography (CT) scan of the pelvis with 3 mm contiguous cuts should be obtained to evaluate the magnitude of the fracture or joint displacement and compression of the sacral foramina. Displacement of the posterior pelvic complex by >5 mm indicates significant posterior or vertical

instability. The CT defines the pelvic injury in greater detail than radiographs and allows for more accurate preoperative planning.

Classification

There are various classification systems used to describe pelvic injuries; however, Tile's classification system based on the instability of the bony injury is the most commonly used (Table 30.2). The force vectors involved during injury correlate with the associated injuries seen with pelvic fractures.[44] Lateral compression fractures are associated with lung, spleen, liver, and closed head injuries, whereas anteroposterior compression fractures are associated with bladder, urethra, rectum, lower extremity, and chest injuries. Vertical shear fractures are associated with neurovascular injury, calcaneal fractures, and thoracolumbar fractures.

Type A fractures are stable, minimally displaced, and usually associated with low-energy trauma (Fig. 30.5A). They are further divided by the presence of pubic rami fractures, avulsion injuries, and transverse sacral or coccyx fractures. Type B fractures are characterized by rotational instability but maintain vertical stability (Fig. 30.5B). The pubic symphysis, rami, or both are involved anteriorly and the sacrum, sacroiliac joint, or both are involved posteriorly. Injuries can be ipsilateral and contralateral. Vertical instability characterizes type C fractures. Disruptions of the anterior and posterior pelvis result in vertical displacement of one or both hemipelvis (Fig. 30.5C).

Treatment

Patients with pelvic injuries can present hemodynamically unstable and require immediate pelvic immobilization during resuscitation (Algorithm. 30.1). Exposed fracture surfaces, venous plexus disruptions, and arterial tears can lead to pelvic hemorrhage. By closing down the potential space in the pelvis, blood loss can be decreased through tamponade. Circumferential pelvic antishock sheeting (CPAS), pelvic binder, C-clamp, military antishock trousers (MAST), or external fixation can be utilized to temporarily immobilize an unstable pelvis.

TABLE 30.2

TILE'S CLASSIFICATION SYSTEM FOR PELVIC RING INJURIES

■ TYPE	■ STABILITY	■ SUBTYPE
A	Stable	A1—Fractures of the pelvis not involving the ring A2—Stable, minimally displaced fractures of the ring
B	Rotationally unstable, vertically stable	B1—Open book B2—Lateral compression: ipsilateral B3—Lateral compression: contralateral (bucket handle)
C	Rotationally and vertically unstable	C1—Unilateral C2—Bilateral C3—Associated with an acetabular fracture

Ref. [43] (From Tile M. Pelvic ring fractures: should they be fixed? *J Bone Joint Surg.* 1988;70:1–12.)
FIGURE 30.5. **A:** Stable, minimally displaced pelvic ring fracture. **B:** Rotationally unstable with pubic symphysis diastasis. **C:** Vertically and rotationally unstable pelvic fracture with disruption of both the anterior and posterior elements with vertical displacement of the hemipelvis.

CPAS has gained great acceptance since it is small, transportable, inexpensive, easily applied, provides satisfactory pelvic stability, and continues to allow access to the abdomen and lower extremities.[45] CPAS is applied by taking a sheet that has been folded lengthwise into widths of approximately 18 inches and placing it around the pelvis at the level of the pubic symphysis. The pelvis is then closed and stabilized as the sheet is tensioned and crossed anteriorly as a compressive force is applied on the lateral buttocks.

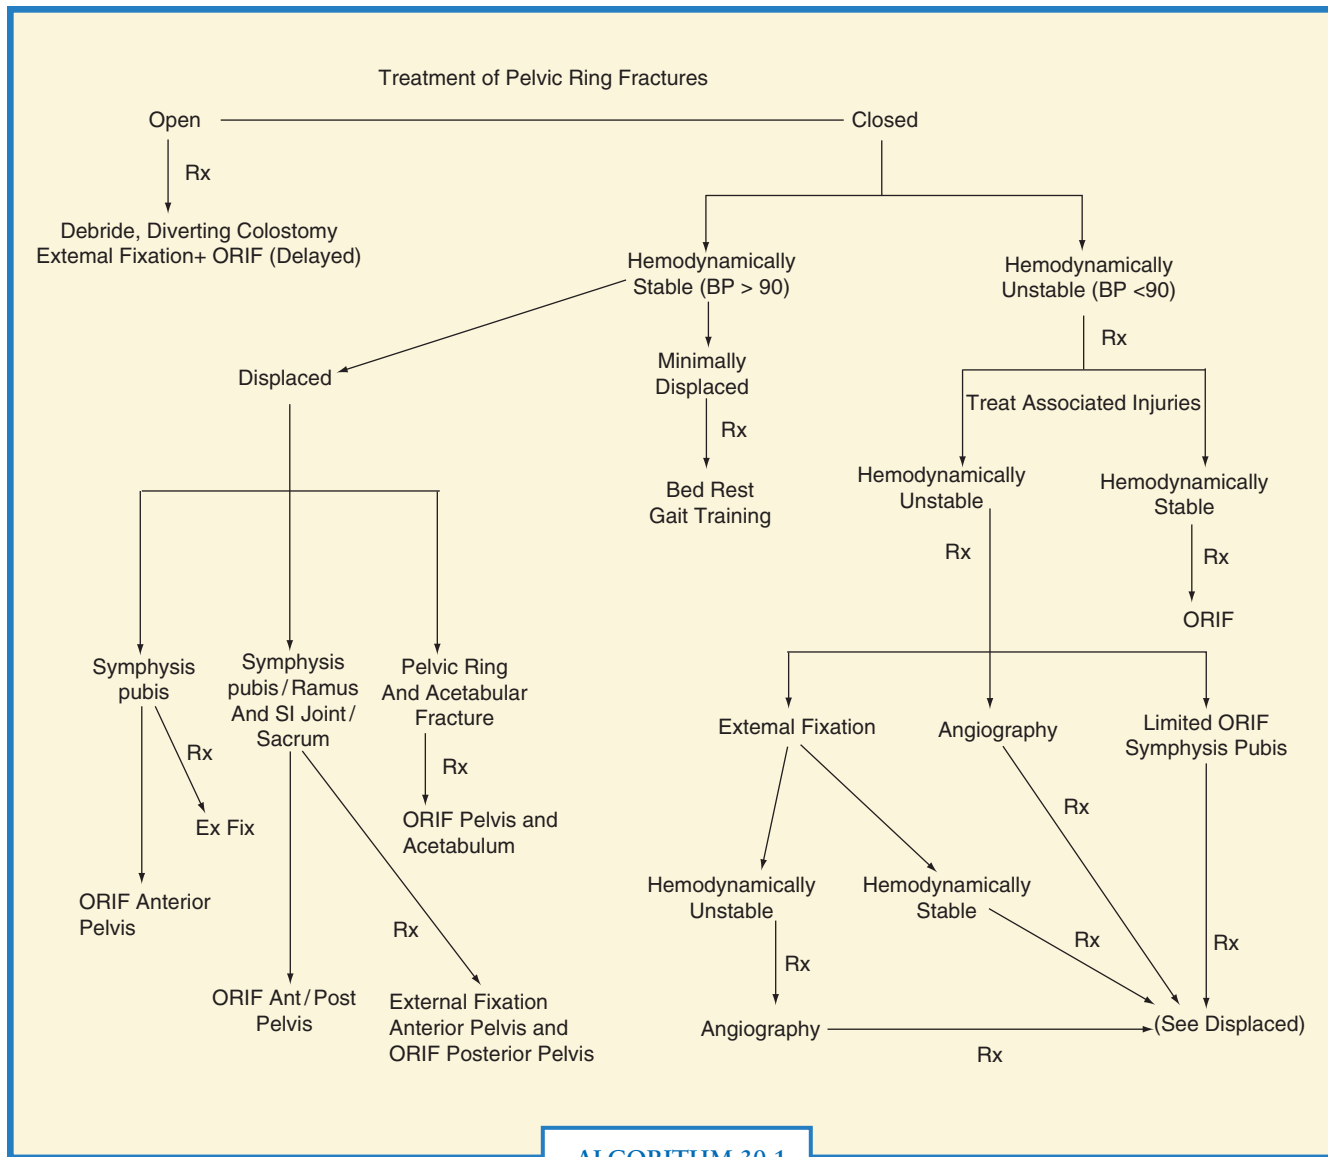
External fixators are commonly used to rapidly stabilize pelvic ring disruptions. There are both anterior and posterior systems available to treat specific injury patterns. Anterior pelvic external fixation provides stability by closing the pelvis anteriorly through the use of pins placed into the iliac crests or supra-acetabular area. In some patients, the posterior pelvic deformity may be increased with anterior pelvic stabilization and a pelvic C-clamp has been advocated.[39] The C-clamp compresses and stabilizes the posterior pelvic ring through two pins that are placed in the posterior ilium. The application of a C-clamp can be challenging especially in patients with posterior pelvic deformities and a too posterior position can result in insufficient stabilization. External fixation is the initial treatment of choice for open pelvic fractures.

Patients who continue to have hemodynamic instability despite adequate volume resuscitation, correction of coagulopathy, treatment of extrapelvic sources of bleeding, and temporary pelvic stabilization require angiographic evaluation and embolization [46]. Hemodynamic instability from the pelvis is defined as ongoing resuscitation of >6 units of packed red blood cells in a 4-hour time span. Superior gluteal artery injuries have been associated with displaced pelvic fractures through the sciatic notch.

Definitive treatment of a pelvic ring disruption is with open reduction and internal fixation in order to stabilize all disrupted elements (Algorithm. 30.1). Internal fixation should be delayed in the setting of an open fracture, and the use of an external fixator with serial debridements should continue until a clean wound is produced. The anterior pelvis can be stabilized acutely during a laparotomy in a hemodynamically unstable patient or on a delayed basis in a stable patient.[47] Incisions used for a laparotomy or placement of a suprapubic tube should be placed as cephalad and central as possible to prevent future compromise of surgical incisions used for anterior pelvic open reduction and internal fixation. Posterior pelvic fractures can be treated with either open reduction internal fixation or percutaneous placement of iliosacral screws under fluoroscopic guidance. A posterior approach with foraminal decompression may be required to treat displaced sacral fractures with nerve root impingement.

KNEE DISLOCATIONS

Knee dislocations are limb-threatening injuries that require evaluation for neurovascular disruptions. Many knee dislocations present spontaneously reduced; therefore, a knee with multiligamentous injuries should be considered a reduced knee dislocation. There can be significant stretching of the popliteal artery with a knee dislocation. The popliteal artery is tethered proximally at the adductor hiatus and distally deep to the soleus. During a knee dislocation, the popliteal artery is tethered at these two fibrous tunnels and a vascular injury can result. Knee dislocations are commonly described as the position of the tibia relative to the femur. Anterior knee dislocations are usually the result of a hyperextension injury and can injure the artery by traction with a resulting intimal tear 39% of the time.[48] A complete arterial transection can occur in up to 44% of posterior dislocations, which are the result of a posterior force applied to the anterior tibia.[48] The initial disruption may be a minor intimal tear and the vascular examination can remain normal.[49] Intimal tears are thrombogenic and a delayed thrombosis can occur many hours after injury. If the lower extremity is splinted to stabilize the knee dislocation, the thrombosis may not be recognized and significant damage can occur that results in subsequent limb loss.

The evaluation of a patient with a knee dislocation begins with a physical examination. The neurovascular status of the


ALGORITHM 30.1

ALGORITHM 30.1 Algorithm for the treatment of polytrauma patients with pelvic ring fractures.

extremity should be noted and an immediate reduction of the dislocated knee should be performed. If pulses (dorsalis pedis and posterior tibial arteries) are absent prior to reduction and do not return following reduction, the patient should be taken immediately to the operating room for vascular exploration. Once a damaged segment is identified, it should be excised and reanastomosed with a reverse saphenous vein graft. A spanning knee external fixator should be considered prior to vascular repair to maintain the joint reduced, prevent damage to the neurovascular structures, and protect the articular surfaces.

If pulses are present before and after reduction, it is recommended to obtain an ankle–brachial index (ABI), especially if pulses are asymmetrical. A palpable pulse can remain despite vascular injury secondary to collateral blood flow.[50] An ABI of <0.9 has yielded sensitivities of 95%-100% in detecting clinically significant popliteal artery injury and warrants further evaluation with a duplex ultrasound.[50] Confirmation of arterial injury on the duplex ultrasound requires arteriography to further delineate the lesion and evaluate for possible vascular

intervention.[51] ABIs of >0.9 have been associated with negative predictive values of 99% for major flow limiting arterial injury and should be followed with serial examinations every 4 hours for 48 hours.[52] Once vascular injuries have been addressed and the knee has been stabilized with an external fixator, surgical versus nonsurgical management can be discussed with the patient.

THE MANGLED LOWER EXTREMITY

The mangled lower extremity includes a wide spectrum of injuries with possible severe bony injury, soft-tissue disruption, vascular compromise, neurologic injury, and gross contamination. These injuries are difficult to manage and require the effort of many subspecialties, including general surgery, orthopedic surgery, vascular surgery, and plastic surgery. It is

critical that prior to undertaking an attempt at limb salvage that the patient be physiologically able to tolerate the multiple surgeries and blood loss associated with limb salvage. A patient's underlying medical comorbidities must be taken into consideration when planning treatment options. The multiply injured patient that is hemodynamically unstable with ongoing hemorrhage or coagulopathy may be better suited with an amputation rather than limb salvage, whereas a stable patient should be counseled regarding the benefits and disadvantages of limb salvage.

Many scoring systems exist to determine the viability of proceeding with limb salvage versus amputation. The most commonly used system is the Mangled Extremity Severity Score (MESS).[53,54] The MESS is based on age, presence of shock, mechanism of injury, and limb ischemia (Table 30.3). Amputation is recommended with a score of 7 or higher. The Lower Extremity Assessment Project (LEAP) study was unable to validate the clinical utility of the MESS and did not find a correlation between the MESS score and functional outcome at 6 or 24 months.[55] The availability of subspecialty resources and surgeon experience at different treatment centers are not factored into scoring systems and can account for substantial outcome variability. Scoring systems are unable to predict outcomes and should not be the determining factor when considering limb salvage versus amputation.

Further recommendations for amputation over limb salvage have included ischemia time and neurologic injury. Amputation has been recommended in the setting of a mangled lower extremity with an ischemia time of over 6 hours or an unreconstructable vascular injury. An insensate foot resulting from a tibial nerve transection has historically been an absolute indication for amputation; however, there was no significant difference in outcomes in the LEAP study based on the presence of plantar sensation.[56]

The Lower Extremity Assessment Project (LEAP) study prospectively compared the outcomes of patients who underwent limb salvage versus amputation at eight level 1 trauma centers in the United States.[57] The primary outcome was based on the sickness impact profile (SIP), a multidimensional measure of self-reported health status. Amputation versus limb salvage and injury severity were not significant prognostic factors. Prognostic factors were rehospitalization for major complication, a low educational level (noncompletion of high school), poverty, nonwhite race, lack of private health insurance, poor social-support network, low self-efficacy, smoking history, or pending injury litigation.[58,59] At 7 years, both groups demonstrated severe disability in 40% of patients and just over 50% of patients had returned to work.[59] Patients that underwent limb salvage were significantly more likely to be rehospitalized than those who underwent amputation; however, projected lifetime health care costs were found to be three times higher in the amputation group secondary to prosthetic costs than those who underwent limb salvage.[60]

TABLE 30.3

MANGLED EXTREMITY SEVERITY SCORE

■ AGE (Y)	■ POINTS
<30	0
30–50	1
>50	2
■ SHOCK	■ POINTS

TRAUMA

CHAPTER 31 ■ EXTREMITY VASCULAR INJURIES

DAVID V. FELICIANO

HISTORY

Vascular injuries in the extremities have been reported since antiquity. Aulus Cornelius Celsus (25 BC-50 AD) first described that hemorrhage from such injuries could be treated by placing "ligatures… above and below the wounded part."[1] For the next 18 centuries, control of hemorrhage dominated all medical writings on extremity vascular injuries. Repair of an injured brachial artery was first performed in 1759 and reported by Hallowell in 1762.[2] The first repair of an injured artery in an extremity (the common femoral artery) in the United States was reported by John B. Murphy in Chicago in 1897.[3] Essentially all the modern suture techniques of vascular repair in the extremities were described by Charles C. Guthrie and Alexis Carrel during and after their collaboration in the Hull Physiological Laboratory at the University of Chicago from 1905 to 1906.[4,5]

Surgeons in military conflicts who made considerable contributions to the repair of vessels in the extremities over the past century have included the following: Sir George Henry Makins (1853–1933) in World War I; Michael E. DeBakey (1908–2008), Daniel C. Elkin (1883–1958), and Harris B. Shumacker, Jr. (1908–2009) in World War II; Frank C. Spencer (1925-) and Carl W. Hughes (1914-) in the Korean War; and Norman M. Rich (1934-) during the Vietnam War.[6] Recognizing that other forms of therapy are now used on occasion to treat vascular injuries in the extremities, the early laboratory description of stents/stent grafts was by the late Charles T. Dotter in 1969.[7]

EPIDEMIOLOGY

When considering all injuries admitted to military or civilian hospitals prior to the current conflicts in Iraq and Afghanistan, vascular injuries are uncommon. Frykberg and Schinco[8] noted that the incidence of vascular injuries in four military reports (1913; 1946; 1952; 1978) ranged from 0.4% to 2%, while two civilian reports (1991; 1992) had incidences ranging from 0.8% to 3.7%. Of interest, the distribution of vascular injuries varies widely in the United States. The incidence of vascular injuries in the extremities as a percentage of all vascular injuries has ranged from 38% to 50% in centers dealing with a significant number of gunshot wounds to >75% in centers dealing primarily with blunt trauma.[9]

TYPES OF INJURIES/ PATHOPHYSIOLOGY

There are seven recognized types of vascular injuries: (1) intimal injuries (flaps, defects, or subintimal hematomas); (2) partial wall defects (intima and media) presenting as traumatic "true" aneurysms; (3) complete wall defects presenting as traumatic "false" aneurysms or hemorrhage; (5) complete transections; (6) arteriovenous fistulas; and (7) spasm. Intimal injuries and partial wall defects continue to be most commonly associated with blunt trauma (i.e., blunt posterior dislocation of the knee joint with secondary thrombosis of the popliteal artery). In contrast, complete wall defects, near-complete or complete transections, and arteriovenous fistulas are most commonly associated with penetrating wounds. Arterial spasm can occur after either blunt or penetrating trauma to an extremity and is frequently noted distal to a proximal arterial injury that is occlusive.

PROGNOSTIC FACTORS

The age of the patient is a major factor in the success of peripheral arterial repair. With most peripheral arterial injuries occurring in patients under the age of 35 years, repairs are straightforward as vessels are soft, mobile, and without appreciable atherosclerosis. These characteristics allow for easy debridement and primary repair or end-to-anastomosis without the insertion of substitute vascular conduits in many patients. On the other hand, young patients do not have as many collateral vessels as might be seen in an older patient with slow atherosclerotic occlusion of the superficial femoral artery at Hunter's canal. For this reason, the superficial femoral artery, popliteal artery, and tibioperoneal trunk should be regarded as "end" arteries in which acute occlusion is a threat to the viability of the ipsilateral leg or foot.

Shock secondary to the injury to the extremity or to other injuries has many adverse effects on a subsequent arterial or venous repair. The "viscerocutaneous vasoconstriction" that is associated with hypovolemic shock decreases whatever arterial inflow that remains through an injured artery or any regional collaterals and increases distal ischemia. With decreased distal flow, in situ thrombosis of capillaries, arterioles, or even named arteries may occur in the lower leg. Finally, ischemia followed by restoration of arterial inflow is the classical sequence of the "ischemia-reperfusion" syndrome.[10] This syndrome increases edema of ischemic tissues distal to an arterial injury and may cause a compartment syndrome in the leg or forearm after arterial repair.[11]

The magnitude of a peripheral arterial or venous injury obviously impacts the success of a repair. When segmental resection of an injured vessel and insertion of an interposition graft, particularly a small Teflon one, are necessary, long-term patency is decreased.[12]

The impact of delay of an arterial repair on the success of salvaging an injured extremity is well known. The original description of the "6-hour window" to complete a major arterial repair in an injured extremity in dogs was described in 1949.[13] Of interest, the 6-hour window continues to be valid in humans with major arterial injuries in extremities based on the time of onset of neural necrosis and myonecrosis when "cold ischemia" (no collateral flow) is present.[14]

The presence of an associated venous injury has a major impact on outcome. The need to simultaneously clamp an injured major artery and vein in a lower extremity increases the likelihood that a postrepair distal compartment syndrome will occur.[11] In addition, ligation of a major vein in the lower extremity, such as the common femoral vein, had a significant adverse effect on femoral arterial inflow in one laboratory study.[15] Finally, the presence of multiple associated injuries to soft tissue, tendons, bones, and nerves in an extremity—the so-called "mangled extremity"—will result in amputation rates of 28%-78% when the major artery is occluded or transected.[16]

DIAGNOSIS

Physical Examination

A patient with "hard" signs of a peripheral arterial injury (external hemorrhage, pulsatile hematoma, decrease in or loss of pulse and distal ischemic signs or palpable thrill/audible bruit) should be moved to the operating room immediately with several exceptions.[17] It is appropriate to realign any displaced fracture with traction or a splint or to reduce any dislocated joint in the pulseless extremity to see if distal pulses return. In patients who are pulseless at the ankle or wrist and there is a shotgun wound to the extremity with wide dispersal of pellets or blunt trauma with fractures at several levels, some type of imaging study will be useful in localizing the site of injury. The final exception would include a patient with multiple injuries in whom there is a need to rule out life-threatening injuries to the brain, thorax, or abdomen using CT before moving the patient to the operating room.

Most patients present with "soft" signs of an arterial injury (history of arterial bleeding, proximity of extremity injury to a named artery, nonpulsatile hematoma, or injury to adjacent nerve).[18] These patients still have an arterial pulse at the ankle or wrist on physical examination or with use of the Doppler device. Depending on which soft sign or combination of soft signs is present, the incidence of arterial injuries in such patients ranges from 3% to 25%.[19–21] Most but not all, of these arterial injuries can be managed without surgery because they are small and, by definition, allow for continuing distal perfusion. In some centers, serial physical examinations alone are used to monitor distal pulses, and no CT—arteriogram or conventional arteriogram—is performed to document the magnitude of a possible arterial injury. This approach has been safe and accurate in asymptomatic patients with penetrating wounds to an extremity in proximity to a major artery.[20,22] Its accuracy is similar in higher kinetic energy injuries associated with blunt fractures or dislocations, particularly dislocations of the knee.[23] Observation is appropriate only with complete and continuing out-of-hospital follow-up.[19,20] When there is concern about a distal pulse deficit, inability to properly examine for distal arterial pulses, or a combination of soft signs of an arterial injury in an extremity, CT, conventional, or surgeon-performed arteriography or a duplex ultrasound should be performed.

Based on the discussion above, it is obvious that a comprehensive physical examination of the injured extremity is the prime diagnostic maneuver in patients with possible peripheral vascular injuries. Relying on physical examination, particularly in patients with "soft" signs of an arterial injury in an extremity, has decreased considerably the number of imaging studies performed in the past 20 years.

Arterial Pressure Index

An adjunct to the physical examination is the measurement of the arterial pressure index (API). The API is defined as the Doppler systolic pressure in the injured extremity divided by that in an uninjured extremity.[24–26] In a study by Lynch and Johansen[25] in which clinical outcome was the standard, an API lower than 0.90 had a sensitivity of 95%, specificity of 97.5%, and accuracy of 97% in predicting an arterial injury. An alternative when both lower extremities are injured is to use the ankle brachial index, which uses brachial artery pressure as the denominator.

When the patient has an API < 0.9, the current standard of care is to perform an imaging study on the injured extremity.[18,24–26]

Imaging Studies

Multidetector computed tomography arteriography (MDCTA) is rapidly replacing conventional radiology suite arteriography or surgeon-performed arteriography in the emergency center or operating room.[27,28] It can be performed rapidly with a reasonable amount of contrast and accuracy approaching conventional arteriography. When MDCTA is not available or the result is equivocal and the patient is hemodynamically stable, percutaneous intraarterial digital subtraction arteriography performed in a radiology suite by the interventional radiologist is the most commonly used invasive diagnostic technique. Of interest, this technique can now be performed in the trauma room with a mobile device.[29] Multiple sequential views of areas of suspected arterial injury can be obtained at differing intervals after injection of limited amounts of dye. The accuracy of this multiple-view technique has been demonstrated in many studies, although false-negative results have occurred. The disadvantages of the technique are the delays in diagnosis when on-call technicians must return to the hospital, the cost of modern equipment, and the distortion of images when metallic fragments are present (e.g., shotgun wound).[16]

When the patient is hemodynamically unstable or has multiple injuries, a rapid one- or two-shot surgeon-performed percutaneous arteriogram can be performed in the emergency center or operating room.[30,31] A thin-walled 18-gauge Cournand-style disposable needle is inserted either proximal to the area of suspected injury (e.g., in the common femoral artery for evaluation of the superficial femoral artery) or distal to it (e.g., in retrograde evaluation of axillary or subclavian arteries above a blood pressure cuff inflated to 300 mm Hg). Rapid hand injection of 35 mL of 60% diatrizoate meglumine dye is performed, and an anteroposterior radiographic view is taken or fluoroscopy is utilized. The timing for exposure of an x-ray film of the patient's extremity depends on which artery is to be evaluated. Proper evaluation of the tibial and peroneal arteries in the patient with a complex fracture of the tibia mandates that exposure not take place until 4–5 seconds after the injection of dye into the common femoral artery. The plane of the film is often changed before the second injection to examine the area in question more thoroughly. False-negative and false-positive results are rare when the technique is performed on a daily basis by experienced practitioners. If a patient has severe combined intracranial or truncal trauma and possible peripheral arterial lesions, life-threatening injuries should be treated first, followed by percutaneous intraoperative arteriography of the involved extremity.[16]

Duplex ultrasonography, a combination of real-time B-mode ultrasound imaging and pulsed Doppler flow detection, has been used extensively to evaluate patients with suspected peripheral vascular injuries. Accuracy has ranged from 96% to 100% in several studies.[32–34] The major disadvantage is the need for the study to be performed and interpreted by an experienced vascular surgeon or registered vascular technologist.

MANAGEMENT IN THE EMERGENCY CENTER

Hemorrhage resulting from a peripheral vascular injury is controlled by direct compression with a finger or compression dressing, compression at a "pressure point" or the application of a blood pressure cuff or tourniquet just proximal to the area of injury. Once hemorrhage is under temporary control in the patient with multisystem blunt trauma, a decision is made on which diagnostic imaging studies are necessary before transfer to the operating room.

TRAUMA

When a peripheral arterial occlusion is associated with a delay in treatment or distal "cold ischemia" (inadequate or no collateral flow), the administration of intravenous heparin (100 U/kg) in the emergency center is appropriate. Contraindications include near-exsanguination from other injuries (coagulopathy may occur), a traumatic brain injury, a traumatic false aneurysm of the descending thoracic aorta or any other truncal artery, or CT documentation of an injury to a solid organ in the abdomen. Hemodynamically stable patients with isolated injuries to the extremities and "soft" signs undergo diagnostic evaluation and/or observation as described previously.

NONOPERATIVE MANAGEMENT/ STENTS/EMBOLIZATION

Nonoperative Management

Nonocclusive arterial injuries including intimal defects or flaps, subintimal or intramural hematomas, spasm, and small pseudoaneurysms that are nonobstructing are present on imaging in some patients with "soft" signs on presentation. On follow-up arteriograms, 87%-95% of these lesions have healed without any surgical or radiologic intervention.[35,36] Early arteriographic follow-up is necessary in patients who develop new symptoms while being observed. Careful follow-up of the injured patient and the extremity in an outpatient setting for a period of 2 months is mandatory.

Endovascular Stents

Currently, there is limited experience with the use of stents or stent grafts to treat peripheral arterial injuries.[37,38] This is a reflection of the excellent results obtained with operative management of these injuries for the past 60 years.[8,12,16] Therefore, the use of endovascular stents or stent grafts for peripheral vascular injuries should be limited to institutions in which there are approved protocols with plans for long-term follow-up of patients.[18]

Therapeutic Embolization by Interventional Radiology

Extravasation, a pseudoaneurysm, and arteriovenous fistula in the profunda femoris artery, one of the arteries in the leg or one of the branches of a major peripheral artery can be managed by embolization by an interventional radiologist. The ideal patient for such an intervention would be one with multisystem injuries, closed fractures, or late diagnosis of a traumatic aneurysm following orthopedic reconstruction.[36]

OPERATIVE MANAGEMENT

Preparation/Draping

Extensive preparation and draping of the skin is necessary. For a vascular repair in the upper extremity, this includes the chin to umbilicus and contralateral nipple to ipsilateral fingernails as well as one entire lower extremity to the toenails. In the lower extremity, preparation and draping would be from nipples to bilateral toenails. The hand or foot is then placed in a sterile plastic bag to allow for easy palpation of pulses after the arterial repair has been performed. Another option is to cover the entire extremity with an orthopaedic stockinette.

Preliminary or Concurrent Fasciotomy

Some patients have symptoms and signs of a compartment syndrome in the upper or lower extremity related to the peripheral vascular injury when first evaluated in the emergency center. For example, a patient with occlusion of the popliteal artery or a large hematoma in the anterior compartment of the leg might present with the following: (1) hypesthesia in the dorsal first web space; (2) weakness of toe extension and foot dorsiflexion; and (3) pain on passive toe flexion and foot plantar flexion.[11] A measurement of compartment pressure is appropriate when symptoms and signs are suggestive, but unclear, or when there does not appear to be excessive swelling of the compartment. If there is physical evidence or a compartment pressure documenting the presence of a compartment syndrome distal to an arterial injury, a preliminary or concurrent (with the arterial repair) fasciotomy is indicated.[39]

Incisions

A longitudinal incision is made over the area of the peripheral vascular injury. Examples would include the medial arm incision in the biceps–triceps groove to expose the brachial artery or the anteromedial thigh incision to expose the superficial femoral artery beyond its origin in the groin. When the area of injury is in proximity to a joint, a gently curved incision is made to prevent a postoperative scar contracture. Examples would include the following: (1) axillobrachial "S" over an injury to the distal axillary/proximal brachial vessels (Fig. 31.1); (2) medial-to-lateral "S" over the antecubital area of the upper extremity to expose the distal brachial artery and its bifurcation; and (3) obtuse incision over the medial knee joint to expose the entire popliteal artery.

Proximal and Distal Vascular Control

Once the skin incision is made, it is deepened proximally and distally around the area of the presumed vascular injury to allow for vascular control. In other words, the part of the incision over the area of the presumed vascular injury is only deepened when proximal and distal vascular control has been

FIGURE 31.1. Standard incision for exposure of entire axillary and brachial arteries. (Reprinted from Feliciano DV. Peripheral vasculature. In: Britt LD, Trunkey DD, Feliciano DV, eds. *Acute Care Surgery. Principles and Practice*. New York: Springer;2007:661, with permission from Springer.)

attained with the use of small DeBakey vascular clamps, bull-dog clamps, or vessel loops.

When hemorrhage cannot be controlled or a large hematoma is present, it is appropriate to enter the area of injury and rapidly apply vascular clamps directly around the perforation in the peripheral artery and/or vein. Adequate suction devices and appropriate retractors are mandatory to limit blood loss during this approach, but it allows for quicker vascular control in experienced hands.

Temporary Intraluminal Vascular Shunts

Once proximal and distal vascular control has been attained, there are two clinical scenarios in which insertion of a temporary intraluminal vascular shunt rather than repair or ligation is appropriate. The first is near-exsanguination with secondary hypothermia, a metabolic acidosis, or a coagulopathy likely to occur during resuscitation and operation. Rather than follow the classical dictum of "life over limb" and perform a ligation of an injured major artery of vein that may lead to an ultimate amputation, a shunt is inserted into the injured vessel. Once damage control resuscitation in the intensive care unit has reversed the "metabolic failure" of near-exsanguination, the patient is returned to the operating room for removal of the shunt and vascular repair.[40,41]

The second scenario is when a "mangled extremity" has resulted from a high kinetic injury impact (i.e., car bumper, motorcycle crash, penetrating wound from a military rifle) (Fig. 31.2). As previously noted, the combination of injuries to artery, bone, soft tissue, muscles/tendons, and peripheral nerves has resulted in ultimate amputation rates of 42%-78% in older series.[42,43] There are, however, patients without all the components of injury listed who will be candidates for limb salvage instead of amputation. These patients have an intact posterior tibial nerve in the lower extremity or a crush injury with a limited warm ischemia time (i.e., <6 hours) in the upper or lower extremity. If limb salvage is to be considered or if the patient and family object to an immediate amputation, a shunt is inserted into the injured vessel.

The technique for insertion of a temporary intraluminal shunt is quite simple. For peripheral arterial injuries, a No. 14-Fr. or smaller rigid carotid artery-type shunt is cut to a

FIGURE 31.2. A 14-F "carotid artery" shunt in the popliteal artery and a 24-F thoracostomy tube shunt in the popliteal vein in a railroad worker with a crush injury to the distal thigh. Principles and Practice.* New York, NY: Springer; 2007:670, with permission from Springer.)

length approximating the distance between the two ends of the debrided vessel plus another 3–4 cm. A 2-0 silk tie is placed around the middle of the shunt as a marker, a hemostat is applied to the same location, and the shunt is inserted into the proximal arterial stump for 1.5–2.0 cm. Another 2-0 silk tie is placed around the end of the artery containing the short segment of shunt and tied tight to compress the artery down onto the shunt. Proximal arterial control is released, the hemostat around the middle of the shunt is removed, and flow through the shunt is verified. The hemostat is placed on the middle of the shunt again, and the distal end of the shunt is directed into the distal end of the artery for 1.5–2.0 cm. Another 2-0 silk tie is placed to compress the distal artery around the distal end of the shunt, and the hemostat on the shunt is removed. Arterial pulsations in the distal extremity are then verified by physical examination or use of a Doppler-device. When a large peripheral vein is to be shunted rather than ligated, thoracostomy tubes in the No. 16–24 Fr. size range are used rather than the smaller arterial shunts described above.

The largest possible shunt that can be inserted in either a peripheral artery or vein is chosen. With use of a large shunt, postoperative anticoagulation is neither necessary nor appropriate in patients with multiple injuries or with substantial defects in soft tissues as might be seen with a mangled extremity. Thrombosis of an arterial shunt occurs when too small or too long a shunt is inserted, when a major adjacent vein is ligated rather than shunted, or when a delay in treatment has allowed for distal in situ thrombosis of multiple small arteries or veins in the leg or forearm. Thrombosis of an arterial shunt is an ominous predictor in that many such patients will eventually require amputation. This is particularly true when there is a delay in recognition of the thrombosis in the intensive care unit.

The longest dwell time for an arterial intraluminal shunt in a recent large civilian series was 52 hours,[41] but there is one report of a patient with a 10-day dwell time in the right axillary artery without anticoagulation.[44] Once the patient is stable or a decision has been reached that limb salvage is appropriate, the patient is returned to the operating room for removal of the shunt. The prior segmental resection of the injured vessel and the placement of crushing 2-0 silk ties on the remaining ends to hold the shunt in place mandate that an interposition graft will be inserted into the injured vessel. Therefore, an appropriate length of saphenous vein from the thigh or ankle of an uninjured lower extremity is removed in the usual fashion prior to removal of the arterial shunt. Should there be a large soft tissue defect over the arterial defect, a much longer segment of saphenous vein will have to be removed so that an extra-anatomic bypass (to be discussed) can be performed.[44,45] When a large peripheral vein such as the axillary, common femoral, or superficial femoral is to be repaired (to be discussed), no retrieval of the saphenous vein will be necessary unless the surgeon is committed to constructing a panel or spiral vein graft. In many centers, this type of complex reconstruction is avoided and a large ringed polytetrafluoroethylene (PTFE) graft is inserted.[12]

Arterial Repair—Upper Extremity

Injuries to the axillary, brachial, radial, or ulnar arteries account for approximately 45%-52% of peripheral arterial injuries treated in civilian trauma centers.[8,9] Because of its length and exposed position in the upper extremity, injuries to the brachial artery are 3–3.5 times more common than those to the axillary artery.

With suspected or documented injuries to the axillary artery, it is helpful to cover the entire upper extremity in an orthopedic stockinette and place it at the side of the patient if

an injury to the first or second portion is suspected. This will allow for more room for the operating team as well as relax the muscles around the shoulder girdle as dissection proceeds. With a suspected injury to the third portion of the axillary artery, the upper extremity is abducted at 90° and placed on an armboard.

The axillary artery starts at the lateral border of the first rib and becomes the brachial artery at the lateral border of the teres major muscle. The operative approach varies depending on whether the arterial injury is located in the first portion (lateral border of the first rib to medial border of the pectoralis minor muscle), second portion (behind the pectoralis minor muscle), or third portion (lateral border of the pectoralis minor muscle to lateral border of teres major muscle). Injuries to the first or second portions that are not actively hemorrhaging are most commonly approached through an infraclavicular incision centered on the midclavicle.[46] After splitting the upper fibers of the pectoralis major muscle in a transverse fashion, the clavipectoral fascia is divided. Proximal arterial control is obtained by retracting the anteriorly positioned axillary vein in an inferior fashion and placing a vessel loop around the axillary artery just inferior to the clavicle. Distal control is obtained, as needed, by extending the infraclavicular incision into an incision in the deltopectoral groove. Should active hemorrhage from the second portion of the artery occur during dissection or the tamponaded injury is in the second portion, lateral retraction of the tendon of the pectoralis minor tendon is necessary. Persistent inadequate exposure of this arterial location mandates division of the tendon of the pectoralis minor muscle near the coracoid process to preserve the medial pectoral nerve. An injury in the third portion can be approached through the aforementioned incision in the deltopectoral groove. An alternate, but uncommonly utilized, approach involves a lateral pectoral incision along the edge of the pectoralis major muscle.

Injuries to the axillary artery, particularly those that are bleeding actively, are challenging because of the adjacent cords of the brachial plexus. The blind application of angled vascular clamps often entraps portions of the cords, leading to a partial brachial plexopathy for 12–24 months. Therefore, elevation of the injured artery proximally and distally with vessel loops is mandatory before vascular clamps are applied. The second problem in dealing with injuries at this location is the somewhat fragile nature of the axillary artery. This artery is rarely involved with substantial atherosclerosis and is extraordinarily soft with a consistency that sometimes approaches that of the subclavian artery. Lateral repairs performed with suture bites that are too thin or end-to-end repairs performed under tension will lead to sutures tearing through when vascular clamps are released.

The brachial artery starts at the lateral border of the teres major muscle, courses through the medial arm, and bifurcates at the radial tuberosity of the forearm. The operative approach in the arm has been described previously. When an injury occurs near the elbow, the standard S-shaped incision extending from the medial biceps–triceps groove is used. This incision crosses the antecubital fossa and then turns longitudinally beyond the midaspect of the volar side of the forearm. The fascia overlying the neurovascular bundle medially and the bicipital aponeurosis beneath the antecubital fossa are divided to allow for complete exposure of the brachial artery proximal to its bifurcation.

There is a logical sequence for performing a complex repair (end-to-end anastomosis or insertion of a graft) of the axillary or brachial artery after proximal and distal arterial control has been obtained with vessel loops (Fig. 31.3). When an end-to-end anastomosis is to be performed, a posterior knot is usually placed at 6 o'clock. If exposure is limited, as in an end-to-end anastomosis performed near the clavicle, it is helpful to

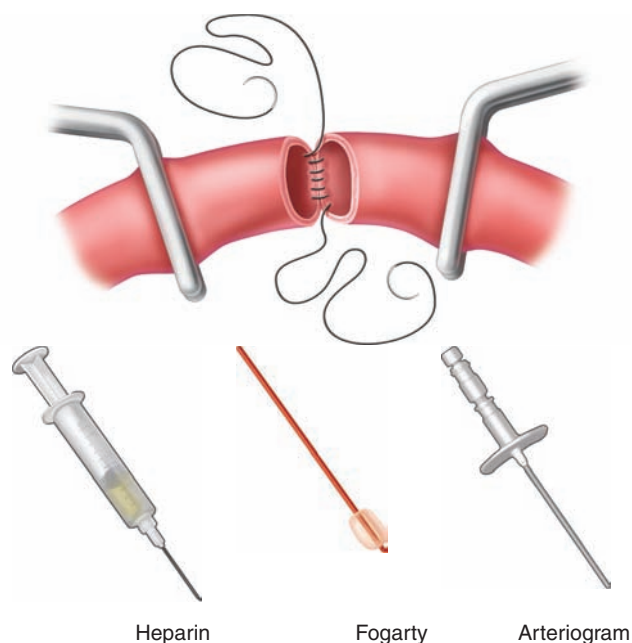
Heparin   Fogarty   Arteriogram


FIGURE 31.3. Fine points in peripheral arterial repair include use of small vascular clamps or Silastic vessel loops, open anastomosis technique, regional heparinization, passage of a Fogarty catheter proximally and distally, and arteriography on completion.

perform the first one-third of the posterior anastomosis in an open fashion (no posterior knot) in both directions to allow for complete visualization of all suture bites.[47] After this portion of the anastomosis is complete, the ends of the artery are pushed together as both sutures are pulled tight. Because both ends of the artery are now stabilized, a No. 5 or 6 Fogarty embolectomy catheter is passed proximally and distally to remove any thrombotic or embolic material. Approximately 10–15 mL of heparinized saline solution (50 U/mL of solution) is then injected into each end of the artery, and the vascular clamps are reapplied. The remaining two-thirds of the anastomosis is completed by running one end of the continuous suture along one side and the other end along the other side. The last few loops of suture, however, are left loose to allow for flushing before the anterior knot is tied. The proximal vascular clamp is removed for flushing and then reapplied. The distal vascular clamp is removed to allow for flushing as well. As air is evacuated by the distal flushing, the two suture ends are pulled up tight and tied. Once the first knot has been tied, the proximal arterial clamp is released. Bleeding from suture holes is controlled by the application of oxidized regenerated cellulose (Surgicel, Johnson & Johnson Medical, Inc., Arlington, TX) or Avitene (Med Chem Products, Inc., Woburn, MA). Because distal in situ thrombosis is very unusual during proximal arterial repairs in the upper extremity, the return of palpable pulses at the ipsilateral wrist obviates the need for a completion arteriogram. When distal pulsations are diminished or absent after removal of the vascular clamps, a completion arteriogram is mandatory.

When an interposition graft will be necessary to restore arterial continuity in the upper extremity, a reversed autogenous saphenous vein graft from the thigh of an uninjured lower extremity is the first choice. In the 15%-20% of young male patients with saphenous veins that are too small for replacement of a major vessel such as the axillary artery, a ringed PTFE synthetic graft is an acceptable alternative. The operative technique for each anastomosis may be as described above, or a more traditional approach may be used. The triangulation

approach described by Carrel[48] involves placing stay sutures at 120 degree intervals on the circumference of the graft and on the recipient vessel. After these are tied and the ends of the graft and recipient vessel are in apposition, each 120 degree segment of the anastomosis may be readily approximated by a continuous suture technique. A related approach that is pertinent to the use of a rigid PTFE interposition graft is to place only two stay sutures 180 degree apart to appose the ends of the graft and recipient vessel. When an interposition graft has been inserted, the terminal flushing maneuvers and evacuation of air are performed as described previously as the second anastomosis is completed.

When an interposition graft has been inserted to complete an arterial repair in the upper extremity, it is the practice of the author to place all adult patients on an intravenous drip of 10% dextran 40 in 5% dextrose (10% Gentran 40, Baxter Healthcare Corp., Deerfield, IL) at a dose of 40 mL per hour × 3 days. This agent can prevent or reverse cellular aggregation and will prolong the bleeding time. In addition, adult patients are started on 81-mg aspirin tablets twice a day by rectal suppository or orally starting in the recovery room and maintained on this medication for the next 3 months.[49]

Venous Repair—Upper Extremity

Injuries to veins in the upper extremities are infrequently discussed. Diagnostic tests such as venograms are not employed to document the presence of a peripheral venous injury as the consequences of missing such an injury are so modest; that is, pressure dressings usually control venous hemorrhage from small injuries, and late venous pseudoaneurysms are extraordinarily rare. The only indications for operation are venous bleeding not controlled by a pressure dressing or the suspected or known presence of an associated arterial injury.

The incisions previously described for arterial injuries in the upper extremities are the same ones used for possible venous injuries. Proximal and distal control around a major venous injury, however, can be awkward because of multiple venous branches. As the venous system is characterized by low pressure, the use of small, medium, and large metal clips for ligation followed by division of venous branches is appropriate as exposure and control are obtained. Proximal and distal control around an area of injury can usually be maintained with use of vessel loops under tension rather than with angled vascular clamps.

Because of the presence of valves in the venous system, injection of heparinized saline toward the hand after distal venous control has been obtained is not performed. For the same reason, passage of a Fogarty balloon catheter toward the hand or toward the heart is inappropriate.

Essentially, all major injuries to the brachial or axillary venae comitantes or veins can be ligated as there are extensive venous collaterals throughout the upper extremity. On rare occasions in stable patients with an isolated major injury to the axillary vein, resection and an end-to-end anastomosis or insertion of a saphenous vein interposition graft has been performed. Lateral venorrhaphies for lesser injuries are performed with interrupted or continuous sutures of 7-0 polypropylene. With a meticulous suture technique, peripheral venous repairs (most studied in the lower extremities) have been documented to have short-term patencies exceeding 75% in several reports.[50,51]

Arterial Repair—Lower Extremity

Injuries to the femoral, popliteal, or shank arteries account for approximately 48%-55% of peripheral arterial injuries treated in civilian trauma centers. Because of its length and exposed position in the lower extremity, injuries to the common or superficial femoral artery are 2–2.5 times more common than those to the popliteal and shank arteries.

Injuries to the common femoral, proximal superficial femoral, or profunda femoris arteries are approached through the previously described longitudinal groin incision inferior to the inguinal ligament. An injury right at the inguinal ligament or the presence of a large pulsatile hematoma overlying the groin and inguinal ligament will mandate obtaining more proximal arterial control. An ipsilateral oblique incision is made in the lower quadrant 3 cm above the inguinal ligament. Successive muscle and aponeurotic layers including the transversus abdominis muscle and transversalis fascia laterally are divided. The peritoneum is pushed medially using spongesticks to enter the retroperitoneal space and expose the psoas muscle. After the ureter is elevated with the peritoneum, the external iliac artery is encircled with a vessel loop and clamped for proximal arterial control.

Once proximal and distal control has been obtained around arterial injuries in the groin, certain principles should be kept in mind. One is that the profunda femoris artery should not be sacrificed for reasons of exposure. Even if an end-to-end anastomosis or insertion of an interposition graft into the common femoral artery has been necessary, it is not difficult to reimplant the end of the profunda femoris artery into this reconstructed segment. This involves rotating the vascular clamps on the common femoral artery 90 degrees toward the midline. A small posterolateral arteriotomy in the common femoral artery or graft replacement will then allow for an end-to-side anastomosis to the profunda femoris artery using 6-0 polypropylene suture. Injuries to arteries below the groin are approached through longitudinal incisions as well. The superficial femoral artery in the proximal three-fourths of the thigh lies posterior to the inferior edge of the sartorius muscle. With anterior mobilization of this muscle and division of the surrounding sheath, the superficial femoral artery (and vein) is easily exposed. In the distal one-fourth of the thigh, exposure of the proximal popliteal artery involves mobilizing the sartorius muscle posteriorly and the vastus medialis muscle anteriorly. Occasionally, the adductor magnus tendon comprising the edge of the adductor hiatus may have to be divided, as well.[52] The entire popliteal artery system is exposed by extending the medial distal thigh incision into an incision 1 cm posterior to the edge of the tibia. The tendons of the sartorius, gracilis, and semitendinosus muscles will often require division 1–2 cm away from their insertions on the tibia for complete exposure. Each tendon should be divided between two colored sutures, with different colors used for each of the three tendons. This will allow for accurate reapproximation of the tendons following the arterial repair.

Exposure of the infrageniculate popliteal artery, proximal anterior tibial artery, tibioperoneal trunk, or proximal posterior tibial and peroneal arteries is obtained through a proximal medial incision in the leg. An 8-cm longitudinal incision beginning at the posterior edge of the condyle of the tibia is made in the medial infrapopliteal area, approximately 1 cm below the posterior edge of the tibia. It is imperative to avoid injury to the greater saphenous vein, which usually lies posterior to the incision described. After the fascia is incised posterior to the edge of the tibia and inferior to the overlying tendons of the sartorius, gracilis, and semitendinosus muscles, the medial head of the gastrocnemius muscle is retracted posteriorly. To obtain appropriate exposure in large patients, the electrocautery may be used to separate the medial attachments of the soleus muscle to the tibia as well. The deep dissection is somewhat tedious, especially if there is associated atherosclerosis at this location. Proper exposure of all vessels will usually involve careful ligation and division of the anterior tibial vein and separation of the posterior tibial and peroneal arteries from their associated veins.

TRAUMA

One area in which the repair of arteries in the lower extremity differs from that in the upper extremity is in the management of extensive distal injuries. Although loss or ligation of the radial or ulnar artery will rarely result in loss of the hand, the loss of two shank arteries from an extensive blunt injury will often lead to a below- or above-knee amputation. Certain patients with these injuries have true mangled extremities and will be served best by an immediate amputation. Others will have disruption or thrombosis of the tibioperoneal trunk or of the anterior tibial artery and one of the branches of the tibioperoneal trunk. The combination of a crushing or shearing injury and loss of two main arteries will often leave one or more muscle compartments of the leg and/or the foot ischemic. In such patients, innovative bypasses originating in the distal popliteal artery and crossing over a fracture site may be necessary to restore adequate arterial flow to the leg and foot.

Venous Repair—Lower Extremity

As with venous injuries in the upper extremities, the only indications for operation are venous bleeding not controlled by a pressure dressing or the suspected or known presence of an arterial injury.

Venous injuries in the lower extremities are approached through the usual longitudinal incisions and managed as previously described. The one unique aspect of management is the much stronger emphasis on repair rather than ligation. The popliteal vein and superficial femoral vein inferior to its junction with the profunda femoris vein are true end veins draining the leg. Ligation of either of these veins has some theoretical disadvantages. There is always the concern that a below-knee compartment syndrome will develop in the early postoperative period, that there will be an acute adverse impact on arterial inflow into the shank, and that chronic edema of the leg will occur.[53–57] Several civilian series have documented, however, that venous ligation in the popliteal and superficial femoral veins is surprisingly well tolerated in young trauma patients.[53,54,56,57] This is particularly true if absolute bed rest and elevation of the injured lower extremity for the first 5–7 days after ligation are mandatory.[55] There is no clear-cut increase in the need for postligation fasciotomy, amputations are rare, and edema of the leg often resolves over time.[53,54,56,57] This is in marked contrast to the 50% edema reported after ligation of the popliteal vein during the Vietnam War.[58]

Nonetheless, in the absence of near exsanguination and sequelae of shock such as severe hypothermia, profound metabolic acidosis, and an intraoperative coagulopathy, the superficial femoral and popliteal veins should be repaired. Options for repair include lateral venorrhaphy with 6-0 polypropylene suture, vein patch venoplasty using the greater saphenous vein from the contralateral ankle, or insertion of an autogenous saphenous vein graft, or externally supported PTFE graft.[12,50,53,54,56,57,59] Because of the time needed to make spiral and panel vein grafts and the mixed patency rates reported, these are rarely performed in American trauma centers.[59,60]

After any type of complex venous repair in the lower extremity, it is the practice of the author to wrap the entire lower extremity with an elastic bandage at modest tension to avoid causing a compartment syndrome. The lower extremity is elevated on three to four pillows for 5–7 days, and strict bed rest is mandatory as previously described. Dextran 40 is administered intravenously at 40 mL per hour × 3 days, and an 81-mg aspirin tablet is administered twice a day by rectal suppository or orally starting in the recovery room and continuing for 3 months. Finally, a duplex venous study is performed before discharge.

Extra-anatomic Bypass

In the acute care setting, the indications for use of an extra-anatomic bypass include the following: (1) loss of soft tissue over injured artery or vein (Fig. 31.4); (2) postoperative wound infection with blowout of underlying arterial repair; and (3) simultaneous infections in soft tissue and underlying native artery secondary to injection of illicit drugs.[44,45] Injured patients in whom this technique has been used include those with shotgun wounds or with high kinetic energy blunt trauma to extremities.

The operative technique involves obtaining proximal and distal vascular control of the injured artery (and/or vein) through the open wound. Intraluminal shunts are inserted to maintain arterial inflow and venous outflow. Contused, necrotic, or infected soft tissue is then debrided rapidly, followed by debridement of the exposed artery to the edges of the defect in soft tissue. Longitudinal incisions are made over the course of the proximal and distal ends of the artery, which are mobilized so that they are no longer in contact with the defect in soft tissue. Following completion of the proximal anastomosis to a saphenous vein graft, the bypass graft is tunneled subcutaneously and, on occasion, intramuscularly around the defect in soft tissue. As has been noted in the use of extra-anatomic bypasses in patients with atherosclerotic disease, unusual courses of such grafts do not impair patency if kinks or twists are avoided (Fig. 31.4). After confirmation of pulsatile flow through the distal end of the graft, the graft is anastomosed in an end-to-end or end-to-side fashion to the distal end of the mobilized artery. Completion arteriography is mandatory to confirm a gentle curve without kinks in the extra-anatomic bypass graft and the absence of distal arterial thrombi or emboli. Because of the large size of the proximal veins of the extremities, it is appropriate to use an externally supported extra-anatomic PTFE graft for venous replacement. The incisions over the proximal and distal anastomoses to the graft then are closed, thereby placing the graft in a protected extra-anatomic subcutaneous tunnel.

In the postoperative period, packing of the defect in soft tissue can be performed as many times a day as the surgeon desires. Vigorous physical therapy is appropriate during the period of packing to avoid the formation of contractures in adjacent joints. Early coverage of the defect in soft tissue with

FIGURE 31.4. Extra-anatomic saphenous vein graft posterior to knee joint in patient with close-range shotgun wound to medial thigh, femur, and popliteal artery and vein. (Reprinted from Feliciano DV, et al. Extraanatomic bypass for peripheral arterial injuries. *Am J Surg*. 1989;58:506–509, with permission from Elsevier.)

a split-thickness skin graft and continuing physical therapy after healing occurs should minimize loss of function in the involved extremity. A baby aspirin tablet (81 mg) is administered every 12 hours to any patient without a history of gastrointestinal hemorrhage or known ulcers for 3 months to aid in patency of the grafts and in decreasing neointimal hyperplasia at the distal arterial suture line. If signs of aspirin toxicity, such as ringing in the ears, occur, the dose is decreased to 81 mg once a day.

Management of Wound in Soft Tissue

In patients with major peripheral vascular injuries and a transfusion-associated coagulopathy, extensive oozing often occurs in soft tissue as the operation is completed. In such patients, placement of closed suction drains into the blast cavity or area of dissection may be required for several hours postoperatively. The placement of drains prevents formation of a postoperative hematoma that could compress and possibly occlude the vascular repairs.

If a large blast cavity is present in soft tissue near the vascular repairs, some muscle or soft tissue should be sutured in a position that separates the two. A closed or open drain or open packing of the cavity exiting on the opposite side of the extremity from the skin incision and vascular repairs should then be inserted. This allows for drainage of the large blast cavity away from the vascular repairs and helps to avoid the problems of compression by hematoma and of cellulitis and late abscesses near a vascular repair.

Occasionally, primary wound closure is undesirable in patients with extensive muscle hematomas, soft tissue edema, or a severe coagulopathy after a peripheral vascular repair. In such patients, porcine xenografts (pigskin) are placed over the vascular repairs and the wound is packed open with antibiotic-soaked gauze.[61,62] After 24 hours of elevation of the injured extremity, the patient is returned to the operating room for delayed primary closure, or closure with a muscle rotation flap, or myocutaneous flap performed by the plastic surgery service.

The Mangled Extremity

As previously noted, a mangled extremity results from high-energy transfer or crushing trauma that causes some combination of injuries to artery, bone, soft tissue, tendon, and nerve. Approximately, two-thirds of such injuries are caused by motorcycle, motor vehicle, or vehicle–pedestrian accidents, reflecting the substantial transfer of energy that occurs during such incidents. Chapman[63] has emphasized that the kinetic energy dissipated in collision with an automobile bumper at 20 mph (100,000 ft-lb) is 50 times greater than that from a high-velocity gunshot (2,000 ft-lb).

When a patient with a mangled extremity arrives in the emergency center, the trauma team must work its way through the following series of decisions in patient care:

1. If the patient's life is in danger, should the mangled limb be amputated?
2. If the patient is stable, should an attempt be made to salvage the mangled limb?
3. If salvage is to be attempted, what is the sequence of repairs? (see previous section.)
4. If salvage fails, when should amputation be performed?

The most difficult decision is whether to attempt salvage of the limb. Since 1985, at least five separate scoring systems that describe the magnitude of injuries in a mangled extremity have been published.[24,64–67] All attempts to predict the need

for amputation based on a total score were derived from the combination of injuries in the extremity and other factors. The applicability of any of these systems outside the institutions in which they originated has been questioned.[68,69]

Two major criteria are used most frequently in clinical decisions regarding immediate amputation versus attempted salvage. If either of the following factors is present, amputation is a better choice than prolonged attempts at salvage.

1. Loss of arterial inflow for longer than 6 hours, particularly in the presence of a crush injury that disrupts collateral vessels[13,70]
2. Disruption of the posterior tibial nerve[24,70,71]

Lange et al.[71] and Hansen[72] have described relative indications for immediate amputation in patients with Gustilo IIIC tibial fractures as well. These include serious associated polytrauma, severe ipsilateral foot trauma, anticipated protracted course to obtain soft tissue coverage, and tibial reconstruction. If two of these are present, immediate amputation is once again recommended.[71,72]

Compartment Syndromes and Fasciotomies

A compartment syndrome is defined as increased pressure within a closed fascial space that reduces capillary perfusion to a level less than that required for the viability of tissues.[73] Most compartment syndromes result from an increase in content of the compartment as caused by edema, hemorrhage, ischemic edema, reperfusion injury, or, on rare occasions, by chronic overexertion of muscles. Trauma and/or ischemia to the extremity remain the most common causes.

A history of a delay in presentation when ischemia in an extremity is present should make the attending physician suspicious that a compartment syndrome is present or is likely to develop. The patient will often complain of pain out of proportion to the extent of an injury. General findings on physical examination that increase the likelihood of a compartment syndrome occurring include systemic shock in combination with an ischemic extremity, evidence of a crush injury, and marked swelling of the extremity.[74,75] The presence of a tender or tight musculofascial compartment does not, however, precisely correlate with the presence of a compartment syndrome.

Rather, pain on passive stretch of muscles in the compartment is strongly suggestive. Other neurologic findings that often suggest the presence of an established compartment syndrome include hypesthesia in the sensory distribution of a nerve that courses through the compartment in question or weakness of the involved muscles. Finally, restoration of arterial inflow after more than a 4- to 6-hour delay, the need to clamp arterial inflow and venous outflow vessels at the time of vascular repair, and ligation of a major outflow vein are procedures at operation that make a compartment syndrome more likely to develop. Also, it is important to note that distal pulses in an extremity are often still palpable or audible by a Doppler device after a revascularization procedure even though a compartment syndrome is present.

One approach in vascular or trauma surgery services has been to perform a fasciotomy to relieve a suspected compartment syndrome whenever any of the historical, physical, or operative factors described earlier are present. An aggressive approach such as this will avoid missing a compartment syndrome, but will surely result in some unnecessary or "prophylactic" fasciotomies. Another approach is to measure the intracompartmental pressure (normal, 4–8 mm Hg) and only perform fasciotomy when a certain elevated pressure has been reached. A large number of techniques for measurement of intracompartmental pressure have been described including (1) needle injection, (2) wick catheter, (3) slit catheter, (4) arterial

transducer, and (5) the STIC device (Solid-State Transducer IntraCompartmental Monitor System, Stryker Surgical, Kalamazoo, MI).[11,76] Unfortunately, there is little consensus in the literature about the absolute intracompartmental pressure that mandates a fasciotomy to avoid permanent muscular or neural damage. A rising pressure of more than 30 mm Hg, a pressure more than 45 mm Hg or a <20 mm, or a 30 mm Hg difference between diastolic blood pressure and the intracompartmental pressure have all been suggested over the past 25 years.[11] In a somewhat ecumenical approach, the American College of Surgeons Committee on Trauma poster entitled "Management of Peripheral Vascular Trauma" (2002) suggests that fasciotomy be performed for pressures ">30–35 mm Hg."[77]

Fasciotomies to relieve compartment syndromes in the upper extremities account for only 20% of all fasciotomies performed after trauma and even less after nontrauma vascular occlusions. Therefore, many surgeons are not familiar with the operative techniques that are utilized.

The forearm is divided into three musculofascial compartments, including volar, dorsal, and the "mobile wad."[78] Other authors describe superficial flexor, deep flexor, and extensor compartments.[76] The volar compartment (flexion, pronation, supination) is opened first using the "volar ulnar approach." The incision begins on the lateral (radial side) of the forearm distal to the antecubital fossa, proceeds transversely across the forearm parallel to the arm–forearm fold, and then makes a right angle turn down the ulnar volar aspect of the forearm (Fig. 31.5). At this right angle turn, the "mobile wad" can be decompressed by opening the underlying fascia. At the wrist, the ulnar incision curves toward the radial side until it crosses the carpal tunnel along the thenar crease of the palm. The fascia overlying the flexor digitorum sublimis and flexor carpi ulnaris muscles is divided from the aponeurosis of the elbow down to the carpal tunnel at the wrist (decompression of superficial flexor compartment). These two muscles are separated with retractors, the ulnar nerve and artery are identified overlying the flexor digitorum profundus, and the fascia overlying this muscle and the flexor pollicis longus is divided as well (decompression of deep flexor compartment). After complete decompression of the volar compartment, it is worthwhile to remeasure the intracompartmental pressure in the dorsal (extensor) compartment. Should its pressure still be elevated, the dorsal compartment is approached through a skin incision in the pronated forearm from the lateral

epicondyle of the humerus to the midline of the wrist. The fasciotomy is performed in the interval between the extensor digitorum communis and extensor carpi radialis brevis muscles toward the radial side of the forearm. The role of the epimysiotomy of decompressed muscles is unclear, and a carpal tunnel release at the wrist is often added if the wrist and hand are swollen.

Any pale forearm muscle that still contracts with stimulation from the electrocautery device should be left in place at the first operation. The entire forearm is then covered with a bulky dressing and elevated by attaching a forearm stockinette to an intravenous pole. After 3–7 days of elevation in patients with obviously viable forearm muscles, the patient is returned to the operating room. Closure of the skin incision is best accomplished by undermining the subcutaneous tissues and placing multiple interrupted vertical mattress skin-only sutures of 2-0 nylon. When the tension is too great to complete the skin closure with sutures, a split-thickness skin graft harvested from the anterolateral thigh is applied.

Because the anterior compartment of the leg is prone to developing a compartment syndrome in high-risk patients, the pressure is always measured first in this compartment. If the pressures in this compartment and in the deep posterior compartment immediately posterior to the tibia are >30–35 mm Hg, a below-knee two-incision four-compartment fasciotomy is performed (Fig. 31.6). The leg is divided into four musculofascial compartments, including anterior, peroneal, superficial posterior, and deep posterior. The anterior and peroneal compartments are approached through a 25- to 30-cm longitudinal incision 2 cm anterior to the upper edge of the fibula. The subcutaneous tissue and skin of both flaps are mobilized using traction with rake retractors and manual pressure with a laparotomy pad over fingers. Perforating vessels are divided and ligated with 3-0 silk ties to eliminate postoperative oozing in coagulopathic patients. When the intermuscular septum is clearly visualized or palpated, separate longitudinal fasciotomies approximately 4–5 cm apart are made over the entire anterior and peroneal compartments. The superficial and deep posterior compartments are approached through a 25- to 30-cm longitudinal incision 2 cm posterior to the lower edge of the tibia. Care should be taken to avoid injury to the greater saphenous vein and nerve. The subcutaneous tissue and skin of both flaps are mobilized as above. The superficial posterior compartment is visualized by further traction on the posterior

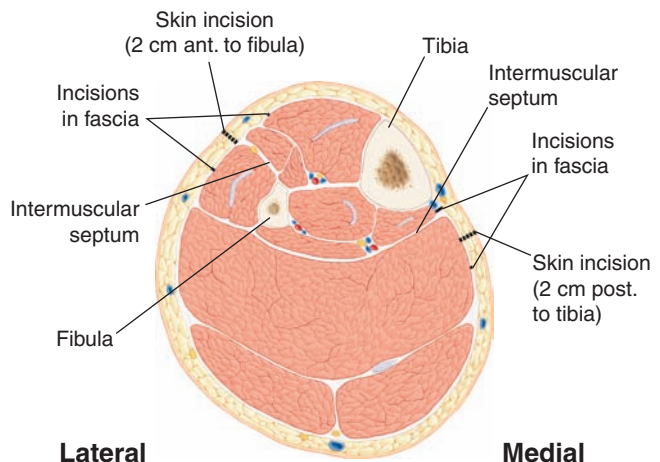
FIGURE 31.5. Proximal aspect of skin incision in volar-ulnar approach to decompress the volar and lateral ("mobile wad") compartments of the forearm. (Reprinted from Dente CJ, et al. Fasciotomy. *Curr Probl Surg.* 2009;46:769–840, with permission from Elsevier.)


FIGURE 31.6. Two-skin incision four-compartment fasciotomy for decompression of compartments of the leg.

skin flap and opened over its entire length with a longitudinal incision. The deep posterior compartment may often be visualized in the distal aspect of the calf through the standard skin incision. Complete decompression of this musculofascial compartment posterior to the tibia and medial to the fibula will, however, require detachment of the soleus muscle from the back of the tibia.[76]

A compartment syndrome of the thigh in uncommon, but it has occurred in patients with severe pelvic fractures, ligation of the common or external iliac vein or common femoral vein, or, on rare occasions, with severe fractures of the femur. This entity will be present in many patients with the secondary extremity compartment syndrome following resuscitation from near exsanguination as well.[74,75] A compartment pressure >30–35 mm Hg in either the anterior or posterior compartment is an indication to perform a thigh two-incision three-compartment fasciotomy. The thigh is divided into three musculofascial compartments, including the quadriceps (anterior), hamstrings (posterior), and adductors (medial). The quadriceps compartment is approached through a 30-cm longitudinal anterolateral incision along the iliotibial tract from the intertrochanteric space to the lateral epicondyle of the distal femur. A longitudinal fasciotomy is made, and the fascia can be lifted off the rectus femoris muscle anteriorly as well. Access to the hamstrings compartment is obtained by mobilizing the vastus lateralis muscle anteriorly. The thick intermuscular septum medial to this muscle is then opened with a longitudinal incision to decompress the hamstrings compartment. If pressure in the adductor compartment is still elevated after the other two compartments of the thigh have been opened, the adductor compartment is approached through a 30-cm medial and longitudinal skin incision posterior to the sartorius muscle. After minimal mobilization of the skin and subcutaneous flaps, a longitudinal fasciotomy incision is made over the adductor muscles.

POSTOPERATIVE CARE

After the patient has been returned to the ward or intensive care unit, the injured extremity should be elevated and wrapped with elastic bandages if venous ligation was performed. Care must be taken to monitor intracompartmental pressure in such a situation, since the combination of venous hypertension and external compression may create an early compartment syndrome. Distal arterial pulses are monitored by palpation or with a portable Doppler unit. Intravenous antibiotics are continued for 24 hours if a primary repair or end-to-end anastomosis was performed. If a substitute vascular conduit was inserted, intravenous antibiotics are continued for 72 hours in some centers, much as in elective vascular surgery.

COMPLICATIONS

Early Occlusion of Arterial Repair

In-hospital occlusion of an arterial repair is always related to delayed presentation of the patient after injury, delayed diagnosis of the injury by a physician, a technical mishap in the operating room, or occlusion of venous outflow from the area of injury. In a patient with a delay in presentation or diagnosis, in situ distal arterial thrombosis may occur within 6 hours.[13] The passage of a Fogarty embolectomy catheter may not be helpful in such a situation, because it does not remove thrombi from arterial collateral vessels.

Technical mishaps at operation that lead to postoperative thrombosis of a repair include too much tension on an end-to-end anastomosis, failure to remove any thrombi or emboli in the distal arterial tree with a Fogarty embolectomy catheter, narrowing of a circumferential suture line, and failure to flush the proximal and distal arteries before final closure of the repair. Also, ligation or occlusion of a repair in the popliteal vein can lead to occlusion of an arterial repair at the same level.

If distal pulses disappear, the patient is returned immediately to the operating room for thrombectomy or embolectomy and revision of the repair as necessary. If there is no obvious reason for occlusion of the arterial repair at a reoperation, standard coagulation tests are performed immediately to screen for a thrombotic disorder. Examples include heparin-associated thrombocytopenia, antithrombin III deficiency, deficiency of protein C or S, and the antiphospholipid syndrome.

Delay in Diagnosis of an Arterial Injury

Occasionally, a patient has a traumatic false aneurysm or an arteriovenous fistula from a previous arterial injury that was not diagnosed.[79] The insertion of an endovascular stent with or without trans-stent angiographic embolization is possible for many of these lesions, and it can be accomplished readily by an experienced vascular surgeon or interventional radiologist.[80] If a major artery is involved, operative intervention using the principles described previously may be necessary.

Soft Tissue Infection over an Arterial Repair

A dreaded complication of combined orthopedic-vascular injuries, particularly in the lower extremity, is infection in the soft tissue overlying the arterial repair. If debridement of the soft tissue infection results in exposure of the arterial repair, one option is to attempt coverage of the arterial repair with a porcine xenograft and hope for the gradual growth of granulation tissue over the healthy artery. If the arterial repair starts to leak or suffers a blowout, the patient is returned to the operating room. The exposed portion of the artery is resected, and the aforementioned extra-anatomic saphenous vein bypass graft is placed around the area of soft tissue infection, making sure that both end-to-end anastomoses are covered by healthy soft tissue outside the wound.

Another option after debridement is for immediate coverage with a local muscle or myocutaneous rotation flap or for coverage with a free flap performed by the plastic surgery service.

Late Occlusion of Arterial Repair

Because saphenous vein grafts placed in peripheral arteries undergo the degenerative changes of atherosclerosis over time, late occlusions of some of these grafts can be expected. Management is the same as if the patient had occlusion of a primary artery—arteriography is performed based on symptoms, and bypass grafting is chosen if runoff is adequate to support another graft.

TRAUMA

CHAPTER 32 ■ BURNS*

BASIL A. PRUITT Jr AND RICHARD L. GAMELLI

The organ system changes that occur following burn injury represent the stereotypic response to injury and make the burn patient the universal trauma model (Table 32.1). Those changes and the frequency of burn injury make burn patient management a challenge often presented to the trauma/acute care surgeon. The acute care surgery components of initial burn care include fluid resuscitation, and ventilatory support, as well as preservation and restoration of function of other organs and tissues. Following resuscitation, burn patient management is focused on wound care and provision of the necessary metabolic support. The involvement of the trauma/acute care surgeon in burn wound management is dependent upon the extent of the wound, depth of the wound, and site of care, that is, a general hospital in which a trauma/acute care surgeon might provide definitive wound care for a patient with burns of limited extent as opposed to a burn center where the wound care of a patient with extensive burns would be provided by a burn surgeon. The trauma/acute care surgeon must be able to identify those patients who are best cared for at a burn center and oversee their safe, prompt transfer.

EPIDEMIOLOGY

Only 21 states require the reporting of burn injury and in 9 of those states, only specific burns defined by etiology or extent must be reported. Consequently, an estimated total number of burns has been obtained only by extrapolation of the data collected in those states to the entire population. In 1996, 1.25 million was regarded as a realistic estimate of the annual incidence of burns in the United States.[1]

On the basis of data from federal surveys and the National Burn Registry, the American Burn Association estimates that in the United States, 450,000 burn injury patients receive medical treatment annually. The percentage of burn patients cared for at burn centers has increased steadily in recent years and of the 40,000 (~130 patients per million population) admitted to hospitals for treatment of their burn injury, two-thirds or 26,400 (~86 patients per million population) are cared for at the 125 hospitals with specialized burn centers of which 54 are verified by the American Burn Association.[2] That subset of patients defined by the American Burn Association (Table 32.2), as best cared for in a burn center[3] consists of 40 patients per million population with major burns and 46 patients per million population having lesser burns but a complicating cofactor. The geographic distribution of burn centers, which correlates closely with population density,[4] necessitates the use of aeromedical transfer by either fixed wing or rotary wing aircraft to transport burn patients to those facilities from remote areas.

There are identifiable populations at high risk for specific types of injuries that will require treatment by the trauma/acute care surgeon. Thermal burns outnumber scald burns by more than a factor of 2 in children of all ages treated in emergency departments for burns[5] even though scald burns are the most frequent form of burn injury overall.[6] The occurrence of tap water scalds can be minimized by adjusting the temperature settings on hot water heaters or by installing special faucet valves that prevent delivery of water at unsafe temperatures.

In adults, flames and the ignition of flammable liquids are the most common causes of burns. In patients of 80 or more years, scalds and flames each cause approximately 30% of burn injuries. Preexisting disease contributes to the injury event in approximately two-thirds of elderly patients and also contributes to their morbidity and mortality rates, which are higher than in younger patients.[7]

The vast majority of the burns treated at hospitals involve <20% of the total body surface area (TBSA) as reflected by the overall survival rate of 94.8%. The American Burn Association National Burn Registry Advisory Committee has estimated that there are only "4,000 fire and burn deaths each year with 75% of those occurring at the scene or during initial transport". Of patients admitted to burns centers, 63% are Caucasian and 70% are male. The cause of the burn injury in those patients was flame/fire 42%, scald 31%, hot object contact 9%, electric injury 4%, chemical injury 3%, and other 11%. Personal assault and self-inflicted injuries each accounted for approximately 2% of the burns. The home was the site of occurrence of the burn injury in two-thirds of the patients and, only 1 in 10 occurred at the work place.[2] However, one-fifth to one-quarter of all serious burns are employment related. Kitchen workers are at relatively high risk for scald injury, and roofers and paving workers are at greatest risk for burns due to hot tar.

In 1988, there were 236,200 patients treated in emergency rooms for chemical injuries.[8] Many chemical injuries are employment related. Strong acid injuries are of greatest incidence in those involved in plating processes and fertilizer manufacture and strong alkali injury is of greatest incidence in those involved in making soap. Injuries caused by phenol, hydrofluoric (HF) acid, anhydrous ammonia, cement, and petroleum distillates are also strongly associated with employment.

Injuries due to white phosphorus and mustard gas are most frequent in military personnel. Civilian recreational explosive devices, fireworks, are a seasonal cause of burn injury. The highest incidence of firework injuries occurs during the 4th of July holiday in the United States, and during religious celebrations in countries such as India.

Electric current causes approximately 1,000 deaths per year.[9] One-quarter of electric injuries occur on farms or industrial sites, and one-third occur in the home. Young children have the highest incidence of electric injury caused by household current as a consequence of inserting objects into an electrical receptacle or biting or sucking on electric cords and sockets. Adults at greatest risk of high voltage electric injury are the employees of utility companies, electricians, construction workers (particularly those manning cranes), farm workers moving irrigation pipes, oil field workers, truck drivers, and individuals installing antennae. National death certificate data document an average of 107 lightning deaths annually.[10] The vast majority (92%) of lightning-associated deaths occur during the summer months when thunderstorms are most common. Slightly more than one-half of patients killed by

ORGAN SYSTEM RESPONSE TO BURN INJURY

■ ORGAN SYSTEM	■ EARLY CHANGE	■ LATER RESPONSE
Cardiovascular	Hypovolemia	Hyperdynamic state
Pulmonary	Hypoventilation	Hyperventilation
Endocrine	Catabolism	Anabolism
Urinary	Oliguria	Diuresis
Gastrointestinal	Ileus	Hypermotility
Skin	Hypoperfusion	Hyperemia
Immunologic	Inflammation	Anergy
CNS	Agitation	Obtundation

FIGURE 32.1. The distribution of the burns on this child (feet, legs, posterior thighs, buttocks, and perineum) is characteristic of abuse by intentional immersion scalding. The bright red moist burns of the buttocks and left posterior thigh were partial thickness burns, while the darker red, dry burns of the legs and feet, which darkened further with time, were full thickness injuries, which required grafting for closure.

lightning were engaged in outdoor activities such as golfing or fishing, and a quarter of patients who died from lightning injury were engaged in employment-related activities.[11]

Child abuse is a special form of burn injury, typically inflicted by parents but also perpetrated by siblings and child care personnel. The most common form of thermal injury abuse in children is caused by intentional application of a lighted cigarette. Burning the dorsum of a hand by application of a hot clothing iron is another common form of child abuse. The burns in abused children who require in-hospital care are most often caused by immersion in scalding water with the injury typically involving the feet, posterior legs, buttocks, and sometimes the hands (Fig. 32.1). It is important that the trauma/acute care surgeon identify and report child

abuse because if it is undetected and the child is returned to the abusive environment, repeated abuse is associated with a high risk of fatality. In recent years, elder abuse has become more common and it too should be reported and the victim protected.

PATHOPHYSIOLOGY

Local Effects

The depth of burn injury produced, that is, partial thickness or full thickness, is related to the temperature of the energy source, the duration of the exposure, and the tissue surface involved. At temperatures <45°C, tissue damage is unlikely to occur in either adults or children even with an extended period of exposure. In the adult, exposure for 30 seconds when the temperature is 54°C will cause a burn injury.[12] In the child with relatively thinner skin, exposure to this same temperature for 10 seconds produces a substantial degree of tissue destruction. When the temperature is elevated to 60°C, a not uncommon setting for home water heaters, tissue destruction can occur in <5 seconds in children. At 71°C, a full thickness burn can occur in a near instantaneous manner. It is no surprise that when patients come in contact with boiling liquids, live flames, or are injured in industrial accidents where temperatures can exceed 1,000°C, substantial depths of injury occur. The systemic consequences of the injuries are proportional to the extent of the body surface area involved and may be modified by the patient's underlying physiological status and the presence of concomitant mechanical trauma. As the depth of the burn increases from partial to full thickness, the systemic response increases but to a lesser degree than that associated with increase in burn extent.

A burn injury causes three zones of damage (Fig. 32.2A). Centrally located is the zone of coagulation necrosis. Surrounding this is an area of lesser cell injury, the zone of stasis, and surrounding that an area of minimally damaged tissue, the zone of hyperemia, which abuts undamaged tissue. In a full thickness burn, the zone of coagulation involves all layers of the skin extending down through the dermis and into the subcutaneous tissue (Fig. 32.2B). In partial thickness injuries, this zone extends down only into the dermis and there are surviving epithelial elements capable of ultimately resurfacing

TABLE 32.2

ABA BURN CENTER REFERRAL CRITERIA

I. Partial thickness burns of >10% TBSA.

II. Burns that involve the face, hands, feet, genitalia, perineum, or major joints

III. Third degree burns in any age group.

IV. Electrical burns including lightning injury.

V. Chemical burns.

VI. Inhalation injury.

VII. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality.

VIII. Any patient with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient's condition may be stabilized initially in a trauma center before transfer to a burn center. Physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.

IX. Burned children in hospitals without qualified personnel or equipment for the care of children.

X. Burn injury in patients who will require special social, emotional, or rehabilitative intervention.

FIGURE 32.2. A: In any burn there are three identifiable concentric zones of injury. The most severe injury is in the zone of coagulation in which all tissue is nonviable. Surrounding that is the zone of stasis in which injured tissue with impaired blood flow can progress to necrosis if resuscitation is inadequate or be salvaged with adequate resuscitation. Surrounding the zone of stasis is the zone of hyperemia that contains the least injured tissue and is characterized by surface erythema and increased blood flow as manifestations of the inflammatory response. **B:** Diagram of the skin showing the levels of tissue injury defining second degree or partial thickness burns in which epithelial cells migrating from skin adnexa will resurface the wound and third degree or full thickness burns in which the dermis and adnexa are destroyed and must be closed by grafting.

the wound. In the zone of stasis, blood flow is altered but is restored with time as resuscitation proceeds. If thrombosis were to occur in a patient who is not adequately resuscitated, the zone of stasis can be converted to a zone of coagulation. The zone of hyperemia is best seen in patients with superficial partial thickness injuries as occur with severe sun exposure.

Along with the changes in wound blood supply there is considerable formation of edema in the burn-injured tissues. Release of local mediators from the burned tissue as well as

from leukocytes causes alterations in local tissue homeostasis. Factors elaborated in the damaged tissues include histamine, serotonin, bradykinin, prostaglandins, leukotrienes, and interlukin-1. Complement is also activated, which can further modify transcapillary fluid flux. The changes in tissue water content have been ascribed to increased capillary filtration as well as changes in interstitial hydrostatic pressure.[13-16] The net effect of these various changes is appreciable movement of fluid into the extravascular fluid compartment. The ongoing

development of edema fluid in the burn-injured tissue conceptually represents increased vascular permeability. Subsequent changes in lymph flow from burned tissue have been ascribed to changes in lymphatic vessel patency with obstruction occurring due to serum proteins that have transmigrated from the damaged capillaries.[17] Maximum accumulation of both water and protein in the burn wound occurs at 24 hours post injury.[18] This accumulation in tissues can remain beyond the first week post-burn. In addition to the changes in transcapillary fluid movement within the burn injured tissues, patients who have greater than a 20%-25% body surface burn have similar fluid movement in undamaged tissue beds including the gut and the lung. This may in part be related to the changes in transcapillary fluid flux and also be in response to the volume of resuscitation fluids administered.[19,20]

The appearance of the injuries is determined by the level of tissue destruction (Fig. 32.3A). When the wounds are superficial, they are associated with hyperemia, fine blistering, increased sensation, and intense pain upon palpation. The wounds are erythematous, warm, and readily blanch. These types of injuries represent first-degree burns or alternatively are termed superficial partial thickness injuries. With a second degree or deeper partial thickness burn, the wound presents with intact or ruptured blisters or is covered by a thin coagulum or crust. The key physical finding is preservation of sensation in the burned tissue although it is reduced (Table 32.3).

With proper care, superficial and even deeper partial thickness injuries are capable of healing. Even though burn blister fluid represents a near pure acellular filtrate of plasma, studies have revealed that this fluid may not necessarily promote wound healing.[21] Infection risk in deep partial thickness wounds is considerable and if an infection develops it can lead to greater tissue destruction and conversion to a full thickness injury. When the injury penetrates all layers of the skin or extends into the subcutaneous or deeper tissues, the wound will appear pale or waxy, be anesthetic, dry, and inelastic, and contain thrombosed vessels (Fig. 32.3B). Occasionally in children or young women, the wound may initially be cherry or brick red in appearance and be mistakenly considered to be partial thickness injury (Fig. 32.1). Such wounds typically have substantial edema, and are inelastic and insensate. Over the ensuing days, the wound darkens and becomes characteristic of a full thickness wound as the extravasated hemoglobin, which when fully oxygenated immediately post injury is responsible for the misleading wound color, undergoes reduction. Full thickness wounds are infection prone wounds, as they no longer provide any viable barrier to invading organisms and if left untreated are rapidly colonized and become a portal for invasive burn wound sepsis.

Systemic Response

The organ system response to a major burn injury results in some of the most profound physiologic changes that can occur. The magnitude of the response is proportional to the burn size and in some organ systems reaches a maximum at about a 50% body surface area burn. The duration of the changes is related to the persistence of the burn wound and the changes resolve with wound closure. The organ specific response follows the pattern that occurs with other forms of trauma with an initial level of hypofunction followed by the hyperdynamic flow phase. The changes in the cardiovascular response are some of the more critical ones and directly impact the initial care and management of the burn patient. Following burn injury, there is a transient period of decreased cardiac performance in association with elevated peripheral vascular resistance. This can be further compounded by failure to replace adequately the patient's intravascular volume loss leading to further impairments of cardiac filling, decreased cardiac output, and worsening organ hypoperfusion. Systemic hypoperfusion can result in further increases in systemic vascular resistance and reprioritization of regional blood flow. Whether the burn is responsible for causing a myocardial depressant to appear in the circulation or the impaired cardiac performance is simply a consequence of inadequate volume restoration remains an open question. What seems to be clear from experimental studies is that when there is a failure to resuscitate a burn patient adequately there is substantial impaired myocardial performance.[22] Conversely, the provision of adequate resuscitation volumes can preserve cardiac performance.[23]

Patients receiving appropriate volume restoration during the course of their resuscitation, develop normal cardiac performance values within 24 hours of injury and by the second

FIGURE 32.3. A: The partial thickness burns on this patient's arm display the characteristic blisters and areas of exfoliation of superficial epithelium revealing a pink moist wound shown just below the elbow. **B:** The full thickness burns on the left leg and foot of this child display the leathery, pallid, coagulated eschar characteristic of third degree burns. Edema beneath the circumferential eschar necessitated the escharotomy incision evident in the midlateral line of the burned leg and the lateral aspect of the foot. Note that the escharotomy was carried across the involved ankle joint.

TABLE 32.3

CLINICAL CHARACTERISTICS OF BURN INJURIES

	■ PARTIAL THICKNESS BURNS		■ FULL THICKNESS BURNS
	■ FIRST DEGREE	■ SECOND DEGREE	■ THIRD DEGREE
Cause	Sun or minor flash	Higher intensity or longer exposure to flash Relatively brief exposure to hot liquids, flames	Higher intensity or longer exposure to flash Longer exposure to flames or "hot" liquids Contact with steam or hot metal High voltage electricity Chemicals
Color	Bright red	Mottled red	Pearly white translucent and parchment-like Charred
Surface	Dry No bullae	Moist Bullae present	Dry, leathery, and stiff Remnants of burned skin present Liquefaction of tissue
Sensation	Hyperaesthetic	Pain to pin prick inversely proportional to depth of injury	Surface insensate Deep pressure sense retained
Healing	3–6 days	Time proportional to depth of burns—10–35 days	Requires grafting.

24 hours, those values further increase to supranormal levels. It is not uncommon to see adult patients with cardiac outputs in excess of 10 Liters per minute. In association with changes in cardiac output, there is a reduction in the systemic vascular resistance to 30%-40% of normal values. This hyperdynamic flow phase, part of the hypermetabolic response to the injury, will decrease toward normal levels with wound closure, but some degree of metabolic rate increase persists in major burn survivors for more than a year as the healed wounds fully mature.

Pulmonary changes following burn injury are the consequences of direct parenchymal damage as occurs with inhalation injury and the pathophysiologic effects of the burn per se. With isolated burn injury, neutrophil sequestration occurs in the lungs and may mediate lung injury. One mediator of this response appears to be the platelet-activating factor, which serves to prime neutrophils.[24] The changes in the pulmonary vascular response parallel those of the peripheral circulation though the increase may be to a greater degree and with a longer duration of change.[25] Capillary permeability in the lung appears to be mostly preserved following burn injury with the primary change being an increase in the lung lymph flow but no change in the lymph-to-plasma protein ratio.[26] Lung ventilation increases in proportion to the extent of burn with the patient having both an increase in respiratory rate and tidal volume. The increases are primarily related to the overall hypermetabolic response to the burn injury. Further perturbations in the patient's ventilatory status not related to the presence of an inhalation injury would indicate a supervening process such as sepsis, pneumonia, occult pneumothorax, pulmonary embolism, congestive heart failure, or an acute intraabdominal process.

The renal response to burn injuries is largely orchestrated by the cardiovascular response. While initially there may be a reduction in renal blood flow, this is restored with resuscitation. If the resuscitation is delayed or the fluid need underestimated, renal hypoperfusion will occur with early onset renal dysfunction secondary to renal ischemia. If the patient also experiences myoglobinuria or hemoglobinuria, which are capable of causing direct tubular damage, sequential injury can occur leading to further impairment of renal function. The changes in renal blood flow following burn injury require adjustment of the dosing schedule of a variety of medications

such as aminoglycoside antibiotics to attain therapeutic levels. In patients who are receiving nutritional support, large doses of carbohydrates can cause glycosuria resulting in an inappropriate osmotic diuresis necessitating therapeutic intervention, that is, reduction of glucose load and/or administration of insulin. Daily urinary outputs in burn patients who are receiving protein loads greater than normal may be increased by the effects of the urinary urea load necessitating adjustment of fluid intake in order to excrete the increased solute load and avoid hypovolemia.

Burn-induced changes in gastrointestinal (GI) tract motility and a reduced capacity to tolerate early feedings had been previously thought to preclude the use of the GI tract as the primary route for nutritional support. With near immediate institution of enteral feedings via nasogastric or nasoduodenal tubes, GI motility can be preserved, mucosal integrity protected, and effective nutrient delivery achieved. It seems that delay in the initiation of enteral feeding is associated with the onset of ileus, which can also occur when the burn resuscitation has been complicated. Patients who are under-resuscitated will have alterations in GI tract motility and mucosal integrity as a consequence of intestinal hypoperfusion. Patients who have received massive resuscitation volumes will have considerable edema of the retroperitoneum, bowel mesentery, and bowel wall leading to a paralytic ileus. In patients who are intoxicated at the time of their burn injury, there may be further alterations in the GI tract with changes in the mucosal barrier function and alterations in local immunity.[27] In the past, the major GI complications following burn injuries were related to upper GI ulceration and bleeding. However, there has been a relative shift in the site of post-burn GI complications with the small bowel and colon now being more often affected.[28]

Burn injury results in an elevated hormonal and neurotransmitter response similar in magnitude to that of the "fight or flight" response.[29] The duration of the neurohumoral response is prolonged and it can be further increased with surgical stress. This can adversely impact the burn-induced metabolic changes and immune response. The increases in glucocorticoids and catecholamines correctly support the stress response of the injured patient except where this response becomes dysfunctional. In pathologic studies in humans as well as in animals, when there is an insufficient stress-hormone

response, an otherwise survivable insult becomes fatal. Many of the multisystem changes occurring postburn can be related in part to the alterations in catecholamine secretion particularly the changes in resting metabolic expenditure, substrate utilization, and cardiac performance. As wound closure is accomplished, the altered neurohumoral response abates as the catabolic hormones recede and the anabolic hormones become predominant.

Burn injury results in the loss of balance in both leukocyte and erythrocyte production and function. Burns of >20% TBSA are associated with alterations in red cell production resulting in anemia.[30] Patients with major thermal injuries may lose up to 20% of their red cell mass in the first 24 hours due to thermal destruction of red cells in the cutaneous circulation. Such loss can be further compounded by frequent blood draws, blood loss related to surgical procedures, hemodilution with resuscitation and transient alterations in erythrocyte membrane integrity. Longer-term changes appear to be related to hyporesponsiveness of the erythroid progenitor cells in the bone marrow to erythropoietin.[31] Burn patients manifest increased circulating levels of erythropoietin following injury and attempts to augment those levels to improve red cell production have met with little success. During the early stages of resuscitation, reductions in platelet number, depressed fibrinogen levels, and alterations in coagulation factors return to normal or near normal values with appropriate resuscitation. Subsequent changes if they occur may be related to a septic process or in the case of platelets, heparin-induced platelet antibodies if heparin flushes are used as part of the maintenance protocol for intravascular devices. Changes in white cell number occur early with an increase in neutrophils due to demargination and accelerated bone marrow release. With uncomplicated burn injury, bone marrow myelopoiesis is relatively preserved.[32] With a septic complication, there appears, based on experimental evidence, to be a reduction in granulocyte formation and a relative shift to monocytopoiesis.[33] This defect appears not to be related to a lack of granulocyte colony stimulating factor but a growth arrest within the bone marrow of granulocyte precursor cells.[34,35]

In addition to the changes occurring in the bone marrow and the nonspecific aspects of the host defense mechanisms, there are substantial further depressions in the immune response. Burn injury causes a global impairment in host defense mechanisms. Alterations of the humoral immune response include reductions in IgG and IgM secretion, decreased fibronectin levels, and increases in complement activation. Cellular changes include alterations in T-cell responsiveness, changes in the T-cell subpopulations favoring the cytotoxic/suppressor T-cell, alterations in antigen processing and presentation, reductions in IL-2 release, and impairment of delayed type hypersensitivity reactions. In addition to the changes noted in granulocytes and monocytes and their release from the bone marrow, there are corresponding functional changes. Granulocytes have been noted to have impaired chemotaxis, decreased phagocytic activity, decreased antibody-dependent cell cytotoxicity, and a relative impairment in their capacity to respond to a second challenge.[36] The relative shift to monopoiesis is associated with an increase in secretion of PGE_2.[37] Dendritic cells, a critical component in the immune response, have also been found to be considerably altered following burn injury with infection.[38] Majetschak et al., who studied circulating proteasomes after burn injury identified elevation of 20 S proteasomes, which peaked on the day of injury, gradually declined during the ensuing 7 days, and had returned to baseline by postburn day 30. The proteasome levels did not discriminate for sepsis, multiple organ failure, or survival, but the circulating 20 S proteasomes were considered to be biomarkers of tissue damage and potentially useful in diagnosing inhalation injury.[39]

Recent studies of 242 pediatric patients with burns of more than 40% of the TBSA by Jeschke et al.[40] have documented the pervasiveness, intensity, and duration of the pathophysiologic response evoked by a major burn. Every patient was markedly hypermetabolic throughout their hospital stay and sustained substantial muscle protein loss and loss of lean body mass. Bone mineral density and bone mineral content decreased as well. Serum proteomic analysis revealed profound changes immediately after injury which, with variable changes across time, persisted throughout hospital stay. Cardiac function was compromised immediately after burn and was still abnormal at discharge. Insulin resistance was evident in the first week after injury and still present at discharge. Striking changes in IL-8, MCP-1, and IL-6 induced an inflammatory state and were associated with infections and sepsis. The clinical importance of these observations is that the burn patient is at significant risk for postburn infectious complications. This mandates the strictest adherence to aseptic technique in the management of the wounds and the insertion of intravascular devices, the judicious use of antimicrobial agents, aggressive nutritional support, and the achievement of rapid wound closure.

RESUSCITATION

Priorities

In the immediate postburn period, the changes induced in the cardiovascular system by burn injury receive therapeutic priority. If the early postburn plasma volume loss is unreplaced, burn shock may occur accompanied by kidney and other organ failure and even death. In all patients with burns of more than 20% of the TBSA and those with lesser burns in whom physiologic indices indicate a need for fluid infusion, a large caliber intravenous cannula should be placed in an appropriately sized peripheral vein underlying unburned skin. If no such sites are available, a vein underlying the burn wound may be cannulated. If there are no peripheral veins available, the cannula can be placed in a femoral, subclavian, or jugular vein. Lactated Ringers solution should be infused at an initial rate of 1 Liter per hour in the adult and 20 mL/kg/h for children who weigh 50 kg or less. That infusion rate is adjusted following estimation of the fluid needed for the first 24 hours following the burn.

Fluid Administration

Resuscitation fluid needs are proportional to the extent of the burn (combined extent of partial and full thickness burns expressed as a percentage of TBSA) and are related to body size (most readily expressed as body weight) and age (the surface area per unit body mass is greater in children than in adults.) The patient should be weighed on admission and the extent of partial and full thickness burns estimated according to standard diagrams (Fig. 32.4) or, in the adult, by the use of the rule of nines that recognizes the fact that the surface area of various body parts represents 9% or a multiple thereof of the TBSA, that is, each upper limb and the head and neck 9%, each lower limb, posterior trunk and buttocks, and anterior trunk 18%, and the perineum and genitalia 1%. Those surface area relationships differ in children in whom the head and neck represent 21% of the TBSA and each lower limb, 14% at age one. The fraction of the TBSA represented by the head decreases progressively and that represented by the lower limbs increases progressively reaching adult proportions at age 16. The fact that the palmar surface of the patient's hand (palm and digits) represents 1% of his or her total body surface can be used to estimate the extent of irregularly distributed burns, that is, the number of the patient's "hands" needed to cover the patient's burn wounds.[41]

FIGURE 32.4. This diagram can be used to determine the extent of a patient's burn. Areas of the figures are colored with a blue pencil to indicate partial thickness burns and a red pencil to indicate full thickness burns. The columns with numbers, to the left below the figures, indicate how the percentage of body surface represented by various body parts changes with age.

In recent years, increased recognition of the association between resuscitation volume and compartment syndromes has focused interest on minimizing resuscitation fluid volume and increased use of those formulae estimating the fluid needed for the first 24 hours as 2.0 mL/kg body weight/percent of body surface burned as opposed to those formulae estimating first 24 hour fluid resuscitation needs as 4.0 mL/kg body weight/percent body surface area burned.[42-44]

In a study of 105 combat casualties with burns of more than 20% of the TBSA, the investigators reported that resuscitation guided by the modified Brooke Formula resulted in significantly lower first 24-hour fluid volume without any greater morbidity and mortality than in those for whom resuscitation was guided by the Parkland Formula. A greater percentage of those patients resuscitated with the Parkland Formula exceeded the Ivy index (250 mL of resuscitation fluid per kilogram body weight), which was associated with a high risk for abdominal compartment syndrome and was an independent predictor of death.[45]

In line with such reports, the American Burn Association's 2010 Advanced Burn Life Support (ABLS) manual has revised the recommendations for estimating the first 24-hour resuscitation fluid needs of burn patients.[46] One half of the estimated volume should be administered in the first 8 hours after the burn. If the initiation of fluid therapy is delayed, the initial half of the volume estimated for the first 24 hours should be administered in the hours remaining before the eighth postburn hour. The remaining half of the fluid is administered over the subsequent 16 hours. The infused volume is increased only as needed to achieve adequate resuscitation (Table 32.4).

The limited glycogen stores in a child may be rapidly exhausted by the marked stress hormone response to burn injury. Serum glucose levels in the burned child should be monitored and 5% dextrose in half normal saline administered if serum glucose decreases to hypoglycemic levels. In the case of small children with small burns, the resuscitation fluid volume as estimated on the basis of burn size may not meet normal daily metabolic requirements. In such patients, maintenance fluids should be added to the resuscitation regimen.

A "Rule of Ten" has recently been proposed as a simplified means of estimating the initial fluid infusion rate for adult burn patients and has been compared with existing formulae.

Rule of Ten.

1. Estimate burn extent to the nearest 10% of the TBSA
2. Extent of burns as estimated × 10 = initial infusion rate in mL per hour (for adults of 40–80 kg).
3. Increase rate by 100 mL per hour for each 10 kg body weight >80 kg.

In 100,000 simulations evaluated in silico, 88% of the initial infusion rates calculated by the Rule of Ten fell between those calculated by the Modified Brooke Formula (MB) and the Parkland (PL) Formula. The majority of the calculated rates clustered about the MB infusion rate.[47]

The infusion rate is adjusted according to the individual patient's response to the injury and the resuscitation regimen. The high circulating levels of catecholamines evoked by the burn and the progressive edema formation in burned and even unburned limbs commonly make measurements of pulse rate, pulse quality, and even blood pressure difficult and unreliable as indices of resuscitation adequacy. Since the hourly urinary output is a generally reliable and readily available index of resuscitation adequacy, an in-dwelling urethral catheter should be placed and the urinary output measured and recorded each hour. The fluid infusion rate is adjusted to obtain 30–50 mL of urine per hour in the adult and 1 ml per kg body weight per hour in children weighing <30 kg. To avoid excessive fluctuation of the infusion rate, the administration of fluid is increased or decreased only

TABLE 32.4

ESTIMATION OF FIRST 24 HOUR FLUID RESUSCITATION NEEDS

I. Adult patients:
  A. Thermal and chemical burns: 2 mL lactated Ringers × body weight in kg × % TBSA[a] with second and third degree burns
  B. High voltage electric injury; 4 mL lactated Ringers × body weight in kg × % TBSA[a] with second and third degree burns

II. Pediatric patients (<14 years and <40 kg);
  A. Thermal and chemical burns; 3 mL[b] lactated Ringers × body weight in kg × % TBSA[a] with second and third degree burns
  B. High voltage electric injury; consult referral burn center immediately for guidance

[a]TBSA, total body surface area.
[b]The greater surface area per unit body mass in children necessitates a greater first 24' resuscitation fluid volume.

if the hourly urinary output is one-third or below or more 25% or more above the target level for 2 or 3 successive hours. If in either adults or children the resuscitation volume infused in the first 12 hours to achieve the desired urinary output or other indices of resuscitation adequacy exceeds estimated needs by more than twofold or will result in administration of six or more mL per percent body surface area burned per kg body weight in the first 24 hours, human albumin diluted to a physiologic concentration in normal saline should be infused and the volume of crystalloid solution reduced by a comparable amount. Inasmuch as functional capillary integrity is gradually restored during the first 24 hours postburn, such use of colloid-containing fluid is best reserved for the latter half of the first postburn day.

Restoration of functional capillary integrity and the establishment of a new transvascular equilibrium across the burn wound are manifested by the fact that both protein and water content of the burn-injured tissue reach maxima at or near 24 hours after injury.[18] Consequently, the volume of fluid needed for the second 24 hours postburn is less and colloid-containing fluids can be infused to reduce further volume and salt loading. Human albumin diluted to physiologic concentration in normal saline is the colloid-containing solution infused in a dosage of 0.3 mL per percent burn per kg body weight for patients with 30%-50% burns, 0.4 mL per percent burn per kg body weight for patients with 50%-70% burns, and 0.5 mL per percent burn per kg body weight for patients whose burns exceed 70% of the TBSA. Electrolyte-free, 5% glucose in water is also given in the amount necessary to maintain an adequate urinary output. The colloid-containing fluids for the second 24 hours for burned children are estimated according to the same formula, but half-normal saline is infused to maintain urinary output and avoid inducing physiologically substantive hyponatremia by infusion of large volumes of electrolyte-free fluid into the relatively small intravascular and interstitial volume of the child.

During the second 24 hours after injury, fluid infusion "weaning" should be initiated to minimize further volume loading. In a patient who is assessed to be adequately resuscitated, the volume of fluid infused per hour should be arbitrarily decreased by 25%-50%. If urinary output falls below target level, the prior infusion rate should be resumed. If urinary output remains adequate, the reduced infusion rate should be maintained over the next 3 hours at which time another similar fractional reduction of fluid infusion rate should be made. This decremental

TRAUMA

process will establish the minimum infusion rate that maintains resuscitation adequacy in the second postburn day.

Escharotomy

As resuscitation proceeds and edema forms beneath the inelastic eschar of encircling full thickness burns of a limb, blood flow to underlying and distal unburned tissue may be compromised. Circulatory compromise can occur in limbs with mixed depth partial thickness burns and on occasion in limbs with less than completely circumferential burns. Edema and coolness of distal unburned skin on a burned limb are normal accompaniments of the injury and are not indicative of circulatory compromise requiring surgical release. Cyanosis of distal unburned skin and progressive parasthesias, particularly unrelenting deep tissue pain, which are the most reliable clinical signs of impaired circulation, may become evident only after relatively long periods of relative or absolute ischemia. Those limitations can be overcome by scheduled (q1–2 h) monitoring of the pulse signal in the palmar arch vessels and the posterior tibial artery using an ultrasonic flowmeter. In an adequately resuscitated patient, absence of pulsatile flow or progressive diminution of the pulse signal on repetitive examinations is an indication for escharotomy.

Since the full thickness eschar is insensate, an escharotomy can be performed as a bedside procedure without anesthesia using a scalpel or an electrocautery device. On an extremity, the escharotomy incision, which is carried only through the eschar and the immediately subjacent superficial fascia, is placed in the midlateral line and must extend from the upper to the lower limit of the burn wound (Fig. 32.5). The circulatory status of the limb should then be reassessed. If that escharotomy has not restored distal flow, another escharotomy should be placed in the midmedial line of the involved limb. A fasciotomy may be needed when there has been a delay in restoring the patient's limb circulation and in particular if the patient is receiving a massive fluid load. Mistakes in the performance of escharotomies include injuries to extensor tendons and digital neurovascular bundles, insufficient depth and length of the incision, and delay in performing the escharotomy. Additionally, delayed bleeding from previously thrombosed vessels transected during the escharotomy should be promptly controlled. Continuous elevation and active exercise of a burned extremity for 5 minutes every hour limits edema formation and may eliminate the need for escharotomy.[48]

Edema formation beneath encircling full thickness truncal burns can restrict the respiratory excursion of the chest wall. If the limitation of chest wall motion is associated with hypoxia and progressive increase in the work of breathing, and peak inspiratory pressure as well, escharotomy is indicated to restore chest wall motion and improve ventilation. These escharotomy incisions are placed in the anterior axillary line bilaterally, and if the eschar extends onto the abdominal wall, the anterior axillary line incisions are joined by a costal margin escharotomy incision (Fig. 32.5). Rarely, encircling full thickness burns of the neck or penis will require release by placement of an escharotomy incision in the midlateral line(s) of the neck or the dorsum of the penis.

Post Resuscitation Fluid Therapy

Fluid management after the first 48 hours postburn should permit excretion of the retained fraction of the water and salt loads infused to achieve resuscitation, prevent dehydration and electrolyte abnormalities, and allow the patient to return to preburn weight by the 8th to 10th postburn day.[41] Infusion of the large volumes of lactated Ringers required for resuscitation commonly produces a weight gain of 20% or more and a reduction

FIGURE 32.5. The *dashed lines* indicate the preferred sites of escharotomy of circumferential burns of the limbs, trunk, and other body parts. The thickened areas on those lines denote the importance of extending the escharotomy incisions across involved joints.

of serum sodium concentration to approximate that of lactated Ringers, that is, 130 mEq/L. Such patients do not need additional sodium and, in fact, have an elevated total body sodium mass in association with increased total body water. Correction of that relative hyponatremia is facilitated by the prodigious evaporative water loss from the surface of the burn wound, which is the major component of the markedly increased insensible water loss that is present following resuscitation. Insensible water loss, which must be taken into account in postresuscitation fluid management, can be estimated according to the formula:

$$\text{Insensible water loss (mL per hour)}$$
$$= (25 + \% \text{ TBSAB}) \times \text{TBSA in square meters}$$

where TBSAB= Total Body Surface Area Burn, and TBSA= Total Body Surface Area.[49]

That water loss should be replaced only to the extent that will permit a daily loss of 2%-2.5% of the resuscitation-associated weight gain (as measured 48 hours after the burn) until preburn weight is attained. Inadequate replacement of insensible water loss makes hypernatremia the most commonly encountered electrolyte disturbance in the extensively burned patient following resuscitation. Such hypernatremia should be managed by provision of sufficient electrolyte-free water to allow excretion of the increased total body sodium mass and replace insensible water loss to the extent needed to prevent hypovolemia.

During resuscitation, hyperkalemia is the most frequently encountered electrolyte disturbance and is typically a laboratory sign of hemolysis and muscle destruction by high voltage

electric injury or a particularly deep thermal burn. Hyperkalemia may also occur in association with acidosis in patients who are grossly underresuscitated. Hyperkalemia in the burn patient is treated as in any other surgical patient. In the case of patients with high voltage electric injury, emergency debridement of nonviable tissue and even amputation may be necessary to remove the source of the potassium. Hypokalemia may occur after the resuscitation period in association with alkalosis as a consequence of hyperventilation and may also accompany postresuscitation muscle wasting. Potassium losses are increased by the kaluretic effect of the mafenide acetate in Sulfamylon burn cream and, as noted below, by transeschar leaching in patients treated with 0.5% silver nitrate soaks.

Major depression of ionized calcium levels is uncommon, but total calcium levels may be depressed if calcium-binding proteins such as albumin decrease as may happen in patients receiving a high volume of resuscitation fluid. In extensively burned children, hypocalcemia has been associated with hypoparathyroidism and renal resistance to parathyroid hormone.[50] Symptomatic acute hypocalcemia should be treated with intravenous calcium (90–180 mg of calcium infused over 5–10 minutes) to control cardiac dysfunction and neuromuscular hyperactivity. Prolonged administration of parenteral nutrition and/or failure to supply sufficient phosphate to meet the needs of tissue anabolism following wound closure may cause hypophosphatemia. Administration of large volumes of antacids for stress ulcer prophylaxis is an infrequent cause of hypophosphatemia now that acid secretion inhibitors are used for that purpose. Hypophosphatemia can be prevented and treated by appropriate dietary phosphate supplementation.

The timely administration of adequate fluid as detailed above has essentially eliminated acute renal failure as a complication of inadequate resuscitation of burn patients. In a recent 10-year period, only 2 out of 2,132 burn patients treated at the U. S. Army Burn Center developed early renal failure, and those patients had established anuria when they were received in transfer from other institutions.[51] Far more common today are the complications of excessive resuscitation, that is, compartment syndromes and pulmonary compromise (Table 32.5). Compartment syndromes can be produced in the calvarium, muscle compartments beneath the investing fascia, and the abdominal cavity. Cerebral edema, which may efface the epidural space and compress the ventricular system, is most apt to occur in burned children and is manifested by obtundation and changes evident on computerized tomographic scans. Such changes should be addressed by maintaining cerebral perfusion pressure and minimizing further edema formation by reducing fluid infusion rate and inducing diuresis. Anterior ischemic optic neuropathy manifested by visual field defects and even blindness, is another manifestation of excessive fluid infusion. This complication has typically occurred in association with other compartment syndromes and anasarca in critically ill patients, particularly in those who are nursed in a prone position. Consequently, prone positioning should be avoided in severely injured, critically ill burn patients requiring large volumes of parenteral fluids. The occurrence of visual field defects should prompt alteration of fluid therapy and induction of a diuresis.[52]

Excessive fluid administration may also cause formation of enough ascitic fluid and edema of the abdominal contents to produce intra-abdominal hypertension. The abdominal compartment syndrome represents progression of intra-abdominal hypertension to the point of organ dysfunction, that is, typically oliguria, and/or altered pulmonary mechanics. Infusion of resuscitation fluid volumes in excess of 25% of body weight has been associated with a high incidence of abdominal compartment syndrome.[53] In all patients who have received that volume of resuscitation fluid, hourly monitoring of peak inspiratory pressure and intracystic pressure should be instituted.

TABLE 32.5

CONSEQUENCES OF EXCESS RESUSCITATION

I. Compartment syndrome
   A. Muscle compartments of unburned limbs
   B. Abdominal compartment syndrome
   C. Cerebral edema
   D. Anterior ischemic optic neuropathy

II. Pulmonary compromise
   A. Airway edema
   B. Pulmonary edema

Elevation of peak inspiratory pressure above 40 mm Hg and/or elevation of intracystic pressure above 25 mm of mercury, as measured through a urethral catheter, should prompt therapeutic intervention beginning with adequate sedation, reduction of fluid infusion rate, diuresis, and paracentesis. If organ failure becomes evident, a midline abdominal incision should be made to reduce the elevated intra-abdominal pressure. That incision can be temporarily closed with a polyethylene "bag," or a vacuum-assisted closure device. The abdomen can be definitively closed as soon as visceral edema resolves.

Compartment syndromes may also occur in the muscle compartments underlying the investing fascia of the limbs of burn patients, even in limbs that are unburned. To assess compartment pressure, the turgor of the muscle compartments should be assessed on a scheduled basis by simple palpation. A stony hard compartment is an ominous finding that should prompt further evaluation. The adequacy of arterial flow in all limbs of a burn patient should be monitored on a scheduled basis using the ultrasonic flowmeter. Ultrasonic detection of pulsatile flow is reassuring but the ultrasonic flow signals can be misleading since flow in large vessels may be maintained even though microcirculatory flow is severely compromised within a muscle compartment. Direct measurement of intracompartmental pressure using either a wick or needle catheter is much more reliable. A muscle compartment pressure of 25 mm of mercury or more necessitates performing a fasciotomy of the involved compartment in the operating room using general anesthesia.

Edema causing airway obstruction, in the absence of inhalation injury, has also been attributed to excessive resuscitation fluid. This complication, which necessitates endotracheal intubation, has been of particular concern in small children with extensive scald burns who have received in excess of 6 mL of lactated Ringers per percent body surface area burned per kilogram body weight. Pulmonary edema is rare during the initial 48-hour resuscitation period, but may occur in patients with extensive burns following resuscitation when the edema fluid is being resorbed and the protective early postburn pulmonary vascular changes have dissipated.

Mackie et al. have recently suggested that the application of mechanical ventilation alters postburn fluid dynamics and complicates fluid management by increasing net fluid balance independent of the presence of inhalation injury. Those investigators recorded a significantly greater cumulative fluid balance on the third and seventh postburn days in 186 patients with burns of more than 20% of the body surface who received mechanical ventilation as compared to that in patients who did not require mechanical ventilation.[54] Careful monitoring of intake and output in such patients is mandatory. The treatment of pulmonary edema in the burn patient is the same as for other patients.

A closed loop computerized system to adjust resuscitation fluid infusion rate on the basis of urinary output measured at

a scheduled frequency, for example, each hour or as recently proposed every 10 minutes has also been evaluated as a means of reducing resuscitation volume and decreasing the incidence of compartment syndromes. When the system was employed in patients with massive burns, the investigators reported better maintenance of the urinary output target and that the prompt response to minute systemic changes resulted in a lower total infused volume and net fluid balance.[55]

Pathophysiologic studies have also identified pharmacologic agents and physiologic mechanisms that may reduce resuscitation fluid needs. In studies of a murine model of a 30% burn, a threefold increase in intestinal myosin light chain kinase (MLCK) was observed 4 hours after burn injury in association with a marked (fivefold) increase in intestinal permeability.[56] Postburn administration of pentoxifylline decreased the burn-induced phosphorylation of intracellular kinases and was associated with a decrease in histologic evidence of gut injury at 6 hours postburn and lung injury at 24 hours postburn.[57] The authors concluded that pentoxifylline attenuated the activation of the tight junction protein (MLCK) as a consequence of its reduction in tumor necrosis factor—alpha synthesis and nuclear factor kappaB activation after burn injury. Because of its anti-inflammatory effects, pentoxifylline has been proposed as an immunomodulatory additive of resuscitation fluid. Recently, that same group of investigators has identified a protective effect of vagal nerve stimulation on intestinal barrier integrity in a murine model of severe burn injury. Vagal stimulation was found to reduce the postinjury increase in intestinal permeability, decrease histologic changes in the intestinal mucosa, and prevent loss of occludin localization at points of intestinal epithelial cell-to-cell contact.[58]

VENTILATORY SUPPORT AND TREATMENT OF INHALATION INJURY

Pathophysiology

Patients suffering both inhalation injury and thermal burns have a considerably increased incidence of complications and probability of death. While an inhalation injury alone carries a mortality of 5%-8%, a combination of a thermal injury plus inhalation injury can easily result in a mortality 20% above that predicted on the basis of age and burn size.[59] Patients who have an otherwise survivable injury may succumb to their burn as a consequence of their inhalation injury and the complications that occur, particularly a gram negative pneumonia.[60] Injuries to the airway are most often due to direct damage by inhaled products of combustion or pyrolysis that cause inflammation and edema. Damage to the airway, while in part related to the heat content of the inhaled material in the oropharynx is, in the more distal airways, principally related to the particulate material contained within the smoke and the chemical composition of inhaled materials. Moist heat, which occurs with steam, has 4,000 times the heat-carrying capacity of dry smoke and is capable of causing more extensive thermal damage of the tracheobronchial tree.[61]

Presenting patient signs and symptoms are stridor, hypoxia, and respiratory distress.[62] The probability that a patient has suffered an inhalation injury is highly correlated with being burned in an enclosed space, having burns of the head and neck, and having elevated carbon monoxide levels. The extent and severity of the inhalation injury are directly related to the duration of exposure and the various toxins contained within the smoke. Injury due to heat is typically confined to the upper airway and supraglottic structures.[63] Particulate material within smoke is the vehicle by which the toxic materials are carried to the distal airway.

Particles of <5 μ in size can reach the terminal bronchi and the alveoli. Upper airway injuries involve the mucous membranes, nasopharynx, hypopharynx, epiglottis, glottis, and larynx. The lining mucous membranes as well as the cartilage of the glottis are easily damaged and can cause acute airway compromise.[63] Direct thermal injury to the lower airway is uncommon as rapid dissipation of heat occurs as the gases move through the upper airway. Injury to the tracheobronchial structures and pulmonary parenchyma is related to the toxins in the inhaled smoke and the ensuing host inflammatory response. Activation of the inflammatory cascade results in the recruitment of neutrophils and macrophages that propagate the injury.[64] Cellular damage is perpetuated by those cells that further the inflammatory response, which in turn leads to progressive pulmonary dysfunction.[65] Altered surfactant release causes obstruction and collapse of distal airway segments.[66] As part of the response to injury there is a marked and near immediate change in bronchial artery blood flow that can increase by up to twentyfold.[64] These changes in bronchial blood flow are also associated with marked alterations in vascular permeability within the lung and are thought to play an important role in the pathophysiologic response to inhalation injuries.[67] The net effect is that extensive destruction and inflammation reduce pulmonary compliance and impair gas exchange resulting in altered pulmonary blood flow patterns and ventilation perfusion mismatches.[68,69]

Asphyxiants

Carbon monoxide and cyanide gases are present in smoke and when inhaled are rapidly absorbed and cause systemic toxicity as well as impaired oxygen utilization and delivery. Carbon monoxide is an odorless, nonirritating gas that rapidly diffuses into the blood stream and rapidly binds to the iron moiety of the hemoglobin molecule. Carbon monoxide has a 240 times greater affinity for hemoglobin than does oxygen; thus it easily displaces oxygen. Carbon monoxide directly impairs the ability of hemoglobin to deliver oxygen to the tissues. Carbon monoxide also binds to enzymes within the mitochondria involved in intracellular oxygen utilization and cellular energetics.[70] Signs and symptoms of carbon monoxide poisoning are typically mild to none at all when carbon monoxide–hemoglobin (carboxyhemoglobin) levels are 10% or less. When carboxyhemoglobin levels are between 10% and 30%, symptoms are present and often manifested by headache and dizziness. Severe poisoning is seen in patients with carboxyhemoglobin levels of >50% that may be associated with syncope, seizures, and coma.

The diagnosis of carbon monoxide poisoning is made in a patient with burns on the basis of circumstances of injury, physical findings, and the measurement of blood carboxyhemoglobin level. It is important to note that pulse oximetry values do not differentiate between carboxyhemoglobin and oxyhemoglobin. Patients with appreciable carbon monoxide intoxication can have elevated oxygen saturations but will not have satisfactory blood oxygen contents. The primary treatment modality for carbon monoxide intoxication is provision of increased levels of inspired oxygen. The carbon monoxide "half-life" will decrease from 6 to 8 hours with room air to 40–80 minutes with 100% of FIO_2. Administration of oxygen in a hyperbaric chamber can further decrease the "half-life" to 15–30 minutes.[71] In a recently reported randomized trial, Weaver et al.[72] found that hyperbaric oxygen therapy significantly benefited patients with acute carbon monoxide poisoning. The utility of this in patients suffering major burns in association with carbon monoxide poisoning is yet to be demonstrated. It is an important practical question whether a patient can safely undergo treatment with hyperbaric oxygen

therapy when there are other life-saving treatments that are needed. An approach that has worked well is to maintain the patient on 100% FIO_2 until carboxyhemoglobin levels are <15% and then to maintain this level of increased oxygen for an additional 6 hours at which time weaning of the FIO_2 can be initiated and conducted in accordance with standard criteria.

Cyanide poisoning, which has been considered uncommon except in combination with carbon monoxide intoxication, further disrupts normal cellular utilization of oxygen by binding to the cytochrome oxidase resulting in cellular lactic acid production and greater cellular dysfunction. Blood concentrations of cyanide >0.5 mg/L are toxic. Treatment of cyanide poisoning includes the administration of oxygen as well as decontaminating agents such as amyl and sodium nitrates. These compounds induce the formation of methemoglobin, which can act as a scavenger of cyanide.[73] Sodium thiosulphate, which can be administered intravenously, enhances the enzymatic detoxification of cyanide to thiocyanate but acts slowly. Hydroxycobalamin, which acts more rapidly and has few side effects, is the antidote of choice. The ready availability of cyanide antidote kits containing amyl nitrite pearls, 10% sodium nitrite, and 25% sodium thiosulfate or Cyanokits containing 5 g of hydroxycobalamin and their frequent use by emergency medical personnel must alert emergency department and burn physicians to the possibility that the patient has received such treatment in the field.[74]

Smoke may also contain a variety of toxic compounds that cause or initiate further damage to the airway (Table 32.6). The composition of each fire is different adding to the difficulty in caring for these patients. Such additional products in smoke include acrolein, hydrogen chloride, phosgene, ammonia, nitric oxide, and sulfur dioxide all of which are capable of causing substantial injury.

Airway Management

The most critical factor in the initial assessment of a burn patient is the patency of the airway and the ability of the patient to maintain and protect the airway. Standard criteria should be used to determine the need for mechanical stabilization of the airway also keeping in mind the systemic response to a major burn and the local response to an airway injury that may combine to cause progressive airway swelling and edema that will impair airflow. In an adult trachea of 14 mm, 1 mm of edema will result in a 25% reduction in cross sectional area. A similar degree of swelling in a 6 mm trachea of a child will result in greater than a 50% reduction in cross sectional area. Circumferential torso burns will further impair

the ability of the patient to respire. Allowing airway compromise to proceed to a critical state before intubating the patient and stabilizing the airway is not appropriate care. The safest approach when there is concern about the airway, particularly in a patient needing transport for definitive care, is to perform early intubation.

Part of the initial management of the patient with inhalation injury should include a thorough evaluation of the airway including bronchoscopy. The clinical findings of an inhalation injury on bronchoscopy include airway edema, inflammation, increased bronchial secretions, presence of carbonaceous material that can diffusely carpet the airway, mucosal ulcerations and even endoluminal obliteration due to sloughing mucosa, mucous plugging, and cast formation (Fig. 32.6). Signs of gastric aspiration may also be evident. Bronchoscopy can be performed repeatedly for removal of debris and casts as well as surveillance for infection.

Direct airway treatment has been attempted with variable response. Desai et al. conducted an open label trial of the use of aerosolized heparin and N-acetylcysteine in children with inhalation injuries. The treated patients had an improved outcome (lesser incidence of atelectasis, decreased reintubation rate, and reduced mortality) compared to an untreated cohort.[75] A randomized prospective study has not yet been performed to confirm the utility of this approach particularly in adults. One noticeable effect with the empiric use of aerosolized heparin is the rapid clearing of particulate material and carbonaceous deposits from the airway. Laboratory studies have shown that the effectiveness of aerosolized heparin was increased when combined with intravenous administration of lisofylline. The synergistic effect of that antiinflammantory agent supports clinical evaluation of such combination therapy.[76] Inasmuch as the development of pneumonia in patients with inhalation injuries negatively impacts outcome, it is disappointing that prophylactic antibiotics have not been effective.[77] As a practical matter, it is best to culture these patients early to identify the organisms that have colonized their airways as a consequence of their injury and urgent airway manipulation. That information can guide therapy should the patient develop the signs and symptoms of early onset pneumonia. Steroids are not recommended in patients with inhalation injuries.[78]

Mechanical Ventilation

The critical feature in the management of patients suffering inhalation injuries is to minimize further damage to the airway and lung parenchyma while providing adequate gas exchange.[79] A major emphasis in the management of patients with inhalation injuries is to control airway pressures and thereby limit

TABLE 32.6

TOXIC AGENTS IN SMOKE

■ IRRITANT	■ CHARACTERISTICS	■ MECHANISM OF TOXICITY
Acrolein	Lipophilic	Direct epithelial damage
Hydrogen chloride	Water soluble	Forms free radicals
Phosgene	Low solubility	Causes the release of arachidonic acid metabolites
Ammonia	Water soluble	Forms hydroxyl ions and causes liquefactive necrosis
Nitric oxide	Lipid soluble	Causes lipid peroxidation
Sulfur dioxide	Water soluble	Causes lipid peroxidation
FIGURE 32.6. A bronchoscopic view of the airway in a patient with inhalation injury. Note the extensive deposition of carbonaceous material on the bronchial mucosa. Note also the erythematous areas of mucosal inflammation and pale focal areas of mucosal ulceration.

ventilation-induced barotraumas.[62] It is important to recognize that lung damage is not homogenous but patchy in distribution and requires that the level of positive end expiratory pressure (PEEP) used to maximize airway recruitment be limited to avoid ventilator-associated lung injury.[80,81] In states of severe lung injury, mechanical ventilation can lead to increases in sheer forces and changes in pulmonary blood flow. This in association with reductions in elasticity and alterations in lung compliance results in further lung injury and ventilation perfusion abnormalities.[82,83]

Using a standard volume mode of ventilation does not represent the best management of the damaged airway. Inverse ratio ventilation provides a strategy one can use in an attempt to counteract these changes and allow reductions in the level of PEEP and respiratory pressures to improve oxygenation.[84] Unfortunately, a clear advantage of inverse ratio ventilation over standard approaches has not been consistently shown.[85]

High-frequency ventilation is widely utilized at present in the form of high-frequency percussive ventilation (HFPV). High-frequency interrupted flow positive pressure ventilation delivers small tidal volumes (4 mL/kg) at flow rates of 250 liters per minutes with a frequency of 100 breaths per minute. In this mode, expiration is passive and thus there is an increased risk of air trapping and over distention. Allan et al.[86] recently reviewed and compared the use of HFPV using the VDR-4, (a volumetric diffusive respirator), high-frequency oscillatory ventilation, and high-frequency jet ventilation. Those investigators considered that HFPV in comparison to conventional ventilation improved oxygen and carbon dioxide tensions, attenuated lung inflammation and histologic lung injury, and improved static lung compliance, ventilation, oxygenation index, and the oxygen tension/fraction of inspired oxygen. That form of ventilation, which was also associated with a decrease in ventilator-associated pneumonia and an increase in survival of inhalation injury patients, was considered to have

the unique capacity to exploit both high- and low-frequency ventilation to favorably influence gas exchange in a lung protective low tidal volume ventilation strategy.

There has been limited experience with the use of extracorporeal membrane oxygenation in the management of inhalation injuries in selected centers.[87] A carbon dioxide removal device has been developed to provide limited extracorporeal support to patients with chronic obstructive pulmonary disease. Investigators have reported that removal of carbon dioxide by that device permitted reduction in a patient's minute ventilation to one-third of baseline values.[88] The device has been proposed as a treatment modality for patients with pulmonary failure as a consequence of inhalation injury.

An approach that has worked well in many patients with inhalation injuries has been to identify promptly the presence of airway compromise and ensure that the patient is intubated with a properly sized endotracheal tube. Currently, it is our preference in the pediatric population to use a cuffed tube that may need to be inflated to achieve maximum ventilatory efficiency. In patients who have signs of inhalation injury on bronchoscopy, there is aggressive management of retained secretions with the use of bronchodilators and mucolytic agents along with aerosolized heparin. Meticulous control of airway pressure is practiced with the early performance of torso escharotomies and prompt treatment of an abdominal compartment syndrome particularly in the burned child. Mean airway pressures are maintained at <32–34 cm of water and ready use is made of chemical paralysis of the patient with a low threshold for conversion to pressure-controlled ventilation with titration of tidal volumes to lessen further the risk of ventilator-associated barotrauma. This may require the acceptance of smaller than usual tidal volumes and permissive hypercapnia, which is acceptable as long as arterial blood pH is above 7.26 and the patient is hemodynamically stable. These approaches along with a tightly controlled fluid resuscitation will in most circumstances avoid the need for alternative ventilator strategies in the care of these patients. Others including the senior author prefer to use HFPV prophylactically. In all patients with documented inhalation injury, HFPV is initiated on admission to minimize airway obstruction, maintain lung volume, and reduce the risk of pneumonia.

Early extubation and cessation of mechanical ventilation in patients with inhalation injury reduce the incidence of ventilator-associated pneumonia and limit barotrauma. The use of sedation "holidays" and spontaneous breathing trials enable one to assess pulmonary reserve and predict extubation success, but the results can be misleading. White and associates at the U.S. Army Burn Center evaluated interbreath interval complexity during spontaneous breathing trials as a means of predicting extubation success and reducing extubation failure.[89] Those investigators identified that lower interbreath interval complexity was associated with extubation failure. Analysis of wave form data identified lower sample entropy in the failure group with other nonlinear metrics moving in concert with entropy.

OTHER ORGAN SYSTEM SUPPORT

Pain Control

The pain experienced by patients suffering from acute thermal injuries is a complex integration of the objective neurologic input from the damaged tissue and the patient's fear and anxiety resulting from the traumatic event. The patient's pain is compounded further by wound care and the therapy required to maintain functional status. If the patient begins to perceive that there is no escape from this situation, fear and anxiety will be amplified and may be magnified further by the appearance and expression of concern by family and friends. Furthermore,

as the burn begins to heal, there may be increased wound sensitivity during dressing changes and therapy sessions. This can further distress patients, as they perceive that instead of the pain improving with recovery it seems to be worsening. Pain is a fifth vital sign and it should be monitored, its level documented, and treatment be properly planned. Appropriate therapeutic options must be available to provide pain control to patients.

In patients who are hospitalized for ongoing care or require surgery, it is best to initiate long acting oral narcotic agents for background pain control and administer shorter acting narcotics either orally or parenterally, along with anxiolytic agents, for procedure related pain. For an acutely injured patient undergoing a procedure in the ICU or ward, intravenous morphine remains the main stay for analgesia along with oral compounds such as hydrocodone, which is preferable to oxycodone, which has a greater propensity for abuse. Clonidine can also be added to the pain regimen in patients who are having an initial poor response to narcotics and anxiolytic agents.[90] In patients who are intubated and are being maintained on mechanical ventilation, the two commonly used regimens are the continuous administration of intravenous morphine and diazepam or propofol and fentanyl to achieve pain control and sedation and prevent unplanned extubation. In the postoperative care of patients having skin graft procedures, the most painful wound is often not the burn wound but the donor site. Jellish et al.[91] have reported that the treatment of the skin graft harvest site with local anesthetic agents significantly improved the patient's pain score postoperatively. Patient-controlled analgesia is also a very effective strategy in patients who understand and can manipulate the delivery system. An important factor leading to effective pain control is to have established protocols that all members of the team understand and can use safely. There must be flexibility in the medication regimen and the patients must be fully informed that every attempt will be made to provide them the greatest comfort within the context of safe and compassionate care.

Neurological Deficits

Immediately following burn injury, the patient with an altered mental status needs to undergo a careful evaluation for injuries occurring during and prior to the time of the fire. Additionally, the patient's preinjury neurological status needs to be determined for any prior impairment. In patients who are obtunded, the primary concern is central nervous system (CNS) injury due to hypoxia and carbon monoxide poisoning. The use of alcohol or drugs in the time leading up to the burn injury can confound the assessment of the burn-injured victim. Testing for alcohol and drugs aids in the evaluation of such patients.[92] This is particularly important since the impact of alcohol appears to substantially modify the patient's chance for survival. The patient, particularly an elderly patient, should also be evaluated for a primary CNS event that might have precipitated their injury such as a seizure, stroke, or intracranial hemorrhage. The possibly of an assault must always be foremost in one's thoughts particularly in children when the history of the injury does not match the findings. It is not uncommon to find that a burn is a signal finding for child abuse.[93] This can also be the case in adults where the initial event was an assault and the burn is an attempt to disguise the physical attack.

Patients presenting with agitation must be rapidly evaluated for hypoxia and treated. The initial management of a patient who has a deteriorating mental status is a review of the medications and medication doses that have been administered to determine whether reversal agents should be given. In the treatment of children, the doses should be age and weight appropriate and carefully titrated to the patient's need. Later in the course of a burn patient's care, changes in mental status require a detailed review of medications for pain and sedation, measurement of serum electrolyte values particularly sodium, and evaluation for a septic process and the onset of renal or hepatic failure. Patients with impaired mental status either early or late must always be assessed for the status of their airway, their ability to maintain a patent airway, and the need for tracheal intubation.

Gastrointestinal Responses and Complications

Impaired GI motility and focal gastric mucosal ischemia occur in virtually all patients with burns involving more than 25% of the total body surface with the severity of change proportional to the extent of the burn.[94] The resulting ileus necessitates nasogastric intubation to prevent emesis and aspiration. If the mucosa is unprotected by instillation of antacid or treatment with an H_2 histamine receptor antagonist, ischemic erosions in the mucosa may progress to frank ulceration with associated bleeding or even perforation. Sufficient antacid (typically 30 mL but 60 mL may be needed) should be instilled each hour to maintain the pH of the gastric contents above 5. At the present, a histamine H_2 receptor antagonist (e.g., 400 mg of cimetidine given intravenously every 4 hours) or proton pump inhibitors are more commonly used for stress ulcer prophylaxis. When GI motility returns, enteral feeding should be initiated and the antacid therapy, for example, a 1,200–2,400 mg daily dose of cimetidine, can be added to enteral feeds. A randomized study comparing antacid prophylaxis and nonacid buffering sucralfate prophylaxis showed no difference in recovery of gram-negative organisms from the upper GI tract, and no difference in the occurrence of gram-negative pneumonia, but lesser gastric mucosal protection and a higher incidence of gram positive pneumonia in the sucralfate-treated group.[95]

WOUND CARE

Initial Wound Care

Initial wound care is focused on preventing further injury. Immediately upon removal of the burn victim from the site of injury, attention should be given to removal of burning clothing, disrupting contact with metal objects that may retain heat, and cooling of any molten materials adherent to the skin surface. Attempted cooling of burn wounds must be done with caution as local vasoconstriction can impair wound blood flow and extend the depth of the injury. The use of surface cooling of the burn is limited to patients with small burns typically not requiring hospitalization. Hypothermia can rapidly occur in children as well as adults particularly elderly patients if they are placed in cool or wet dressings. Patients being prepared for transport or admitted for definitive care should be placed in sterile or clean dry dressings and be kept warm. Prolonged exposure of the burn victim's wounds leads to cooling and further impairs the patient's response to their injury. Items of clothing or jewelry that may impair circulation should be removed prior to the onset of burn wound edema to prevent further compromise of the circulation. In cases of chemical injury, removal of contaminated clothing and copious water lavage of liquid chemicals and removal by brushing of powdered materials at the scene can limit the extent of the resultant burn injury. The ability to perform these maneuvers at the scene must be balanced against the patient's associated injuries that would mandate immediate transport for the care of life threatening injuries. No attempt should be made at chemical neutralization of the suspected chemical agent as such treatment would result in an exothermic reaction and cause additional tissue damage. The care provider must exercise extreme caution when working with victims of chemical injury to prevent self-contamination and personal injury. In all

circumstances, those individuals caring for burn patients should wear personal protection devices. After admission to the hospital and as soon as resuscitative measures have been instituted, the patient should be bathed and the burn wounds cleansed with a detergent disinfectant. Chlorhexidine gluconate is a cleansing agent with an excellent antimicrobial spectrum.

During cleansing of the wound, the patient must not be allowed to become hypothermic. The treatment area and the cleansing fluids should be warm and the procedure should be done expeditiously. Materials that are densely adherent to the wound such as wax, tar, plastic, and metal should be gently removed or allowed to separate during the course of subsequent dressing changes. Sloughing skin, devitalized tissue, and ruptured blisters should be gently trimmed from the wound. No formal attempt is made to remove the burned tissue during these wound-dressing debridements. Patients may experience considerable pain and apprehension during these dressing changes and should receive adequate pain medication. In the patient on whom blisters are present, whether to remove them or allow them to remain is a matter of opinion. Blisters that are intact, particularly thick blisters on the palm of a hand maybe left intact.[96] Intact blisters must be closely monitored for signs of infection or rupture at which time they should be debrided and the wound treated. If a blister can be kept intact wound healing should be complete in <3 weeks. The notion that intact blisters are an effective biologic dressing has been called into question and some authors recommend removing all blisters and treating the burn as an open wound.[21] Careful wound cleansing should be done at each dressing change with serial debridement of devitalized tissue performed as necessary. The wound should be monitored for signs of infection and change in depth from the initial assessment. It is not uncommon for the initial wound depth to have been underestimated in children and young women. Additionally, the extent of body surface involvement should be recalculated to ensure that the initial burn size determination was accurate.

Topical Antimicrobial Therapy

The burn injury sets in progress a series of events leading to impaired local and systemic immunity. The damaged skin surface can serve as the portal for microbial invasion if it becomes progressively colonized. As microbial numbers increase within the wound to levels of 100,000 organisms per gram of tissue, an invasive wound infection and ultimately systemic sepsis may occur. Topically applied antimicrobial agents, which penetrate the burn eschar, are capable of achieving sufficient levels to control microbial proliferation within the wound. Systemic antibiotics do not achieve sufficiently high concentrations in the wound to achieve therapeutic levels, as the eschar is in large part avascular. These concepts form the basis for the use of topical antimicrobial agents in the prophylactic treatment of the burn wound and as a part of the management of burn wound infections.[97] Topical agents per se do not heal the wound but prevent local burn wound infection from destroying viable tissue in wounds capable of spontaneous healing. In burns that will require excision and grafting, control of the burn wound microbial density prevents the development of systemic sepsis secondary to invasive burn wound infection. The utility of topical agents is most clearly apparent in improving patient outcome in burns of >30% TBSA. The need for the use of topical antimicrobial compounds in the management of small burns has never been demonstrated and these injuries can be effectively managed with a petroleum-based dressing.[98-101] That being said, it has become common practice to apply topical antimicrobial agents to even small burn wounds despite the fact that there are no data to support this approach. Topical antimicrobial burn wound agents include cream, ointment, and liquid based products that require daily to twice daily dressing changes and reapplication. Also available are materials impregnated with antimicrobial compounds that typically are changed following a several day period of application.

Silver sulfadiazine, the most widely used agent, is available as a 1% suspension in a water-soluble micronized cream base. The cream is easily applied, causes little or no pain on application, and can be used open or as a closed dressing. As a closed dressing, the cream can be directly applied to the wound as a continuous layer, then covered over with a dressing or be impregnated into the dressing, which is then applied to the wound. At each dressing change, the cream should be totally removed and not allowed to form a caseous layer that will obscure the wound bed. When silver sulfadiazine is used in the management of superficial partial thickness burns, the dressing becomes discolored, the wound exudate appears infected, and the wound develops a yellow-gray pseudoeschar that is easily removed. The ability of silver sulfadiazine to penetrate an eschar and prevent wound infectious complication in burns >40%-50% TBSA is thought to be poor. However, wound cleansing with chlorhexidine as a part of the wound management along with silver sulfadiazine has proven to be a very effective combination in patients with larger burns. The most common toxic side effect of silver sulfadiazine is a transient leukopenia, which when it does occur in up to 15% of treated patients, resolves spontaneously without discontinuation of the drug.[102] The proposed mechanisms for this response have ranged from leukocyte margination in the wound (not drug related) to a direct cytotoxic effect of the drug on the bone marrow granulocyte and macrophage progenitor cells.[103] Silver sulfadiazine is active against a wide range of microbes including *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella* species, many but not all *Pseudomonas aeruginosa*, *Proteus* species, and *Candida albicans*.

Mafenide acetate was one of the first effective topical agents introduced for the management of the burn wound. It was initially available as Sulfamylon burn cream (an 11.1% suspension in a vanishing cream base). It is commonly used on exposed wounds treated by the open technique though it is possible to use it under a light dressing. Mafenide acetate is highly effective against gram-positive and gram-negative organisms, but provides little antifungal activity.[104] Mafenide acetate readily diffuses into the eschar and is the agent of choice for major burns of the ears because it is also capable of penetrating cartilage. Drawbacks with the use of mafenide acetate include pain on application to partial thickness burns, and limited activity against methicillin-resistant S. *aureus*. Mafenide acetate also inhibits carbonic anhydrase, which increases urinary loss of bicarbonate, which may cause hyperchloremic acidosis and accentuate postburn hyperventilation. Fortunately, this affect is time limited because the kidney typically escapes from such inhibition in 8–10 days. Mafenide acetate has more recently become available as a 5% aqueous solution and is an excellent agent to use on freshly grafted wounds and is not associated with the problems found with the cream formulation.

Silver nitrate as a 0.5% solution has also been available since the 1960s and is effective against gram-positive and gram-negative organisms. The silver moiety is deposited on the burn wound and does not penetrate the eschar to any great extent. Silver nitrate soak solution leaches sodium, potassium, chloride, and calcium from the wound in association with transeschar water absorption, which can result in mineral deficits, alkalosis, and water loading. Those side effects can be minimized by giving sodium and other mineral supplements and modifying fluid therapy. These problems and the labor required to use silver nitrate effectively limit its routine use currently and most see silver sulfadiazine as a highly acceptable alternative.

Silver impregnated dressings consisting of a polyethylene mesh coated with a nanocyrstalline film of pure silver ions

bonded to a flexible rayon-polyester sheet have recently become available for clinical use.[105] When the fabric base is in contact with wound fluids, the silver is released continuously to maintain a silver concentration of 50–100 mg/L on the wound for up to 48 hours. The treatment interval with such a composite may extend up to several days depending on the fabrication design with dressing changes needed only once or twice per week. On the basis of a multicenter randomized controlled trial it was concluded that Acticoat has better antimicrobial activity and fewer adverse effects than topical silver sulfadiazine, and reduces healing times.[106] The investigators considered the ease of application and low frequency of change to make Acticoat an ideal dressing for burn wounds. However, one must know that the wound has not become compromised during extended periods between reapplication. It is not advisable to use this approach in the care of perineal wounds particularly in small children with frequent bowel movements or wounds with excessive drainage or difficulty in maintaining contact between the dressing and the burn wound surface. The effectiveness of this membrane in treating extensive full thickness burns is unconfirmed and at present it is used to treat partial thickness burns.

In superficial partial thickness burns, the use of bacitracin ointment represents a satisfactory alternative particularly in patients with a known sulfa allergy. It may be used open especially with superficial facial burns or as a component of a closed dressing. Other topical agents include antibiotic combinations such as triple antibiotic ointment (neomycin, bacitracin zinc, and polymyxin B) and polysporin (bacitracin zinc and polymyxin B). In the case of methicillin-resistant staphylococci, mupirocin represents a useful agent.[107] These agents are also capable of being used with open or closed dressing techniques.

The application of topical antimicrobial agents to the burns of patients who will be transferred to a burn center may preclude the use of biological membrane dressings that will adhere to the wound surface to be effective. Additionally, upon admission to a burn center, any previously placed dressing will be removed to permit the burn team to make a precise assessment of the extent of the burn and the depth of injury. In addition to burn wound evaluation, the burned child must be inspected for any signs of abuse, which includes a detailed examination of the entire skin surface. Unless there will be an extended period of time before patient transfer to a burn center, placing the patient in a dry dressing, particularly if it is one with a nonadherent lining, and keeping the patient warm is the preferred initial management.

The sterile gloved hand is used to apply the burn cream of choice in a thickness sufficient to obscure the surface of the burn (Fig. 32.7). The wounds are then either left exposed or covered by a light occlusive dressing. Twelve hours later, the topical agent is reapplied to the entire burn wound. If a dressing is used over the topical agent, it is removed prior to reapplication of the topical agent following which a new dressing is applied. To optimize antimicrobial coverage and minimize side effects, one can alternate topical agents, that is, apply Sulfamylon burn cream after the morning cleansing and apply Silvadene burn cream in the evening.[108] If 0.5% silver nitrate soaks are used for topical wound care (as may be necessary in a patient allergic to sulfonamides), they should be changed two or three times a day and kept moist between changes by infusing additional soak solution every 2 hours. All environmental surfaces and equipment as well as the clothing and exposed skin of attending personnel must be protected from contact with the silver nitrate solution, which will cause dark brown discoloration of virtually anything with which it comes in contact.

Each day the topical agent is totally removed in the course of the daily cleansing and the entirety of the burn wound is examined to detect any signs of infection. If signs of infection are identified, a biopsy of the eschar and the underlying viable tissue should be obtained from the area of the wound

FIGURE 32.7. Following the initial cleansing and debridement, the burn wounds are covered with a topical antimicrobial burn cream as shown here. The topical agent is reapplied 12 hours later. The wounds are cleansed each day and thoroughly examined to identify signs of burn wound infection and if no such signs are evident the burn cream is reapplied.

suspected of harboring infection (Fig. 32.8). The biopsy sample is subjected to histologic examination and should also be cultured to determine predominant organisms. Histologic confirmation of invasive infection (the presence of bacteria or fungi in viable tissue underlying or adjacent to the burned tissue) necessitates a change to Sulfamylon burn cream topical therapy (mafenide acetate can diffuse into nonviable tissue to limit microbial proliferation), subeschar antibiotic infusion, physiologic fine tuning of the patient, and prompt surgical excision of the infected tissue.[109]

FIGURE 32.8. The dark brown areas in the leg burns of this child were sites of bacterial invasion. The smaller foci of black/red discoloration in unburned tissue at and near the periphery of the leg burns were ecthyma gangrenosa, which are pathognomonic of hematogenous spread of invasive Pseudomonas burn wound infection as confirmed by histologic examination of tissue biopsied from one of the lesions.

Burn Wound Excision and Grafting

Topical antimicrobial chemotherapy is typically employed to control microbial density on and in the burned tissue prior to excision with emphasis placed on early excision that is now considered to be optimum management of full thickness burns and those of mixed depth. If the patient is otherwise stable, burn wound excision can be carried out within a matter of hours postinjury. In the patient with a small burn, delay is often related to scheduling of the operating room and the surgical team. Timely excision for the patient with a small burn reduces the period of disability and the overall cost of the injury. In patients with a large burn wound, the timing and extent of the surgery is based on the patient's relative physiologic stability and his capacity to undergo a major operative procedure. Early burn wound excision and closure in patients with large wounds shortens the length of hospitalization, reduces cost, and favorably impacts overall burn mortality.[110,111] The presence of the burn wound is the primary stimulus for the ongoing problems facing the burn patient. Closure of the burn serves to ameliorate much of the postburn pathophysiology and is one of the most effective means by which to improve a burn patient's outcome. Wounds that are capable of spontaneous closure within two to three weeks postinjury can be managed expectantly provided the cosmetic and functional outcomes will be acceptable.

Wounds that are small in size or linear in shape can be managed by excision of the burn and primary wound closure. This is of use in burns of the upper inner arm in the elderly, localized burns of a pendulous breast, abdominal burns, buttock injuries, and thigh burns. Primary wound closure can also be achieved in some wounds with local tissue transfer techniques. This approach works quite well when these wounds are excised early before substantial microbial colonization of the wound occurs. In such cases, the burn is transformed into a healing surgical incision and creation of a skin graft donor site is avoided.

In selected cases, the injury may be of such a nature that amputation of the burned part is the most appropriate plan. In the patient with considerable multisystem trauma, the expeditious removal of the burn injury might be seen as the best option for the patient's overall survival. In a recent report, Santaniello et al.[112] found that the mortality in trauma victims with significant burn injuries and trauma was 28.3%, whereas in patients with burns only it was 9.8% and in patients with trauma only it was 4.3%. The management of these challenging patients requires a coordinated well-conceived plan of care that accounts for all of the patient's injuries and integrates the treatment needs of each injury to achieve an overall satisfactory outcome. A mangled extremity, which has also suffered a severe burn that is deemed nonsalvageable, should undergo early amputation. It is not necessary to extend the amputation to a level that allows closure with unburned tissue. If viable muscle is available to close the amputation site, that wound bed can be resurfaced with an autogenous skin graft. A grafted amputation site can, with a modern prosthesis, function as a durable stump. In a patient who is paraplegic and suffers an extensive deep lower extremity burn injury, amputation can be a viable alternative to excision and grafting.

A similar option may need to be considered for the patient in whom substantial preexisting peripheral vascular disease makes the likelihood of a healed and functional extremity highly unlikely. This unfortunately has become an all too frequent occurrence in the care of elderly burn patients who have progressive complications from long standing diabetes mellitus. The amputation level should be that which will maintain maximum function. This might be a transmetatarsal or Chopart-type amputation in patients with injuries of the distal foot. In patients confined to a wheel chair who have injuries to the leg, a through-knee amputation as opposed to an above-knee amputation provides a weight-bearing platform for sitting. In the patient in whom the initial insult represents a deep composite injury, repeated failed attempts at salvage are not in the patient's ultimate best interest. Such wounds often become infected and tissue that could have been preserved now must in the end be sacrificed with the functional end result less than that which would have occurred with early amputation.

Excision and grafting will be required for wounds not amenable to primary closure. The extent of the procedure that a patient can undergo is related to the patient's age, physiologic status, and skill of the operating team. A 17% surface area burn should be a universally survivable injury in 17-year-old patient while in patients in the eighth decade of life the mortality can easily be 50%. An otherwise healthy individual with available donor sites can well tolerate a 20%-25% total body burn excision and autografting in one procedure. Implicit in this approach is the use of experienced operating teams, an anesthesiologist who thoroughly understands the unique problems of the patient with a major body surface area burn, and an operating room fully equipped to treat such a patient, as well as ready availability of blood products and the capacity to care for the patient postoperatively. A patient having this extent of surgery in essence undergoes a doubling of the surface area of "injury"—the now excised and grafted wound along with the partial thickness wound produced by the donor site. In patients with wounds of a larger size (>30% TBSA) or those who cannot tolerate a single procedure to achieve closure, staged excision of burned tissue is performed and the resulting wounds are closed with available cutaneous autografts or a biologic dressing.[113]

The technique of burn wound excision is based on the depth of the wound and anatomic site to be excised. Excision of deep partial thickness wounds to the level of a uniformly viable bed of deep dermis, by the tangential technique pioneered by Janzekovic, and immediate coverage with cutaneous autograft results in rapid wound closure with a typically excellent result.[114] This can be done with an unguarded Weck knife, a Goulian/Weck guarded knife, a hand held dermatome or by using a powered dermatome set at 0.0016–0.0030 of an inch depending on the area to be excised and the age and gender of the patient. Optimally, the desired wound bed is achieved in one pass of the knife as evidenced by diffuse bleeding. If that end point is not realized another pass of the knife will be needed. A frequent error is attempting this technique in wounds of an inappropriate depth and assuming that punctate bleeding indicates a viable bed. Such wounds will heal with a poor take of the grafted skin as the bed contains marginally viable tissue incapable of supporting the cutaneous autograft. These wounds at the initial graft dressing change may appear to be doing well only to fail at 5–10 days postoperatively. Tangential excision as originally reported, was employed early in the first week postburn, however, it can be successfully applied any time to a wound that is not infected or heavily colonized. During the performance of this procedure, the amount of blood loss can be minimized with the use of a tourniquet on extremity burns or subeschar clysis containing epinephrine or ornithine vasopressin. The decision that the depth of the excision is satisfactory with these adjuncts will be based primarily on the appearance of the wound, an appreciation of which most experienced burn surgeons have had to learn to some degree through trial and error. High-pressure hydrosurgical devices are also available to excise burned tissue but are considered by some to be associated with greater blood loss and the sacrifice of more viable tissue.

A modification of tangential excision is wound excision via layered escharectomy. Using this technique, the wound

is sequentially excised to a viable bed of subcutaneous tissue and elements of deep dermis particularly at the wound margin. This allows relative preservation of body part contour, a graft with ultimately more pliability, decreased limb edema, and a cosmetically more acceptable transition at the juncture of the grafted wound with the unburned skin of the wound margins.

An alternative to layered excision is to excise the wound with a scalpel or electrocautery. Using knife excision, the wound is excised to the muscle fascia or to viable deep subcutaneous tissue. As bleeding can be substantial with such procedures, the excision and control of bleeding must be done efficiently. The use of electrocautery to perform the dissection limits the blood loss without compromising the recipient graft site. Imperative with electrocautery excision into the deep fat is avoidance and limitation of thermal injury to the wound bed, which will compromise the "take" of the applied skin graft. The use of the cutting mode with rapid dissection is necessary. In cases where excision to fascia has been performed, the viability of the fascia should be assessed. The surgeon must determine if the fascia requires removal and the underlying muscle used as the graft bed. In the performance of fascial excisions, caution should be exercised during the dissection to avoid entrance into a joint or bursa and injury of extensor tendons in the hand or the Achilles' tendon at the ankle.

The blood loss occurring with burn wound excision is related to the time of excision postburn, the area to be excised, the presence of infection, and type of excision, that is, fascial or tangential. Donor sites can also represent a considerable portion of the blood loss. The use of the scalp or previously harvested donor sites is associated with increased bleeding. The quantity of blood loss has been estimated to range from 0.45 to 1.25-mL/cm^2 burn area excised.[115] Adjunctive measures that can be used to control blood loss include elevation of limbs undergoing excision, applications of topical thrombin and/or vasoconstrictive agents in solutions to the excised wound and donor site, clysis of skin graft harvest sites and/or the eschar prior to removal, and application of tourniquets. Spray application of fibrin sealant can also reduce bleeding from the excised wound after release of the tourniquet. Blood loss will be compounded if the patient has become coagulopathic, hypothermic or acidotic during the procedure. Perioperative cold stress, which may induce hypothermia, can be reduced by maintaining the temperature of the operating room between 30°C and 32°C and by using warmed fluids for wound irrigation. Oda et al.[116] have emphasized the importance of maintaining a warm operating room environment and limiting the duration of excision and other procedures to prevent hypothermia in patients with extensive burns. In 16 patients with extensive burns, pulmonary compromise characterized by a significant decrease in the PaO$_2$/FIO$_2$ ratio in association with an increase in neutrophils in bronchoalveolar lavage fluid occurred if body temperature decreased more than 1°C during the operation. The authors concluded that hypothermia during surgery showed little correlation with blood loss, transfusion, or duration of surgery alone but was significantly correlated with the development of acute lung injury.

The harvest, application, and postoperative care of split thickness skin grafts and skin graft donor sites are the same as for any other surgical patient. A silver containing hydrofiber gel sheet has recently been evaluated as a dressing for split thickness skin graft donor sites.[117] When applied to donor sites, either under a gauze dressing or a transparent film, the hydrofiber dressing was assessed to have the advantages of ease of application, management of drainage, and removal; reduction in donor site pain; and the ability to remain in place for up to 5 days. Grafting of the burn wound is usually done at the time of excision, but the surgeon must be aware of the patient's status throughout the surgical procedure and if necessary reassess the extent of the planned procedure. There will be instances where it will be best to perform the excision only and stage the timing of skin graft application. Additionally, if the wound bed is suspect as to its viability then only excision should be performed. The wound can be dressed with a 5% Sulfamylon solution dressing or covered with allograft skin or any of several biologic dressings and subsequently reevaluated. The use of cutaneous allografts is a very useful approach when excising facial burns where the goal is to preserve all possible elements and perform the definitive grafting procedure on a "tested" recipient bed. In cases where an infected wound is being excised, no attempt at placing autograft skin should be considered until the infection has been resolved following treatment with topical and systemic antimicrobial agents as determined by culture results and inspection of the wound.

The choice of the donor site in the performance of a cutaneous autograft will in some patients be limited to those skin sites that have not been injured with burns. When there is a choice of donor sites, the requirements of the recipient site and the potential for donor site morbidity should be factored into selecting the site of graft harvest. In the grafting of facial burns, color match is an important consideration and obtaining a graft from a site above the clavicles or the inner aspect of the thigh will provide the best result. In children, harvest of a graft from the scalp results in a donor site that is not particularly painful postoperatively and has no long-term cosmetic consequences. The harvest of grafts from posterior body surfaces provides, in general, a more acceptable wound for most patients. While the anterior thigh is an often-selected site, it can heal with considerable hypertrophic change and cause a patient more problems and distress than the grafted burn.

The use of sheets of autograft skin for resurfacing the burn represents the gold standard. This is the only acceptable approach for burns of the face and neck and the best choice in grafting of the hands and breast. Every attempt should be made to use such autografts in children, since they provide the best long-term results. It may not be possible to achieve these objectives in patients with extensive burns or those in whom the pattern and location of the injury limits donor site availability. The use of meshed cutaneous autografts allows the surgeon to increase the area covered. Skin graft meshing devices of various design and manufacture are available with expansion ratios from 1:1 to 1:9. The wider the mesh the greater the wound area covered, however, it will take the wound longer to close by ingrowth from the margins of the mesh reticulum to fill the open interstices during which time there is the very real potential for graft loss and wound infection to occur. Additionally, widely meshed autografts have a greater propensity to form hypertrophic burn scars, and may provide a skin surface with unsatisfactory mechanical stability, inadequate pliability, permanently poor cosmetic appearance, and restricted joint mobility. Despite these potential limitations, the use of meshed cutaneous autografts is an important strategy and potentially lifesaving approach in patients with extensive body surface area burns.

The technique of skin graft harvesting would seem a relatively simple procedure, yet it is often not done well. As noted above, the harvest site should be the one that will yield a graft with the desirable characteristics and the least donor site morbidity. Grafts should be of sufficient size to achieve wound closure with a minimum of intergraft seams. Powered dermatomes are available with up to 6 inch cutting widths that provide excellent sheets of skin for facial grafts or when meshed can cover a major burn area. Donor site preparation is essential to obtain a uniform graft. Powered clysis can rapidly be accomplished over an extensive harvest site using an air

powered surgical wound irrigating system equipped with a 14 or 16 gauge needle attached to 3 L bags of normal saline. This provides a stable uniform surface for graft harvest and limits the difficulties encountered when harvesting over contoured surfaces or bony prominences. The thickness of the harvested graft should be related to the site to be grafted, whether the graft is to be meshed, the mesh ratio, and to some degree surgeon preference. The desired thickness of the graft also influences donor site selection, that is, a "thick" graft should be harvested from an area of "thick" skin. Harvest of a "thick" graft from an area of "thin" skin, that is, the inner arm, can produce a full thickness wound that will have to be grafted.

Skin grafts through which one can read printed material are primarily epithelial autografts with a minimal amount of dermis (0.004–0.006 inch) while those, which are more opaque contain a variably greater amount of dermis (0.008–0.012 inch). Thinner grafts yield a better donor site and function well on a dermal wound bed but may not do well when placed on a wound excised to fascia. In elderly patients, thin grafts that contain insufficient numbers of keratinocyte progenitor cells are considered the cause of melting graft syndrome and prolong the time of re-epithelization. Thicker grafts are more pliable, heal with less contraction, and will do better than thin grafts when meshed. The thicker grafts may result in donor site scarring and delay in donor site closure especially in the elderly patient.

The harvested graft should be placed on the prepared burn wound parallel to the major flexion creases and can be attached mechanically with staples or sutures or secured with tissue adhesives such as fibrin glue. A properly placed set of grafts on an extremity should at the end of the operation be able to remain in place as the extremity is put through a gentle range of motion. One of the most important aspects of a skin grafting procedure is the application of a proper dressing. A highly successful approach is to use multiple layers of a nonadherent linen dressing moistened with a 5% solution of mafenide acetate applied circumferentially to the excised and grafted wounds on an extremity. A bolster produced by using net dressings drawn tightly over the burn dressings and stapled to the skin is used to "fix" the grafts on torso wounds. Graft failure occurs as a result of inadequate excision, inadequate hemostasis, infection, subgraft seroma formation, mechanical sheering during postoperative care, or rarely, "upside down" application. The first dressing change is typically done 48–72 hours postoperatively. If a sheet graft is well intact at that time, a nonadherent dressing is reapplied to protect the wound. In the case of meshed autografts, the moist dressings of mafenide acetate solution, changed daily or more often as required, are continued until the mesh is closed.

To increase graft conformity to wound base, remove exudate, and to reduce shearing, topical negative pressure therapy is often used to cover and hold freshly applied split thickness skin grafts in place. Recently, investigators have reported that topical negative pressure dressings reduce shearing forces, restrict seroma and hematoma formation, simplify wound care, and improve patient tolerance.[118] Contrary to the speculation of others, those investigators could identify no major beneficial effects of topical negative pressure dressings on the rate of neovascularization of skin grafts.

Skin Substitutes

While split thickness cutaneous autografts are the usual method of wound closure there is often the need for a skin substitute. Alternative wound coverings are used to achieve wound closure when the available donor surface area is not sufficient, there is a need to test the wound bed, or for primary management of selected partial thickness wounds. The goal with a skin substitute is to obtain temporary physiologic wound closure and protect the wound from microbial invasion. Although a wide variety of skin substitutes have been developed and evaluated to replace the epidermis, the dermis, or the epidermis and dermis together, all currently available skin substitutes except for cultured autologous keratinocytes, must be considered temporary with autografting required for definitive wound closure.[119]

The two most commonly used naturally occurring biologic dressings are human cutaneous allograft and porcine cutaneous xenograft. Human allograft skin is commercially available as split-thickness grafts in either fresh viable or cryopreserved form. Both of these preparations are capable of becoming vascularized, however, this best occurs with fresh allograft skin. Allograft skin can provide wound coverage for 3–4 weeks before rejection.[120] Porcine xenograft tissue is available as reconstituted sheets of meshed porcine dermis or as fresh or frozen split-thickness skin. Porcine skin impregnated with silver ions to suppress wound colonization is also available. Xenograft skin can be used to cover partial thickness injuries or donor sites, which reepithelialize beneath the xenograft.[121] Using a murine model of burn injury, Wang et al. found that transgenic expression of cytotoxic T-lymphocyte—Associated Antigen4-immunoglobulin (CTLA4Ig) increased xenogeneic skin graft survival almost twofold without inducing systemic immunosuppression.[122] Such tissue may represent a readily available source of extended survival skin grafts for use in patients with massive burns. Similarly, nanofiber patches containing poly-n-acetyl glucosamine have been reported to accelerate closure of a murine model full thickness skin wound in association with an increase of cell proliferation and vascularity in granulation tissue.[123] This treatment was also credited with hemostatic action by virtue of platelet activation and vasoconstrictive properties all of which suggest usefulness in the treatment of complicated wounds.

Various synthetic membranes have been developed that provide wound protection and possess vapor and bacterial barrier properties. Biobrane (Dow-Hickham, Sugarland, Texas), is one such product that has been used in the management of partial thickness and donor site wounds.[124] This bilaminate membrane consists of a collagen gel adherent to a nylon mesh as the dermal analog to promote fibrovascular ingrowth and a thin outer silastic film as the epidermal analog to provide barrier properties. Biobrane has also been used as the scaffold for the growth of allogenic fibroblasts that secrete, while in culture, various growth factors along with other mediators. The fibroblasts are then removed by freezing to complete preparation of the membrane. These membranes are currently approved for use in fully excised wounds, donor sites, and superficial partial thickness burns.[125] Another collagen-based skin substitute is the dermal replacement developed by Burke and Yannas, presently in use as Integra (Integra LifeScience Corporation, Plainsboro, New Jersey). This membrane consists of an inner layer of collagen fibrils with added glycosaminoglycan and an outer barrier membrane of polysiloxane. It is placed over freshly excised full-thickness wounds and once fully vascularized, the epidermal analog is removed, and the vascularized "neodermis" is covered with a thin split thickness cutaneous autograft.[126]

StrataGraft skin tissue is another skin substitute that has a dermal equivalent populated with human dermal fibroblasts and a stratified biologically active epidermis derived from a pathogen free, long-lived, human keratinocyte progenitor near-diploid immortalized keratinocyte S (NIKS) cells. A comparison of StrataGraft® with cadaveric allograft applied to full thickness wounds for 1 week prior to autografting on 15 patients found there to be no differences in the number of T or B lymphocytes or Langerhans cells present in the grafts after 1 week. In the patients to whom the skin substitute was applied, no proliferation of peripheral blood mononuclear cells to NIKS, no enhancement of cell-mediated lysis of NIKS, *in vitro*, and no antibody generation targeted to NIKS were

observed.[127] The authors concluded that StrataGraft "is well tolerated and not acutely immunogenic in patients…" and proposed it for use "in epidermal development, tissue engineering, and transplant studies" as well as facilitation of the healing of traumatic cutaneous wounds.

A permanent skin substitute represents a definitive means of wound closure for extensively burned patients. Presently, cultured epithelial autografts are commercially available but have been limited in use because of suboptimal graft take, fragility of the skin surface, and high cost.[128] Sood et al.[129] recently reported, on the basis of a retrospective review of the use of cultured epithelial autografts placed on an allodermis base, that take of the cultured autografts at 7 and 21 days was 72% and 67%, respectively. Those investigators concluded that when applied to an allodermis base, cultured epithelial autografts are useful in the treatment of extensive burn wounds.

New directions in the development of cultured epithelial autografts include the production of chimeric allogeneic-autologous cultured epithelium, the use of keratinocyte suspensions, and the application of low amperage direct current to allodermal/autoepidermal composite grafts as well as the development of culture-derived bilaminate membranes. Black et al have identified what they consider to be a neovascular network to form in a tissue-engineered skin equivalent in which keratinocytes, fibroblasts, and umbilical vein endothelial cells were cocultured in a collagen biopolymer.[130] Development of an autogenous vascular system in such a skin equivalent would permit inosculation to establish prompt vascularization by the host and achieve permanent adherence.

Sheng et al. have reported that bone marrow mesenchymal stem cells can be induced to acquire the phenotype of sweat gland cells. Implantation of such cells into anhydrotic areas of scars of healed, deep burn injury in five patients was reported to restore perspiration function in the transplanted areas. Histologic and biochemical studies confirmed that the transformed cells were involved in the recovery of functional sweat glands that produced sweat similar to that produced in areas of normal skin.[131] Confirmation of these findings offers the possibility of improved thermoregulation in patients who survive extensive thermal injury. Luo et al.[132] have assessed the ability of mesenchymal stem cells from human umbilical cord blood to promote cutaneous wound healing in an animal model of burn injury. Such cells differentiated into keratinocytes in the wound tissues and enhanced the healing of the burn wounds. The authors noted that mesenchymal stem cells can be isolated and proliferated but the need for human umbilical blood may limit subsequent clinical applicability.

Use of any biologic dressing requires that the excised wound and the dressing that has been applied be meticulously examined on at least a daily basis. Submembrane suppuration or the development of infection necessitates removal of the dressing, cleansing of the wound with a surgical detergent disinfectant solution, and even reexcision of the wound if residual nonviable or infected tissue is present. Following such

wound care, a biologic dressing can again be applied and if it remains adherent and intact for 48–72 hours without suppuration, that biologic dressing can be removed and the wound closed definitively with cutaneous autografts.

The proper management of the patient's burn wounds is critical to achieve the optimum cosmetic and functional outcome and the timely return of the patient to full activity. In patients with major burns, the wound must be properly cared for and closure achieved expeditiously to lessen the level of physiologic disruption that accompanies a major burn. Failure to do so can result in invasive wound infection, chronic inflammation, erosion of lean body mass, scar formation, progressive functional deficits, and even death. As more patients with extensive burns survive, scar formation that impairs joint motion or limb function or causes disfigurement has become of greater concern. Recent studies of keloid scars have assessed the role of proteoglycans in the scaring process. Tissue from keloid scars was characterized by increased expression of syndecan-2 and fibroblast growth factor-2, and downregulation of decorin.[133] Decorin decreased extracellular matrix protein production and that action as well as its antifibrotic effect suggests therapeutic potential to ameliorate scaring.

Similarly, increased survival of extensively burned patients has focused attention on other outcomes such as the incidence of posttraumatic stress disorder (PTSD). A recent study has identified the fact that the incidence of PTSD is similar in military burn patients from the current conflicts in Iraq and Afghanistan and in civilian burn patients.[134] In both groups, the extent of burn and severity of injury but not age were significantly associated with PTSD. Earlier studies of burned children identifying an association between acute stress (ASD) and PTSD prompted a study to evaluate the effect of propranolol on the incidence of ASD.[135] A diagnosis of ASD was made in only 22 of 363 acutely burned children who had participated in a randomized trial of propranolol for control of postburn hypermetabolism. The incidence of ASD was found to be indifferent to propranolol, a result credited to "aggressive" treatment of anxiety and pain with opiates and benzodiazepines which appears to have decreased the incidence of ASD and reduced the incidence of the PTSD in burned children.

Effective topical antimicrobial therapy and early burn wound excision have considerably reduced the incidence of invasive bacterial infections. In a recent multiyear period, only 2.3% of patients treated at the U.S. Army Burn Center developed invasive burn wound infection but 72% of the 90 invasive infections that occurred in 3,876 patients were caused by opportunistic fungi (Fig. 32.9). Of the 90 patients who developed invasive burn wound infections, 55% or 61% expired. The most common nonbacterial opportunists recovered from burn patients are *Candida* species. Compared to the filamentous fungi, *Candida* sp. seldom invade but may be recovered from the blood of patients with multiple sites of colonization, extensive burns, prolonged hospital and ICU stay, multiple operative procedures, and receipt of total parenteral nutrition. A mortality of 15% has been attributed to candidemia
FIGURE 32.9. A: The rapid centrifugal spread of the necrosis in the scalp burn of this patient was caused by invasive mucormycosis. **B:** The extent of excision required to remove all the infected tissue encompassed the edematous tissue shown in "A" and produced a wound, which could be closed with split thickness skin grafts as shown in "C".

with early empirical antifungal therapy recommended for burn patients with multiple site colonization.[136] A review of patients treated at the U.S. Army Burn Center who developed infections caused by filamentous fungi has identified a comorbid effect equal to that of an additional body surface area burn injury of 33%.[137]

The immunosuppression induced by burn injury also renders extensively burned patients susceptible to systemic viral infections typically caused by herpes simplex viruses and cytomegalovirus. A recent retrospective review of autopsy reports of 97 burn patients attributed death to bacterial infection in 27 and viral infection in 5.[138] In the patients in whom death was attributed to bacterial infection, the predominant organisms were *P. aeruginosa*, *E. coli*, *Klebsiella pneumoniae*, and *S. aureus*. The principal sites of infection were the blood stream in 50%, lungs in 44%, and the wound in only 6%. In two-thirds of those patients, the time of death was 21 or less days. The viral infections uniformly arose in the lower respiratory track and the time of death was often later ranging from 4 to 42 days. The herpes infections have typically been caused by HSV1 but recently a fulminant and fatal HSV-2 infection with pneumonitis and hepatitis has been reported in a patient with a 68% TBSA full thickness burn.[139]

TREATMENT OF SPECIAL THERMAL INJURIES

Electric Injury

The principal mechanism by which electricity damages tissue is by conversion to thermal energy. Currents of 1,000 V and above are classified as high voltage. Upon contact with such currents, the body acts as a volume conductor with small differences in conductivity among tissues of little consequence. At contact points where current density is greatest, tissue charring may limit current flow but at very high voltages current flow persists until the contact is interrupted. The electric current may induce cardiac and/or respiratory arrest necessitating cardiopulmonary resuscitation at the site of injury, on the way to the hospital, and in the emergency department. Arrhythmias may also occur after admission to the hospital necessitating electrocardiogram (EKG) monitoring for at least 24 hours after the last recorded episode of arrhythmia.

Two characteristics of high voltage electric injury increase the incidence of acute renal failure in patients with such injury. First, there may be only a small charred contact site evident with extensive inapparent subcutaneous tissue injury in a limb underlying unburned skin. The limited cutaneous injury may lead to gross underestimation of resuscitation fluid needs. Secondly, the mass of muscle injured by the electric current may liberate large amounts of hemochromogens that may damage the renal tubules. In addition to the electric injury, arcing of the current may ignite the patient's clothing to cause conventional thermal burns. Resuscitation fluids should be based on the extent of burn visible plus the estimated daily needs of the patient and adjusted according to the patient's response. If the urine contains hemochromogens (dark red pigments) fluid should be administered to obtain 75–100 mL of urine per hour with sodium bicarbonate added to the fluids to alkalinize the urine. If the hemochromogens do not clear promptly, or the patient remains oliguric, 25 g of mannitol should be given as a bolus and 12.5 g of mannitol added to each liter of lactated Ringers until the pigment clears. After administration of mannitol, urinary output is no longer an index of resuscitation adequacy and other indices of physiologic well being must be monitored to assess resuscitation status.

When the body functions as a volume conductor, current flow is proportional to the cross-sectional area of the body part involved. Consequently, severe tissue destruction may occur in a limb with relatively small cross section area and relatively little tissue damage occurs as current flows through the trunk. With cessation of current flow, body parts that acted as volume conductors now act as volume radiators with periosseous tissue deep in the limbs being exposed to elevated temperatures for longer periods of time.[140] Damage to the muscle in a limb is often associated with marked increase in the pressure within the compartment containing the damaged muscle which, if unrelieved, may cause further tissue necrosis. A limb muscle compartment that is stony hard to palpation should alert one to the need for surgical exploration. Evidence of extensive deep tissue necrosis, development of a compartment syndrome, and persistent or progressively severe hyperkalemia mandate operative intervention. At the time of exploration, the investing fascia is widely opened and the muscles of the involved limb thoroughly examined including the periosseous muscles of the limb, which can be necrotic yet overlain by more superficial viable muscle (Fig. 32.10). The extent of destruction may necessitate amputation at the time of exploration, particularly if the nonviable muscle is the source of persistent hyperkalemia. If the extent of muscle necrosis in a limb is indefinite, an arteriogram may be helpful. The identification of "pruning" of the intramuscular branches of the arterial tree identifies injured muscle and defines the level of amputation required to encompass the nonviable tissue.[141] Following debridement or amputation, the wound should be dressed open. The patient is returned to the operating room in 24–36 hours for reinspection and further debridement of nonviable tissue if necessary. When all tissue in the wound is viable, it may be closed definitively.

A detailed neurologic examination must be performed on all patients with high voltage electric injury at the time of admission and at scheduled 24–48 hour intervals thereafter. Signs of peripheral nerve and central nervous system impairment may be evident immediately after injury or may appear later. It is uncommon

FIGURE 32.10. High Voltage electric injury caused desiccation and destruction of toes and the distal feet where cross-sectional tissue area was least. Thrombosed vessels are visible in the base of the linear incisions over the metatarsals of each foot. Edema of the pale damaged muscles which underlaid uninjured skin of the legs causes them to bulge above the edges of the fascia at the base of the fasciotomy incisions on the legs. The severity and extent of muscle damage necessitated bilateral below knee amputations.

for a nerve directly injured by electric current to regain function. The immediate functional impairment caused by nondestructive injury to which motor nerves are more sensitive than sensory nerves commonly resolves. Late occurring parasthesias and other polyneuritic symptoms causing deficits in the function of peripheral nerves remote from the sites of electric contact have been attributed to electroporation, the cellular effects of millivoltage electric fields.[142] Immediate neurologic impairments caused by direct nerve damage of the spinal cord more commonly resolve than do spinal cord deficits of later onset. Delayed onset spinal cord dysfunction can range from quadriplegia to localized nerve deficits with signs of ascending paralysis and even an amyotrophic lateral sclerosis-like syndrome.[143]

Remote organ injury is rare in patients with high voltage injury, but intestinal perforation, gall bladder necrosis, and direct liver injury have all been reported. Delayed hemorrhage from medium to large sized vessels has been attributed to electric injury-induced arteritis but inadequate debridement of injured tissue or transmural necrosis of the vessel wall as a consequence of exposure and desiccation appear to be more likely causes.

The formation of cataracts has also been associated with high voltage electric injury, particularly in those patients with a contact site on the head or neck. The patient should be informed that such cataracts may occur, commonly 3 or more years after the injury, but often much sooner. In patients with a head contact site, exfoliative debris may be evident in the anterior chamber of the eye immediately after injury. Such debris is slowly cleared and typically requires no specific treatment.

Tissue damage can also be caused by low voltage house current. Burns of the oral commissure occur in young children who bite electric cords or suck on the end of a live extension cord or an electric outlet. The lesion may have the characteristics of full thickness tissue damage but early surgical debridement may only accentuate the defect and should be avoided. These injuries will usually heal with minimal cosmetic sequelae, which can be addressed electively if needed. In the course of spontaneous healing, labial artery bleeding may occur. The parents should be warned that such bleeding, which can be impressive, may occur and instructed in how to apply manual pressure for temporary control until the vessel can be ligated.

Cardiopulmonary arrest is particularly common in patients struck by lightning and necessitates the immediate institution of cardiopulmonary resuscitation. Subsequent ECG abnormalities are uncommon and signs of acute myocardial damage, though rare, may become evident later. Coma immediately following injury is common, but typically transient. Keraunoparalysis (lightning paralysis) characterized by paresthesias and paralysis typically involving the lower limbs may develop over several days after lightning injury in association with vasomotor disorders.[144] This paralysis typically resolves without residual deficit. Lightning injury of the skin is generally superficial with a "splashed on" arborescent and spidery appearance.[145] The tip-toe sign refers to the small, circular full thickness burns on the tips of the toes that are common in patients with lightning injury. Prompt institution of cardiopulmonary resuscitation has increased the survival rate of patients struck by lightning to 70% and improved management of the systemic effects of lightning injury has reduced the incidence of acute renal failure and other complications.[11]

Chemical Injuries

A variety of chemical agents can cause tissue injury as a consequence of an exothermic chemical reaction, protein coagulation, desiccation, and delipidation. The severity of a chemical injury is related to the concentration and amount of chemical agent and the duration with which it is in contact with tissue.[146] Consequently, initial wound care to remove or dilute the offending agent takes priority in the management of patients with chemical injuries (Fig. 32.11). Immediate copious water lavage should be instituted while all clothing, including gloves, shoes, and underwear exposed to the chemical are being removed. The lavage is continued for at least 30 minutes or until dilution has lowered the concentration of the agent below that which will cause tissue damage or until testing the involved surface with litmus paper confirms that the agent has been removed. For patients in whom extensive surface injury has occurred, the irrigation fluid should be warmed to prevent the induction of hypothermia. Although seldom needed, if a patient with concentrated alkali injuries requires prolonged irrigation and is hemodynamically stable he can be cared for while sitting in a chair under a shower.

The appearance of skin damaged by chemical agents can be misleading. In the case of patients injured by strong acids, the involved skin surface may have a silky texture and a light brown appearance that may be mistaken for a suntan rather than the full thickness injury that it is. Skin injured by delipidation caused by petroleum distillates may be dry, show little if any inflammation, and appear to be undamaged but found to be a full thickness injury on histologic examination.

Variable degrees of pulmonary insufficiency may occur in patients with cutaneous injuries caused by volatile chemical agents that can also be inhaled, such as anhydrous ammonia, the ignition products of white phosphorus, mustard gas and chlorine, and even the vapors of strong acids. Additionally, pulmonary insufficiency may be caused by the inhalation of the gaseous products of petroleum distillates as may occur in patients who sustain delipidation injuries due to partial immersion in gasoline and other petroleum products.

In the case of patients with anhydrous ammonia injury, any powdery condensate adherent to the skin should be brushed off prior to irrigation. Irrigation is initiated at the scene and continued for the first 24 hours.[147] HF acid injury is most common in those involved in etching processes, the cleaning of air conditioning equipment, patio grills and other metallic objects with spray products containing HF, and petroleum refining. After contact with HF acid there is a characteristic pain-free interval of variable duration with subsequent appearance of focal pallor that progresses to penetrating necrosis, typically accompanied by severe pain. Immediately after injury, calcium gluconate gel should be applied topically, or prolonged irrigation with a solution of benzalkonium chloride instituted. The

FIGURE 32.11. Failure to remove the glove into which concentrated lye had spilled and failure to start water lavage to remove the lye prior to arrival at the hospital resulted in the severe liquefaction necrosis of the skin, thrombosis of the vessels, and destruction of extensor tendons on the dorsum of the hand of this soap factory worker.

persistent severe pain that may occur in digits injured by HF acid can be relieved by injecting 10% calcium gluconate into the artery supplying that finger. Local tissue injection of calcium gluconate is an alternate route of delivery but may in itself compromise the blood supply of the involved digit. Persistent pain caused by subungual HF acid is best treated by removal of the nail under digital block anesthesia. The pain typically relents and the nail grows back with little or no deformity. If these measures fail to control pain, local excision and skin grafting will be needed to remove the damaged tissue and achieve pain relief.[148] Extensive HF acid injury may induce systemic hypocalcemia that is treated by intravenous infusion of calcium.

Burns caused by phenol should be treated with immediate water lavage to remove, by physical means, the liquid phenol on the cutaneous surface. Following that lavage, the involved area should be washed with a lipophilic solvent such as polyethylene glycol to remove any residual adherent phenol, which is only slightly soluble in water.[149] Intensive systemic support is required for patients with extensive phenol burns, in whom absorption of the agent can cause central nervous system depression, hypothermia, hypotension, intravascular hemolysis, and even death.

Injuries caused by white phosphorous are usually discussed with other chemical injuries but are actually conventional thermal burns caused by the ignition of the particulate phosphorus. These injuries are most commonly encountered in military personnel injured by explosive antipersonnel devices (grenades) that may cause mechanical tissue damage and drive fragments of white phosphorus into the soft tissues. All wounds containing white phosphorus particles should be covered with a wet dressing that is kept moist to prevent ignition of the particles by exposure to air. If the interval between injury and definitive wound care will be so long as to permit dessication of the wet dressings, the wounds can be briefly washed with a freshly mixed dilute 0.5%-1% solution of copper sulfate followed by copious rinsing. Such treatment generates a blue-gray cupric phosphide coating on the retained phosphorus particles that both impedes ignition and facilitates identification.[150] Whatever form of topical treatment is employed, the wound should be debrided and all retained phosphorus particles, which can be readily identified with an ultraviolet lamp, removed. The removed particles should be placed under water to prevent them from igniting and causing a fire in the operating room.

Strong acids and alkali can cause devastating ocular injuries and must be treated immediately, even before leaving the scene of the injury, by irrigation with water, saline, or phosphate buffer. In the hospital, eye irrigation must continue until the pH of the eye surface returns to normal. The rapid penetration of ocular tissue by strong alkalis necessitates prolonged irrigation (12–72 hours). Such irrigation is best carried out with a modified scleral contact lens with an irrigating side arm. The effects of iritis induced by chemical ocular injury are minimized by installation of a cycloplegic such as 1% atropine following irrigation. If irrigation and removal of the offending agent is delayed, the entire globe may be so damaged as to lose turgor and all visual function. Even with early irrigation, corneal damage can be severe and late complications of symblepharon and xerophthalmia may occur. An ophthalmologist should be involved in the care of such patients from the time of admission.

Bitumen Burns

Bitumen injuries are commonly caused by hot tar coming in contact with the skin. The injury that results is a thermal contact burn that is not associated with any important component of a chemically mediated injury. There is no appreciable absorption of materials unless the patient is in an explosion and has ingested or inhaled the material. The primary initial treatment is urgent cooling of the molten material with no attempt made to remove the tar. By cold application the transfer of heat can be limited and the degree of tissue damage minimized. There are various agents that have been advertised as being effective for the removal of tar and asphalt products. These have varied from mayonnaise to simple petroleum-based jellies and seem to be similar in terms of efficacy. Considering that the initial temperature of liquid tars and asphalts are typically in excess of 600°F, early concerns about infection would seem to be unfounded and offer no support for urgent removal with potential destructive consequences to underlying otherwise viable tissue. It is preferable to apply an emulsifying petroleum-based ointment and allow the tar to separate during the first day or two after admission.[146]

Cold Injuries

Injuries occurring secondary to environmental exposure can result in local injuries, frostbite, or systemic hypothermia. During the wintertime in urban environments, the most common mechanism of injury involves homeless persons or an elderly patient who has become disoriented and wandered from home. The pathophysiology of the local injuries consists essentially of crystal formation due to freezing of both extracellular and intracellular fluids. Consequently, the cells dehydrate and shrink and blood flow is altered to the exposed area resulting in tissue death. During the thawing of damaged tissues, micro emboli that have formed further occlude the microvascular circulation adding insult to injury.[151] It is important to note that the initial clinical presentation of the patient is not likely representative of the ultimate degree of tissue loss. Patients presenting with frostbite will have coldness of the injured body part with loss of sensation and proprioception. On initial exam, the limb may well appear pale, cyanotic or have a yellow white discoloration. During rapid rewarming for 15–30 minutes in water at 40–42°C, hyperemia will occur followed by pain, paresthesias, and sensory deficits. Over the subsequent 24 hours, edema and blistering will develop and it may be the better part of a week before one can determine the true depth and extent of the injury. In the initial management of the patient, rewarming is critical but it must be done only when there is no chance for an episode of refreezing. If blisters appear, whether they should be preserved or debrided has proponents on both sides of the answer. Some authors suggest that white blisters can be debrided while purplish blue blisters should be left intact. The injured extremity should be elevated in an attempt to control edema and padded to avoid pressure-induced ischemia as a secondary insult. Administration of pain medication is based on the patient's response. Frostbite wounds are tetanus prone wounds and therefore tetanus toxoid should be administered based on the patient's immunization status.

Before any definitive plans are made for surgical intervention, sufficient time should be allowed to pass so that a clear demarcation between viable and nonviable tissue is apparent (Fig. 32.12). If only minimal distal digital necrosis is evident and remains dry, spontaneous separation and healing with minimal soft tissue loss are commonly achieved. However, if extensive tissue loss is evident it is not in the patient's best interest to follow the adage of "freeze in January and amputate in June."[152] While it will take some time for definitive delineation of the depth of the injury, once the wounds have begun to mummify the thought that there will be tissue salvage seems more than naive. Patients suffering frostbite injuries should be evaluated for other potential trauma and treated for systemic hypothermia if it is present. The posthospitalization disposition of cold injury patients requires a clear understanding of their preexisting health status and the factors that predisposed them to injury such as dementia or major psychological disease.[153]

FIGURE 32.12. A: This photo taken 11 days after frostbite injury sustained during arctic maneuvers shows the extent of tissue damage, which was greatest on the great and second toes of the left foot. **B:** This photo shows the extent of healing that had occurred after 67 days of nonoperative management. Subsequent separation of the necrotic eschar from the left great and second toes revealed the wounds to be healed with minimal loss of distal digit soft tissue.

NON THERMAL CUTANEOUS INJURIES

Radiation Injury

Radiation exposure secondary to the detonation of a thermonuclear device is not as likely as is exposure from an industrial or medical accident, misuse of radiation materials, or acts of terrorism. The dispersal of radioactive substances can take several forms including accidents during storage and mishandling, accidents during transportation of radioactive materials, intentional dispersal either alone or in combination with other agents, and intentional dispersal through an explosive device. In both storage and transport accidents, the dispersal and subsequent exposure to radioactive materials is usually limited to the people immediately involved and is well contained geographically once the event is recognized. It is typically difficult to expose large numbers of individuals to substantial doses of radiation at any given time and the risks are limited to those involved in a given incident. Small-dose radiation exposure does not affect health for many years and is associated with few acute problems although it is still a major health risk. In the event of intentional radiation dispersal, the risk of exposure and injury as well as the source involved needs to be evaluated. The risk of trauma is related to the primary explosive device itself as well as trauma related to the secondary effects of the explosion such as shell fragments, structure collapse, or injury from debris. Psychological trauma due to either patients witnessing the primary event or the experience of living through the event with the associated physical manifestations may pose a further problem in the handling of a large number of injured victims.

Exposure risk is related to primary contamination from the particles released from the explosive device, secondary contamination from particles that have become mixed with debris, debris dust and fallout, and tertiary contamination from exposure to particles in contact with patients. Ionizing radiation is composed of two types: radiation that has mass and that which is energy only. Exposure to alpha particles, which are relatively large, slow moving, highly charged particles, and penetrate only a few microns into tissue can be effectively shielded with ordinary substances such as paper, cardboard, or clothing. Alpha particles can be a source of secondary and tertiary contamination. Beta particles made up of either positively or negatively charged species have greater energy and can penetrate more deeply into tissues and require shielding with material such as aluminum to prevent exposure. Both alpha and beta particles result from the decay of a radioactive source. Gamma and x-rays are produced by radioactive decay or an x-ray source; they have neither mass nor charge; however, they penetrate deeply and shielding requires the use of such materials as lead, steel, or thick cement. Following removal from the source of radiation no further exposure occurs and the patient poses no danger to those providing care. Radiation due to neutrons requires special consideration. Nuclear reactors are the major source of neutron emission and create radiation that penetrates deeply causing widespread damage to underlying tissues.

Radiation exposure of 2–4 gray (Gy) can cause nausea and vomiting, hair loss, and bone marrow injury leading to death from infection up to 2 months after exposure. Exposures of 6–10 Gy result in the destruction of the bone marrow, and injury to the GI tract with a mortality approaching 50% within 1 month. When the exposure is 10–20 Gy, there is severe injury to the GI tract and death may occur in as little as 2 weeks. When exposure is >30 Gy, cardiovascular and nervous system damage occur primarily as a result of hypotension and cerebral edema. There is almost immediate nausea, vomiting, prostration, hypotension, ataxia, and convulsion, and death can occur in a matter of hours. At present, there appears to be no effective treatment following radiation exposure. For treatment to be effective, it would need to be given prior to the exposure. In cases of accidental exposure, treating

bone marrow suppression while successful has not prevented death, which usually occurs from radiation pneumonitis, GI tract injury, and hepatic and renal failure.[154,155]

The burn injuries resulting from radiation exposure are usually localized and represent a high radiation dose to the skin. They appear identical to a thermal burn and may present with erythema as with a first-degree burn that will heal following some sloughing of the skin. With higher dose exposures, blisters may occur as with a partial thickness burn and healing occurs in a similar manner. When the radiation exposure has been substantial such as 20 Gy, radionecrosis occurs. If the event leading to the radiation exposure causes surface contamination, decontamination needs to be done prior to dealing with the wound. This consists of saline irrigation of the wound and treatment with standard aseptic techniques. It is not necessary to excise the wound urgently unless it is contaminated with long-life radionuclides such as alpha emitting particles. Patients who have greater than a 1 Gy, whole body exposure should be considered for early wound closure so that the wound itself does not become the site of a lethal infection.[156]

To manage radiation-exposed victims effectively, a hospital must have a well-organized plan in place and the appropriate decontamination facility within the emergency room. The goals are to save the patients life and to prevent further injury. The decontamination must be done so that the personnel providing care to the patient do not become exposed. All contaminated materials must be carefully handled to prevent contamination of the hospital and its facilities and the public sewage system.

Toxic Epidermal Necrolysis (TEN)

TEN is a rare life threatening mucocutaneous form of exfoliative dermatitis that is often secondary to drug sensitivity. The incidence of TEN has been estimated at 0.4–1.2 cases per million population per year.[157] These patients may give a history of sore throat, burning eyes, fever, and malaise, and present with systemic toxicity. Physical findings can include rash, bullae, and diffuse exfoliation with the large areas of separation having the appearance of a partial thickness burn. When lateral stress is applied to the involved skin it separates at the dermal–epidermal junction, Nikolsky's sign. The resulting wounds give the appearance of a wet surface as seen in a second-degree burn. The mechanism of injury is thought to be keratinocyte apoptosis induced by interactions between the cell surface death receptor Fas and its receptor FasL or CD95L.[158] Lyle in 1956 was the first to describe two entities in the initial description of TEN consisting of staphylococcal-scalded skin syndrome (SSS) and what today is recognized as TEN.[159]

Staphylococcal-SSS is a generalized exfoliative dermatitis due to infections with staphylococcal organisms. In SSS, the lesion is at the intraepidermal layer with blister formation followed by desquamation of large sheets of skin with relatively rapid reeptheliazation over 7–10 days. The outcome in patients with SSS is significantly better than that in TEN patients. In TEN, there is necrosis of all layers of the skin and mortality between 30 and 40% while with SSS it is 3%-4%. Stevens Johnson Syndrome (SJS) is an entity in which there is also extensive epidermolysis often presenting with target shaped skin lesions with differentiation from TEN related to the extent of cutaneous involvement. One current delineation classifies patients with <10%-30% cutaneous involvement as SJS and those with >10%-30% as TEN particularly if it involves oral-genital and ocular mucosa.[160] Whether SJS and TEN represent the same process differing only in the extent of cutaneous involvement and sites affected or are pathologically distinct entities has not been answered with any degree of certainty.

Patients with TEN have wound care needs identical to those of patients with extensive second-degree wounds. They exhibit considerable fluid losses and have specialized nutritional needs. Care of these patients in a Burn Center by experienced surgeons has resulted in a substantial improvement in outcome.[161] General principles of management in these patients include the cessation of potential precipitating drugs, the discontinuance of systemic steroids if recently initiated, ophthalmologic evaluation, and skin biopsy confirmation of the diagnosis.[162] Additionally, systemic antibiotics should be reserved for those cases in which infection is highly likely. Replacement of fluid and electrolytes and provision of nutritional support and aggressive wound care are critical elements in the care of these patients. Wound care may consist of the application of a biologic dressing once all of the nonviable tissue is fully debrided or the use of silver-impregnated dressings (Fig. 32.13). The most frequent mistakes in the care and management of these patients are underestimating the extent of the cutaneous involvement, airway compromise, and not understanding how rapidly these patients can become critically ill. To date, the results of studies of various modalities that can be employed to control the degree of skin slough have been too inconsistent to recommend their general use.[163]

Mechanical Injury

The combination of burn injury and multisystem trauma occurs in up to 4%-5% of all burn patients.[164,165] Patients suffering combination injuries are typically male with their injuries having occurred from a flame ignition during an assault or motor vehicle crash. Victims suffering a combination of burns and trauma tend to have a higher incidence of inhalation injury, higher mortality, higher injury severity score (ISS), and longer length of stay despite no differences in TBSA burned when compared to patients with only burns. Trauma victims with burns with an inhalation injury have a near threefold increase in their mortality rate.[110] Those victims not surviving their injuries typically are considerably older, have a higher ISS, and a larger body surface area burn compared to trauma victims with burns who survive their injuries. The management priorities in patients suffering burns plus trauma must be as for patients with trauma. Understanding the mechanism of injury is vital in determining the probability of associated injuries and provides a guide in the work-up of the patient. A formal trauma evaluation should

FIGURE 32.13. After the exfoliating epidermis was cleansed with sterile saline and gently debrided, the wounds on this patient with TEN were covered with a translucent collagen-based skin substitute (Biobrane) as shown here. The membrane decreases pain, prevents desiccation of the exposed dermis, and serves as a microbial barrier. If the membrane remains adherent to the wound, it can be left in place until the wound heals at which time the Biobrane will slough.

be performed on all burn victims when the history of the event points to the possibility of combined mechanisms of injury. In patients with major long bone injuries, early operative intervention with stabilization by use of an external fixator if necessary will facilitate the patient's overall management as well as that of the burn. In selected circumstances, early burn excision with skin graft wound closure may be the best approach to facilitate the operative management of the orthopedic injury.

The management of patients with substantial burn injuries in conjunction with mechanical trauma requires a highly coordinated plan of care. The patient must be continuously reassessed to avoid missing an injury and the surgeon vigilant to the development of trauma-related complications.

METABOLIC AND NUTRITIONAL SUPPORT

Estimation and Measurement of Metabolic Rate

Burn injury alters central and peripheral thermoregulatory mechanisms, the predominant route of heat loss, the distribution and utilization of nutrients, and metabolic rate. All of these postburn metabolic changes must be considered in planning the metabolic support and nutritional management of the hypermetabolic burn patient necessary to minimize loss of lean body mass, accelerate convalescence, and restore physical abilities. Metabolic support includes patient care procedures and environmental manipulations in addition to the provision of adequate nutrition.

The perceived temperature of comfort of burn patients (on average 30.4°C) is higher than that of unburned control patients and necessitates maintaining the ambient temperature at that level in the patient's room to prevent the imposition of added cold stress that would exaggerate an already elevated metabolic rate.[166] Physical therapy with active motion to the extent possible and passive motion to stretch muscles in the absence of spontaneous motion is instituted on admission to minimize muscle wasting secondary to disuse. Analgesic and anxiolytic agents should be used as needed to prevent pain- and anxiety-related increases in circulating catecholamine levels, which can further increase metabolic rate. Assiduous monitoring is necessary to facilitate early diagnosis and prompt treatment of infections and thereby reduce their metabolic impact. The importance of excision and grafting of the burn wound has been emphasized by recent studies showing that such treatment reduces resting energy expenditure in burn patients, even if the entire wound cannot be excised and grafted at a single sitting.

Even though metabolic rate can be reduced by pharmacologic means, studies indicating that the hypermetabolic response to burn injury is wound-directed speak for meeting caloric needs rather than reducing nutrient supply to the burn wound by pharmacologic intervention. One must determine the resting energy expenditure in order to calculate the nutrients required to meet the patient's needs. Bedside indirect calorimetry is the most accurate means of determining metabolic rate, but a bedside metabolic cart may not always be available. A number of formulas permit one to make close approximations of daily energy expenditure in a variety of surgical patients. A formula based on studies of extensively burned patients is useful in estimating burn patient calorie needs.[167]

$$EER = [BMR \times (0.89142 + 10.01335 \times TBS)] \times m^2 \times 24 \times AF$$

where EER = estimated energy requirements, BMR = basal metabolic rate, TBS = total burn size, m^2 = total body surface area in square meters, and AF = activity factor of 1.25 for burns.

A rule of thumb estimate for nutritional needs of patients whose burns involve >30% of the body surface is 2,000–2,200 kilocalories and 12–18 g of nitrogen per square meter of body surface per day.[41]

Nutritional Support

Meeting the metabolic needs of the burn patient can be accomplished by providing nutritional support via the GI tract or by the intravenous route. After determining what the metabolic needs will be for an individual burn patient, the next question is will the patient be capable of meeting the needs by oral intake? In patients who can eat, it is not likely that a standard hospital diet will meet the calculated needs and it is often necessary to supplement the patient's intake with various nutritional supplements. A calorie count should be recorded to verify that the patient is capable of consistently meeting the daily nutrient intake goal. In the patient who is incapable of achieving the necessary nutrient intake or cannot eat, one must decide how to deliver the feedings. Total parenteral nutrition in the past provided a way by which patients could receive the majority or all of their calorie and protein needs but at present has largely been supplanted by the use of enteral nutritional support. As compared to total parenteral nutrition, enteral nutritional support is technically easier to accomplish, lower in cost, supports the health of the GI tract, and ameliorates the systemic inflammatory response syndrome.[168-172]

At the time of admission, a patient who will require specialized nutritional support should have either a nasogastric or nasoduodenal tube placed. Patients can safely and effectively be fed by either of these routes with appropriate precautions. It is not necessary that one use custom made feedings to meet the patient's nutrient needs. It is possible by using combinations of currently available commercial products to obtain the necessary blend of nutrients, feeding density, water, and protein requirements while avoiding the cost of compounding specialized enteral feedings. It is preferable to start enteral feedings soon after the patient is admitted. The patient should be fed with the head of the bed elevated to 30° with feeding residuals checked frequently to avoid gastric distention and possible aspiration. A potential advantage of early enteral feedings is modulation of the hypermetabolic response although the actual ability of early feedings to achieve this goal has been called into question.[173-175] When feedings are initiated early postinjury, the desired rate of administration can typically be reached within 24–48 hours of admission. There are multiple recommendations regarding the initial concentration, rate, incremental increase, and the frequency of the increases. Starting a tube feeding of standard concentration at 20–40 mL/hour and advancing the rate by a similar amount every 4 hours works well in most patients. The most important issues are that the nursing staff understands the goals, knows how to monitor for feeding intolerance, and appreciates the attention to detail necessary to achieve consistent delivery of the feedings.

If a patient is intolerant of gastric feedings and gastric aspirate volume exceeds the total of two hourly feedings, the administration of metaclopramide will often resolve the problem. If the patient fails to respond to metaclopramide, an attempt should be made to place either a nasoduodenal or nasojejunal feeding tube, which will minimize this feeding difficulty and lessen the risk of aspiration. Patients who become septic will often manifest changes in feeding tolerance along with new onset hyperglycemia or changes in insulin needs as early signs pointing to this problem. In patients receiving central vein alimentation, the risk of catheter sepsis must be evaluated as an etiology for the patient's septic process. In patients who become intolerant of enteral feedings or develop GI complications that prevent use of the GI tract, total

parenteral nutrition will be required. However, with careful attention to detail and a well-designed, patient-specific enteral feeding protocol, this should rarely be needed in the care of a burn patient.

Blood is not part of the initial resuscitation for patients with only burn injuries but when there is multiple trauma, blood transfusions may be necessary in the early management of the patient. Often the presence of a major burn wound results in the patient being viewed as having only a burn and the standard assessment of a trauma patient is not done. Patients with impaired neurological status should undergo a computerized axial tomographic scan to rule out intracranial pathology along with evaluation for a spinal injury. This is particularly important if the patient jumped from a burning building to escape the fire, was injured in an industrial accident, or involved in a motor vehicle crash. Potential thoracic, abdominal, or pelvic injuries should be evaluated with chest, abdominal, and pelvic roentgenograms as well as with abdominal CT and Focused Assessment with Sonography for Trauma (FAST) examinations. Diagnostic peritoneal lavage may also be used in the unstable patient to verify the presence of an injury requiring exploratory laparotomy.

The nonoperative management of substantial injuries of the spleen or liver requires thoughtful consideration in patients with a major burn and it maybe prudent to opt for surgical management particularly if the abdominal wall is extensively burned.

Monitoring

The complications associated with the use of enteral or parenteral support in the burn patient are in large part similar. Burn injury induces insulin resistance that may lead to hyperglycemia. The maintenance of blood glucose values with aggressive insulin replacement has a favorable impact on the outcome of critically ill patients.[176] In critically ill patients, the preferable route of administration of insulin is intravenously with the goal of maintaining plasma glucose values between 80 and 110 mg/dl. There is a well-recognized limit to the carbohydrate calorie load that a critically ill patient can tolerate and for a 70-kg patient this is approximately 1,800 kilocalories per day from glucose.[177] Excessive amounts of glucose can result in respiratory quotient (RQ) values >1, which may cause hepatic steatosis and complicate ventilatory management. The effect of thermal injury on metabolic rate and insulin function has been further dissected by Duffy et al.[178] Those investigators identified elevation of circulating resistin levels in association with postburn elevation of insulin and glucose. "Insulin resistance" increased in concert with resistin expression. The marked increase in resistin transcript expression by the activated macrophages present in the soft tissues at the burn wound margins was considered to impair insulin function in the burn patients studied.

Sufficient protein to meet metabolic demands must be provided. To estimate protein needs 24-hour urine urea nitrogen is measured to which an additional 0.1–0.2 g of nitrogen per % TBSA burn remaining is added to account for wound exudate protein loss. These determinations can be done on a weekly basis unless there is a special need to perform them more frequently. Numerous studies have been done to determine precise protein needs and the optimum balance of protein and nonprotein calories. In adult patients, 1.5–2.0 g of protein per kg lean body mass per day is a reasonable goal and for children 3 g of protein per kg lean body mass.[179,180] A nonprotein calorie-to-nitrogen ratio of 100:1 provides the patient with sufficient calories to support protein synthesis in the face of ongoing protein breakdown and reduces net protein loss.[181,182] The provision of dietary protein at these levels has been shown to positively impact patient outcome.[183] An increasing blood urea nitrogen level must be evaluated in terms of nitrogen over feeding and

the protein load recalculated to avoid uremia and an associated diuresis. Measurements of visceral proteins such as serum transferrin and albumin can be used to monitor the impact of the nitrogen content of the diet on the patient's nutritional status. Those proteins are simply markers that can be followed over time and are probably best utilized in a trend analysis based on weekly determinations since albumin has a half-life of 20 days and transferrin 8 days. Thyroid prealbumin with a half-life of 2 days and retinal binding protein with a 12-hour half-life can be used to track short-term responses in selected patients.

To prevent the development of essential fatty acid deficiencies, lipids must be included in the diet but should not exceed more than 40% of the total calorie load or more than 3 g/kg BW/day. Most enteral diets will contain adequate fat to prevent the development of essential fatty acid deficiency and parenteral diet formulations typically contain long chain fatty acids. The serum triglyceride concentration and the triene/tetraene ratio should be measured weekly to assess fatty acid status. If that ratio is >0.4 an essential fatty acid deficiency exists, which necessitates adjustment of the dietary fat content.[184] Supplemental medium chain triglycerides can be given enterally but are associated with increased ketone production and may cause diarrhea.[41]

Complications

Serum electrolytes must be monitored to make necessary adjustments in the amount of free water, sodium, chloride, potassium, phosphorus, calcium, magnesium, copper, and selenium provided to the patient. Laboratory values should be obtained at initiation of the feedings and daily during the stabilization phase and with each change in the patient's clinical status. During the first several days after admission, and with the initiation of nutritional support, there can be dramatic shifts in serum and plasma values of electrolytes and minerals. As noted above, hypernatremia can develop if free water replacement is insufficient to account for insensible water loss through the burn wound, which can be 2.0–3.1 mL/kg body weight/% burn/day.[185] Hypernatremia can also develop with persistent febrile episodes if free water replacement does not match the patient's needs. Hyponatremia may represent under replacement of sodium but typically is related to free water excess. Correction of hyponatremia should be attempted with restriction of free water intake. In adults, an increase in body weight of more than 400 g per day reflects water loading and should prompt a review of fluid intake and output records and adjustment of fluid administration.[12] Potassium and phosphorous must be given to meet the patient's needs, which often exceed initial estimates particularly when large loads of glucose are being given along with exogenous insulin. Recent reports have called attention to the effects of trace metal deficiency and the need for assiduous nutritional monitoring. Copper deficiency was implicated as a cause and copper then given to reverse indolent donor site healing in a pediatric burn patient receiving total parenteral nutrition.[186] A report of high urinary selenium excretion and low plasma selenium levels in association with an increased incidence of infection during the first 8 weeks in pediatric burn patients suggests that the recommended selenium intake for healthy children is insufficient for burned children and should be increased until the wound is healed.[187]

In the course of the patient's care, as the open wound area decreases and the hypermetabolic state slowly resolves, the nutrient load should be adjusted so that balance is maintained between metabolic needs and substrates delivered and the patient is not overfed. Alternatively, if a patient is found to have lost more than 10% of his or her admission weight, it is likely that caloric estimates are not being achieved or were underestimated. While most experienced clinicians possess the skill to assess patient needs accurately, the performance of

bedside indirect calorimetry can provide objective information as to the patient's resting energy expenditure, respiratory quotient, oxygen consumption, and carbon dioxide production. The results may indicate the need to adjust the total calorie load if the resting energy expenditure has been underestimated or modify the fuel substrate load if the respiratory quotient is approaching or is >1.

The burn patient should receive increased amounts of vitamin C, at recommended doses of a gram per day in adults and 500 mg per day in children, which will aid in wound healing.[188] In patients with burns of >20% of the TBSA, zinc at doses of 220 mg per day will support wound healing as well as white cell function.[189] The routine provision of these nutrients avoids complications related to insufficient delivery and obviates the need to measure their levels in the patient.

In patients with prior surgery or preexisting medical conditions, special attention may be required to monitor for feeding intolerance and to insure that adequate amounts of iron, folate, and vitamin B$_{12}$ are being effectively delivered. In patients who have received extended courses of broad-spectrum antibiotics, vitamin K replacement beyond standard recommendations may be required to avoid the development of nutritionally related coagulopathy. The preservation of lean body mass requires more than just the appropriate amounts and blend of nutrients. Physical activity is important in directing the nutrients to muscle and reducing truncal fat deposition and the risk of hepatic steatosis.

In addition to providing appropriate calorie, protein, and nutrient loads to burn patients, it is now possible to modulate the metabolic response. Administration of beta antagonists in children has been shown to be safe and to have an appreciable positive effect on outcome.[190] The administration of growth hormone, which is depressed following burn injury, has met with variable results. Herndon et al.[191] have reported a positive effect in burned children given growth hormone but a recent multicenter trial from Europe in critically ill patients showed an increased mortality in treated patients.[192] An alternative strategy that seems not to be associated with problems in adults and is efficacious in children is the use of the drug oxandrolone, although a recent study reported that the agent was associated with prolonged need for mechanical ventilation in trauma patients.[193-196] Additional strategies that might be utilized are the provision of selected nutrients in increased amounts. Glutamine, arginine, nucleotides, and omega-3 fatty acids have all been used in attempts to improve immune function above that seen with the optimal use of standard nutritional formulations.[197-201] The routine use of these measures requires a full understanding of the therapeutic benefits and the potential adverse consequences of each. Additionally, some studies have found such supplements to be ineffective.[202]

In patients who have established chronic renal failure or develop renal insufficiency during their course of care, changes in the nutritional formulation will have to be made to accommodate their altered clinical status. In patients who require dialysis, the frequency of dialysis should be adjusted so that the protein intake needed to meet metabolic needs can be given. In patients with substantial injuries who are receiving large amounts of feeding through the GI tract, the health of the GI tract itself must be continuously monitored. The development of major GI complications while not common can adversely impact the patient's outcome. Complications can include ischemic necrotic bowel disease, intestinal obstruction, the development of *Clostridium difficile* colitis and noninfectious diarrhea.[203-207] The patient's clinical status should be continuously monitored and any changes in abdominal findings on physical examination should be aggressively followed up with appropriate diagnostic radiographic studies, endoscopy, stool cultures, and abdominal exploration before the patient deteriorates and develops an irreversible condition.

TRANSPORTATION AND TRANSFER

Many important advances have been made in the care and management of burn-injured victims during the past 50 years. One of the more important advances has been the recognition of the benefits of a team approach in the care of critically injured burn patients. The American College of Surgeons and the American Burn Association have developed optimal standards for providing burn care and a burn center verification program that identifies those units that have undergone peer review of their performance and outcomes. Patients with burns and/or associated injuries and conditions listed in Table 32.2 should be referred to a burn center.

Once the decision has been made to transfer a patient to a Burn Center, there should be physician-to-physician communication regarding the patient's status and need for transfer.[208] Institutions should have preexisting interhospital transfer policies in place to facilitate communication and patient transfers. It is critical that the patient be properly stabilized in preparation for the transfer. The flight transfer team should have the capability of providing the care required for a critically injured, severely burned patient throughout the entire transfer procedure. A surgeon, a respiratory therapist, and a licensed practical nurse, all experienced in burn care comprise such a team for long distance, fixed wing aircraft transfers (Fig. 32.14). For short distance transport by rotary wing aircraft, inclusion of a burn physician in the flight team optimizes the safety and quality of care of extensively burned patients, but patients with lesser burns may be adequately cared for by nonphysician helicopter flight team members (a flight nurse and/or an advanced paramedic) who are in ready contact with medical control. A flight team roster should be maintained and published so the surgeons and other members of the team will be available when needed. Physicians and other team members should be assigned to the flight (transfer) team only after 6–12 months experience at a burn center, which will enable them to become familiar with the complications that occur in burn patients during resuscitation and develop competence in the prevention, treatment, and resolution of those problems.

During transport, the need to perform life-saving interventions such as endotracheal intubation or reestablishing vascular access may be very difficult to accomplish in the relatively unstable and limited space of a moving ambulance or a
FIGURE 32.14. Long-distance transfer of severely burned critically ill patients is best carried out in fixed wing aircraft in which ICU capabilities can be provided including mechanical ventilation as well other supportive and monitoring equipment as shown here.

FIGURE 32.15. Patients are often transported to burn centers by helicopter. The noise, poor lighting, and vibration compromise monitoring. This photo of a U.S. Army UH-60 Blackhawk helicopter loaded with three simulated patients illustrates that space limitations and restricted patient access limit therapeutic interventions and necessitate preflight stabilization of patients being transferred.

TABLE 32.7

CHANGES IN BURN PATIENT MORTALITY AT U. S. ARMY BURN CENTER, 1945-2002

■ AGE GROUP–	■ PERCENTAGE OF BODY SURFACE BURN CAUSING 50% MORTALITY (LA_{50})	
	■ 1945-1957	■ 1992-2002
Children (0–14 y)	51	71[a]
Young adults (15–40 y)	43	75[b]
Another young adult		65[c]
Older adults	23	45[d]

[a]5 years.
[b]21 years.
[c]40 years.
[d]60 years.

helicopter in flight (Fig. 32.15). That difficulty makes it important to institute hemodynamic and pulmonary resuscitation and achieve "stability" prior to undertaking transfer by either aeromedical or ground transport. A secure large-bore intravenous cannula must be in place to permit continuous fluid resuscitation. Patients should be placed on 100% oxygen if there is any suspicion of carbon monoxide exposure. If there is any question about airway adequacy an endotracheal tube should be placed and mechanical ventilation instituted before transfer begins. Inflight mechanical ventilatory support can be provided by a transport ventilator with oxygen supplied from a lightweight kevlar tank transported in backpack fashion by the respiratory therapist. Patient safety during transport may necessitate chemical paralysis of the patient to prevent loss of the airway or vascular access. In-transit monitoring for helicopter transfer includes pulse rate, blood pressure, EKG, pulse oximetry, end tidal CO_2 levels, and respiratory rate. For long distance transfer, the same physiologic indices should be monitored. In addition, the ultrasonic flow meter should be used to assess the presence and quality of pulsatile flow in all four limbs on a scheduled basis and excursion of the chest wall should be monitored to identify a need for limb or chest escharotomy, respectively. The hourly urinary output should also be monitored with fluid infusion adjusted as necessary. All patients should be placed NPO (nothing by mouth) and those with a >20% body surface area burn require placement of a nasogastric tube. In essence, a mini ICU should be established for the duration of the long-distance flight.

The burn wound should be covered with a clean and/or sterile dry sheet. The application of topical antimicrobial agents is not necessary prior to transfer, since they will have to be removed on admission to the burn center. Maintenance of the patient's body temperature is vital. Wet dressings that can lead to hypothermia, particularly in small adults and children, should be avoided. The patient should be covered with a heat reflective space blanket to minimize heat loss. Pain medication is given in sufficient dosage to control the patient's pain during transport while avoiding respiratory depression, airway comprise or hypotension. Burn wounds, as tetanus prone wounds, mandate immunization in accordance with the recommendations of the American College of Surgeons. As in the case of the transfer of any trauma victim, documentation must be thorough, flow sheets should be clearly marked, and a listing

of all medications, including IV fluids that have been given must be provided to the receiving physician. In the case of a patient suffering from substantial multisystem trauma and burn injuries, it may be necessary to treat the patient's life-threatening mechanical injury prior to transfer if the transport time will be of long duration or the patient is unstable. [113]

SURVIVAL DATA

During the course of the past half century, early postburn renal failure as a consequence of delayed and/or inadequate resuscitation has been eliminated and inhalation injury as a comorbid factor has been tamed. Invasive burn wound sepsis has been controlled and early excision with prompt skin grafting and general improvements in critical care have reduced the incidence of infection, eliminated many previously life threatening complications, and accelerated the convalescence of burn patients.[209] All of these improvements have considerably reduced the mortality of burn patients of all ages.

A simplified "Rule of Thumb" method of predicting mortality in burn patients has been the BAUX score, which consisted of adding the patient's age and extent of burn to estimate the percentage of mortality. That score has now been refined to account for the effect of inhalation injury and recent advances in burn care.[210] A single-term logistic regression model based on data from 39,888 patients in the National Burn Registry included inhalation injury to recalibrate the BAUX score. The authors identified a mortality effect of age and percent burn, which was virtually equal with inhalation injury adding the equivalent of 17 years or 17% burn. A recent report has suggested that pre-injury statin use reduces the odds of sepsis and death in elderly burn patients.[211] If that is confirmed by additional studies, further revision of mortality predictors may be necessary.

Revised BAUX Score (RBS) = age + persent burn + 17*

The revised BAUX score can be readily used at the bedside but the inverse logit transformation that requires the use of a calculator or nomogram provides more precise mortality predictions. The more complex thermal injury mortality model (TIMM) had better discrimination and calibration achieved by the use of nonlinear transformations of age and burn extent and two-way interactions among main effects.

---

*only if inhalation injury is present

A more detailed analysis has documented the improvement in burn patient survival over the past half century. At the midpoint of the last century, a burn of 43% of the total body surface would have caused the death of 50 of 100 young adult patients (15–40 years) with such burns. Since that time, the extent of burn causing such 50% mortality (the LA_{50}) in 21-year-old patients has increased to 75% of the total body surface and in 40-year-old patients to 65% of the total body surface. In children (0–14 years), the LA_{50} has increased from 51% of the total body surface in the 1950s to 71% today, and in the elderly (>40 years), the LA_{50} has increased from 23% of the TBSA to 45% (Table 32.7). Not only has survival improved, but the elimination of many life threatening complications and advances in wound care have improved the quality of life of even those patients who have survived extensive severe thermal injuries.

CHAPTER 33 ■ EVALUATION OF THE ACUTE ABDOMEN

GRETA L. PIPER, MATTHEW R. ROSENGART, ANDREW B. PEITZMAN, AND RAQUEL FORSYTHE

Abdominal pain is one of the most common conditions encountered, serving as the chief complaint in 5%-10% of emergency department visits.[1] Although this prevalence has not changed significantly over the last few decades, diagnostic accuracy has markedly improved. Hence, a more appropriate definition of an acute abdomen is the presence of abdominal pathology, which if left untreated (<72 hour history), will result in patient morbidity and mortality.

The goal of this chapter is to provide a guideline for the evaluation of the acute abdomen in the increasingly varied and complex populations of patients that has evolved with medical advancement and innovation. As risk factor analysis clearly identifies an association between time to diagnosis and therapy and outcome, a systematic approach is paramount.[2-6] *Pathophysiology.* Abdominal pathology can cause visceral, parietal, or referred pain.

Visceral pain originates from bilateral innervation of the autonomic and visceral afferent type C fibers. Pain is sensed secondary to stretch but also distension, contraction, traction, compression, and torsion. In addition, mucosal pain receptors respond to chemical stimuli including ischemia and inflammation. The pain perceived is usually dull, not well localized, midline, and corresponds to the embryologic origin of the affected organ. Epigastric pain generally indicates a foregut etiology, as visceral afferent nerves from the foregut travel with the celiac trunk. Periumbilical pain indicates a midgut etiology as these afferent nerves travel with superior mesenteric artery branches. Lower midline pain indicates hindgut or pelvic pathology as these fibers travel with the inferior mesenteric artery branches. Parietal pain results from irritation of the parietal peritoneum leading to somatic nerve activation (type C and A delta fibers).[6,7] Chemical peritonitis occurs from irritation by blood, urine, or gastrointestinal (GI) secretions. However, intraperitoneal blood alone causes little inflammation or pain. Secondary infection of blood or breakdown products of blood leads to chemical peritonitis.

In contrast to visceral pain, parietal pain is sharp and well-localized. Appendicitis demonstrates both visceral and parietal pain. The inflammation and distension of the appendix (part of the midgut) classically results in poorly localized, dull periumbilical pain. As the inflammation progresses and irritates the parietal peritoneum, pain becomes sharper and better localized to the right lower quadrant (RLQ).

Referred pain is pain that is sensed on the superficial surface but caused by a visceral process; common patterns associated with certain abdominal processes are shown in Figure 33.1.[8] Referred pain is the result of nerves carrying both autonomic and somatic innervation with both being activated. For example, the phrenic nerve and other afferents (derived from C3–C5 dermatomes) innervate the diaphragm and the associated peritoneum. Somatic C3–C5 dermatomes innervate the shoulder. Thus, the pain from intra-abdominal pathology irritating the underside of the diaphragm is referred to the shoulder via the common C3–C5 dermatome.[6]

Differential diagnosis is extensive for acute abdominal pain. Thus, it is a clinical challenge for the acute care surgeon. Etiologies of acute abdominal pain can be divided into GI, vascular, gynecologic, urologic, and nonabdominal causes (Table 33.1).[7]

HISTORY

A comprehensive *history of present illness (HPI)*, complete review of systems, and past medical history will rapidly narrow the differential diagnosis, and generally, yield an accurate diagnosis. A careful and detailed history is the most helpful factor in leading to a diagnosis. Ideally, the HPI would be the patient's own description of the onset and progression of abdominal pain including duration, quality, location, intensity, radiation, and any ameliorating or aggravating factors. Identification of the *location* of pain helps to narrow the differential (Fig. 33.2).[7,8] However, location of the pain can be deceptive. For example, in perforated peptic ulcer disease, the source is the stomach but pain may be perceived along the RLQ secondary to gastric and pancreatic/biliary fluid tracking down the right paracolic gutter.

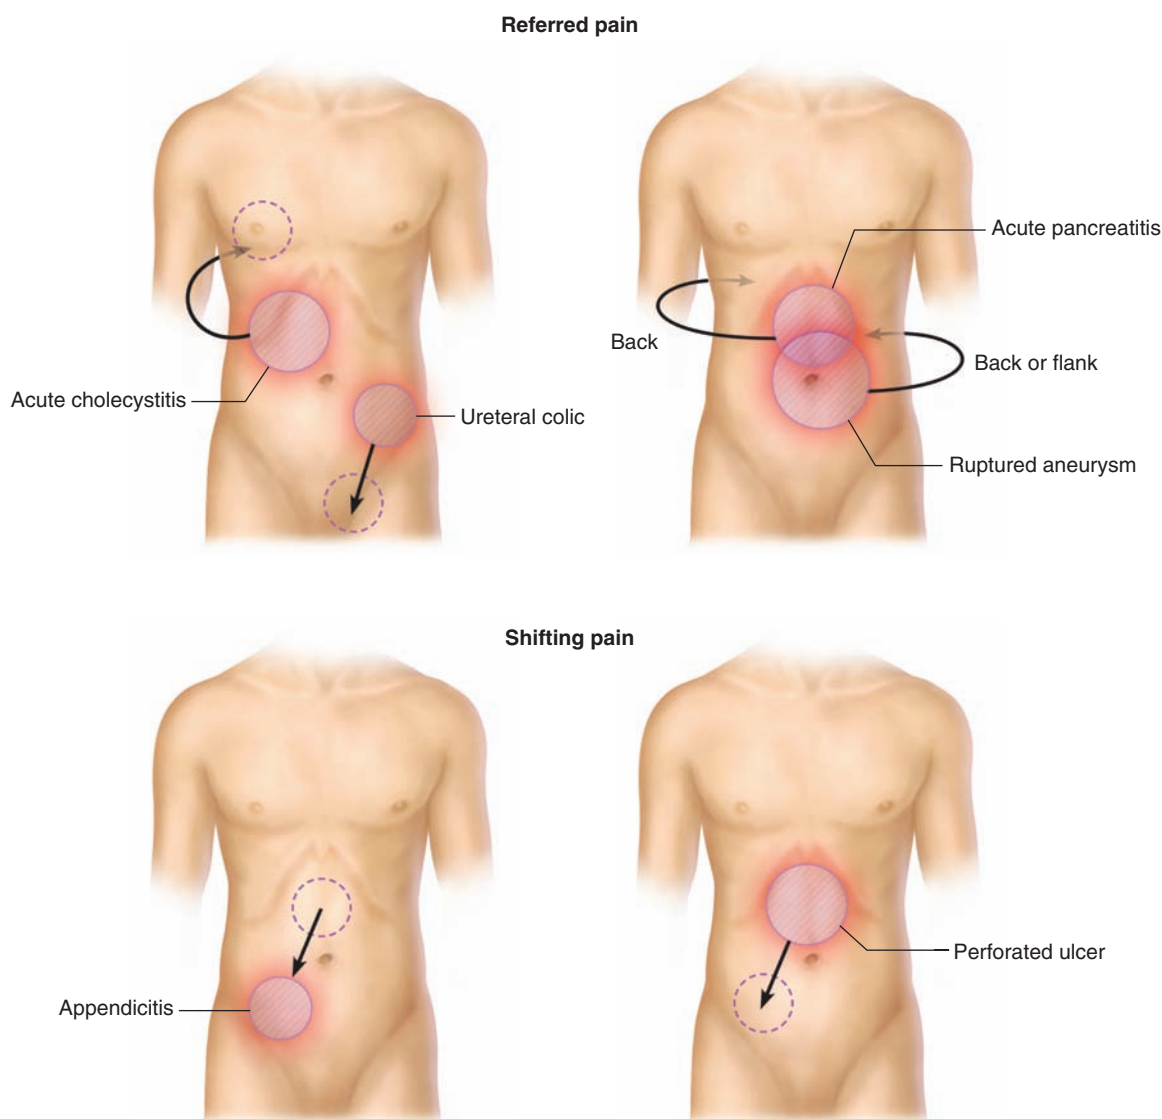
Radiation of Pain. There are classic pain radiation patterns that strengthen a diagnosis (Fig. 33.1).

Periumbilical pain radiating to the back is associated with pancreatitis, perforated peptic ulcer disease, or aortic dissection. Subcostal left-sided abdominal pain with radiation to the shoulder may indicate an evolving myocardial infarction (MI), splenic pathology, or left subdiaphragmatic abscess. Right-sided abdominal pain may be seen with pleurisy or pneumonia. Pain from the flank radiating to the groin may indicate the presence of a ureteral stone.

Onset of Pain. Acute or abrupt onset of pain can be associated with a vascular etiology (acute mesenteric embolism, abdominal aortic aneurysm [AAA] rupture) or a perforated viscus. On the other hand, more gradual onset of pain is more characteristic of nonperforated peptic ulcer disease, cholecystitis, pancreatitis, diverticulitis, or appendicitis.

Character of Pain. Taken together with location, the character of pain gives further insight as to the abdominal process (Fig. 33.2). Cramping pain (colicky) is characteristic of bowel obstruction or gastroenteritis. Steadily increasing, constant pain indicates inflammatory and infectious etiologies, such as appendicitis, pancreatitis, cholecystitis, or diverticulitis.

Severity of Pain. Usually the greater the severity of the pain, the higher the likelihood of significant abdominal pathology.

Referred pain


Shifting pain

FIGURE 33.1. Referred pain and shifting pain in the acute abdomen. *Solid circles* indicate the site of maximum pain; dashed circles indicate sites of lesser pain. (Adapted from Doherty GM. The acute abdomen. In: Doherty GM, ed. *Current Surgical Diagnosis and Treatment*. 13th ed. New York, NY: McGraw-Hill/Lange; 2009: Figure 21.2, pg 453.)

On the other hand, patient characteristics, such as personality, medications, age, comorbidities, can influence the perceived pain. Serially following the severity of abdominal pain is important; this should be performed by the same examiner whenever possible to avoid interobserver variability. Pain scales can also help reduce this variability. Determination of *aggravating or alleviating factors* can be helpful in evaluation of the pain. Sitting up and leaning forward classically decreases pain in patients with pancreatitis. Any movement aggravates pain in patients with peritonitis; someone bumping the bed, hitting potholes on the ride to the hospital. *Associated symptoms* help narrow a differential diagnosis. For example, bloody diarrhea, fever, and abdominal pain may indicate acute mesenteric ischemia or inflammatory bowel disease. Nausea and vomiting with diarrhea prior to the onset of pain helps make the diagnosis of gastroenteritis. *Gynecologic/menstrual history* must be obtained in all women. Pain in the middle of the menstrual cycle may indicate ovulatory pain. Absence of menses when expected may indicate the possibility of an

ectopic pregnancy. Previous pelvic infections or sexually transmitted diseases may raise suspicion of pelvic inflammatory disease. Monthly cyclical lower abdominal/pelvic pain may indicate endometriosis.

Past medical history paints a picture of the patient's overall health. In addition, known medical problems, prior operations and procedures (especially in our era of coronary stents and percutaneous angioplasty, and arterial stents), and current medications should be detailed. Comorbidities should be interpreted as potential sources of abdominal pathology (i.e., thromboembolic, mesenteric ischemia due to chronic atrial fibrillation). Diabetes or an immunosuppressed state may diminish perceived abdominal pain and minimize physical findings; the threshold for operative or other definitive intervention may be lower. Previous operations may suggest a postoperative complication or adhesions as a cause of bowel obstruction. A medication history is also important; certain diagnoses become more likely. For example, the use of nonsteroidal antiinflammatory drugs (NSAIDs) or corticosteroids would raise suspicion of a peptic ulcer or a perforated ulcer; digoxin use may raise the possibility of acute mesenteric ischemia; corticosteroids may mask significant underlying abdominal pathology. Allergies should be documented. A social history includes smoking, alcohol, and drug. Equally important are home, occupational, and travel exposures. For the unresponsive ICU patient, interview close family members, question the nursing staff, and review medical records.[7]

PHYSICAL EXAM

The general appearance of a patient helps with diagnosis and determination of the acuteness of treatment. Begin treatment of the acutely ill patient while working through the assessment and search for a diagnosis; treat the sick patient empirically, without a definitive diagnosis. A hypotensive patient with acute abdominal pain usually indicates concomitant septic shock, ruptured ectopic pregnancy, or rupture of a visceral or AAA. Other findings on examination may suggest the etiology of the abdominal pain. Patients with jaundice usually have a hepatobiliary source of their pain. A patient who is restless suggests renal colic as opposed to the patient with peritonitis who tries to lie motionless. Findings such as lethargy, sunken eyes, and poor skin turgor indicate dehydration, seen in cases of bowel obstruction, pancreatitis, and colitis with prolonged diarrhea.

Attention should then focus on the patient's vital signs, considering that the threshold for concern must be tailored to the information gleaned from the historical exam. For instance, elderly patients will not match the physiologic response of younger patients. Similar forme fruste presentations are encountered in immunosuppressed or immunocompromised patients, who comprise an increasing proportion of the general population.

The abdominal examination is performed with the patient supine. *Inspection* of the abdomen for signs of bruising, mottling, erythema, and prior surgical scars should be noted. A bulge in the groin or umbilicus may be secondary to an incarcerated hernia and also the cause of the patient's bowel obstruction. A flank hematoma (Grey-Turner's sign) or periumbilical hematoma (Cullen's sign) suggests severe hemorrhagic pancreatitis or ruptured AAA. *Auscultation* of the abdomen should document presence and character of bowel sounds. The presence of active, high-pitched bowel sounds indicates a mechanical small bowel obstruction. Absent or hypoactive bowel sounds suggest peritonitis or ileus. Bruits over the renal veins or visceral aneurysms may also be heard.

Abrupt, excruciating pain

Myocardial infarction

Biliary colic

Ureteral colic

Perforated ulcer

Ruptured aneurysm

Rapid onset of severe, constant pain

Acute pancreatitis

Mesenteric thrombosis strangulated bowel

Ectopic pregnancy

Gradual, steady pain

Acute cholecystitis, acute cholangitis, acute hepatitis

Appendicitis, acute salpingitis

Diverticulitis

Intermittent, colicky pain crescendo with free intervals

Early pancreatitis (rare)

Small bowel obstruction

Inflammatory bowel disease

FIGURE 33.2. The location and character of pain are helpful in the differential diagnosis of the acute abdomen. Adapted from Doherty GM. The acute abdomen. In: Doherty GM, ed. *Current Surgical Diagnosis and Treatment*. 13th ed. New York, NY: McGraw-Hill/Lange; 2009: Figure 21.3, pg 454.)

If the patient is able, have him or her indicate with one finger the point of greatest pain. *Percussion* of the abdomen in all four quadrants may reveal tympany or dullness, and at times, peritonitis. Start with shallow *palpation* in the area of least pain and progress to the most painful area; this will help maintain a relaxed patient and enable a thorough exam. Involuntary guarding and rebound tenderness indicate peritonitis. A patient with rebound tenderness has exacerbation or onset of pain immediately after rapid removal of the examiner's hand pushing deeply into the abdomen. The presence of peritonitis should not be tested by this method because of the extreme pain it causes; you will lose your patient's trust. Instead, peritonitis can be assessed effectively by percussion, gentle palpation, rocking the patient's bed, or tapping the patient's heel. In a child, this can be assessed by having the child hop on one foot. Furthermore, the diffuseness of peritonitis dictates management. Diffuse peritonitis usually indicates an abdominal catastrophe and mandates surgical exploration. In a patient with altered mental status, grimacing, increased agitation, or purposeful attempts to move the hand of the examiner are "peritonitis equivalents," as are physiologic changes of tachycardia, tachypnea, and hypertension in response to palpation. The costovertebral areas should also be palpated or lightly tapped. Tenderness may indicate acute pyelonephritis. *Rovsing's sign* is more pain in the RLQ when pressure is applied to the left lower

quadrant (seen with appendicitis). *Psoas sign* is pain with flexion or extension of the hip (seen in patients with psoas abscess or appendicitis, often retrocecal). The *obturator sign* is pain with internal/external rotation of the hip (appendicitis). *Murphy's sign* is an abrupt stop in inspiration during palpation over the right subcostal area (seen in patients with acute cholecystitis).

The rectal exam with stool guaiac is an important part of a complete physical exam. Tenderness along the right rectal vault supports the diagnosis of appendicitis or an abscess. A guaiac-positive study suggests colitis, GI bleeding (i.e., peptic ulcer or colitis), or cancer.

In women with abdominal pain, a pelvic exam is essential to differentiate gynecological from other abdominal causes of pain. Cervical discharge is consistent with pelvic infection and pelvic inflammatory disease. A bimanual exam should be performed and can help diagnose pelvic inflammatory disease, an ovarian mass, or a tubo-ovarian abscess (TOA). Right upper quadrant pain may be from Fitz-Hugh-Curtis disease, perihepatitis from pelvic inflammatory disease.

Palpation of an uninvolved region (i.e., thorax) can help distinguish pain of true abdominal pathology from a response to mere tactile stimulation. Serial exams can provide invaluable information in the patient without an obvious indication for operative intervention. Ideally, serial exams are performed by the same individual to allow more accurate comparison

and avoid interrater variability. Analgesia is often withheld under the premise it obfuscates evaluation of the pain and its progression. A 2007 Cochrane Review by Manterola et al. identified six randomized control trials evaluating the use of narcotic analgesia in the evaluation of acute abdominal pain. The review demonstrated that administration of pain medication increases patient comfort without impact on the timing or accuracy of diagnosis.[3,4]

LABORATORY DATA

Laboratory data are adjunctive measures to support a diagnosis and should be tailored to the circumstances of the patient's history and physical (Table 33.2). The commonly encountered "shotgun" battery of biochemical testing does little other than consume valuable resources and potentially obscure the diagnosis with superfluous information.[5] However, in evaluation of a complex intensive care patient, in which time is of the essence, a broader approach is employed, which may incorporate an initial comprehensive set of biochemical and hematological studies. Nonetheless, these too should be customized to a differential obtained from the historical and physical examination. Test results should be evaluated not only as low, high, or normal, but also trended over time. Although the patient with an acute abdomen generally presents with an elevated white blood cell (WBC) count, an elevated WBC is not always seen in the acute abdomen. A "left shift" or "bandemia" can occur even if the total WBC is normal and is also indicative of an infection. The patient with dehydration (i.e., after excessive vomiting, third-spacing, or diarrhea) will present with hemoconcentration (elevated hemoglobin and hematocrit); an increased blood urea nitrogen/ creatinine (BUN/Cr) ratio (>20:1) is also indicative of dehydration. Hypochloremic, hypokalemic, metabolic alkalosis is often seen after prolonged vomiting. An anion gap metabolic acidosis (serum [Na]–serum [Cl]–serum [HCO$_3$] >= 12) indicates uremia, diabetic ketoacidosis, or lactic acidosis as concomitant processes. Creatinine determination is often needed prior to a contrast computed tomography (CT) scan to determine risk versus benefit.

Liver Function Tests. Transaminases (aspartate aminotransferase/alanine aminotransferase (AST, ALT)) may be elevated from numerous hepatobiliary disease states. Significant elevations indicate a hepatic process (i.e., viral hepatitis, abscess, ischemia, acetaminophen poisoning), usually with levels greater than three times normal. Lower levels can be nonspecific and due to a variety of causes including common bile duct stones, pancreatitis, steatohepatitis, and medications (i.e., statins). Alkaline phosphatase is produced by the cells lining the biliary tree. Elevation in its levels suggests a biliary process such as common bile duct stone, cholangitis, primary biliary sclerosis, or primary sclerosing cholangitis. However, alkaline phosphatase is produced by other organs including the gut, placenta, and bone. Therefore, a gamma-glutamyl transpeptidase GGTP level can be useful as it isolates the increased alkaline phosphatase as originating from the biliary tree.

The prothrombin time (PT) and albumin level indicate synthetic *function* of the liver. An elevated PT or decreased albumin level can indicate long-standing liver disease such as cirrhosis, important in the event a patient needs an operation. *Pancreatic Enzymes.* Amylase levels are elevated in pancreatitis with rise within 2–12 hours of symptoms and return to

TABLE 33.2

BIOCHEMICAL AND HEMATOLOGICAL LABORATORY ANALYSES

■ STUDY	■ COMPONENTS	■ INTERPRETATION/CAVEATS
Arterial blood gas (Acid–base status)	• Base deficit (BD) • Lactate	• Initial BD > 6 or lactate > 4, as well as, failure to correct these values within 24–48 hours are independent risk factors for increased mortality. • Elevated lactate levels may occur in the setting of accelerated production (i.e., catecholamine administration) or diminished metabolism (i.e. hepatic dysfunction).
Complete blood count	• WBC count and differential • Hemoglobin (Hgb) • Platelet count	• Normal WBC with bandemia is synonymous with leukocytosis. • Leukocytosis may be induced with corticosteroid use. • Acute anemia may indicate bleeding or dilutional effects of resuscitation. • Normal platelet count may not reflect normal platelet function (i.e., Aspirin, Clopidogrel)
Chemistry	• Electrolytes • BUN/creatinine • Glucose	• Consider GI losses, fluid resuscitation, diuretics, medications, and transcellular shifts due to acid-base disorders in the evaluation of electrolyte abnormalities. • BUN/creatinine ratio > 20 suggests hypovolemia (i.e., dehydration), but may also occur with upper GI hemorrhage • Hyperglycemia or hypoglycemia may occur with sepsis or corticosteroid use, in addition to diabetes. • Hypoglycemia due to hepatic insufficiency is indicative of severe hepatic dysfunction
Hepatobiliary tests	• Liver function tests (LFT) • Bilirubin • Amylase/lipase	• Elevated LFTs, in particular the transaminases, may be induced by severe shock due to hemorrhage or sepsis. • Elevated bilirubin, gamma-glutamyl transferase, and alkaline phosphatase are markers of biliary obstruction. • Hyperamylasemia typically occurs with pancreatitis, but may also be secondary to acute renal insufficiency or a perforated hollow viscus.
Coagulation studies	• Prothrombin time • INR	• Markers of hepatic synthetic function. • May be abnormally elevated from DIC, hepatic insufficiency, prior Coumadin use, or severe malnutrition.

normal over next 3–5 days. Peak levels occur within the first 48 hours of symptoms.[3,9] Because of pancreas "burn-out" in chronic pancreatitis, levels can be normal despite an episode of acute, often severe, pancreatitis. Thus, amylase levels do not correlate with etiology or severity of pancreatitis. In addition, hyperamylasemia is nonspecific and may be seen with inflammation of the GI tract, many gynecological diseases, renal failure, and salivary gland inflammation. Lipase levels are elevated in pancreatitis, will rise slightly later (4–8 hours), peak earlier (24 hours), and return to normal longer (8–14 days) than amylase.[3] Similar to amylase levels, lipase levels can be elevated in other intraabdominal pathology and renal insufficiency. Lipase levels are considered more specific than serum amylase for acute pancreatitis, especially in alcoholic pancreatitis.[3,9] However, levels *do not* correlate with etiology or severity.

Urinalysis (UA). Microscopic hematuria raises the possibility of a kidney stone or urological cancer. Pyuria, positive nitrite, and leukoesterase indicate acute pyelonephritis or cystitis. On the other hand, a "positive" urinalysis (i.e., with positive leukoesterase and few WBC's) may be secondary to an inflammatory process in the abdomen such as appendicitis rather than a urinary tract infection. A *pregnancy test* is mandatory in women of child-bearing age.

Erythrocyte sedimentation rate and C-reactive protein are nonspecific markers of inflammation and acute stress that are not useful in the acute abdomen but may be followed over time to trend a patient's response to treatment. Further study is needed to delineate the diagnostic utility in the acute abdomen of biomarkers such as procalcitonin.[10]

IMAGING

Improvements in abdominal imaging modalities have fostered a better appreciation of the advantages and limitations of each study in the evaluation of the acute abdomen.

X-ray. Plain radiographs of the abdomen and chest are inexpensive, portable, quickly performed tests, yet insensitive. They are a 'confluence of shadows,' dependent upon contrasting densities of apposed organs. Nonetheless, plain radiographs can reveal the dilated loops of a mechanical bowel obstruction, pneumoperitoneum of a perforated hollow viscus, or the thumbprinting indicative of pneumatosis. Portal venous gas may be seen in plain radiographs, related to intestinal ischemia or gas producing organisms. Calcifications may be seen in the pancreas, gallbladder, or aorta. Only 15% of gallstones are radiopaque, but 90% of kidney stones are opaque. The finding of a fecolith, occurring in 50% cases of appendicitis can be helpful.

Serial x-rays may be used to show the passage of previously administered oral contrast. However, if a CT scan is planned, no additional value is obtained from plain films in the evaluation of undifferentiated acute abdominal pain.[11-13]

Computed Tomography Scan. CT is a rapidly performed exam, although more expensive than plain films, which provides specific information about hollow and solid viscera, vasculature, muscles, and bones. However, the patient must be physiologically stable, as the CT suite is rarely equipped with resources to treat an unstable patient. Furthermore, the data would suggest that for moribund patients, the decision to operate should not be based on CT findings, and completion of the scan only delays surgical intervention.[14]

CT can be performed with or without intravenous or oral contrast. Patients with contrast allergies can be premedicated with a steroid and benadryl protocol. The administration of intravenous contrast provides an evaluation of organ perfusion, parenchymal injury, areas of differing perfusion (i.e., hematoma vs. parenchyma), and even thrombosis of vessels, but it has not been demonstrated to increase the rate of diagnosis.[15-17] Oral contrast requires time for intestinal passage. It is generally not necessary for the evaluation of small bowel obstruction or trauma patients and is relatively contraindicated in patients for whom an emergent scan is desired. A recent retrospective study of various combinations of intravenous, oral, and rectal contrast for CT of patients with an acute abdomen noted no difference in accuracy of diagnosis in enhanced compared to unenhanced scans.[16,17] In the acutely ill patient, an unenhanced scan eliminates the risks associated with contrast aspiration and renal injury. If contrast is used, extraluminal free fluid can be evaluated by Hounsfield units (HU) to help determine its source and significance. Typically, serous fluid is 0–20 HU, exudative or purulent fluid is 20–40 HU, and blood is 40 HU.[18] Although CT may be used to confirm the inflammatory changes of acute cholecystitis, remember that gallstones are commonly not seen (one-third) on CT.

Ultrasound. Ultrasound exams are noninvasive tests that can be performed at the patient's bedside. Focused abdominal sonography for trauma (FAST) is a rapid ultrasound exam used in trauma patients to evaluate the presence of fluid in four regions: the pericardium, the perihepatic region, the perisplenic area, and the pelvis. Right upper quadrant ultrasound can be used to evaluate liver parenchyma and the biliary system for ductal dilatation, stones, and surrounding fluid. Sensitivity is less than that of a CT scan in diagnosis of acute abdominal pathology (70% vs. 89%), but it is noninvasive and eliminates the risks of radiation.[19] Vaginal and RLQ ultrasound can be used to diagnose ovarian torsion and cysts and to confirm the diagnosis of appendicitis. Sonograms are routinely used in the pediatric population to evaluate abdominal pain. The primary limitations of ultrasonography include poor acoustic windows (i.e., obesity, clothing, or splints) and the study is operator-dependent.

Magnetic Resonance Imaging. MRI studies are less practical in the acute abdominal setting due to the time required to perform the test. An unstable patient does not belong in the MRI scanner; the closed environment is even less conducive to prompt treatment than CT. Also, patients with pacemakers or other metallic implants are not candidates for an MRI. MRI is often more useful in the investigation of chronic abdominal pain and abdominal masses. Magnetic resonance cholangio-pancreatography is sensitive in the diagnosis of biliary and pancreatic pathology, associated with equal accuracy as endoscopic retrograde cholangiopancreatography (ERCP), but it is not a therapeutic option.[20] Unlike plain radiography and CT imaging, surgeons are less proficient at reading MRI than x-rays, ultrasound, and CT, and so a radiologist's interpretation is often necessary.

Angiography. Although the gold standard for vascular imaging and rapidly becoming the first line of intervention for vascular pathology, angiography has been supplanted by CT angiography as the diagnostic method of choice. There are circumstances, however, in which angiography is invaluable: type B aortic dissection, acute thromboembolism, chronic mesenteric ischemia, and rectus sheath or retroperitoneal hematomas. These are clinical situations in which angiographic therapies (i.e., stenting, embolization) may be the best treatment option.

DIAGNOSTIC ADJUNCTS

Once the differential diagnosis of acute abdominal pain has become more focused, specific invasive adjunctive tests can aid precise diagnosis, and may also be therapeutic.

Diagnostic Peritoneal Lavage (DPL). Introduced in 1965, diagnostic peritoneal lavage (DPL) had been primarily limited to the evaluation of the unstable trauma patient. Performance of a DPL involves the insertion of a catheter into

the peritoneum, followed by lavage with warm saline. For trauma patients, frank blood, intestinal contents, or a cytologic assessment >500 WBCs per mm^3 or >100,000 RBCs per mm^3 is considered indicative of injury, necessitating either CT to evaluate solid injury in the hemodynamically stable patient or surgical exploration in the unstable patient. Recent studies have shown that DPL may be useful in the assessment of the nontraumatic acute abdomen to confirm or disprove the presence of intraabdominal pathology in the hypotensive, septic patient.[21,22] Equipoise persists regarding the WBC threshold for operative intervention. Cytology results of >200 WBCs per mm^3 is our generally accepted threshold for operative exploration in the nontrauma patient suspected of harboring acute abdominal pathology.

Endoscopy. Upper endoscopy allows evaluation of the esophagus, stomach, and first part of the small intestine. It can be performed in the patient's ICU room, provided that sedation can be administered, and adequate oxygenation and respiration can be maintained and monitored. Esophagitis, gastritis, and peptic ulcer disease can be diagnosed, biopsies can be taken, and if bleeding is noted, cautery, clipping, or injections of epinephrine may be therapeutic as well.

Colonoscopy/Sigmoidoscopy may be helpful in diagnosis or exclusion of certain pathology. Flexible sigmoidoscopy or colonoscopy is often used to diagnose colonic ischemia, especially in the setting of abdominal pain and diarrhea after abdominal aorta surgery. They can also be used in the evaluation of possible inflammatory bowel disease, infectious colitis (i.e. presence of pseudomembranes), and volvulus.

Laparoscopy. While exploration of the abdomen is one endpoint of the algorithm in evaluation of the patient with an acute abdomen, an unstable patient may not tolerate a nontherapeutic trip to the operating room. Diagnostic laparoscopy can be an extension of a DPL and can be performed under sterile conditions in the ICU if necessary. Walsh et al.[23] found bedside laparoscopy to be more accurate than DPL at prediction of need for laparotomy.

Hepatobiliary Imaging (HIDA). Nonfilling of the gallbladder 60 minutes after administration of intravenous biliary radiopharmaceutical can be used to diagnose cholecystitis with equivocal ultrasound results or in acalculous cholecystitis. The specificity can be increased by giving morphine. False positives do occur in critically ill, malnourished, or patients on total parental nutrition.

COMMON CAUSES OF THE ACUTE ABDOMEN

Acute appendicitis can occur in any patient (see chapter 37). A history of several hours of periumbilical or epigastric pain that eventually settles in the RLQ is classic. It is frequently associated with anorexia and nausea; emesis may also be present. No specific past medical history is predictive except the presence of an appendix. On exam, focal peritonitis at McBurney's point (one-third of the distance between the anterior superior iliac spine and the umbilicus) is the most common finding. A psoas sign, pain upon active flexion, or passive extension of the right hip, supports the diagnosis. With associated leukocytosis, no further studies or imaging are needed prior to operative intervention. In female patients, gynecologic etiologies must also be considered, including a ruptured ovarian cyst, ovarian torsion, TOA, and ectopic pregnancy. The differential diagnosis also includes terminal ileitis associated with inflammatory bowel diseases. Ultrasound or CT scan can be performed to confirm the diagnosis of appendicitis.[24-26] Alternatively, a laparoscopic approach to appendectomy allows intraoperative evaluation of the appendix, small bowel, and pelvic structures when the diagnosis is unclear.

Cholelithiasis/Cholecystitis. (See Chapter 39) Ultrasound is the study of choice for diagnosis. Gallstones can be detected in most (>95%) patients with cholelithiasis. CT is commonly used as a screening test in patients with abdominal pain; one-third of gallstones are not visualized on CT. The patient with postprandial right upper quadrant abdominal pain, gallstones, but no tenderness, leukocytosis, or fever has biliary colic. This patient can be scheduled for elective cholecystectomy. However, the patient with right upper quadrant tenderness, confirmed gallstones, and leukocytosis or fever has acute cholecystitis. Positive findings of cholecystitis on ultrasound or CT include gallbladder wall thickening (>3mm), pericholecystic fluid, and sonographic Murphy's sign, in addition to the presence of stones. Dilation of the common bile duct (CBD) (variable according to age but >7–8 mm) may indicate biliary obstruction secondary to a stone, stricture, or mass. The treatment for acute cholecystitis is intravenous antibiotics, bowel rest, and ideally laparoscopic cholecystectomy within 24 hours of admission.

Acute Pancreatitis. Acute pancreatitis is most commonly due to choledocholithiasis or alcohol ingestion. Acute pancreatitis is an inflammatory process diagnosed by the combination of epigastric abdominal pain, elevation of serum pancreatic enzymes (amylase or lipase), or CT evidence of pancreatic inflammation. In the majority of patients, pancreatitis is a self-limited process with mild abdominal pain and rapid resolution. If the etiology is choledocholithiasis and the patient improves clinically within several days as generally occurs (presumably with the stone passing through the common bile duct), laparoscopic cholecystectomy should be performed during the same hospital admission. The utility of intraoperative cholangiogram in this setting is still debated (see Chapter on Pancreatitis). However, in one-quarter of patients, acute pancreatitis is a severe, life-threatening condition. Thus, optimal treatment varies significantly, based on severity of the disease, underlying etiology and potential complications such as pseudocyst, necrosis, infection, or abdominal compartment syndrome (ACS) (see Chapter 38).

Acute Mesenteric Ischemia commonly presents as sudden onset of severe, diffuse abdominal pain frequently in the context of preexisting coronary artery disease, peripheral vascular disease, or atrial fibrillation. Prior AAA repair eliminates the inferior mesenteric artery, making more of the bowel dependent upon perfusion from the superior mesenteric artery. Vital sign abnormalities include tachycardia (if the patient is not receiving beta blockade), with or without hypotension, and tachypnea depending on the degree of ischemia and acidosis. The classic physical finding is pain which is out of proportion to examination; deep palpation may elicit a degree of tenderness less than anticipated. Aortic occlusion or a state of global low perfusion can also cause mottling of the skin of the lower abdomen and lower extremities. High doses of vasopressors can exacerbate this condition. Decreased or absent urine output is associated with mesenteric ischemia, and an elevated WBC count, lactate, and base deficit are generally seen. Abdominal x-rays may demonstrate a thumbprinted appearance of the intestine and Doppler ultrasound may reveal decreased or occluded mesenteric blood flow. CT tends to be more specific, showing thickened bowel wall, pneumatosis, free fluid, or occlusion of the aorta, celiac, or superior mesenteric artery.[27,28] Diagnosis is confirmed at the time of laparotomy. Eltarawy et al. showed that surgical consultation >24 hours after disease onset and operation >6 hours after the time of consult were associated with increased mortality.[14] Patients with delayed surgical consultation were more likely to have abdominal distension, elevated lactate concentration, acute renal failure, and vasopressor administration, and performing a CT scan further delayed definitive treatment.[14] Hence, the ideal approach is a good history and exam, combined with a low threshold of suspicion.

EMERGENCY SURGERY

Bowel Obstruction. The history of illness includes abdominal pain and distension associated with nausea, emesis, obstipation or constipation, typically in a patient with prior abdominal surgery. Distension, with or without focal or diffuse tenderness, is typical. Abdominal scars and hernias should be carefully noted; an incarcerated hernia is especially concerning. Leukocytosis is not uncommon. X-rays may show air-fluid levels; a paucity of air in the distal colon and rectum indicates complete obstruction. CT can identify a specific transition point of obstruction. Bowel obstruction due to an internal hernia is seen as spiraling of the mesentery on CT imaging. CT may also provide evidence of impending or complete strangulation; thickened bowel wall, ascites, or lack of enhancement with IV contrast.[29] Oral contrast provides little benefit and poses the risks of emesis and aspiration pneumonitis.[17] Symptoms of a partial small bowel obstruction often improve with nasogastric decompression, while acute mesenteric ischemia continues to progress until treated.[14] Complete bowel obstruction or closed loop obstruction requires immediate laparotomy (see Chapter 36).

Clostridium difficile Colitis. The epidemiology of *Clostridium difficile* has changed significantly over the last two decades, although it remains the most common cause of antibiotic-associated colitis. *C. difficile* colitis is an increasing nosocomial problem in North America and Western Europe. Since 2002, the incidence has increased, relapses have become more frequent, and the fatality rate has increased.[30] The three major risk factors are the administration of antibiotics, age > 65 years, and prior hospitalization.[31] Even a single dose of antibiotics can induce the disease. Abdominal cramping, fever, and diarrhea are common symptoms at presentation. Diarrhea may be absent in up to 20% of patients. On exam, the patient is often distended and diffusely tender. The most notable change is a marked leukocytosis (WBC ≥ 30,000/mm³).[32] Stool specimens should be evaluated for the presence of toxins A and B, although if suspicion is high, treatment should be initiated without delay. Radiographs are nonspecific. CT will show a thickened colon with or without associated ascites. On lower endoscopy, the patient will have pseudomembranes, although this is rarely performed in the acute setting. In a study by Dallal et al. the false negative rate of stool studies and endoscopy approached 15%, while the sensitivity of diagnosis by CT scan was 100%.[31] As the infection progresses, tachycardia, hypotension, and renal failure can develop quickly. A prompt response to metronidazole is consistent with this antibiotic-associated colitis, although with increasingly virulent and resistant strains, enteral vancomycin is now recognized as the first line treatment of severe *C. difficile* infection in the ICU setting.[30] When patients fail to respond to medical management, operative intervention is necessary. Traditionally, these patients underwent total abdominal colectomy and end ileostomy. A colon-sparing technique of laparoscopic loop ileostomy with subsequent serial vancomycin flushes through the colon is currently being evaluated at our institution with encouraging initial results (see chapter 35).

Peptic Ulcer Disease. Risk factors for peptic ulcer disease include NSAIDs, smoking, chronic illness, burns, steroid use, and a prior history of peptic ulcer disease (see chapter 35). Postprandial epigastric pain is a classic symptom, although with perforation, the pain becomes sharp and diffuse. It is not uncommon for the patient to report the exact time of symptom onset. The pain may be associated with nausea and vomiting, and peritonitis is frequent. The most common lab abnormality is leukocytosis, and hyperamylasemia may be seen. Upright chest x-ray will often show free air under the diaphragm. CT may show thickening, inflammation, and stranding around the stomach and duodenum as well as free air or free fluid. In the absence of perforation, upper endoscopy is highly accurate for peptic ulcer disease, and enables the acquisition of tissue for assessment of *Helicobator pylori*. Details regarding management are in chapter 35.

Ovarian/Uterine Pathology. Ovarian cysts or masses leading to ovarian torsion, TOA, or ectopic pregnancy usually present as unilateral lower abdominal pain, while pelvic inflammatory disease presents with more midline pelvic pain. The investigation of lower abdominal pain in a female patient must include a detailed gynecologic, obstetric, and social history. All females of childbearing age should undergo a pregnancy test. Women who have ovarian cysts may experience sharp pain around the time of ovulation and cyst rupture. Cysts or masses >5 cm in size are at risk for torsion, which is typically accompanied by severe, sharp, and continuous pain. The pain often resolves with spontaneous detorsion. Pain due to ectopic pregnancy lateralizes to one side of the abdomen soon after a missed period, and may be accompanied by vaginal spotting bleeding. Ectopic pregnancy can be life-threatening due to fallopian rupture and hemorrhage. Primary TOA develops in the majority of cases as a complication of pelvic inflammatory disease (PID), although they may develop after pelvic surgery.[33] Secondary TOAs result from bowel perforation (appendicitis, diverticulitis) with intraperitoneal spread of infection or in association with pelvic malignancy. Distinguishing between primary and secondary TOA is difficult. Primary TOA is the most common diagnosis in premenopausal women who are sexually active. However, in postmenopausal women, the presence of a gynecologic malignancy or other pelvic pathology causing secondary TOA must be excluded.[34] Pelvic ultrasound is the most frequently used method for characterization of ovarian pathology (see chapter 44).[35]

Intraabdominal Hypertension (IAH)/Abdominal Compartment Syndrome (ACS). The World Society of Abdominal Compartment Syndrome defines normal intraabdominal pressure (IAP) in critically ill adults as 5–7 mm Hg and abdominal hypertension as IAPs > 12 mm Hg. ACS is a sustained IAP > 20 mm Hg associated with new organ dysfunction. IAH and ACS occur in approximately 35% and 5% of ICU patients, respectively.[36] ACS is traditionally thought of as a traumatic or surgical entity, but it is being equally recognized in medical ICUs.

Patients at risk for IAH include critically ill patients, who have some element of decreased organ perfusion with a systemic inflammatory response that leads to capillary leakage. Aggressive fluid resuscitation leads to tissue edema, including the bowel wall and the mesentery, resulting in IAH.[37] This increased pressure compresses tissues and vessels leading to decreased perfusion and organ dysfunction. Conditions that predispose patients to the development of ACS include sepsis; ascites; intraperitoneal, retroperitoneal or abdominal wall bleeding; intraabdominal malignancy; laparotomy closed under tension; a positive intraoperative fluid balance >6 L; and polysystem traumatic or thermal injury.[36]

IAH leads to physiologic alterations that can result in falsely elevated central venous pressure and pulmonary artery wedge pressure. All patients at risk for ACS should have IAP measured and trended. Kirkpatrick et al. and Sugrue et al. compared IAP measurements to physical examination. Clinical judgment failed to detect significant IAH > 40% of the time.[38,39] IAP can be measured using gastric, bladder, or rectal manometry. Obeid et al.[40] found bladder pressure to be the most accurate and the most technically reliable method. Measurements are obtained by instilling 25–50 mL of saline into the bladder with the foley clamped, attaching IV pressure tubing to the foley, and transducing at the level of the bladder. Using volumes >50 mL may cause overestimation of IAP.[41]

The treatment of ACS is urgent surgical decompression. Interventions to manage IAH include the following: (1) decompression of intraluminal contents (stomach, bladder, colon), (2) evacuation of extraluminal contents (i.e., ascites), (3) increased abdominal wall compliance by neuromuscular

blockade, (4) careful fluid and vasopressor management to maintain tissue perfusion, and (5) treatment of the underlying source of the inflammatory response.

UNIQUE POPULATIONS

Certain patient populations may present a more complicated picture of acute abdominal pain. Pregnant, immunosuppressed, and morbidly obese patients may present the same pathology with different signs and symptoms, obscuring the diagnosis. Consideration of etiologies specific to these populations and prompt diagnosis are important, as these patients may present late in the course of their disease, already with compromised physiology.

Pregnancy. The anatomic, physiologic, and biochemical changes associated with pregnancy must be taken into consideration in evaluation of the pregnant patient. As the gravid uterus increases in size, other structures including small and large intestine and appendix are displaced laterally and superiorly. Peritoneal signs are often absent because of the lifting and stretching of the anterior abdominal wall; the inflamed viscera are not apposed to the parietal peritoneum, thereby precluding any muscular response or guarding. GI motility is decreased due to elevated levels of progesterone, leading to constipation. Gallbladder function is impaired because of the hypotonia of the smooth muscle wall. Thus, emptying time is slowed and often incomplete, and bile stasis may lead to gallstone formation. There are no apparent morphologic changes in the liver during pregnancy, but there are functional alterations. Serum alkaline phosphatase activity may increase due to placental alkaline phosphatase isoenzymes. Plasma volume increases earlier and faster than red blood cell volume, until the end of the second trimester, when an increase in the red blood cells compensates. Hence, a mild anemia (e.g., Hct 33%) should be interpreted with caution. Total blood leukocyte count increases during pregnancy to as high as 16,000/mm^3 in later trimesters. Polymorphonuclear (PMN) leukocytes primarily contribute to this increase, as lymphocyte and monocyte numbers remain stable.[42-44]

The most useful diagnostic modalities in the pregnant patient are the history and serial exams. Laboratory values are unpredictable with the normal changes of pregnancy. Ultrasound is a useful noninvasive adjunct with no risk to the fetus. In general, maternal mortality is rare, but fetal mortality is higher when diagnosis is delayed. The most common reason for an acute abdomen in the pregnant patient is *acute appendicitis*. If the appendix progresses to perforation, fetal mortality may be as high as 36%; thus, suspicion must be high.[45] The appendix is displaced upward starting in the third month and progresses to the level of the iliac crest in the sixth month. Despite these changes, the most reliable symptom is still RLQ pain.[45] Symptoms of nausea and heartburn are nonspecific in the pregnant patient, as is leukocytosis.[46] Ultrasound is the diagnostic imaging method of choice with close to 100% sensitivity and 96% specificity, though the yield is user-dependent.[47] The risks of radiation (i.e., CT scan) are greatest during fetal organogenesis. The most sensitive time period for central nervous system teratogenesis is between 10 and 17 weeks of gestation. Of note, appendiceal rupture is twice as frequent during the third trimester.[48]

Cholecystitis affects 1/1,600–1/10,000 pregnancies.[43] Typical signs and symptoms occur, although Murphy's sign is uncommonly present. Laboratory data may demonstrate an elevated direct bilirubin and transaminases, although an elevated alkaline phosphatase is usually physiologic. Ultrasound is again the test of choice with 95% accuracy. The differential diagnosis includes MI, acute fatty liver of pregnancy, and HELLP syndrome. HELLP syndrome (hemolysis, increased liver function tests, and low platelets) carries a significant risk of both maternal and fetal mortality. It is easily confused with cholecystitis/cholelithiasis, as 65%-90% of patients with HELLP present with right upper quadrant pain.[49] HELLP must be excluded in all patients with preeclampsia, although it can present without hypertension.

Bowel obstruction occurs in 1/2,500- 1/3,500 pregnancies, usually during the third trimester.[43] Adhesions are the etiology in >60% of cases. Less common causes include volvulus, intussusception, hernia, and tumor. Patients complain of crampy abdominal pain, obstipation, and emesis. In small bowel obstruction, the pain tends to be diffuse, poorly localized upper abdominal pain that occurs in 5-minute intervals. Large bowel obstruction presents as lower abdomen or perineal pain that occurs in 15–20 minute intervals. Abdominal x-rays are generally the only imaging needed.[50] Morbidity is related to diagnostic and therapeutic delay. A common misdiagnosis is hyperemesis gravidarum, which also occurs late in pregnancy.

Pancreatitis, commonly associated with choledocholithiasis, most frequently occurs in the third trimester because of increased abdominal pressure on the biliary ducts.[43] Patients have sudden, severe epigastric pain that radiates to the back. Diagnosis is confirmed with elevated amylase and lipase levels, although these levels may be mildly elevated at baseline during the first and second trimesters. Ultrasound typically shows gallstones, ductal dilatation, or pseudocyst. *Adnexal torsion* is more common in the pregnant than in the nonpregnant patient. It presents as lateralized lower quadrant pain and is diagnosed with Doppler ultrasound to confirm decreased blood flow.

Immunosuppression. Circumstances of immunosuppression occur with organ transplantation, chemotherapy for malignancy, immunosuppressive therapy (i.e., Crohn's disease, idiopathic pulmonary fibrosis), and immunodeficiencies (i.e., HIV and AIDS). Causes of acute abdominal pain in this population can be categorized as (1) pathology closely associated with the immunocompromised state, or (2) illnesses that occur in any patient, independent of immune status.

Because recent and continuing medical advances have increased the life expectancies for this population, acute abdominal pain in immunosuppressed patients is more frequently encountered.[51,52] Classic clinical, laboratory, and radiographic evidence of intraabdominal pathology may be absent. As patients experience blunted symptoms, they tend to seek care later, often after the illness has progressed to a severe state.[53-55] The most common cause of the acute abdomen in the neutropenic patient is *neutropenic enterocolitis*, or typhilitis, with reported incidences of 0.8%-26%.[56] It has been described in other immunosuppressive states, and neutropenia is not requisite. The pathology involves mucosal injury often by cytotoxic drugs, profound neutropenia, and impaired host defense to invasion by microorganisms. Microbial infection leads to necrosis of various layers of the bowel wall.[57,58] The cecum is almost always affected because of its distensibility and decreased vascularization, compared to the rest of the colon.[59] The process often extends into the ascending colon and terminal ileum. Patients typically present with fever, RLQ pain, nausea with emesis, and watery or bloody diarrhea. CT demonstrates circumferential terminal ileum and cecal thickening with stranding of the mesentery.[60] Initial medical management is supportive; bowel rest, fluid resuscitation, total parenteral nutrition (TPN), and broad-spectrum antibiotics. Surgical intervention is reserved for cases with evidence of perforation, ischemia, persistent hemorrhage, or unresolving sepsis or peritonitis. Mortality rates are reported between 30% and 50%.[56-60]

Between 50% and 80% of the world's population is seropositive for cytomegalovirus (CMV), but primary *CMV infection* in the immunocompetent host typically is mild and clinically undetectable. Symptomatic reactivation occurs with immunocompromise or immunosuppression and may present

as CMV enterocolitis. Mucosal ulcers can develop throughout the entire GI tract, although most commonly in the colon and esophagus.[61,62] These ulcers begin with bleeding and may progress to perforation. The diagnosis may be difficult. If endoscopic biopsies are negative for CMV, testing for the presence of CMV DNA in peripheral blood by polymerase chain reaction and for CMV antibodies may confirm the diagnosis. Gancyclovir is the initial medical treatment.

The incidence of *radiation enteritis* has increased with the current trend of combined chemotherapy and radiation.[63] Caused by a progressive occlusive vasculitis, it results in bowel lumen narrowing and mucosal damage that may lead to ulceration, obstruction, fistula, and perforation. Current treatment is mainly supportive.

Ascites associated with increased abdominal girth and nausea may cause abdominal pain. The diagnosis is made through biochemical and cytologic analysis of ascitic aspirate. These patients are also at risk for spontaneous bacterial peritonitis (SBP), particularly with low protein ascites that lacks complement factors. Bloody ascites may result from a traumatic tap or be secondary to malignancy. Dark brown ascitic fluid may indicate biliary perforation or leak. The upper limit of an absolute PMN leukocyte count in uncomplicated ascitic fluid is 250 per mm³.[64] SBP is the most frequent cause of an increased ascitic WBC count with PMN predominance. A positive culture in conjunction confirms the diagnosis and is used to guide antibiotic therapy. Tuberculous peritonitis and peritoneal carcinomatosis give rise to an increased ascitic WBC count, but with lymphocyte predominance.

Posttransplant lymphoproliferative disorder (PTLD) refers to a group of B cell lymphomas occurring in immunosuppressed patients following organ transplant. The immunosuppression impairs T cell immunity and allows uncontrolled proliferation of Epstein-Barr virus (EBV)-infected B cells, resulting in monoclonal or polyclonal plasmacytic hyperplasia, B-cell hyperplasia, B-cell lymphoma, or immunoblastic lymphoma. PTLD can present as localized or disseminated disease. Clinical features may include fever, lymphadenopathy, pulmonary symptoms, central nervous system alterations, and weight loss. GI manifestations can result in an acute abdomen from bowel obstruction, ischemia, or perforation. The incidence varies with the type of allograft, occurring in 2%-3% of liver transplant recipients.[65] A higher risk is observed in children and recipients of heart and small bowel transplants. The diagnosis is based on a high index of suspicion. EBV titers should be noted, although this does not always correlate with the presence of disease.[66] Initial management of PTLD involves reduction or discontinuation of immunosuppressive agents. Several chemotherapy and radiation protocols are also available. EBV titer trends can be followed; a declining viral load suggests response to treatment. It is a difficult balance between eradication of the disease and preservation of graft function, but the diagnosis must be considered in all transplant patients with an acute abdomen.

The Obese Patient. The prevalence of obesity in the United States has been steadily increasing; overweight and obese adults constitute more than 60% of the population.[67] These patients are at greater risk of Type 2 diabetes mellitus, hypertension, hyperlipidemia, obstructive sleep apnea, cardiovascular disease, gallbladder disease, and gastroesophageal disease. The annual rate of bariatric surgical procedures performed to decrease these risks increased nearly sixfold between 1990 and 2000.[68] Obese patients with acute abdominal pain are a diagnostic challenge both before and after they have had weight loss surgery.

Physical examination can be more challenging in the overweight patient. Hernias and masses are difficult to palpate, and the degree of abdominal distension is difficult to ascertain. Radiologic imaging of the obese patient is difficult; imaging equipment and tables have size and weight limitations. Poor acoustic penetration and increased attenuation of the beam by dense subcutaneous and intraperitoneal fat yield low quality images. Low-frequency ultrasound provides the best opportunity for quality images.[69] CT can be used for a patient who does not exceed the diameter or weight limits of the machine.

Causes of the acute abdomen in this population include incisional and internal hernias, gastric outlet stenosis, marginal ulcers, band erosions, and gallstone disease. Any obese patient with epigastric pain should also be evaluated for acute cardiac pathology. Hernias from both open and laparoscopic bariatric and nonbariatric surgical procedures can lead to pain from obstructive symptoms. Increased abdominal wall laxity and difficulty performing adequate fascial closures at laparoscopic port sites contribute to the significant prevalence.[70] Internal hernias occur in up to 6% of all patients who have had gastric bypass surgery.[71] They typically occur at three locations: the transverse colon mesentery at the Roux limb hiatus, around the mesentery of the Roux limb, or at the mesenteric defect of the enteroenterostomy. CT findings may include a dilated gastric remnant, oral contrast that refluxes into the gastric remnant, or swirling of the mesenteric vessels. Persistent tachycardia despite fluid resuscitation, leukocytosis, and lactic acidemia are ominous signs of ischemia. Stenosis of the gastric outlet occurs in up to 12% of both gastric bypass and vertical banded gastroplasty patients.[72,73] The gastrojejunostomy may become inflamed and edematous or stricture due to marginal ulceration. Patients who have undergone gastric banding are at risk for band erosion into the stomach with an incidence of 0.3%-1.9%.[74-76] Pain, emesis immediately after eating, or hematemesis should prompt endoscopic evaluation.

Obese patients are more likely to have gallbladder disease than nonobese patients; however, routine cholecystectomy during bariatric surgery is not uniformly practiced. Right upper quadrant pain, nausea, and emesis after eating are common presenting symptoms. Liver function tests should be evaluated. It should be noted that after gastric bypass surgery, common bile duct stones cannot be removed via traditional ERCP. ERCP may be performed via open or laparoscopic approach through the gastric remnant at the time of cholecystectomy.[77,78]

CONCLUSION

While diagnostic and treatment innovations continue to evolve, the need for prompt diagnosis and intervention for the patient with acute abdominal pain persists. A thorough history and physical followed by specifically indicated labs and imaging provide the foundation for solving the diagnostic dilemma of the acute abdomen in increasingly complex patient populations.

EMERGENCY SURGERY

CHAPTER 34 ■ ACUTE GASTROINTESTINAL HEMORRHAGE

CHRISTOPHER J. CARLSON AND GRANT E. O'KEEFE

GENERAL CONSIDERATIONS, DEFINITIONS, AND EPIDEMIOLOGY

Gastrointestinal (GI) hemorrhage is common and remains an important cause of morbidity and mortality. The differential diagnosis of acute GI hemorrhage includes a large number of conditions and lesions, which are listed in Tables 34.1 and 34.2. The implications for the surgeon vary and depend upon the cause, location, and severity of the hemorrhage. Bleeding may be the initial manifestation of an underlying condition that requires surgery in its own right (typically GI tract malignancy). In other cases, surgery may only be required to control hemorrhage and in increasingly rare situations, may be required to control active bleeding and also treat the underlying disease (recalcitrant peptic ulcer disease). This chapter will focus on bleeding of recent onset and duration that may result in hemodynamic instability and the need for blood transfusion.

Many lesions cease bleeding spontaneously and others are so effectively treated with endoscopic methods that they rarely require surgical therapy. That surgical therapy is not often needed for the majority of GI bleeding has likely led to a general lack of experience on the part of surgeons in their management. Given that when surgery is needed, it is often emergent and patients are often critically ill, there is little room for error. With this in mind, this chapter aims to address GI hemorrhage as it is encountered by surgeons and discusses important components of nonoperative and operative management in general and where important, for specific sources of bleeding.

Bleeding has historically been categorized as "upper" or "lower" depending upon its origin relative to the ligament of Treitz. However, recent diagnostic advances (double-balloon enteroscopy and capsule endoscopy) have lead to a reevaluation of this classification scheme, in part, because small intestinal sources can now be directly visualized, which allows them to be classified separately from colonic sources.[1,2] Upper GI hemorrhage (bleeding from the esophagus, stomach, or duodenum) accounts for 80% of cases of acute GI blood loss. Lower intestinal bleeding (colon and rectum) is responsible for 15%–20% of cases. Small intestinal lesions are responsible for <1% of cases in adults. Although difficult to estimate, approximately 100 hospital admissions per 100,000 persons in the United Kingdom were related to GI hemorrhage in 1989. The incidence of both upper and lower GI hemorrhage increases markedly with age.[3]

Patients with overt GI bleeding typically present to the hospital after an episode of hematemesis (the vomiting of blood), melena, or hematochezia. Melena is a black, tarry stool due to bacterial degradation of blood and can be evident after a 100 mL hemorrhage. Bleeding from the small intestine or right colon may also appear black. Hematochezia is the passage of bright red blood from the rectum and is usually indicative of a lower GI source. However, it may also be present in cases of massive upper GI hemorrhage. Patients with acute GI bleeding may present with the hemodynamic consequences of hemorrhage, including orthostatic syncope or near-syncope,

complaints of dizziness, lightheadedness, and shortness of breath or palpitations.

History and physical examination can provide important clues to the cause and severity of bleeding. For example, melena after several days of worsening epigastric pain suggests peptic ulcer disease; whereas hematemesis or melena following vomiting or retching strongly suggests a Mallory-Weiss tear. Massive, painless upper GI hemorrhage in a patient with cirrhosis suggests bleeding from gastroesophageal varices, although other causes are responsible for bleeding in a significant number of patients with chronic liver disease.

A systematic physical examination is aimed at estimation of the magnitude of bleeding and the patient's ability to compensate. Signs and symptoms of hypovolemia include cool, clammy, mottled skin, tachycardia, tachypnea, collapsed jugular veins, oliguria, and perhaps hypotension. Advanced age, concomitant medical conditions, and their treatment (β-adrenergic blockade) can obscure these physical findings. Physical examination should also document evidence of cirrhosis and portal hypertension, and rectal examination is mandatory and may demonstrate bright red blood or melena.

INITIAL RESUSCITATION AND OVERALL DIAGNOSTIC APPROACH

Many patients will require intravenous fluid resuscitation. The need for two large-bore peripheral intravenous lines is determined by the estimated blood loss based upon history and physical examination. Most bleeding stops spontaneously and intravenous crystalloid resuscitation may be all that is required. However, in all cases, blood is drawn for type and crossmatch, complete blood count with platelet count, serum electrolyte, glucose, BUN and creatinine concentrations, liver function tests, and coagulation profile.

Patients presenting with hypotension or evidence of impaired end organ perfusion (oliguria, confusion, cardiac ischemia) should receive blood and blood products early. There are no data to support a target hemoglobin concentration, and the goal is to achieve hemodynamic stability and restore tissue perfusion and oxygen delivery rapidly. The observation that transfusion of stable critically ill patients only when hemoglobin concentration drops below 7 mg/dL is safe cannot be applied to patients with active GI hemorrhage who were excluded from the study.[4] In patients with active GI hemorrhage, a lower hemoglobin concentration was found to correlate with elevated troponin concentrations with several patients having chest pain to indicate ischemia.[5] In summary, blood transfusion should be used when there is evidence of hemodynamic compromise and not based upon predefined transfusion thresholds.

Recently, resuscitation strategies have focused on an earlier and more balanced use of red blood cells (RBCs), plasma and platelet transfusions, and a relatively more restricted use of crystalloids. This approach has been considered beneficial primarily in the context of traumatic hemorrhage requiring

EMERGENCY SURGERY

massive resuscitation, but seems applicable to patients with GI bleeding who also require multiple units of packed RBCs. It is particularly important to correct coagulopathy and thrombocytopenia with plasma and platelets. Platelet transfusion can also be considered in patients taking aspirin or other nonsteroidal anti-inflammatory agents who may have impaired platelet function. However, data to support this practice is limited and platelet transfusion is not routinely recommended.[6,7]

Careful hemodynamic monitoring is vital to successful management. Patients who are actively bleeding and those who have sustained substantial hemorrhage should be admitted to an intensive care unit for close hemodynamic monitoring. The presence of chronic comorbidities, such as cardiac, renal, hepatic, or pulmonary disease, increases the risk of death and requires close observation, ideally in an intensive care unit. Bladder catheterization to monitor urine output, continuous transcutaneous oxygen saturation monitoring, frequent measurement of heart rate and blood pressure and the assessment of mental status are required. Invasive monitoring (central venous pressure and oxygen saturation monitoring, pulmonary artery catheter, arterial catheter for continuous pressure and blood gas monitoring) may be helpful in certain situations. However, none have been clearly demonstrated to improve outcomes in patients with GI hemorrhage. An organized system for caring for patients with GI hemorrhage that includes observation in a dedicated intensive care unit and management by a multidisciplinary team has been shown to improve processes of care and, in some studies, to improve outcomes.[8,9]

Flexible endoscopy will identify the source of bleeding in the majority of cases and is the mainstay for the evaluation of acute GI hemorrhage. Upper endoscopy (esophagogastroduodenoscopy [EGD]) should also be considered as the initial test in patients presenting with hemodynamic instability and hematochezia, as 13% of patients presenting with maroon stools or bright red blood have an upper gastrointestinal (UGI) source.[10] Nasogastric saline lavage and aspiration with bloody return confirms an UGI source. However, a non-blood effluent does not reliably eliminate an UGI source nor does it confirm cessation of bleeding. Timely colonoscopy can identify the source of lower gastrointestinal hemorrhage (LGIH) in the majority of cases. Thorough cleansing of the colon facilitates visualization of mucosal lesions, and improves diagnostic accuracy. For this reason, colonoscopy is generally delayed to allow mechanical cleansing with a large volume polyethylene glycol-based solution.

Prognostic Factors and Scores

Several classification systems have been developed and tested for their ability to characterize a patient's risk for rebleeding and for death after GI hemorrhage. Prognostic systems for upper GI hemorrhage have been more widely adopted than

those for bleeding from the lower GI tract. The Rockall score was developed to estimate the risk of death in patients with upper GI hemorrhage and is summarized in Table 34.3. A clinical or preendoscopic Rockall score can be assigned and is useful to identify patients at low risk who can be managed as outpatients, without early endoscopy.[11] The addition of endoscopic findings increases the accuracy of mortality predictions. The score can also be used, but is less predictive, to estimate the risk of recurrent bleeding. Based upon the original data, and including endoscopic findings, rebleeding and death were rare in patients with scores of 0–2.[12] A score of ≥ 5 was associated with a 10% risk of death and >25% risk of rebleeding. Other scores, based solely on clinical factors are less accurate than those that include endoscopic findings and have not been widely adopted. Three risk stratification scores have been developed for the assessment of lower gastrointestinal bleeding; however, none has garnered widespread use.[13]

NONSURGICAL DIAGNOSTIC MODALITIES AND INTERVENTIONS

The most useful diagnostic studies are also the primary therapeutic approaches in the majority of cases of GI hemorrhage. Most lesions that can be visualized endoscopically can be successfully treated with endoscopic methods. Diagnostic angiography with transcatheter embolization has demonstrated effectiveness as a second-line approach and may safely allow the patient to avoid operation, particularly in high-risk patients and situations. When endoscopy does not identify the source of bleeding, other tests may be helpful. These diagnostic and therapeutic tests are discussed in this section. Algorithm 34.1 highlights a suggested approach to management of GI bleeding.

Esophagogastroduodenoscopy

EGD is the procedure of choice in patients suspected of bleeding from the esophagus, stomach, or duodenum and will identify the site of bleeding in 95% of cases. There are advantages to performing EGD within 12–24 hours of presentation ("early upper endoscopy"). First, early endoscopy has been shown to reduce transfusion needs and hospital length of stay, in part, through more rapid control of bleeding.[14,15] Endoscopy can identify peptic ulcers at high risk of ongoing and recurrent bleeding (active bleeding, visible vessel, adherent clot) and allow patients without high-risk features to be discharged. Endoscopy will also identify non-peptic ulcer causes with a high risk of continued hemorrhage and mortality, (i.e., gastroesophageal varices) and distinguish them from lesions with a low risk, for example, Mallory-Weiss tears. Other causes of bleeding, such as Dieulafoy lesions, while often difficult to identify are typically treated successfully with endoscopic methods.[16] Effective endoscopic control of hemorrhage from a duodenal ulcer is shown in Figure 34.1. An example of perhaps the greatest benefit of upper endoscopy has been in the diagnosis and management of variceal hemorrhage secondary to portal hypertension; relegating surgery to a minimal role in the acute management. Because of its prominence in the differential diagnosis of acute upper GI hemorrhage and despite the rarity with which surgery is required to control bleeding, portal hypertension is discussed in detail in the section Four.

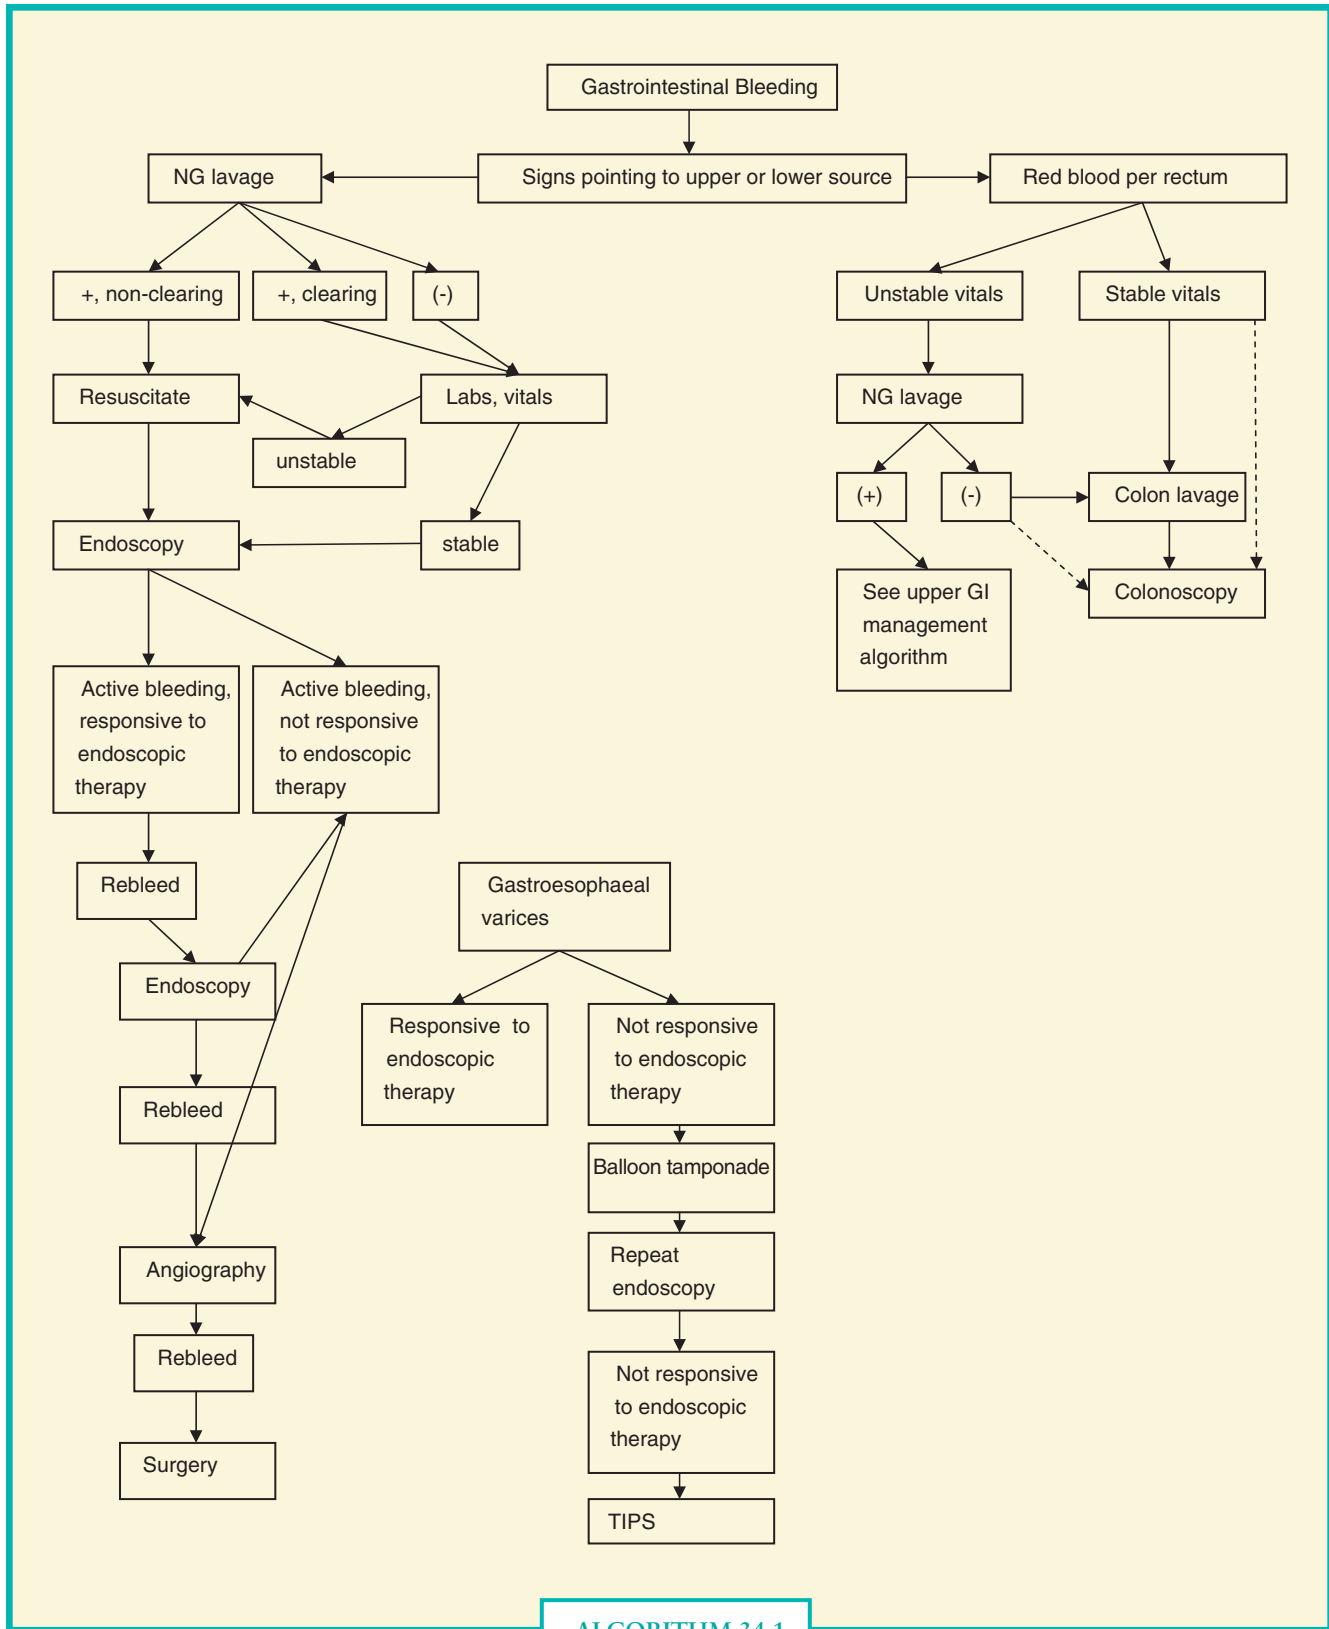
Colonoscopy

Colonoscopy is the diagnostic and sometimes the treatment modality of choice for most patients with lower GI bleeding.[1] The role of early or urgent colonoscopy in the evaluation of patients with acute lower GI bleeding is less clear than is the role for endoscopy in upper GI bleeding. While best suited for patients who are actively bleeding at the time of the study, massive colonic bleeding may obscure the bleeding site and lesion, limiting the utility of colonoscopy.

Stigmata of recent hemorrhage for lower GI bleeding are similar to those of upper GI lesions and include an actively bleeding site, a non-bleeding visible vessel, and an adherent clot. Although more difficult to discover in the colon, given the large surface area and potential issues with the preparation, these findings have been associated with continued hemorrhage and the need for urgent colectomy.[17] Not all studies have found colonoscopy to be accurate in the diagnosis of

TABLE 34.3

ROCKALL RISK SCORING SYSTEM

■ VARIABLE	■ SCORE			
	■ 0	■ 1	■ 2	■ 3
Age	<60 y	60–79 y	≥80 y	
Shock	"No shock" Systolic blood pressure ≥ 100 mmHg, heart rate <100/min	"Tachycardia" Systolic blood pressure ≥ 100 mmHg, heart rate ≥ 100/min	"Hypotension" Systolic blood pressure < 100 mmHg	
Comorbidity	None	None	Cardiac failure Ischemic heart disease Any major comorbidity	Renal Failure Liver failure Disseminated malignancy
Diagnosis	Mallory-Weiss tear No lesion identified No stigmata of recent hemorrhage	All other diagnosis	Malignancy of the upper GI tract	
Major stigmata of recent hemorrhage	None or dark spot only		Blood in upper GI tract Adherent clot Visible or spurting vessel	


ALGORITHM 34.1

ALGORITHM 34.1 General diagnostic approach to gastrointestinal hemorrhage. The initial approach to any source of GI bleeding starts with resuscitation and stabilization of vital signs. Nasogastric lavage can help risk stratify and direct the initial endoscopic approach, but note that a negative nasogastric lavage does not rule out an UGI source of bleeding. In general, in UGI bleeding not responsive to up to two attempts at endoscopic therapy, surgery or alternative techniques (angiography) are considered. For lower gastrointestinal bleeding, colon lavage is not essential as blood can act as a cathartic, but is typically given when possible as visualization is usually much better.

EMERGENCY SURGERY

FIGURE 34.1. Endoscopic view and control of duodenal ulcer hemorrhage. **A:** Demonstrates intraduodenal blood with active hemorrhage evident from the upper posterior wall of the first portion of the duodenum. **B:** Demonstrates the same lesion after treatment. The blood has been irrigated from the duodenal lumen, and the ulcer crater is evident. Epinephrine has been injected adjacent to the bleeding vessel.
lower GI bleeding. Nevertheless, it is valuable in many cases and should be part of the early evaluation of patients with blood per rectum.

Diverticular bleeding is the most common source of lower GI hemorrhage in most series. However, indirect findings are often the only clue that a diverticulum is the source. Active bleeding is rarely seen, as are visible vessels. One or more diverticula may contain clot, but this is not a reliable indicator of the bleeding site. In some cases, massive bleeding caused by colonic diverticula can limit the diagnostic usefulness of colonoscopy.

Colonic angiodysplasia has a characteristic appearance and colonoscopy has been reported to have a sensitivity of 80% in identification. Angiodysplasia can be subtle and in some cases difficult to discern from subtle erosions or from traumatic or endoscopic suction artifacts. In addition, after appreciable bleeding and hypovolemia, the shunting of blood flow away from the intestinal mucosa may obscure these lesions. In cases of active bleeding from both diverticula and angiodysplasia, colonoscopy is often effective therapeutically. In diverticular bleeding, hemoclips are typically used with or without submucosal epinephrine injection; prior to the advent of hemoclips, bipolar cautery was used. In angiodysplasia, argon plasma coagulation is used as an alternative to cautery. The bipolar cautery probe can stick to the mucosa, which can complicate treatment.

Visceral Angiography and Transcatheter Treatment

Similar to endoscopy, angiographic methods can be a tool in both the diagnosis and management of upper and lower GI hemorrhage. However, its role is less established and may vary depending upon individual and institutional experience. As a diagnostic study, visceral angiography can be useful in patients with upper or lower GI bleeding in whom endoscopy has failed to identify the site of ongoing, rapid hemorrhage. This situation is particularly likely in the case of massive lower GI bleeding where colonoscopic visualization can be hampered by large amounts of blood. However, given the intermittent nature of most cases of GI bleeding, angiography is often negative, despite considerable blood loss. Unfortunately, there are no clinical features (e.g., shock, large amount or bright red appearance of blood) that correlate with positive angiographic findings.

Certain lesions often have characteristic angiographic findings that can assist in the diagnosis and guide treatment, whether angiographic, endoscopic, or surgical. Characteristic angiographic findings of angiodysplasia include a densely opacified and slowly emptying, dilated, tortuous vein (90% of patients), a vascular tuft (66%–75% of patients), and an early filling vein.

Transcatheter therapy, based upon angiographic findings, is an important treatment option, particularly in many cases of the most common causes of acute colonic bleeding. Bleeding from a variety of causes can be effectively and safely treated with angioembolization. Transcatheter therapies generally involve super-selective injection of one or a combination of materials (micro-coils, gelfoam, and vasopressin).[18] Generally, series have been small but have provided important guidance. First, technical success is common (often >90%), but clinical success is much lower (50%–65%), with most failure evident as recurrent bleeding. Ischemia is another important complication, but is relatively uncommon (< 5%). It appears that clinical success is most likely for diverticular hemorrhage in comparison to other colonic sources such as angiodysplasia and neoplasms.[19] Successful angiographic treatment of small intestinal sources is less common than for colonic hemorrhage.

In the case of hemorrhage from peptic ulcer disease, angiographic embolization can be used after failure of endoscopic treatment as an alternative to surgery but is generally limited to cases where the risks of surgery are prohibitive. The presence of chronic or acute comorbidities, such as morbid obesity and acute myocardial infarction should be weighed in the decision between attempts at angiographic control or surgical treatment. Angiography in peptic ulcer disease has a high initial technical success rate, but recurrent hemorrhage occurs in close to 50% of patients. Due to the rich collateral circulation of the stomach and duodenum, ischemic complications are less likely than when embolization is used for bleeding from the colon or small intestine. Successful embolization may be less likely than for mid and lower GI sources, also because of the rich collateral circulation. Therefore, while useful in select patients, it should not be considered a routine treatment option for bleeding peptic ulcers.

Radionuclide Scans

Scintigraphy using ^{99m}technetium (Tc)-labeled RBCs has been used to aid in the identification and attempted localization of lower GI bleeding. It has been shown to detect bleeding occurring at rates lower than that detected by angiography but lacks the spatial resolution and diagnostic precision of angiography and endoscopy. It may be useful in the detection of intermittently bleeding lesions or those with very low rates of hemorrhage. In the past, scintigraphy was often used in cases of obscure bleeding. However, in the case of rapid bleeding, angiography may be the better option when upper and lower endoscopy have not been diagnostic. The choice between angiography and scintigraphy has typically

been guided by estimates of the rate and nature of bleeding. Angiography is considered able to detect bleeding rates of >0.5–1 mL/min (30–60 mL/h) and scintigraphy is able to detect slower (>0.1 mL/min [6 mL/h]) or intermittent bleeding. However, the clinical use of these thresholds is questionable and generally they are not relevant in the determination of the appropriate test. Active hemorrhage can be detected, localized and potentially treated with angiography. Therefore, the use of scintigraphy is limited and has typically been replaced by other studies.

One area where radionuclide scanning has a clear role is in the diagnosis of Meckel's diverticulum. ^{99}Tc-pertechnetate is secreted by ectopic gastric mucosa in Meckel's diverticula. This study should be considered early in the evaluation of children and young adults with lower GI bleeding.

Abdominal Computed Tomography Angiography

Standard computed tomography (CT) scanning has historically not been a reliable tool in the diagnosis of GI hemorrhage. However, technological advances allow for rapid acquisition and accurate timing of contrast administration with scanning to visualize vascular anatomy, abnormalities, and contrast extravasation.[20] Multi-detector CT angiography has a number of advantages over conventional angiography. CT angiography is possible in situations where conventional angiography may not be available. Movement artifact (from respiration and peristalsis) is essentially abolished with rapid acquisition times and the use of multi-planar images to remove overlying bowel loops. Cross-sectional imaging and multi-planar reconstruction facilitates accurate anatomical localization of the bleeding site and assessment of the underlying pathology.

Approaches to Obscure Gastrointestinal Hemorrhage

Obscure GI bleeding refers specifically to bleeding that persists or recurs without an obvious source after endoscopic evaluation.[2,21] Repeat endoscopy when the patient is better resuscitated may detect lesions such as ulcers or vascular ectasias that were obscured by blood or vasoconstriction at the time of initial examination. Generally, radiographic evaluation of the small bowel, including angiography or radionuclide scanning has failed to determine a source of bleeding. Most cases of obscure bleeding will eventually be found in the stomach, duodenum, or colon, and only 5% are eventually localized to the small intestine. The need for surgical evaluation is rare and is now almost entirely limited to treatment as newer diagnostic techniques have allowed lesions of the small bowel to be visualized. The techniques of balloon enteroscopy and wireless capsule enteroscopy have each facilitated the diagnosis of small intestinal sources that were previously impossible to visualize directly. Algorithm 34.2 illustrates a suggested diagnostic approach to patients with obscure GI hemorrhage.

Balloon Enteroscopy

Balloon endoscopy was developed as a technique to visualize the entire small intestine, in which the bowel is held apart by a balloon attached to the distal end of a soft overtube, through which a long enteroscope is passed. The technique has been reported to be useful for not only diagnosis but also endoscopic therapy. Single- and double-balloon techniques have been developed. Single-balloon enteroscopy is considered easier; however, double-balloon enteroscopy may have an edge in rate of complete enteroscopy and therapeutic yield. Both methods are labor intensive (require general anesthesia) and time-consuming and are performed in relatively few centers.[22,23] Enteroscopy may be primarily useful in situations where standard endoscopy, CT angiography, and angiography have failed to determine the source of obscure hemorrhage and bleeding is ongoing.[24,25]

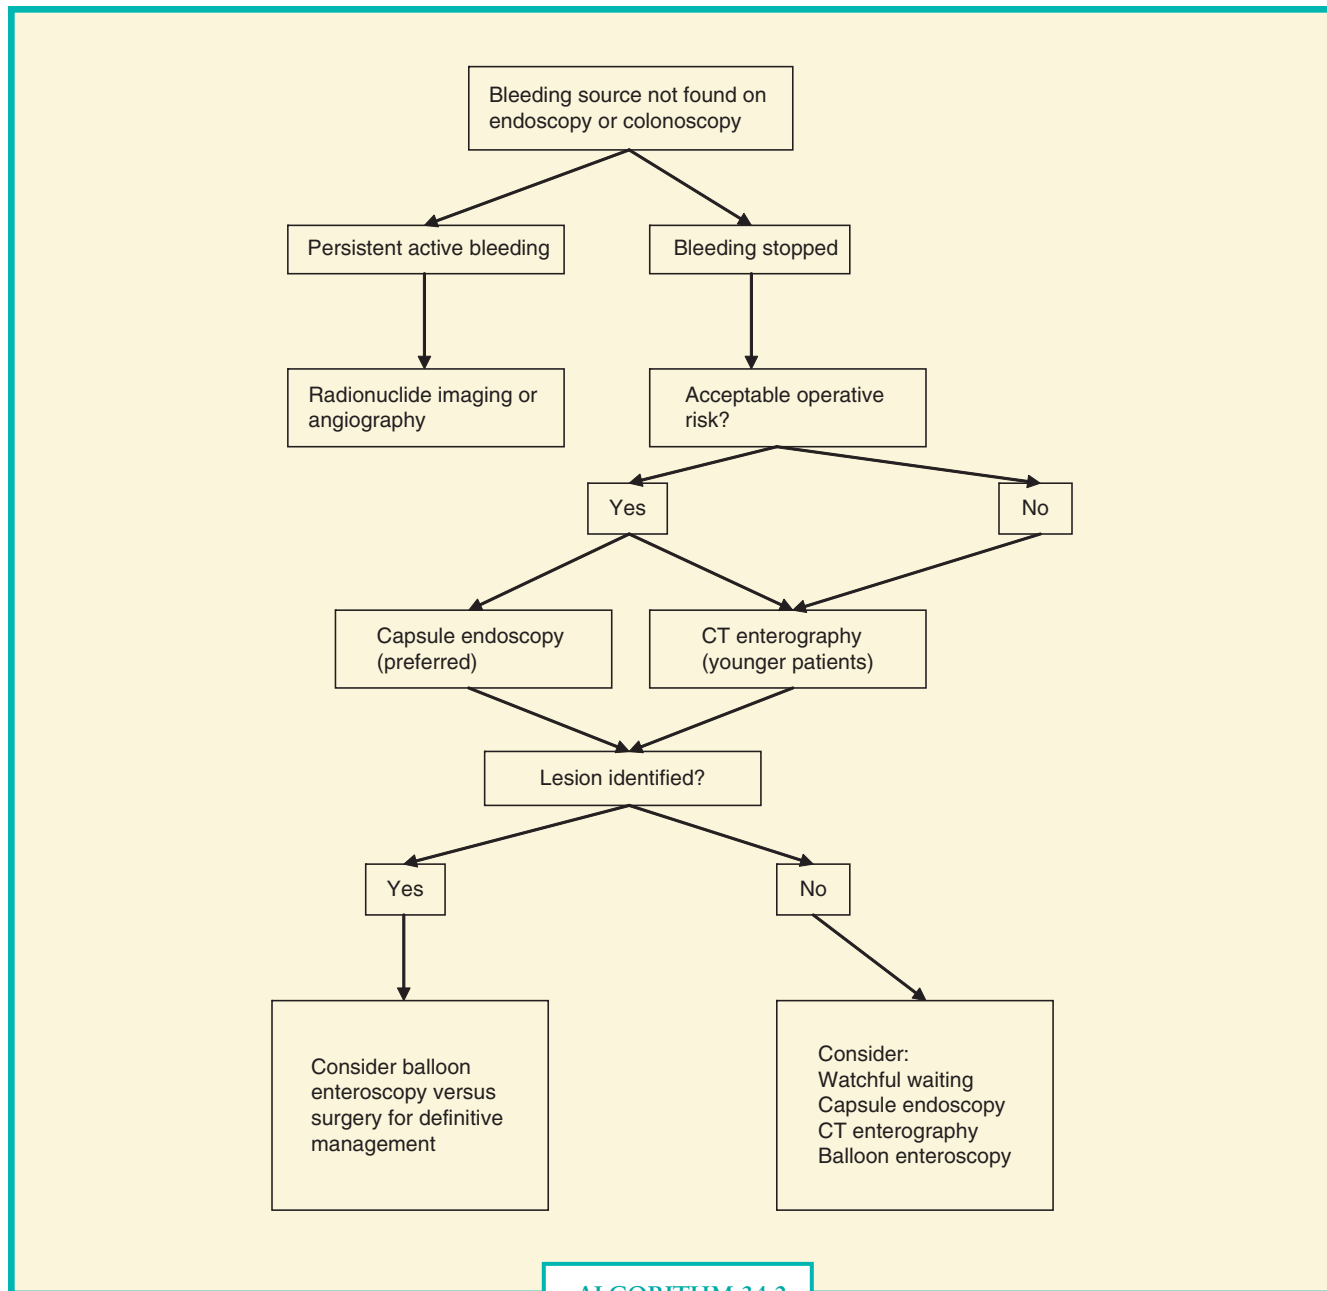
Wireless Capsule Endoscopy

Imaging of the small intestine is also now possible with a wireless capsule endoscope consisting of a battery, light source, imaging-capturing system, and transmitter. The typical capsule endoscope is 11 mm × 26 mm and is moved solely by peristalsis. This system captures and sends up to two images per second for about 8 hours to an ultra-high frequency band radiotelemetry unit worn by the patient. The location of the capsule is suggested by the strength of the signal. Several studies have shown high diagnostic yields using this technique and found it to be superior to push enteroscopy in patients with obscure GI bleeding.[26] For an 8-hour study, approximately 57,000 images are generated. Although still considered tedious, with software advancements allowing up to four viewing frames at a time, the experienced reviewer can read an 8-hour study in <1 hour.

Intraoperative Endoscopy

Intraoperative enteroscopy using a combination of push enteroscopes per os and per rectum or via enterotomy can allow examination of the entire small bowel. While the endoscopist manipulates the scope, the surgeon manually advances the bowel over the endoscope. After the bowel is telescoped onto the endoscope, it is slowly withdrawn while the endoscopist examines the mucosal lumen and the surgeon watches the transilluminated bowel wall. With the advent of balloon enteroscopy and capsule endoscopy, interoperative endoscopy is rarely required.

SURGICAL CONSIDERATIONS AND PROCEDURES IN PATIENTS WITH GASTROINTESTINAL HEMORRHAGE

Surgery is generally reserved for patients with life-threatening hemorrhage who have failed previously discussed management options. Perhaps the greatest challenge is to identify patients requiring surgical therapy as early as possible in their course and avoid delays that may lead to increased instability and risk for complications while safely pursuing the nonsurgical approaches discussed in previous sections. Previously recommended indications for surgery, which have often reflected the severity of hemorrhage (shock, need for >4–6 units of RBCs), may no longer be appropriate. For example, in the case of bleeding from peptic ulcer disease, endoscopic retreatment after initial control of bleeding has been shown to decrease the need for surgery and results in fewer complications than surgical management, even in the presence of large-volume blood transfusion.[27] In the setting of colonic diverticular disease, an association between number of units of blood transfused and risk of rebleeding has been observed; however, no clear threshold exists for units of blood transfused and the need for operation.[28] In all cases, multiple factors including the source of hemorrhage, the appearance of the bleeding site at time of endoscopy, and patient comorbidities must be considered. Thus, the decision to proceed with surgery ultimately


ALGORITHM 34.2

ALGORITHM 34.2 Approach to obscure gastrointestinal hemorrhage. In overt obscure bleeding that is active, radionuclide imaging and angiography may complement each other for the highest diagnostic and therapeutic yield. If bleeding has stopped, capsule endoscopy is preferred, although multiphase CT enterography should be considered in poor operative candidates (given the 1.4% rate of capsule retention), younger patients (where small bowel tumors are higher in the differential), and cases of suspected obstruction or neoplasm. Balloon enteroscopy may be considered to follow up on a positive preliminary study, or if bleeding persists and there is a high index of clinical suspicion for a small bowel lesion.

depends on clinical judgment rather than predefined, objective thresholds. In this section, the focus is on specific circumstances where operation is indicated and important aspects of specific procedures are detailed.

Peptic Ulcer Disease

Close collaboration between the endoscopist and surgeon is important when managing patients with high-risk peptic ulcers. Ideally, the surgeon should be available to view the endoscopy. This is particularly important in patients at high risk for needing surgical therapy (e.g., patients undergoing a repeat endoscopy for recurrent bleeding). This will facilitate surgical planning as the site of the bleeding lesion is rarely evident visually or by palpation without incision of the stomach or duodenum.

Even in cases of massive bleeding, patients can be stabilized with blood and blood product transfusion prior to induction of anesthesia. In most cases, access to the peritoneal cavity is via an upper midline incision. For proximal gastric ulcers, mobilization and retraction of the lateral segment of the left

lobe of the liver is helpful for exposure and critical for the management of ulcers near the GE junction and for access to the esophagus if a truncal vagotomy is being considered.

For bleeding gastric ulcers, the operation of choice depends primarily on the location of the ulcer. Extensive gastric resections such as antrectomy, subtotal or total gastrectomy are generally not performed given that these patients are generally quite ill, at high risk of complications, and are best served by the quickest procedure that controls bleeding. Where possible, excision of the ulcer and closure of the resultant defect is ideal. This is generally applicable to ulcers of the gastric fundus, body and proximal antrum. Ulcers located near the GE junction pose a challenge, both in obtaining access and in determination of the appropriate method to control bleeding. Excision and primary closure should be done if possible without narrowing the GE junction. Alternatively, the ulcer can be oversewn after exposure through a high anterior gastrotomy.

Rarely, large ulcers on the posterior wall of the gastric antrum or body have eroded into the splenic artery or its branches, causing brisk hemorrhage. Resection is generally not possible and this circumstance is best treated by direct ligation, proximal and distal to the bleeding site, through the ulcer base. As with ulcers located near the GE junction, access to these posterior ulcers is obtained via an anterior longitudinal gastrotomy. The stomach should not be dissected from the pancreas to access the bleeding. When a gastric ulcer is left *in situ*, biopsy at the time of surgery is generally not necessary and instead follow-up endoscopy 6–8 weeks later is used to confirm healing or obtain tissue to exclude malignancy.

The typical duodenal ulcer that requires surgical therapy is located on the posterior–medial aspect of the first portion of the duodenum and has eroded into the gastroduodenal artery, often where it bifurcates into the superior pancreaticoduodenal and the right gastroepiploic arteries. Attention to the arterial anatomy is important to ensure successful control of bleeding. This rich anastomotic plexus often requires control of retrograde flow from these two branches in addition to suture ligation of the gastroduodenal artery. Access is obtained via a longitudinal duodenotomy and if additional exposure is needed, the incision is extended proximally across the pylorus. The ulcer and bleeding site are exposed, and active bleeding controlled with direct pressure. Ligation with 2.0 nonabsorbable suture must be done carefully as the common bile duct is typically located near and just to the right of the gastroduodenal artery. U-stitches must be placed in three quadrants to ensure control of the bleeding. Stitches are placed cephalad and caudally to the bleeding ulcer (12 o'clock and 6 o'clock) to directly control the gastroduodenal artery. A U-stitch must also be placed medially (3 o'clock) to control collateral flow from a transverse pancreatic artery. At times, the gastroduodenal artery may be additionally ligated at the superior border of the duodenum, as it dives behind the duodenum. The duodenum can then be closed longitudinally or transversely. However, if the pylorus is divided, a Heineke-Mikulicz pyloroplasty is generally indicated. The need for a vagotomy in this circumstance is debated and its reported use had been variable but definitively declining in recent years.[29,30] Postoperative treatment with proton-pump inhibitors and *Helicobacter pylori* infection can safely prevent recurrence in lieu of vagotomy.[31] Nevertheless, there may be circumstances, such as failure following *H. pylori* treatment, where control of gastric acid secretion by vagotomy is indicated. Vagotomy is contraindicated in the presence of hemodynamic instability, coagulopathy or acidosis. Cirrhosis, particularly when accompanied by portal hypertension, makes access to the esophagus hazardous and is a contraindication. A truncal rather than selective or highly selective vagotomy is indicated when vagotomy is performed.

Stress-Related Mucosal Disease (Gastritis and Ulceration)

Minor bleeding from gastric mucosal damage in critically ill patients is frequent, but clinically important hemorrhage is uncommon. Although surgery is rarely required, an organized management approach may reduce mortality associated with this condition.[32]

Coffee-ground or bloody emesis or nasogastric aspirate, coupled with hemodynamic instability, or the need for a blood transfusion mandates upper endoscopy to determine the source of bleeding. Endoscopic findings range from diffuse and superficial mucosal erosions to discrete, typically multiple, deeper ulcerations throughout the stomach.

A variety of techniques have been employed with variable success in arresting hemorrhage from stress gastropathy including endoscopic and embolization techniques and the selective catheterization of the left gastric artery with continuous infusion of vasopressin.

Surgical treatment options include gastrotomy with suture ligation of bleeding sites, hemigastrectomy, total gastrectomy, and gastric devascularization. Unfortunately, these critically ill patients poorly tolerate the more extensive procedures and lesser operations often fail to control hemorrhage. As with other causes of upper GI bleeding, endoscopic findings are important to guide surgical therapy. Regardless of the operation performed, mortality risk depends on the underlying illness, particularly in the presence of multiple organ failure. Mortality rates between 30% and 60% are commonly quoted, with as many as one-fourth of the deaths resulting from continued hemorrhage. Recurrent bleeding rates from 25% to 61% have been reported. The combination of vagotomy, hemigastrectomy, and oversewing of bleeding points has been touted as more successful in these patients. However, rebleeding rates of 11%–44% and operative mortality ranging from 33% to 63% have been associated with this procedure. More extensive operations such as near total gastrectomy or total gastrectomy are associated with significant mortality, although they successfully stop hemorrhage.

Gastroesophageal Varices

In developed countries, variceal hemorrhage is typically secondary to cirrhosis leading to portal hypertension. Generally, endoscopic therapies achieve effective immediate and longer-term control of hemorrhage and surgery is very rarely required. As a result, few surgeons have experience with emergent operative treatment of portal hypertension and variceal hemorrhage. This has further reduced the role of emergent surgery to specific and highly limited situations.

As with other sources of upper GI hemorrhage, early endoscopy is imperative for successful diagnosis and therapy in most situations. The identification of varices alone is not adequate to incriminate them as the source of the hemorrhage and it is helpful to visualize active bleeding or stigmata of recent hemorrhage. The entire esophagus, stomach, and duodenum must be adequately visualized to exclude alternate sources of hemorrhage, such as peptic ulcer disease and gastritis, which may coexist with portal hypertension and varices.

Endoscopic ligation (banding) is the most widely used modality for control of bleeding esophageal varices and is effective in up to 95% of cases. In general, a patient bleeding from esophageal varices should undergo urgent banding of the varices at the initial endoscopy.

EMERGENCY SURGERY

In addition to endoscopic therapy, medical management is crucial to successful outcome. Avoiding excessive crystalloid resuscitation, which contributes to ascites formation, is important. Pharmacologic reduction in splanchnic blood flow can be helpful in reduction of variceal hemorrhage. Somatostatin or its synthetic analog, octreotide are the agents of choice and have replaced vasopressin for this indication. Meta-analyses have shown that the infusion of somatostatin is equally effective and safer than vasopressin in the pharmacologic control of variceal hemorrhage.[33] In the United States, the somatostatin analog octreotide is preferentially used because it is widely available. Octreotide is typically given as an initial injection of 50 μg, followed by a 50 μg/h continuous infusion for 2–5 days. Somatostatin and its analogs are an adjunct to established methods of controlling hemorrhage, as they have never been shown to reduce mortality and their effect is to reduce transfusion requirement by about one-half unit of packed RBCs per patient.[34]

The use of prophylactic antibiotics in cirrhotics with GI bleeding has been shown to decrease the rate of all infections, reduce the rate of variceal rebleeding, and decrease mortality.[35,36] This benefit applies to patients with and without ascites. Typically, a 3–7 day course of antibiotics, which covers gut organisms, is used, for example, ciprofloxacin 500 mg orally twice per day times seven days. Ceftriaxone is considered the preferred agent in centers with a high prevalence of quinolone-resistant organisms.[37]

In massively bleeding patients, balloon tamponade can be effective in temporary control of hemorrhage, and allows resuscitation, stabilization and attempts at endoscopic control when the patient is more stable. A Sengstaken-Blakemore tube consists of a single gastric lumen with proximal gastric and esophageal balloons. In a Minnesota tube, a second, proximal esophageal lumen allows the aspiration of secretions proximal to the balloons. Inflation of the gastric (and if required esophageal) balloon compresses the varices, and effectively controls hemorrhage in the majority of cases. However, hemorrhage recurs in 25%–50% of patients upon deflation, limiting this technique to a temporizing role, allowing time for resuscitation and stabilization in anticipation of definitive endoscopic treatment or as a bridge to TIPS.

These tubes can be associated with significant morbidity and mortality. Complications occur in 4%–9% of patients with the most frequent being aspiration pneumonitis. Measures to prevent pulmonary complications include endotracheal intubation before tube insertion and the placement of an esophageal tube to remove swallowed salivary secretions. Other important complications include esophageal rupture or necrosis and airway occlusion during the attempted removal of an incompletely deflated gastric balloon.

Typically, portal decompression has been recommended in the 10%–15% of cases where endoscopic and medical therapy has failed to control bleeding. Transjugular intrahepatic portosystemic shunting (TIPS) has replaced emergent surgical decompression in the acute management in these patients, but its use has typically been limited to manage recurrent hemorrhage.[9] Recently, earlier use of TIPS has been advocated and appears to be associated with both better control of bleeding and increased survival at 1 year.[38] Therefore, it may be reasonable to consider TIPS in patients whose bleeding has been controlled with endoscopic methods but who remain at high risk for recurrence (Child-Pugh Class C disease, or Class B with active bleeding at the time of endoscopy).

Hemorrhage from gastric varices in the context of cirrhosis and portal hypertension has been more resistant to standard endoscopic therapies.

Gastric Varices Secondary to Sinistral Portal Hypertension

This represents a unique variant of portal hypertension in which surgical therapy is primary and generally curative.[39] Splenic vein thrombosis leads to portal hypertension that is generally limited to the gastrosplenic circulation and manifest as gastric varices. Chronic pancreatitis is the most common factor leading to splenic vein thrombosis, which, in turn, leads to gastric varices. The natural history of asymptomatic splenic vein thrombosis and gastric varices is benign, with few patients apparently progressing to hemorrhage. Figure 34.2 demonstrates the appearance of gastric varices that have recently bled. Splenectomy is the procedure of choice in patients who have bled from gastric varices secondary to splenic vein thrombosis.

Aortoenteric Fistula

Most aortoenteric fistulae are secondary to prosthetic replacement or bypass of the infrarenal abdominal aorta. Erosion into the distal duodenum at the proximal anastomosis is the most frequent site. Less commonly, fistulae may involve an iliac limb of a bifurcated graft and the distal small intestine or sigmoid colon and present as hematochezia. It is postulated that erosion of the graft through the bowel wall results in perigraft infection, leading to dehiscence of the vascular anastomosis and eventually to GI hemorrhage. Primary aortoenteric fistulae (no aortic prosthetic graft) are a rare cause of GI hemorrhage, but should be considered in the differential diagnosis of obscure bleeding, particularly in patients with aneurismal disease.

Patients may initially experience a non-catastrophic episode of GI bleeding that is eventually followed by massive hemorrhage. This window of time may provide an opportunity for treatment if the diagnosis is entertained. Therefore, the diagnosis must be considered early in patients with GI hemorrhage and a history of aortic bypass grafting. Accompanying symptoms may include back or abdominal pain. Signs of infection, when present, are minimal.

The diagnosis can be made endoscopically (Figure 34.3) and every effort must be made to visualize the distal duodenum and proximal jejunum in patients who have bled and have a history of abdominal aortic grafting. However, even if endoscopy fails to demonstrate a fistula, the diagnosis must still be considered unless another convincing source of bleeding is
FIGURE 34.2. Endoscopic view of proximal gastric varices. This is a view of gastric fundal varices through the retroflexed gastroscope. In this case, the varices are evident as protuberances with intact, overlying mucosa, without active hemorrhage.
FIGURE 34.3. Endoscopic view of aortoenteric fistula. In some cases of hemorrhage from aortoenteric fistula, the graft, having eroded into the duodenum, may be visualized endoscopically. Here, the prosthetic aortic graft is seen in the proximal jejunum.

identified. If the patient is hemodynamically stable, CT is the next diagnostic test of choice.

In recent years, endovascular stent management has been employed, either as sole treatment in high-risk patients or in combination with open repair or resection of the fistula. The long-term outcome with endovascular repair is unknown and suspect if the original graft is left *in situ*.[40]

Other Causes of Gastric and Duodenal Bleeding

A *Mallory-Weiss tear* is a mucosal tear near the GE junction that leads to acute upper GI hemorrhage that occurs after retching or vomiting. While classically described as occurring in a patient who retches and vomits after a drinking binge, Mallory-Weiss tears may also be found following any bout of vigorous emesis. Initially, the emesis consists of gastric contents without blood and, subsequently, the patient develops hematemesis or melena. These lesions account for 5%–10% of cases of upper GI bleeding.

Most tears have stopped bleeding by the time endoscopy is performed and endoscopic treatment is typically effective when active bleeding is encountered. If surgery is required, treatment is simply oversewing the laceration. The main challenges are localization and access to the tear. The endoscopist can aid the surgeon by injecting tattoo ink, which can then be seen on the serosal surface and guide placement of the gastrotomy.

Dieulafoy lesions are an uncommon source, in which bleeding originates from an unusually large (1–3 mm diameter) artery running through the submucosa. Most are located in the stomach, but can be found in the duodenum, small bowel, and colon. They may therefore present as lower GI hemorrhage or may be the source of obscure GI bleeding. Erosion of the mucosa overlying the vessel results in necrosis of the arterial wall and brisk hemorrhage. The size of the mucosal defect is usually small (2–5 mm) and without evidence of chronic inflammation. Dieulafoy lesions of the stomach and duodenum can cause massive hemorrhage and, as discussed above, are usually successfully treated with endoscopic or angiographic methods. When surgery is required, treatment is generally oversewing the lesion via an appropriately placed enterotomy. Localization is the challenge and can be facilitated as described for Mallory-Weiss tears.

Uncommonly, the source of the GI bleeding may be a tumor. Metastatic or primary cancers may erode and induce GI bleeding anywhere in the GI tract. GIST, lymphoma, and vascular tumors account for a small percentage of GI bleeding. Treatment of these tumors is bowel resection.

Colonic Diverticular Disease

Colonic diverticula are common, but fewer than 5% hemorrhage. Classically, patients present with a sudden occurrence of mild lower abdominal discomfort, rectal urgency, and the subsequent passage of a large maroon stool. Despite considerable hemorrhage, often presenting with hypovolemic shock, bleeding typically ceases spontaneously but frequently recurs. Recurrent episodes also typically stop spontaneously or can be localized and treated angiographically. As a result, surgery is infrequently required.

However, when surgery is needed, the bleeding diverticulum is often not precisely localized preoperatively. For this reason, and to assure inclusion of the source of hemorrhage in the resection, segmental colectomy is the minimal procedure.

Subtotal colectomy for ongoing colonic hemorrhage that has not been successfully localized may occasionally be necessary. However, it is associated with greater perioperative morbidity than segmental resection and postoperative diarrhea may present a considerable problem to elderly patients. Nevertheless, operation may be necessary when a patient continues to bleed massively and preoperative localization has failed. In this circumstance, intraoperative colonoscopy has been suggested in an attempt to localize the bleeding and avoid subtotal colectomy. There are no data to support whether this approach is effective and its use is rare in most series of lower GI hemorrhage.[41] Intraoperative colonoscopy may prolong the operation, leading to increased complications.

Colonic Angiodysplasia

The approach to surgical therapy for bleeding from colonic angiodysplasia is similar to that described above for diverticular hemorrhage. In comparison to diverticular bleeding, hemorrhage from angiodysplasia is usually less severe, but somewhat more likely to recur. However, and as with diverticular bleeding, the majority of patients will stop bleeding spontaneously after the initial episode of hemorrhage.[42] The lesions are located most frequently in the cecum and ascending colon, although they may be found more distally in 20%–30% of cases. Multiple lesions may be present in as many as 40%–75% of all cases. The prevalence of colonic angiodysplasia in the general population appears to be <1%.

The rare patient acutely bleeding from angiodysplasia, in whom endoscopic or angiographic methods are unsuccessful or unavailable, can be treated with colectomy following preoperative localization of the bleeding site. The value of preoperative localization cannot be overstated as it will facilitate appropriate segmental colon resection.

Thus, the majority of cases of lower GI bleeding are related to diverticulosis or angiodysplasia. Although diverticula are more common in the left colon than right colon, substantial lower GI bleeding is generally from right-sided diverticulosis where there has been erosion through the vasa vasorum within the thin-walled diverticulum. Considering both diverticulosis and angiodysplasia, two-thirds of cases of massive lower GI bleeding are from the right colon. Thus, a blind right hemicolectomy results in rebleeding in one-third of patients. The alternative, a total abdominal colectomy, effectively eliminates the bleeding but adds morbidity.

Ischemic Colitis

Ischemic colitis is a common cause of lower GI hemorrhage, especially in the elderly. Bleeding is a common presentation occurring in approximately one-half to three-fourths of
FIGURE 34.4. Endoscopic view of acute ischemic colitis. Pale, ischemic mucosa, in conjunction with mucosal ulceration and hemorrhage together are hallmarks of ischemic colitis. All are seen in this colonoscopic view.

patients, but is usually not massive. In most cases, it results from impaired local microvascular perfusion of the colonic wall. It occurs most commonly in the elderly who often have substantial medical comorbidities. Renal failure requiring hemodialysis, hypertension, cardiovascular disease, vasoactive medications, and a variety of other risk factors have been associated with ischemic colitis, but in many cases a specific initiating event cannot be identified. Any segment of the colon may be involved. Transmural necrosis can result in peritonitis and perforation. Mucosal ischemia may result in vague abdominal pain, diarrhea, and mild to moderate bleeding. Life-threatening hemorrhage is uncommon.

The endoscopic features of ischemic colitis are varied, but include erythema, granularity, friability, and sometimes erosions or ulcers, all of which may be patchy or confluent. Active hemorrhage is uncommon (Fig. 34.4). Once the diagnosis is made, treatment is generally observational as many patients will recover uneventfully with supportive care alone. Surgery may be indicated acutely for ongoing bleeding or for signs of full-thickness necrosis and peritonitis. There is no role for angiography in the acute management of these patients. If the patient recovers from the initial event, healing may be accompanied by fibrosis and clinical evidence of obstruction that may require resection weeks to months after the initial presentation.

Meckel's Diverticulum

Meckel's diverticula are present in approximately 2% of the population and the lifetime risk of a complication is low. Bleeding from a Meckel's diverticulum is rare, but is one of the most common causes of lower GI hemorrhage in children. It is an exceedingly rare cause of bleeding in adults, but must be considered in the differential diagnosis of obscure bleeding. The bleeding is due to ectopic gastric mucosa in the diverticulum with peptic ulceration of adjacent bowel mucosa. Abdominal scintigraphy following the intravenous injection of [99]technetium pertechnetate demonstrates the ectopic gastric mucosa within the diverticulum, suggesting the correct diagnosis. Treatment requires resection of the diverticulum with a cuff of adjacent bowel. Diverticulectomy alone will be associated with persistence of the ulcer and the possibility of recurrent hemorrhage.

EMERGENCY SURGERY

CHAPTER 35 ■ INFLAMMATORY CONDITIONS OF THE GASTROINTESTINAL TRACT

MATTHEW SCHUCHERT, VAISHALI SCHUCHERT, AND BRIAN ZUCKERBRAUN

INFLAMMATORY EMERGENCIES OF THE ESOPHAGUS

Acute, inflammatory conditions of the esophagus requiring urgent treatment are associated with significant morbidity, and can result in the rapid progression of mediastinitis, sepsis and death.[1] Thoughtful and expeditious diagnostic testing and prompt operative intervention (when required) are critical in optimization of patient outcome. In this section, we review three severe inflammatory conditions of the esophagus: esophagitis, perforation, and caustic ingestion. Other esophageal emergencies related to obstruction, bleeding, trauma, and foreign bodies will be covered in the respective chapters devoted to these conditions.

Esophagitis

Acute inflammation of the esophagus can occur due to a variety of causes (Table 35.1). A careful History and Physical Examination can frequently reveal the probable etiology. Symptoms may include heartburn, chest pain, dysphagia, or odynophagia. Chest radiograph is frequently negative, but may reveal effusion or signs of aspiration. Barium esophagography may demonstrate irregular mucosal contour, ulceration, or stricture. Computed tomography (CT) can reveal esophageal thickening or distension. Esophagogastroduodenoscopy (EGD) is the most accurate diagnostic modality, providing both visual inspection and the opportunity for biopsy and pathologic confirmation of the underlying inflammatory process.

Gastroesophageal Reflux Disease. The most common cause of esophageal inflammation is gastroesophageal reflux disease (GERD). It is the most common benign condition affecting the esophagus encountered in the emergency room,[2] and accounts for up to 75% of patients with esophageal pathology.[3] Over 60 million Americans suffer from heartburn and indigestion (overall prevalence: 10%–20%).[4] The prevalence of GERD has been steadily increasing over the last two decades and may contribute to the rapid rise in the incidence of other complications of GERD (Barrett's esophagus, adenocarcinoma) along with the large societal costs associated with the treatment of reflux disease.[3]

Reflux esophagitis arises from repeated exposure of the distal esophagus to both acidic and bilious gastric contents secondary to an incompetent lower esophageal sphincter, hiatal hernia, or impaired gastric emptying. Symptoms are frequently episodic, and can be acute in nature. At endoscopy, the degree of mucosal damage can be assessed and graded based upon severity. The most widely-recognized grading systems are that of Savary and Miller[5] and the Los Angeles Classification[6] (Table 35.2). The degree of esophagitis can range from focal mucosal erythema to severe, circumferential hemorrhagic esophagitis. The optimal management for severe, reflux esophagitis is the institution of proton-pump inhibitor (PPI)

therapy, which will resolve the inflammatory mucosal changes and patient symptoms in the majority of cases.[7] Other antacid therapy (calcium carbonate, H2-blockers, carafate) can be added to PPI therapy, as necessary. Acute surgical intervention is rarely required beyond endoscopy to secure the diagnosis. In patients with refractory end-organ damage and persistent symptoms despite maximal medical therapy, a definitive antireflux procedure (e.g., Nissen fundoplication) may be beneficial.[8]

Candida Esophagitis. Infectious causes of acute esophagitis are rare, and most commonly encountered in the immunocompromised host (e.g., HIV or posttransplantation setting), in cases of prolonged antibiotic use or in association with an underlying structural esophageal abnormality (e.g., stricture).[9] The most commonly encountered infectious pathogen within the esophagus is *Candida albicans*. The most common symptoms of *Candida esophagitis* are dysphagia and odynophagia. The diagnosis should be suspected if oral thrush is evident on physical examination, although the absence of thrush does not negate the possibility of esophageal candidiasis. The diagnosis is confirmed with EGD, which reveals characteristic white mucosal plaques and pseudomembranes (Fig. 35.1). For mild cases, the institution of fluconazole or ketoconazole, in addition to oral nystatin swish and swallow, is effective in eradication of the infection in conjunction with the withdrawal of any predisposing antibiotic or corticosteroid therapy. *C. esophagitis* can become severe, with circumferential, pseudomembranous exudative infiltrates. The infectious process can penetrate the esophageal wall, leading to the development of candidal sepsis or massive hemorrhage.[10] Patients manifesting signs of systemic illness are frequently treated with amphotericin B or caspofungin.

Viral Esophagitis. The most commonly encountered causes of viral esophagitis are cytomegalovirus (CMV) and herpes simplex virus (HSV). CMV is more common in the setting of AIDS, but each of these infections can occur in immunocompetent patients as well.[11] The most prominent presenting complaint is odynophagia. EGD reveals multiple shallow ulcerations or vesicles, in the case of HSV esophagitis. The degree of esophagitis can be severe, and patients can present with inability to swallow or gastrointestinal (GI) hemorrhage. Endoscopic biopsy confirms the diagnosis. Cytologic specimens reveal cytopathic effect restricted to the squamous epithelium and intranuclear eosinophilic inclusion bodies (Cowdry type A bodies). Severe HSV esophagitis generally responds to 2–4 weeks of acyclovir therapy.

CMV esophagitis is unusual in the normal host. CMV esophagitis can be associated with deep, longitudinal ulcers. The cytologic damage extends through the mucosa to involve underlying mesenchymal cells. Gancyclovir given over 2–4 weeks is the treatment of choice for CMV esophagitis. Long-term prophylaxis may be required in the transplant setting.

Bacterial Esophagitis. Bacterial etiologies of acute esophagitis are extremely rare. *Mycobacterium tuberculosis* has been associated with the development of esophagitis and ulceration.

TABLE 35.1

CAUSES OF ESOPHAGITIS

Gastroesophageal reflux disease

Infectious—*Candida*, Herpes, CMV, Bacterial

Iatrogenic—Nasogastric tube, EGD, Endoluminal Therapy

Drug-induced

Eosinophilic

Radiation

Caustic ingestion

This disease is believed to be more commonly the result of direct extension from infected nodal tissue.[12] Primary tuberculous infection can also present as an exophytic mass, or pseudotumor.[13] Patients typically present with dysphagia. EGD with biopsy typically will reveal the diagnosis. Standard antimycobacterial regimens are the treatment (e.g., isoniazid, rifampin, ethambutol).[14]

Radiation Esophagitis. Patients who have undergone prior radiation for intrathoracic malignancy (e.g., lung or esophageal cancer, lymphoma) can develop inflammatory changes within the esophagus that are proportional to the dose administered.[15] The esophageal mucosa becomes thickened and friable. Swallowing can become painful (odynophagia). Dysphagia can result from esophageal muscular fibrosis and stricture formation. Treatment is typically symptomatic (viscous lidocaine) until symptoms improve. Dilation or stenting of strictures may ultimately become necessary for recurrent, refractory dysphagia.[16]

Pill Esophagitis. The esophagus can become acutely inflamed from direct contact with ingested medications. Symptoms typically include chest pain and dysphagia within 4–6 hours of medication consumption. Common causes include antibiotics (esp. tetracycline), quinidine, potassium, and antiinflammatory medications. Treatment requires washing down the medication with water or physical removal of the pill by endoscopy in cases of underlying esophageal motor disorder or obstruction.[17]

Eosinophilic Esophagitis. Eosinophilic esophagitis is a unique disorder of the esophagus more commonly found in men. Patients present with dysphagia, heartburn, and recurrent

TABLE 35.2

ESOPHAGITIS GRADING SYSTEMS

Savary-Miller
Stage I—Nonconfluent erythematous changes or erosions
Stage II—Confluent, but not circumferential, erosions
Stage III—Circumferential erosive and/or exudative lesions
Stage IV—Chronic ulcer, stenosis or Barrett's esophagus

Los Angeles Classification
Grade A—Mucosal break ≤ 5 mm in length
Grade B—Mucosal break > 5 mm
Grade C—Mucosal break continuous over > 2 mucosal folds
Grade D—Mucosal break ≥75% of esophageal
circumference

FIGURE 35.1. *C. esophagitis*. Severe inflammation of the esophagus is accompanied by the development of white plaques and pseudomembranes. (From Postma GN, Belafsky PC, Aviv JE. *Atlas of Transnasal Esophagoscopy*. Philadelphia, PA: Lippincott Williams & Wilkins. Figure 4.6.)

food impaction. Symptoms typically will not respond to conservative measures or standard antisecretory therapy. EGD reveals multiple concentric rings in the proximal-mid esophagus. Mucosal biopsies reveal the presence of >20 eosinophils per high power field.[18] The etiology of this condition is not well understood, but is believed to represent an immunologic derangement in cytokine and T-cell function.[19] Symptomatic treatment with systemic or topical corticosteroids is recommended.

Iatrogenic Causes. Significant esophageal erosions can occur following long-term placement of nasogastric or feeding tubes. These erosions are typically an incidental finding of no clinical significance. Rarely, erosions can become severe resulting in esophagitis or bleeding. Treatment is removal of the offending foreign body to allow mucosal healing.[20] Esophageal inflammation can also occur following esophageal instrumentation (EGD), PEG tube placement, or following endoscopic esophageal interventions (photodynamic therapy, endoscopic mucosal resection).[21]. In select cases, patients may demonstrate an elevated white blood cell count and chest discomfort. Conservative management with intravenous antibiotics and hydration typically will lead to resolution of symptoms. Barium esophagography can be utilized to exclude full thickness perforation.

Uncommon Inflammatory Disorders. The esophagus can demonstrate involvement with primary dermatologic conditions, such as epidermolysis bullosa, pemphigus, erythema multiforme, or Behcet's disease. Sarcoidosis may present with nodularity and ulceration of the esophagus. Crohn's disease can occur anywhere from the mouth to the anus, but esophageal involvement is noted in only 1%–3% of cases.[22] Similar to ileocolic disease, Crohn's disease is characterized by aphthous ulceration, esophagitis, and long fibrotic strictures. In patients undergoing bone marrow transplantation, graft-versus-host disease may present with dysphagia, ulceration, and fibrosis. Protozoan infections (e.g., cryptosporidiosis and pneumocystis) in the setting of AIDS are rare, but have also been reported.[17]

Esophageal Perforation

Esophageal perforation is a life-threatening problem associated with high mortality rate (9%–36%).[23,24] Perforation can occur spontaneously in the setting of forceful retching/vomiting (Boerhaave's syndrome). More commonly perforation results from penetrating trauma or following esophageal instrumentation (EGD, dilation). Typical presenting symptoms include acute chest pain, shortness of breath and fever. Additional symptoms include dysphagia, odynophagia, epigastric pain, or productive cough. The clinical presentation may be fulminant, with signs of toxicity and shock. Chest x-ray reveals pneumomediastinum and subcutaneous emphysema, mediastinal air-fluid levels, and pleural effusions. Esophagography confirms and localizes the site of leak. CT is valuable in further definition of the site and extent of the leak, as well as the detection of undrained fluid collections, which is of particular value to plan the most appropriate surgical approach.[25]

The hallmarks of therapy include expeditious diagnosis, prompt institution of broad-spectrum antibiotics and early, aggressive surgical intervention directed at drainage, débridement, and control of the perforation site to prevent or treat sepsis.[26] Several surgical approaches can be employed in the management of spontaneous or iatrogenic esophageal perforation including débridement and primary closure, mediastinal drainage, placement of an esophageal T-tube, esophageal exclusion with proximal diversion, and esophagectomy. The selection of approach is influenced by the underlying cause and duration of the perforation, the degree of tissue injury and inflammation as well as the clinical condition of the patient. As expertise is gained in video-assisted esophageal surgery, minimally invasive surgical approaches to esophageal perforation and leak have been developed, and have become the preferred approach in many situations.[27] Given the lack of level 1 evidence to establish clear standards, a lack of consensus exists regarding various aspects of management of this complex and life-threatening problem.

The decision to operate is typically based upon the extent of mediastinal contamination and systemic sepsis rather than cause of perforation. The extent of perforation may be classified as contained or noncontained. A *noncontained* perforation is defined by free extravasation of contrast in the mediastinal or peritoneal cavities (Fig. 35.2). A *contained* perforation is defined as minimal extravasation of contrast at the perforation site, or the presence of pneumomediastinum or pneumoperitoneum without apparent extravasation of contrast (Fig. 35.3). The interval between the time of perforation and initiation of treatment is also considered in the management decision. The surgical tenets in management of esophageal perforation include: (1) identification and localization of the esophageal perforation, (2) débridement of all infected and necrotic tissue, (3) control of the leak (primary closure or T-tube placement), and (4) wide drainage of the mediastinum.[28]

Nonoperative management can be considered in patients with contained perforation and no clinical signs of sepsis. Patients are managed with no oral intake (NPO) for 24–72 hours, intravenous hydration, and antibiotics. Covered esophageal stents can be placed in select patients to occlude the perforation. The extent of contamination and signs of sepsis are the most important clinical variables in the outcome of esophageal perforation. The patient with a contained leak without signs of sepsis may generally be safely managed with a nonoperative approach.[29] Surgical intervention can subsequently be performed if clinical signs of sepsis arise.

In cases of noncontained perforation, esophageal repair represents the preferred surgical approach, when feasible. Primary repair is typically undertaken in patients with limited mediastinal contamination and necrosis, regardless of the time interval
FIGURE 35.2. Esophageal perforation. Uncontained perforation with free flow of contrast material into the left pleural space. (Figure 1 from Abbas G, Schuchert MJ, Pettiford BL, et al. Contemporaneous management of esophageal perforation. *Surgery*. 2009;146(4):749–756.)

from perforation event to surgery.[30] During repair, it is critical to identify the full extent of injury. Devitalized esophageal and mediastinal tissues are first debrided. The full extent of mucosal injury is exposed, and the esophagus is closed in layers. Mobilization of a flap of vascularized tissue (e.g., intercostal muscle, pleura, pericardial fat, omentum) is recommended to buttress the repair. Multiple closed suction drains and chest tubes are inserted to achieve wide drainage of the mediastinum and pleura. Repair over a drain (e.g., T-tube) is a useful option when formal repair is not feasible. Repair can be performed by either minimally-invasive or open technique. The side chosen for thoracotomy or VATS is selected on the basis of known extravasation within the pleural space, taking into consideration extent of contamination and CT or endoscopic findings. Laparotomy or laparoscopy can be performed for the repair of gastroesophageal junction perforation into the peritoneal cavity. Gastrostomy and jejunostomy tubes are placed as adjuncts
FIGURE 35.3. Esophageal perforation. Contained perforation of the distal esophagus. (Figure 2 from Abbas G, Schuchert MJ, Pettiford BL, et al. Contemporaneous management of esophageal perforation. *Surgery*. 2009;146(4):749–756.)

for drainage and enteral feeding access, respectively. Esophagectomy may be required in the setting of perforation and cancer or severe esophageal stricture. Esophageal exclusion is rarely performed, but can represent a life-saving option to the unstable patient with severe contamination.

Transcervical drainage is efficacious in the control of proximal esophageal perforation, usually secondary to trauma (gunshot wound, difficult intubation). This approach allows adequate exposure to control and repair perforations extending into the upper mediastinum down to the level of the carina. Transcervical drainage is also useful in the treatment of descending cervical mediastinitis, which may be odontogenic, peritonsillar, cervicofacial, or esophageal in origin.[31] Aided by gravity, as well as negative intrathoracic pressure, organisms and pus rapidly accumulate in the deep cervical and mediastinal fascial planes, with mortality rates as high as 30%–40%.[32] Esophageal leak after esophagectomy can be managed in most instances by opening the neck incision and packing the wound. Cervical exploration via this wound allows access to the upper mediastinum, facilitating assessment of the leak, the condition of the gastric tube, and esophagogastric anastomosis. It permits adequate exposure for débridement and drain placement.

Mid-distal esophageal perforation typically requires transthoracic drainage. Some authors advocate the routine use of thoracotomy to provide maximal exposure for thorough débridement, repair, and drainage. Increasingly, thoracoscopy is supplanting thoracotomy when conditions are appropriate.[33] The initial step is retraction of the lung and evacuation of fibrinous debris and purulent exudate. Intraoperative endoscopy is performed to assist in identification of the site of perforation. The suspected region can be submerged under irrigation during endoscopic insufflation to pinpoint the precise location of perforation. Once identified, the devitalized margins of the perforation are debrided, and the decision whether to attempt a primary closure, depending on the degree of surrounding tissue injury as well as the clinical condition of the patient, is made. If the defect is small (<1 cm), and surrounded by viable tissue, a primary closure can be performed with interrupted sutures. In the case of larger injury or perforation, surrounded by severely inflamed tissue, wide drainage is performed with placement of a T-tube to control the leak. Wide defects may allow direct placement of a T-tube through the perforation site. Jackson-Pratt drains as well as a 28–32 French chest tube are positioned strategically to provide wide drainage of the mediastinum and chest.

Special circumstances encountered during esophageal perforation provide opportunities for creative surgical approaches to this serious problem. Perforation involving an esophageal diverticulum can be managed by diverticulectomy (when possible) and drainage.[34] An important part of the surgical approach is to relieve distal obstruction with myotomy of either the cricopharyngeus (Zenker's diverticulum) or lower esophageal sphincter (epiphrenic diverticulum). Perforation of the distal esophagus after esophageal dilatation for achalasia occurs with a frequency of up to 15%. The location of the perforation is typically the left posterior esophagus. Full-thickness perforation tends to begin within a centimeter of the squamocolumnar junction, and extends proximally from a few millimeters to as much as 10 cm. These perforations can usually be repaired utilizing a thoracoscopic[35] or trans-abdominal[36] laparoscopic technique with suture closure of the perforation, contralateral Heller myotomy, and Toupet posterior fundoplication. A contralateral myotomy is performed extending 5 cm along the length of the esophagus and extending 1 cm onto the surface of the stomach, with care taken to spare the vagus nerves. A posterior fundoplication is then performed in the manner of Toupet, suturing the edges of the myotomy to the edges of the plicated stomach over a length of 4 cm.[37] This technique has the advantage of covering the closed esophageal perforation with a gastric serosal patch, at the same time treating the underlying motility disorder. A closed suction drain is placed into the mediastinum prior to closure.

Caustic Injury of the Esophagus

Caustic ingestion can result in significant injury to the esophagus and stomach. This condition is most commonly encountered with accidental ingestion in children, adults with underlying psychiatric conditions, or those with suicidal ideation. Caustic ingestion can involve both acidic and alkaline substances which produce severe esophagitis and gastritis. Full thickness esophageal and gastric injuries are not uncommon in this setting. Inciting agents include strong alkali products such as sodium or potassium hydroxide (lye), commonly utilized in drain/pipe cleaners. Strong acid compounds include hydrochloric, sulfuric, and phosphoric acid that are primary constituents of many household cleaners. Bleach ingestion (sodium hypochlorite) is commonly encountered in this setting but is rarely associated with significant esophageal injury.[38] The degree of damage depends upon the specific corrosive properties of the ingested agent, the amount, concentration, physical form (solid, liquid), and the duration of contact with the esophageal and gastric mucosa.

Acid burns result in coagulative necrosis. Given their reduced viscosity, these solutions typically pass quickly to the stomach resulting in a greater degree of gastric injury, and a lesser degree of esophageal damage. Outcome following acid injury has been reported to be worse than following alkaline injuries, with an associated higher rate of transmural injury and perforation.[39] In contrast to acid ingestion, alkaline injuries typically result in more extensive damage to both the esophagus and stomach. The degree of mucosal damage can be deep and penetrating (liquefaction necrosis); esophageal injury may be severe in this setting. The stomach itself may be partially preserved by neutralization by gastric acid. The affected mucosa is devitalized by direct contact with the alkaline agent. Severe concomitant inflammation ensues in viable tissues with vascular thrombosis, mucosal ulceration, and sloughing. Depending upon injury severity, progressive thinning of the esophageal wall may ultimately result in perforation and mediastinitis several days after the initial injury.

Patients will typically present with a known or suspected history of toxic substance ingestion reported by family members or EMS personnel. Symptoms commonly include severe nausea, vomiting, and hematemesis. The patient may complain of chest pain and severe abdominal pain. Inability to swallow and drooling may also result. The presence of fever, tachycardia, or hypotension portends a severe injury and a poor prognosis. Patients may have severe lip and oropharyngeal burns, associated with dysphonia and stridor. These findings should heighten suspicion of laryngeal and airway involvement, and early definitive control of the airway should be accomplished.[40] If there is evidence of significant laryngeal edema or stridor, tracheostomy should be performed urgently.

Initial therapeutic measures include prompt assessment and control of the airway, volume resuscitation, and institution of intravenous antibiotics. No attempt should be made to induce vomiting, as this may worsen the caustic injury. Nasogastric tubes should not be placed blindly as this may induce vomiting and may create a full thickness esophageal perforation. Radiographic evaluation with chest and abdominal x-rays is performed. Upper endoscopy is performed within the first 24 hours following ingestion. This permits assessment of the extent of esophageal and gastric damage and is critical in guiding therapy. The development of clinical manifestations of mediastinitis, peritonitis, and sepsis are indications for emergent surgery.

EMERGENCY SURGERY

At endoscopy, mucosal injury can be categorized based upon the degree of injury. Grade 1 is associated with esophagitis and hyperemia. Grade 2 is denoted by esophageal mucosal ulcerations. Grade 3 is associated with necrosis extending into the wall of the esophagus, and may be focal or circumferential.[41] Superficial (grade 1) injuries typically resolve without chronic sequelae. Grade 2 injuries associated with significant or penetrating ulcers are associated with a significant risk of stricture formation. Grade 3 injuries typically result in mediastinitis and sepsis. Esophagectomy is commonly required in Grade 3 injuries, with delayed reconstruction following recovery from the initial presentation. The stomach is frequently unsuitable for reconstruction, and delayed re-construction with a colonic conduit is often required. Late sequelae of caustic injuries include the development of strictures and squamous cell carcinoma within the injured segment. Long-term endoscopic surveillance is recommended.[42]

INFLAMMATORY DISEASES OF THE STOMACH AND SMALL INTESTINE

When planning elective operations surgeons have the luxury of time to properly consider and execute an operation under optimal circumstances. Under emergent conditions, however, acute care surgeons and general surgeons must make rapid decisions both inside and outside the operating room. The decision of whether and if so, which operation should be performed, will usually determine surgical success. The patient's underlying medical condition and hemodynamic status should guide the type of operation and approach. This section focuses on inflammatory emergencies of the intestine that the acute care and general surgeons are likely to encounter in practice.

Gastroduodenal Perforation

Surgeons may encounter perforations of the stomach or duodenum secondary to trauma, neoplasm, foreign body ingestion, and iatrogenic perforations from diagnostic or therapeutic procedures. The most common cause of gastroduodenal perforation today remains ulcer disease with an incidence between 2% and 10% in patients with ulcers.[43,44]

Surgery is almost always indicated in the case of perforated peptic ulcer. Nonsurgical management can occasionally be considered in the carefully selected stable patient without evidence of a free leak. It is estimated that approximately half the perforations will seal spontaneously. Patients under the age of 70 without peritonitis or signs of sepsis and with the onset of symptoms of <24 hours may be candidates for a trial of nonoperative management. CT abdomen with oral contrast or gastroduodenography with water-soluble contrast should be performed. Free contrast extravasation mandates operation regardless of the patient's symptoms or clinical status.

The treatment plan for nonoperative management should include nasogastric tube decompression, fluid resuscitation, intravenous PPI, antimicrobial therapy, and close observation of hemodynamic status with serial abdominal exams. Any clinical deterioration warrants operation. Observation longer than 12 hours without improvement worsens the outcome and is not recommended. While favorable outcomes have been demonstrated in healthy patients, results in patients with major comorbidities are unknown.[44–46]

Most perforated peptic ulcers occur in the first portion of the duodenum (35%–65%); 25%–45% occur in the pylorus, and 5%–25% in the stomach. The pathophysiology of peptic ulcer has shifted from acid hypersecretion to *Helicobacter*

pylori infection. Most patients with peptic ulcer disease will have evidence of *H. pylori* infection of the antral mucosa. The proportion of peptic ulcer caused by NSAID use is increasing, particularly in the elderly population. This is likely a significant contributing factor to the increasing frequency of complicated peptic ulcer disease requiring surgical intervention. Cigarette smoking and excessive alcohol consumption have traditionally been considered risk factors in the development of peptic ulcer but recent studies have not definitively confirmed their significance. Smoking does appear to increase the likelihood of requiring surgery for complications of peptic ulcer.[47–51]

In an emergency operation the surgeon must focus on the goals of the operation. Indeed, there is inherent danger in trying to accomplish more than what is necessary to achieve a good outcome for the patient. In the case of a gastroduodenal perforation, the primary goal is closure of the perforation, providing adequate drainage, and controlling abdominal sepsis. The patient's age, medical comorbidities, nutritional status, NSAID use, history of previous peptic ulcer disease, prior medical therapy for ulcer disease, and most importantly, hemodynamic status must be considered in plan and emergency operation for perforated peptic ulcer. Simple closure is associated with decreased morbidity and mortality in the acute setting, but with a higher rate of recurrence when compared with definitive resective procedures.[52] With the currently available highly effective acid suppression medications and *H. pylori* treatments, a definitive acid-reducing operation in the emergent setting is rarely indicated. Simple patch closure alone should be performed in patients with hemodynamic instability and with perforation of more than 24 hours' duration[53–56] (Fig. 35.4). In more stable patients, truncal vagotomy with pyloroplasty incorporating the ulcer has shown favorable results. Postoperative medical therapy with PPIs with or without therapy to eradicate *H. pylori* is indicated (Table 35.3). *H. pylori* infection can be demonstrated by tissue biopsy, serologic studies, or urea breath test. *H. pylori* eradication rates are similar between quadruple and triple therapy with comparable compliance. Prescribed therapy should be tailored to the individual patient.[57,58]

Formal gastric resection with reconstruction (Billroth I, Billroth II, Roux-en-Y) with or without vagotomy is rarely required today but should be considered for stable patients with recent (<12 hours) perforation and history of chronic or refractory ulcer disease.[44,59] The stable patient who is deemed unreliable or noncompliant may also be better served with a definitive ulcer operation. Any ulcer clearly associated with NSAID use may be managed with simple closure and discontinuation of the offending medication.

Unlike duodenal ulcers, gastric ulcers (GUs) are generally treated by excision. There are five types of GUs classified according to location and relationship to acid hypersecretion (Fig. 35.5). Type I GUs are the most common and are found at the incisura along the lesser curvature. There are two ulcers present in type II GUs—one in the body of the stomach and the other in the duodenum. Type III GUs are prepyloric. Type IV GUs are the least common and are found high on the lesser curve near the gastroesophageal junction. Type V GUs are caused by NSAIDs and respond to discontinuation of NSAID use.[52,60]

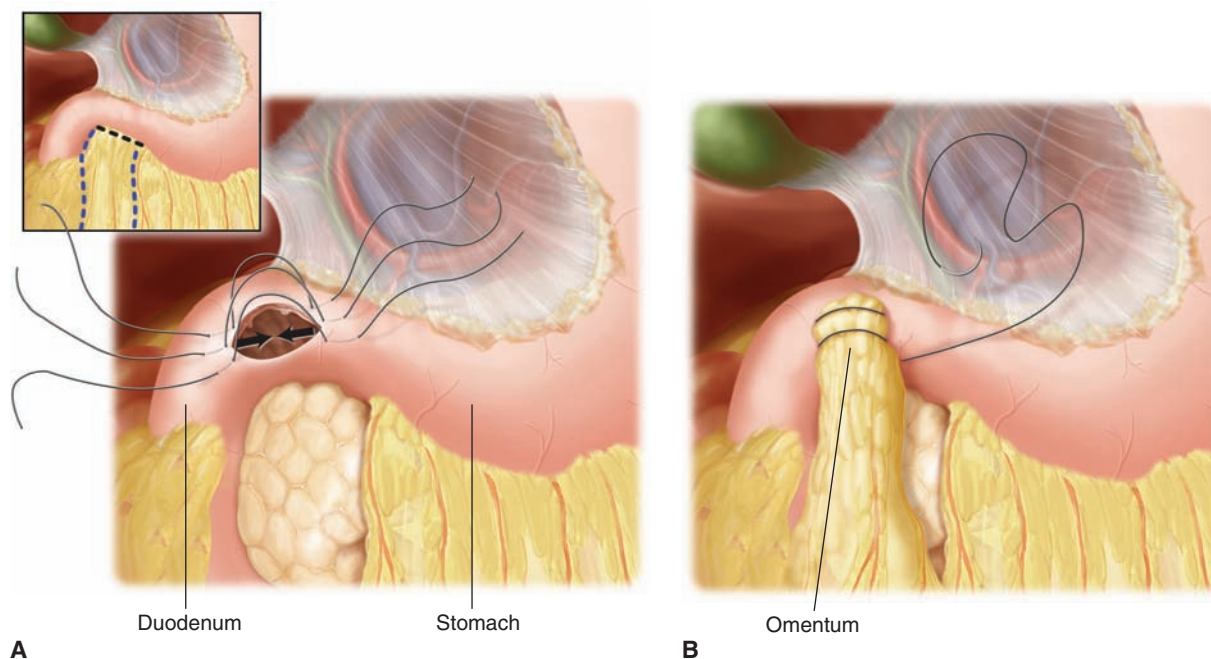
In elective or semielective surgery for intractable or recurrent ulcer, the operation of choice depends on the type of GU. Type II and Type III GUs are associated with acid hypersecretion and are typically treated with vagotomy and antrectomy including the GU. In an emergency operation for perforation, the surgeon must focus on the primary goals of the operation—to eliminate the defect, ensure adequate drainage, and treat abdominal sepsis. Perforated GUs tend to occur in elderly patients with multiple medical comorbidities and carry


FIGURE 35.4. Omental patch closure of perforated ulcer. **A:** The right upper quadrant may be accessed through an upper midline incision. **B:** Adjacent omentum is placed over the perforation site.

an associated mortality rate as high as 40%.[61,62] Local wedge excision with or without truncal vagotomy and drainage are recommended for perforation (Figs. 35.6 and 35.7). In the stable patient with a history of chronic peptic ulcer disease or failed prior operation, distal gastrectomy is preferred with the addition of vagotomy in type II or III GUs. When excision or resection is not possible because of patient instability or prohibitive risk, eight to ten biopsies of the ulcer should be taken to evaluate for malignancy and *H. pylori* infection. Follow-up endoscopy should be performed in 6 weeks to ensure healing of the ulcer and eradication of *H. pylori*.[63] The operation performed for a given patient will depend on the patient's history, preexisting and current clinical status, as well as the type and location of the ulcer (Algorithm 35.1).

TABLE 35.3

MEDICAL TREATMENT FOR ERADICATION OF *H. PYLORI* (10–14 DAY REGIMEN)

Triple therapy	PPI[a] Amoxicillin 1 g bid Clarithromycin 500 mg bid
Penicillin allergy	PPI[a] Metronidazole 500 mg bid Clarithromycin 500 mg bid
Quadruple therapy (in cases of resistance or recent use of clarithromycin and/or metronidazole)	PPI[a] Bismuth 525 mg qid Metronidazole 250 mg qid Tetracycline 500 mg qid

[a]PPI (proton pump inhibitor) choices include: lansoprazole 30 mg bid, omeprazole 20 mg bid, pantoprazole 40 mg bid, rabeprazole 20 mg bid, and esomeprazole 40 mg qd.

Morbidity after perforation is common, ranging from 17% to 63%.[44,64] The Boey score is a useful scoring system to predict perioperative morbidity and mortality for a given patient[65–67] (Table 35.4). Pneumonia is the most common complication (up to 30%) followed by wound and intraabdominal infections. Fungal infection after perforation is common and associated with high mortality (up to 21%). Perioperative shock, renal failure, cirrhosis, advanced age, immunocompromise, and delayed operative intervention are identified risk factors for major morbidity and mortality. A history of diabetes mellitus or cardiopulmonary disease is associated with mortality up to 50%. Delay of more than 24 hours dramatically increases mortality. Morbidity and mortality is significantly higher with perforated GUs than with duodenal ulcers.[44,46,65,68]

The minimally invasive approach to perforated gastroduodenal perforation is increasingly utilized for select patients with good results.[69,70] As with many other minimally invasive operations, laparoscopic repair of perforated duodenal ulcer has been associated with decreased postoperative analgesia requirements, decreased incidence of wound infection, shorter hospital stay, and earlier return to work.[71] In a recent review of 56 papers, overall conversion rate from laparoscopic to open correction of perforated peptic ulcer was 12.4% (range 0%–28.5%). The main reason for conversion was diameter of the perforation. Generally, perforations larger than 1 cm should be converted to open repair. The next two most common reasons for conversion are inability to adequately localize the ulcer and technical difficulties in placing reliable sutures due to inflammation.[43] A Boey score of 2 or 3, age over 70 years, and symptoms >24 hours were associated with higher morbidity and mortality and should be considered relative contraindications to laparoscopic intervention,[64,72] although several authors have demonstrated good results with laparoscopic repair in patients with prolonged peritonitis.[43,73] A few papers have reported higher incidence of leakage with a laparoscopic approach, but the techniques used for repair were not necessarily comparable.[43,72] Shock is a contraindication to a laparoscopic approach.

FIGURE 35.5. Types of GUs.

1 Truncal

FIGURE 35.6. Truncal vagotomy.

Available data on recurrence rates should be considered in the context that most data predates the routine use of PPIs and eradication of *H. pylori*. Ulcer recurrence is <2% with vagotomy and antrectomy, 5%–15% with vagotomy and pyloroplasty, and 5%–20% with proximal gastric vagotomy.[50,52,60] Recent studies have shown patch closure of perforated duodenal ulcer followed by *H. pylori* eradication and a PPI to yield excellent results with low recurrence. This lends support to current practices of performing simple patch repair in the acute setting.[74,75] A careful history should be obtained from patients with recurrent ulcers with attention to potential contributing risk factors such as smoking, alcohol intake, and NSAID use. In patients who underwent resective procedures without identifiable etiology for ulcer recurrence, incomplete vagotomy, retained gastric antrum, or Zollinger-Ellison's syndrome should be considered. The diagnosis of Zollinger-Ellison's syndrome is confirmed by fasting hypergastrinemia while off PPIs and a secretin stimulation test. An increase in serum gastrin of 200 pg/mL (or possibly 120 pg/mL) or greater suggests the presence of a gastrinoma.[76]

Marginal Ulcer

A perforated marginal or perianastomotic ulcer presents a unique problem in a patient whose anatomy is already surgically altered from previous gastrojejunostomy or other gastric anastomosis. With increasing number of patients undergoing bariatric surgery, short- and long-term complications are better understood.[77] Elective surgery is occasionally performed for intractable ulcers, or ulcers not responding to maximal medical therapy after 3 months. Emergency surgery may be necessary in the case of perforated marginal ulcer and quite often it is the on-call general or acute care surgeon who finds himself/herself performing these challenging operations.

Roux-en-Y-gastric bypass (RYGB) remains the most commonly performed operation for obesity in the United States (Fig. 35.8). The reported incidence of marginal ulcers after RYGB varies widely, from <1% up to 16%.[78,79] A large single center study reported a 1% incidence of perforated marginal ulcer with the median time of presentation 18 months after RYGB.[78] A higher incidence of marginal ulcer may be associated with gastric partition without transection (commonly performed in open gastric bypass) than with transection of the stomach. Smoking, excessive alcohol intake, NSAID use, and steroids have been implicated as risk factors for the development of marginal ulcers, but results of studies have varied. The role of *H. pylori* is unclear although most authors recommend treatment if positive. Ulceration is more often on the jejunal side of the anastomosis, suggesting acid exposure from the stomach as an instigating factor. However, neither prophylactic acid suppression nor vagotomy has definitively been shown to reduce the rate of marginal ulcers after RYGB. Some studies suggest decreased incidence of marginal ulcer formation with retrocolic rather than antecolic gastrojejunal anastomosis.[78–83]

The goals of an emergency operation for perforated marginal ulcer are the same as in any upper GI perforation—close the defect, ensure adequate drainage, and manage sepsis. Establishment of alternate enteral access for nutritional support may be required. In the case of a prohibitively large ulcer or abscess, resection may be necessary. Creation of an anastomosis in the face of frank purulence or shock is not advisable and should be deferred until the patient has recovered physiologically and inflammation has subsided. Laparoscopic repair of perforated marginal ulcer has been described with favorable results in stable patients without abscess.

Iatrogenic Perforation

Iatrogenic injury is an increasingly common cause of gastroduodenal perforation with more liberal use of esophagoduodenoscopy for diagnostic and therapeutic purposes. ERCP (endoscopic retrograde cholangiopancreatography) carries a risk of perforation between 0.5% and 2%.[84,85] Perforation has also been described as a complication following placement of inferior vena cava filters and biliary stents.[86,87] Microperforation, secondary to a wire or sphinchterotomy during ERCP may be managed conservatively in many cases. However, the standard therapy for free duodenal wall rupture has traditionally been surgical repair. Advances in endoscopic techniques now allow for possible closure of a duodenal perforation endoscopically if recognized immediately and the defect is not

The predicted mortality is 0% with a score of 0, 10% with a score of 1, 45.5% with a score of 2, and 100% with a score of 3. (Adapted from Boey J, Choi SK, Poon A, et al. Risk stratification in perforated duodenal ulcers: A prospective validation of predictive factors. *Ann Surg*. 1987;205:22.)

FIGURE 35.8. Roux-en-Y gastric bypass.

too large.[88,89] Intravenous antibiotics and close observation are mandated. If surgical repair of an iatrogenic gastric or duodenal perforation is indicated, the patient's hemodynamic status should guide surgical management.[90] Repair of the defect, peritoneal lavage, and placement of drains can be achieved laparoscopically as well as with laparotomy. The patient with frank peritonitis and in shock is better managed with laparotomy.[91] A repaired gastric defect may not require extraluminal drains, but a duodenal injury should be drained widely. Proximal decompression in either case is achieved adequately with a well-positioned nasogastric tube on sump suction. We do not recommend lateral duodenostomy, but rather favor placement of closed suction drains near the site of repair to provide an outlet for potential duodenal leak in the form of a controlled fistula. Surgical enteral access for postoperative nutritional support should be obtained. In cases of gross peritonitis or septic shock antifungal coverage should be included in the perioperative antimicrobial therapy.

Crohn's Disease of the Small Bowel

Crohn's Disease is the most common primary surgical disease of the small intestine. It is an inflammatory process that can affect any portion of the alimentary tract from mouth to anus but most commonly affects the terminal ileum. Forty to fifty-five percent of patients with Crohn's disease have ileocolic disease, 30% have small bowel disease, and 15%–30% have disease involving only the colon or anorectum.[92,93] Grossly, the affected bowel is characterized by creeping fat and a thickened

FIGURE 35.9. **A,B:** Crohn's disease of the small intestine.

bowel wall and mesentery (Fig. 35.9A). Cobblestoning of the mucosa is characteristic but is not pathognomonic of Crohn's disease (Fig. 35.9B). In contradistinction to ulcerative colitis, Crohn's disease is transmural and discontinuous (segmental) with rectal sparing. Crohn's disease is also associated with a greater degree of extraintestinal manifestations as compared to ulcerative colitis with up to 25% of patients having at least one extraintestinal manifestation of disease (Table 35.5). The incidence of Crohn's disease is highest in North America and

Northern Europe. African Americans and Caucasian Americans are affected equally though certain ethnic groups, particularly Jews, have a greater incidence. Males and females appear to be affected equally. Risk is increased in smokers and in urban populations. Peak incidence is in the third decade of life with a smaller peak in the sixth decade of life. Genetic, immunologic, and infectious etiologies have been proposed and there appears to be a familial association but the cause of Crohn's disease remains elusive.[92,93]

There is no cure for Crohn's disease. The goals of treatment are amelioration of symptoms and improvement in quality of life.[94] Symptoms and complications of Crohn's disease are treated medically with operation reserved for refractory cases or serious complications. Most patients (50%–70%) will require surgery at some point in their lives. Patients with Crohn's disease are optimally managed using a multidisciplinary team approach involving gastroenterologists and surgeons who specialize in inflammatory bowel disease, as well as radiologists, nutritionists, and stoma and wound care nursing specialists. Venous thromboembolism prophylaxis should be routine in hospitalized patients as inflammatory bowel disease is a risk factor for development of deep venous thrombosis.[95]

The three clinical patterns of Crohn's disease are *stricturing*, *perforating*, and *inflammatory*. Fibrosis and stenosis of discontinuous segments of bowel are the hallmark of the stricturing pattern. Repeated episodes eventually lead to strictures that no longer respond to medical therapies and patients ultimately require surgery. The perforating pattern is characterized by abscess or fistula formation. A combination of medical and surgical therapy is generally utilized. The inflammatory pattern is characterized by a more diffuse distribution along the alimentary tract and is treated medically with operation reserved for refractory cases.

Treatment of Inflammatory Crohn's Disease

The first line of therapy for mild symptoms is 5-ASA (Pentasa, Asacol). For a severe acute episode, or Crohn's flare, corticosteroids are the gold standard treatment to induce remission. Budesonide, a synthetic glucocorticoid, is often used to induce remission because of its reduced systemic absorption and more tolerable side effects when compared with prednisone. Antibiotics, typically metronidazole, may be used as adjunctive therapy. Infliximab, a monoclonal antibody against tumor necrosis factor-α (TNF-α), is used for the treatment of

EMERGENCY SURGERY

severe active Crohn's disease resistant to conventional therapy. Infliximab is effective as an induction agent with up to 70% patients responding within 1–2 weeks from a single infusion. Unfortunately infliximab use is associated with an increased risk of opportunistic infections such as tuberculosis, aspergillosis, and listeriosis. It is also generally necessary to administer immunosuppressants concomitantly with infliximab to prevent transfusion reactions due to the formation of antibodies to infliximab. Following successful induction therapy the goal of treatment becomes maintenance of remission. Steroids are ineffective as maintenance therapy. The two most common agents used for maintenance of remission are azathioprine and 6-mercaptopurine. Treatment with these agents is usually initiated during induction therapy because of their delayed onset of action. Patients must be monitored closely for complications such as bone marrow suppression, hepatotoxicity, and pancreatitis.[96]

Treatment of Perforating Crohn's Disease

The primary goal of treatment for abscess or fistula is control of sepsis. Image-guided drainage of an abdominal abscess with parenteral antibiotics is the mainstay of therapy (Fig. 35.10). Nutritional and metabolic support is essential. The three most important types of fistulae are enterocutaneous, enteroenteral, and enterovesical.

Enterocutaneous fistulae (ECF) occur in 4% of patients with Crohn's disease, either as a direct extension from the diseased bowel to the skin or from ongoing drainage via a percutaneous drainage site. They may also occur as a postoperative complication in patients who have recently undergone operation. Medical management should be initiated with antibiotics, nutritional support, and infliximab.[97] Infliximab has been associated with >60% response rate for closure of Crohn's related fistulae.[98,99] However, more recent studies have not demonstrated a positive impact of infliximab on operative rates for bowel resection or fistula repair.[100]

Enteroenteral fistulae in themselves also do not necessarily mandate operation. Surgery is indicated, however, if the fistulae are associated with an acute inflammatory exacerbation refractory to medical management, abdominal mass, hemorrhage, or uncorrectable malnutrition. Enterovesical fistula is characterized by chronic or recurrent urinary tract infections (88%), pneumaturia (88%), fecaluria (38%), and hematuria (63%).[92,93] CT of the abdomen and pelvis typically shows air in the bladder (Fig. 35.11). Diagnosis is confirmed by cystoscopy. Operative repair of enterovesical fistulae should be performed to prevent injury to the kidneys from recurrent urinary tract infections.

Surgical therapy in Crohn's disease is aimed at treatment of complications, relief of symptoms, and optimization of quality of life. Urgent operation may be necessary for free perforation (rare), acute hemorrhage, or uncontrolled sepsis from abscesses not amenable to percutaneous drainage. Less urgent operations are indicated for enterovesical fistula or acute Crohn's flare, obstruction, or fistula refractory to medical management.[101]

The preoperative workup for an elective operation for Crohn's disease should include a contrast radiographic study (small bowel follow through) to determine the length of bowel, location of disease, identify fistulae, and evaluate strictures. CT identifies masses, fluid collections, and bowel wall thickening. Colonoscopy and video capsule endoscopy may help establish

enterocutaneous fistula

the presence and extent of disease. The patient's nutritional status should ideally be optimized prior to surgery. Except in the case of high-grade obstruction, a standard mechanical and antimicrobial bowel prep should be performed. Consultation with the stoma care nursing team for preoperative counseling and marking for potential stoma sites is helpful to both the surgeon and to the patient. It is imperative that a history of any recent corticosteroid use be elicited to determine whether perioperative steroid replacement will be necessary. Other immunosuppressive medications may be safely discontinued preoperatively. Corticosteroid use in the perioperative period is associated with increased postoperative complications so a rapid taper postoperatively should be the goal when possible.[102]

In emergency operations for abdominal catastrophe with significant contamination or shock, a damage control approach may be prudent. The emergency "damage control" operation would consist of resection of the offending segment of bowel to grossly negative margins and peritoneal lavage with evacuation of any GI spillage or purulence. The surgeon must then determine whether to complete the operation with an assessment of the length of disease-free bowel, creation of an end ostomy (if applicable), and primary closure of the fascia, or to defer the second stage until hemodynamic stability has been achieved and gross peritonitis resolved. Primary anastomosis in the face of shock or gross contamination is associated with a high incidence of anastomotic leak and should be avoided if possible. Temporary closure may be achieved with either a running nonabsorbable suture closure of the skin or placement of a negative pressure vacuum dressing designated for the abdomen. The second, reconstructive operation 24–48 hours later consists of further lavage of the abdominal cavity, reestablishment of GI continuity with creation of an end ostomy or with primary anastomosis with or without protective loop ileostomy, and definitive closure of the abdomen. In the difficult case of duodenal disease, options include resection or bypass with gastrojejunostomy if resection is not feasible.

Operative management of fistulae involves identification of the inciting segment of bowel and the target structure. The abnormal connection is divided and the instigating segment of bowel resected. Resection of the target organ should only be performed if it is not amenable to simple repair. In cases of enterovesical fistula, division of the fistula is followed by primary repair of the bladder. Preoperative placement of ureteral stents may prove useful for identification of the ureters while navigating through the complex inflammatory mass. Foley catheter drainage of the bladder postoperatively is generally sufficient although an additional perivesical drain may be utilized in cases of severe inflammation or tenuous repair.

When dealing with obstruction due to stricture, viable alternatives to resection include balloon dilatation or stricturoplasty, particularly for short segment strictures (<4 cm). These alternatives may be more appropriate than resection when there is concern for short gut.[103–105] A Heinecke-Mikulicz-type stricturoplasty (longitudinal enterotomy with transverse repair) is typically used for strictures <10–12 cm in length. For longer strictures up to 25 cm in length a Finney-type stricturoplasty is preferred. In the case of duodenal stricture, options include endoscopic balloon dilatation, stricturoplasty, bypass with gastrojejunostomy, or resection.[106] Leaving the diseased segment of bowel does however expose the patient to potential future complications such as hemorrhage or malignant degeneration.[107]

Recurrence rates after bowel resection and anastomosis have not been shown to have increased with microscopic involvement of resection margins.[108] The type of anastomosis, stapled or hand sewn, also does not seem to have impact on anastomotic recurrence rate, although patients with a side-to-side anastomosis may have a lower incidence of reoperation for anastomotic recurrence than those with end-to-end anastomosis.[109–111] We prefer a two-layer side-to-side hand sewn anastomosis when bowel is inflamed or edematous.

Selected patients are candidates for laparoscopic surgery for Crohn's disease.[112,113] Length of stay, morbidity, and overall cost in the first 3 postoperative months have been shown to be lower in patients who underwent a minimally invasive surgical approach. A laparoscopic approach also allows faster initiation of steroid therapy when needed and potentially reduces adhesion formation for future operations. Diagnostic laparoscopy is an excellent tool in the workup of patients in whom Crohn's disease is suspected but cannot be confirmed otherwise.[114,115] Contraindications to laparoscopic surgery in Crohn's disease include a known "frozen" abdomen and emergency surgery in an acutely ill patient with peritonitis, bleeding, or complete bowel obstruction. General medical contraindications to laparoscopy such as severe COPD, severe heart failure, and coagulopathy must be considered in planning the operative approach. The presence of dense adhesions is the most common reason for conversion from laparoscopic to open operation. Extensive inflammation, large inflammatory mass, and the inability to safely dissect a fistula are other cited reasons for conversion.[116] The number of prior abdominal operations has not been shown to be a predictor of conversion. When laparoscopy is utilized, resection may be performed externally or within the abdomen using the Ligasure device or ultrasonic scissors. A 5 cm periumbilical or suprapubic incision is used to deliver the specimen. Anastomosis is typically performed externally.

When Crohn's disease is first diagnosed during laparoscopy or laparotomy for suspected appendicitis or bowel obstruction, it may be advisable to treat the Crohn's disease medically rather than with resection. Intraoperative decision-making should take into account the patient's age, clinical status, and nature of the disease (inflammation, stricture). If the surgeon elects to treat surgically he/she should adhere to the basic principles of surgical management in Crohn's disease.

Whether elective or emergent, open or laparoscopic, certain basic principles apply to the surgical management of Crohn's disease. (1) Only the segment causing complications should be resected and only to grossly (not microscopically) negative margins. (2) Stricturoplasty may be the better choice when dealing with obstruction. (3) Bypass should be considered a last resort because of the risk of bleeding, perforation, and future malignancy in the bypassed portion, though it may be the only viable option with duodenal disease. (4) In high-risk patients (high dose steroids, profound malnutrition) end ostomy or protective loop ileostomy for a distal anastomosis is

EMERGENCY SURGERY

advisable. (5) Appendectomy should be performed when possible and safe to avoid future diagnostic dilemmas.

Crohn's Disease During Pregnancy

Active Crohn's disease during pregnancy is associated with increased risk of fetal loss, preterm delivery, low birth weight, and developmental defects.[93] Diagnosis and workup become challenging and may involve endoscopy, ultrasound, and magnetic resonance imaging in lieu of traditional studies associated with radiation exposure. Continued severe disease poses greater risk to both mother and fetus than does surgery. A frank, detailed discussion of risks, benefits, and alternatives is indicated preoperatively as is consultation with Maternal-Fetal Medicine. If surgical resection is required, ileostomy may be preferred to anastomosis to reduce the risk of postoperative complications.

Enterocutaneous Fistula

The management of ECF continues to challenge even seasoned surgeons. Fistulae are often complicated by sepsis, fluid and electrolyte abnormalities, malnutrition, and complex wound management issues. Mortality ranges from 10% to 20% depending upon coexisting conditions. ECF develop as a result of technical factors from a previous operation, factors related to healing and tissue integrity inherent to the patient, and factors related to specific disease processes.[117]

The vast majority of ECF occur as a complication of an abdominal operation. ECF may occur as a result of anastomotic leak, unrecognized enterotomy, incorporation of bowel in the fascial closure, and ischemia. Emergency abdominal procedures and contaminated operations are additional risk factors. Factors related to the patient's ability to heal include severe malnutrition, steroid use, radiation, and chemotherapy. A serum albumin <3.0 g/dL is a well-established risk factor for the development of ECF.[117] Enterocutaneous or enteroatmospheric fistulae are common among patients with an open abdomen related to multiple trauma or abdominal compartment syndrome. We recommend managing the open abdomen with vacuum negative pressure dressings specialized for the abdomen with a nonadherent plastic sheet placed over exposed bowel before the vacuum sponge is applied (Fig. 35.12A). While some studies have suggested increased risk of fistula

formation with the use of negative pressure dressings, other studies have not been able to demonstrate this. When early fascial closure cannot be achieved after open abdomen we close the abdomen either with a skin-only closure with a heavy, running nonabsorbable suture (Fig. 35.12B), or with an absorbable mesh followed by skin grafting when a satisfactory bed of granulation tissue is present. The resulting ventral hernia can be repaired electively in 6–12 months.

An ECF classically presents as a wound infection following abdominal surgery. Drainage from the wound with the appearance and odor of enteric contents is diagnostic. The underlying fascial integrity should be evaluated as ongoing leakage of enteric contents may lead to fascial dehiscence and evisceration. Conversely, ECF should be in the differential diagnosis of a patient presenting with fascial dehiscence or evisceration.

An upper GI contrast study or CT with oral contrast may demonstrate an ECF. A chronic fistula tract can be injected with oral contrast to locate the site of communication with the intestinal tract (fistulogram). In general, the more proximal the fistula, the more pronounced the electrolyte abnormalities, fluid losses, and malnutrition. Distal fistulae may essentially function as an ileostomy or colostomy and may not be associated with any fluid, electrolyte, or nutritional abnormalities. More proximal fistulae may produce management problems with volume loss and electrolyte abnormalities.

The initial primary goal of treatment of an ECF is source control and control of sepsis. Correction of fluid and electrolyte imbalances, nutritional support, and skin care are essential adjuncts. Uncontrolled sepsis is the major cause of mortality in patients with ECF. Image-guided drainage of an abdominal abscess usually precludes the need for early operation which is associated with high morbidity and mortality. Early surgical intervention may be necessary in septic patients with uncontrolled leakage of enteric contents into the abdomen or abscesses not amenable to percutaneous drainage. If the patient is not septic despite having an intra-abdominal fluid collection, an attempt at nonoperative management can be made. A trial of medical management may eliminate the need for surgery in some patients altogether; in those patients who still require operation, the additional time allows the fistula tract to mature and inflammation to subside, creating a less hostile abdomen at the time of operation. Consultations should be held with the wound and ostomy care nursing team to assist with the complex wound management that most of these patients will have. Many surgeons champion the use of specially-fashioned abdominal negative pressure vacuum

FIGURE 35.12. **A:** Abdominal VAC dressing. **B:** Running suture for skin-only closure of the abdomen.

dressings in the management of enteroatmospheric fistulae to promote healing. Creative skin grafting around the fistula may simplify wound care and provide patient comfort while the fistula matures or closes.

Adequate nutritional support is essential for spontaneous closure of an ECF. Patients with ECF are often profoundly catabolic and depleted in lean body mass, albumin, and prealbumin. Protein and caloric requirements may be double their baseline requirements. Enteral feeding, either by mouth or by a small-caliber nasogastric or nasoenteral tube, should be the first line of nutritional support in the absence of a contraindication.[118] Providing as little as 10%–20% of nutritional needs enterally is associated with maintenance of gut mucosal integrity and immunological function. Parenteral nutrition is associated with more infectious complications but may be the only means of providing nutrition to a patient with a high output fistula, obstruction, or short gut. Parenteral nutrition may sometimes be used to supplement enteral feeding for profoundly malnourished patients or patients who cannot tolerate full enteral feeds. If fistula output increases in response to enteral feeding it may be beneficial to provide nutritional support parenterally to try to allow for spontaneous closure of the fistula.[119]

The overall spontaneous closure rate of an ECF is 10%–40% with conservative management. The use of octreotide, an analogue of somatostatin, as adjunctive therapy may decrease fistula output, making a high-output fistula more manageable, but has not been shown to definitively impact spontaneous closure.[120,121] An ECF that persists 6–8 weeks after resolution of sepsis and correction of nutritional deficits is unlikely to close spontaneously, especially if the output is high (>500 mL/d). Up to 90% of ECF that are going to close spontaneously, close within 5 weeks after sepsis is controlled. Factors associated with failure of an ECF to close spontaneously include high output fistula, ongoing malnutrition, distal bowel obstruction, short fistula tract, abscess, and foreign body (including mesh). Malignancy, radiation, and steroids are also risk factors for nonclosure of ECF.

In planning an elective operation to repair an ECF preoperative imaging such as fistulogram and CT is obtained to identify the location of the fistula, evaluate for distal obstruction or potential foreign body, and to evaluate the abdominal wall in cases of loss of domain (large ventral defect) for possible abdominal wall reconstruction. A small but important subset of patients may benefit from earlier operation rather than delaying time to operation which exacerbates the catabolic state and leads to further debilitation and morbidity despite control of sepsis and aggressive nutritional support.

A mechanical and oral antimicrobial bowel prep should be performed when possible preoperatively. At laparotomy the bowel should be fully mobilized to allow proper identification of involved segments, ensure patency of the length of the bowel, and to perform segmental resection of the fistulae with tension-free anastomosis; fastidious technique is essential. Closure of the abdominal wall and distancing the repair from the incision should be routine. Surgical enteral access for postoperative nutritional support should be considered.

Infectious Enteritis

About 200–500 cases of typhoid fever and typhoid enteritis are reported annually in the United States. About 80% of cases occur in people with a history of recent travel to endemic areas. Typhoid enteritis is an acute systemic infection caused by ingestion of Salmonella typhi through contaminated food or water. Fever, abdominal pain, rash, and diarrhea (sometimes bloody) along with lymphadenopathy

and hepatosplenomegaly are characteristic. Diagnosis is by positive blood or stool culture.[92] Because of high resistance to the original first-line therapy (ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole) the recommended treatment for adults with typhoid fever and uncomplicated typhoid enteritis is now with fluoroquinolones or third generation cephalosporins. In areas of high fluoroquinolone resistance, azithromycin 1 g orally for 5 days is recommended.[122,123] Hemorrhage or perforation through an ulcerated Peyer's patch may necessitate operation. Perforation is usually solitary in the antimesenteric terminal ileum and managed with either simple closure or segmental resection. In the unusual event of multiple perforations resection with primary anastomosis or creation of end ileostomy may be required.[124]

Patients with AIDS or on immunosuppressive agents after organ transplantation are susceptible to GI infection by a host of pathogens. Protozoa (Cryptosporidium, Isospora, Microsporidium) are the most frequent class of pathogens causing diarrhea in patients with AIDS. The small bowel is the most common site of infection. Cryptosporidial transmission is by fecal–oral route. Public swimming pools have been implicated as a significant source of infection. Cryptosporidial enteritis generally resolves spontaneously in nonimmunocompromised hosts. In patients with AIDS, it is characterized by severe watery diarrhea (>10 L/d), cramps, nausea, and weight loss. Biliary involvement is common. Diagnosis is by isolation of oocysts in stool, bile, or tissue. Treatment is primarily HAART (highly active antiretroviral therapy) as raising the CD4 count to >100 cells/mm^3 usually leads to resolution of enteritis. Supportive care with oral or parenteral hydration and antidiarrheal agents may be life-saving and continues until there is resolution of diarrhea. A trial of nitazoxanide in conjunction with HAART may be considered.[125]

Enteric bacterial infection with *Salmonella*, *Shigella*, and *Campylobacter* are more common and more virulent in immunocompromised patients than healthy individuals. Affected patients present with abdominal pain, high fever, tenesmus, and hematochezia. Stool cultures will usually diagnose Salmonella and Shigella but may be falsely negative with *Campylobacter* infection. Treatment is parenteral antibiotics.

Mycobacterial infection in the immunocompromised patient may be due to either *M. tuberculosis* or the atypical *Mycobacterium avium* complex (MAC). Infection is characterized by fever, night sweats, abdominal pain, diarrhea, and weight loss. Routes of entry to the intestinal tract include the oral route (infected sputum or contaminated food or milk), hematogenous spread from pulmonary or military tuberculosis, or by contiguous spread. Intestinal tuberculosis involves the ileocecal region in 85%–90% of cases. Up to half of affected patients will have a palpable right lower quadrant mass and ascites is often present. Gross findings include ulcerations or tubercles covering the bowel surface and mesenteric lymphadenopathy. Strictures and fistula formation may be present. The diagnosis of mycobacterial infection is made by identification of the organism in tissue, either by acid-fast stain, by culture of the excised tissue, or by PCR. The treatment is similar for immunocompromised and immunocompetent hosts with multi-drug antimicrobial therapy. Most fistulae will respond to medical management.[126,127] Obstruction is the most common indication for surgery. Stricturoplasty may be an option for obstruction related to stricture as may be colonoscopic balloon dilatation.

The MAC organisms (*M. avium* and *M. intracellulare*) are ubiquitous in the environment and contracted by inhalation or ingestion.[128] Risk of infection is increased with CD4 count <50 cells/mm^3. Diagnosis is made with positive blood culture. MAC infection is characterized by massive thickening of the proximal small bowel. Perforation or other surgical emergencies are rare. Multi-drug therapy with clarithromycin or

azithromycin and ethambutol is standard therapy. MAC infection in patients infected with HIV increases the risk of death independent of CD4 count.[125]

CMV is the most common viral cause of diarrhea in immunocompromised patients. Patients present with abdominal pain, fever, and weight loss. Diagnosis is made by demonstration of viral inclusions histologically or by serology. The treatment is usually ganciclovir or foscarnet.[129] Perforation of the distal small bowel or colon or massive hemorrhage may rarely necessitate urgent operation.

GI histoplasmosis occurs in association with disseminated histoplasmosis, a disease primarily of immunocompromised patients. Diagnosis is made by fungal smear and culture of infected tissue or blood. Treatment is most often amphotericin B.[130]

Small Bowel Diverticular Disease

Small bowel diverticulosis is a relatively rare entity and <4% of all small bowel diverticula will become symptomatic in a person's lifetime. Because the clinical presentation may be dramatic with bleeding, perforation, or acute inflammation, the acute care surgeon should be prepared to manage complications that may arise from these diverticula. There are two types of small bowel diverticula. False diverticula are acquired defects with herniation of mucosa and submucosa along the mesenteric side of the bowel where vessels penetrate the bowel wall. True diverticula are congenital anomalies arising in the antimesenteric side of the distal ileum (Meckel's diverticula).[131,132]

Duodenal Diverticula

A duodenal diverticulum typically presents during or after the fifth decade of life as a solitary outpouching along the mesenteric side of the duodenal wall. Duodenal diverticula are the most common small bowel diverticula, 45%–79% of all small bowel diverticula. Less than 1% require treatment.[133,134]

Diagnosis is by EGD, ERCP, contrast radiography, or CT with oral contrast. They are reported to be found in 10%–20% of patients undergoing ERCP.[135]

The majority of duodenal diverticula (61%–75%) are located in the periampullary area, or within 2 cm of the ampulla of Vater. The inherent defects in the muscularis propria caused by the penetration of the pancreatic and biliary ducts predispose to the development of these false diverticula. Patients typically present with symptoms related to biliary or pancreatic ductal obstruction including cholangitis, jaundice, or pancreatitis. Patients with duodenal diverticula have a higher incidence of choledocholithiasis and pigment and bilirubinate stones. Duodenal diverticula should be considered in the differential diagnosis for patients with pancreatitis of unclear etiology.[135–138]

Asymptomatic or incidentally found duodenal diverticula should not be resected. The patient should be informed of the incidental finding and potential sequelae. Choledocholithiasis in association with a duodenal diverticulum should be managed conventionally as in patients without duodenal diverticula. Inflammation, perforation into the retroperitoneum or peritoneal cavity (Fig. 35.13), and hemorrhage occur less frequently but may necessitate intervention acutely.

Surgery for duodenal diverticula is associated with significant morbidity and mortality related to the patient's age, comorbidities, and technical challenges of the operation itself. The surgical approach begins with a complete Kocher maneuver and identification of the pancreaticobiliary structures and their relationship to the diverticulum. Cannulation of the ampulla of Vater with a metal probe or red rubber catheter helps to maintain orientation and avoid injury. Diverticulectomy with primary closure is the procedure of choice when the ductal structures are not involved and when there is no retroperitoneal contamination. For duodenal diverticula distal to the ampulla, options include diverticulectomy with jejunal serosal patch repair or segmental resection with end-to-end anastomosis. Roux-en-Y biliary bypass may be necessary when the ampulla is involved. In cases of retroperitoneal contamination secondary to a perforated duodenal diverticulum, options include antrectomy with Billroth II reconstruction or
A

B

FIGURE 35.13. Duodenal diverticulum.

duodenal exclusion with placement of gastrostomy and jejunostomy tubes. To avoid biliary stasis and future diagnostic dilemmas, cholecystectomy should be performed in patients requiring surgery for duodenal diverticula.

Intraluminal or "windsock" diverticula are large, congenital, saccular diverticula in the second portion of the duodenum. They are associated with a myriad of other congenital anomalies including annular pancreas, choledochocele, malrotation, and superior mesenteric artery (SMA) compression syndrome. Cardiac and urogenital anomalies are also common. Obstruction is the most frequently encountered complication associated with an intraluminal diverticulum. The preferred treatment for symptomatic intraluminal diverticula is duodenotomy and excision.[139] Endoscopic excision has also been performed successfully.[140,141]

Jejunoileal Diverticula

Jejunoileal diverticula occur in 1%–3% of the general population and comprise only 25% of all small bowel diverticula, but are the most likely to be symptomatic.[142] They are often multiple, with 80% occurring in the jejunum, 15% in the ileum, and 5% along the full length. Patients typically present at age 50 or greater. Patients may present acutely with perforation, obstruction, hemorrhage, or inflammation causing peritonitis. More commonly, patients present with symptoms related to the intestinal dysmotility that is the underlying pathophysiology for the development of these acquired diverticula. Signs and symptoms related to stasis and malabsorption may include abdominal pain, steatorrhea, megaloblastic anemia, and neuropathy. Small bowel follow through establishes the diagnosis. CT with oral contrast has the added benefit of assessment of inflammation or subtle signs of perforation as well as the anatomic relationship of diverticula to surrounding structures. Diagnosis is often made at laparoscopy or laparotomy. In patients with symptoms related to malabsorption due to bacterial overgrowth, medical therapy with metronidazole and amoxicillin clavulanate, and nutritional support with vitamin supplementation is successful in 75% of cases. Surgical intervention may be indicated in patients in whom medical therapy fails. Segmental resection of the involved diverticula is the treatment of choice for symptomatic diverticula. Diverticula encountered incidentally during laparoscopy or laparotomy should not be excised.[142–144]

Meckel's Diverticulum

Meckel's diverticula, true diverticula on the antimesenteric side of the bowel, are the most common congenital anomaly of the small bowel and account for 25% of all small bowel diverticula (Fig. 35.14). Failure of the vitelline (omphalomesenteric) duct to obliterate may manifest as an ileoumbilical fistula, vitelline duct cyst, but most commonly as a Meckel's diverticulum. Its blood supply is derived from a persistent right vitelline artery from the SMA. The defining features of a Meckel's diverticulum are described by the "rule of two": 2% of the population, 2 inches long, within 2 feet of the ileocecal valve, and two types of heterotopic mucosa. It typically presents within the first 2 years of life but occasionally presents in adult patients. Half of Meckel's diverticula contain heterotopic mucosa with 75% being gastric mucosa and 15% pancreatic. It is the most common cause of lower GI bleeding in pediatric patients. Acid secretion from heterotopic mucosa within the diverticulum leads to ulcer formation on the opposite side of the bowel wall which may bleed. A "Meckel's scan," used to identify uptake of radioisotope by gastric mucosa, may be helpful in the workup of GI bleeding but plays no role in the workup of an acute

FIGURE 35.14. Meckel's diverticulum.

abdomen. The most common presentation of a symptomatic Meckel's diverticulum in adults is bowel obstruction which may be secondary to intussusception, volvulus, or incarceration within an inguinal hernia (Littre's hernia).[145,146] Meckel's diverticulitis occurs in 25% of symptomatic patients and is often found at laparoscopy for what is initially thought to be appendicitis. In cases of obstruction or localized inflammation, stapled diverticulectomy or wedge excision with primary closure is adequate. With significant inflammation or with a wide-based diverticulum, segmental bowel resection is preferred. With hemorrhage, segmental resection is necessary to include the bleeding ulcer on the opposing bowel wall. Appendectomy should be performed to avoid future diagnostic dilemmas.

Incidentally found Meckel's diverticula in the pediatric population should be removed. Removal of an incidentally discovered Meckel's diverticulum in adults is controversial. Relative indications for removal include evidence of heterotopic tissue, signs of prior diverticulitis, or the presence of a mesodiverticular band. The initial indication for operation and implications for future planning should also be considered. Presently, most surgeons do not favor removing a Meckel's diverticulum found incidentally in an adult patient.[143,147]

INFLAMMATORY AND INFECTIOUS DISEASES OF THE COLON

An understanding of the management of inflammatory and infectious diseases of the colon is essential for the acute care surgeon. Multiple pathologies of the colon will prompt

EMERGENCY SURGERY

surgical consultation and consideration of operative management; these include colonic ischemia, bleeding, obstruction, diverticulitis, infectious colitides, and acute, severe manifestations of inflammatory bowel disease. This section will focus on inflammatory and infectious pathophysiology of the colon and will review current strategies of diagnosis and management. Under conditions of health, the complex microbiome of the colonic wall and lumen exists in symbiotic harmony. However, in the setting of the diseased colon, the colonic microbiome can result in life-threatening infection that may require source control, including surgical management.

Anatomy/Physiology

The colon extends from the end of the ileum to just above the peritoneal reflection at the junction of the sigmoid colon and rectum. Embryologically, the colon is derived from two origins.[149] The cecum, ascending, and proximal transverse colon are derived from the midgut and receive blood supply from the SMA, while the distal transverse colon and beyond are derived from the hindgut and receive blood supply from the inferior mesenteric artery (IMA) (Fig. 35.15). In general the venous and lymphatic drainage parallel the arteries. Grossly, the colon is 115–150 cm in length and ranges in diameter from 7.5 cm at the cecum to 2.5 cm at the rectosigmoid junction.[149] The colon rotates during development and attaches laterally on the right as the ascending colon and on the left as the descending colon. The mesentery at these locations most often fuses to the posterior peritoneum. The transverse and sigmoid colons have long, mobile peritoneum and allows significant variability in the location of these structures.

Histologically, the colon is divided into a mucosa, submucosa, muscularis propria, and serosa.[150] The mucosa is comprised of an epithelial layer, lamina propria and the muscularis mucosa. The epithelium is organized into crypts of non-branching tubules. Various cell types include simple columnar cells, goblet cells, and undifferentiated amine precursor uptake and decarboxylation and enterochromaffin cells. The mucosa is in continuity with the lumen of the colon. The submucosa is a layer of connective tissues containing blood vessels, lymphatics, and nerves. The muscularis propria of the colon is an inner, continuous, circular muscle that is innervated by the myenteric plexus of Auerbach. The longitudinal muscle is organized into three cables of muscle, the tenia coli, which run from the cecum to the distal sigmoid, at which point these fibers disperse to form a circumferential layer over the rectum. The peritonealized surfaces of the colon are covered by a serosa throughout its length.

The major functions of the colon are absorption and digestion. Absorption of salts and water from the output of the small intestine is essential for normal physiological maintenance of fluids and electrolytes. Sodium is actively absorbed against concentration and electrical gradients and this drives the absorption of water. Chloride is also actively absorbed and exchanged for bicarbonate. Urea metabolizing bacteria in the colon form ammonia, which is also absorbed.[151] The colonic mucosa secretes mucus that contains high levels of potassium.

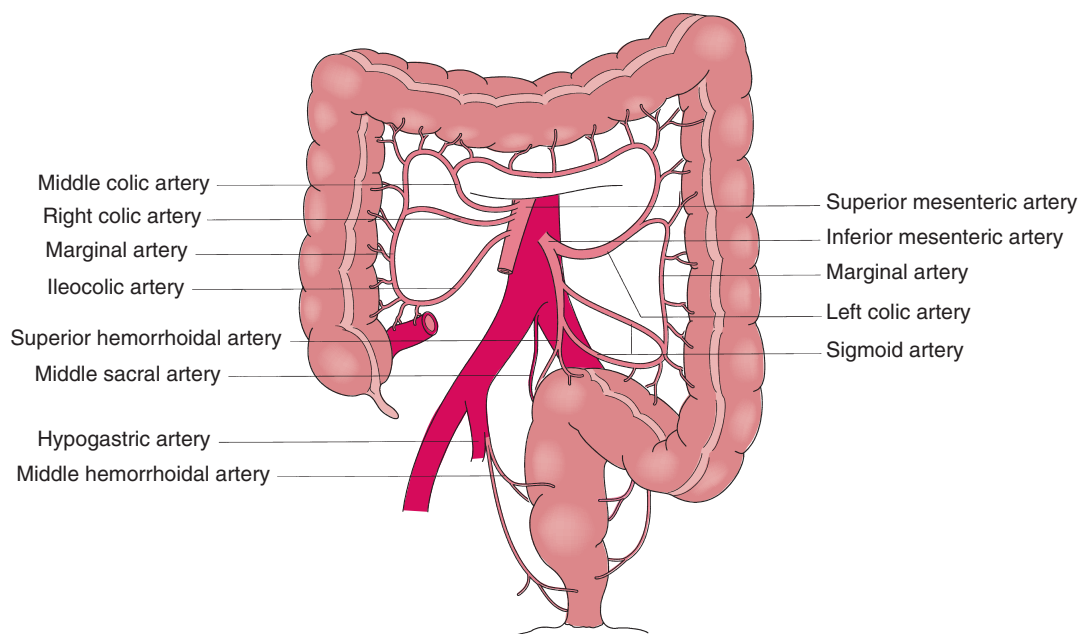
Colonic metabolism is interesting and depends at least in part on the symbiotic relationship with the colonic microflora. Colonic bacteria are predominately anaerobic, followed by gram negative aerobes.[152] Colonic bacteria ferment proteins, fibers, and carbohydrates. Bacteria ferment carbohydrates to short chain fatty acids (SCFA). These fatty acids are the preferred metabolic fuel of colonocytes and are readily absorbed. SCFA increase sodium, chloride, and water absorption and may also regulate proliferation, differentiation, motor, and immune functions in the colon.[149]


FIGURE 35.15. *Arterial anatomy of the colon.* The right colon and proximal transverse colon, which are embryologically derived from the midgut, have blood supply from the SMA, while the distal transverse, descending, and sigmoid colon, which are derived from the hindgut, have blood supply from the IMA. Rectal blood supply is from the IMA and the internal iliac arteries. (Reprinted from Greenfield LJ, Mulholland MW. *Greenfield's Surgery: Scientific Principles and Practice.* 4th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2006, with permission. Figure 65.3. Arterial blood supply of the colon.)

The motor function of the colon is complex and involves an interplay between propulsive and storage functions.[149,151] Contractions can be nonpropulsive, as well as both retrograde and antegrade propulsive movements. Grossly understated, segmental colonic motility matches functional properties of the colon. The right colon acts as a reservoir to mix and store, allowing the interplay of the complex microbiome and luminal nutrients, as well as absorption of salts and electrolytes. The left colon functions as a conduit, and the rectum and anus enable storage and continence.

An understanding of normal colon anatomy and physiology is essential to understand pathophysiology and disease, as well as to guide management of both acute and chronic colonic disease.

INFLAMMATORY AND INFECTIOUS EMERGENCIES OF THE COLON

The risk with most inflammatory processes of the colon is associated with compromise of the integrity of the colonic mucosa or perforation, both of which can result in life-threatening infection and sepsis. It is imperative as a surgeon to understand the natural history of these disease processes, appreciate the role of medical and surgical therapies, and to achieve timely source control if necessary. For most of these disease processes, delayed operative management in the setting of colonic necrosis or perforation significantly increases mortality. This section will focus on the most common inflammatory/infectious disease processes relevant to acute care surgery including diverticulitis, ischemic colitis, inflammatory bowel disease, and *Clostridium difficile* associated disease (CDAD).

Diverticulitis

Colonic diverticulosis refers to the presence of diverticulum in the colon in the absence of inflammation, while diverticulitis refers to the presence of inflammation and infection associated with a diverticulum.[153,154] The clinical spectrum of diverticulitis can range from relatively mild abdominal pain to sepsis. The term "diverticular disease" refers to all pathophysiological processes associated with colonic diverticulosis, including diverticulitis and diverticular bleeding. The diverticula in diverticulosis are pulsion or "false" diverticula, containing mucosa that essentially herniated through the muscular layers of the colon. Diverticula are typically 0.5–1 cm saccular outpouchings of the colon.[153]

Colonic diverticulosis is common in Western population and the incidence increases with age.[155] Diverticulosis is rarely seen in individuals younger than age 30. However, in Western society, the prevalence increases to 40% by the age of 60 years and 60%–80% by 80 years of age.[155–157] In most cases, diverticula involve the sigmoid and left colon. With increasing age, there is an increased prevalence of diverticulosis that extends more proximally in the colon. Interestingly, diverticulosis in Asian countries occurs more commonly as isolated diverticulosis of the right colon.

It is estimated that 10%–25% of patients with diverticulosis develop diverticulitis.[158–160] Although it is difficult to determine, the number, size, or extent of diverticula, it does not seem to correlate with the risk of developing diverticulitis. Studies suggest that the incidence of diverticulitis has been increasing over the past several decades in the U.S. population, but this may be in part secondary to the increased availability and use of CT.

Pathophysiology. As previously stated most colonic diverticula are pulsion diverticula. The formation is thought to be associated, in part, to increased intraluminal pressure.[153] The diverticula typically "herniate" or penetrate the colonic wall where the nutrient vessels (vasa recta) penetrate the circular muscle layer. Diverticula typically occur along either side of the mesenteric tenia or on the mesenteric border of the two antimesenteric tenias. Several hypotheses to explain the development of diverticulosis include generation of high intracolonic pressures secondary to disordered motility and the role of dietary fiber.[161–165] An alternative hypothesis has focused on collagen deposition in the colon wall and decreased colonic elasticity. This is referred to as tenia specific elastosis.[166] Additional risk factors for the development of diverticulosis include increasing age, geographic factors, cigarette smoking, nonsteroidal antiinflammatory use, obesity, decreased physical activity, and caffeine ingestion.[157]

The etiology of acute diverticulitis is thought to be similar to the development of acute appendicitis, in which obstruction of the diverticulum can lead to bacterial overgrowth, distention, and tissue ischemia. This results in localized inflammation, and possibly contained perforation with the formation of a peridiverticular abscess or free intraperitoneal perforation with peritonitis.[154,155] It is also possible for the inflammatory process to fistulize into adjacent structures, most commonly the bladder. The most commonly cultured isolates from abscesses or perforations associated with diverticulitis are anaerobic bacteria (*Bacteroides, Clostridium, Peptostreptococcus,* and *Fusobacterium*) followed by gram negative aerobes (*Escherichia coli*). *Enterococcus* is the most common gram positive aerobe.[167,168]

Symptoms/Clinical Manifestations. Approximately 10%–25% of patients with diverticulosis develop diverticulitis. The symptoms of diverticulitis range from mild abdominal pain to peritonitis and sepsis. Although the extent of symptoms often varies with the extent of inflammation, the degree of symptomatology likely depends on a number of other features including location of inflammation, extent of muscular dysfunction, and varying visceral sensitivity. The most common symptom complex during acute diverticulitis involves left lower quadrant pain and fever. Depending upon the location of inflammation and the redundancy of the sigmoid colon, pain may be also midline or in the right lower quadrant. Patients often describe a change in bowel habits with mild diarrhea. Bleeding per rectum is usually not associated with diverticulitis and would suggest other etiologies of colitis, including inflammatory bowel disease or ischemia. Nausea or vomiting may be present secondary to an associated ileus, a small bowel or large bowel obstruction secondary to phlegmon formation or inflammatory stricture. Physical examination most often reveals tenderness, at times with an associated mass. Laboratory evaluation often demonstrates leukocytosis.

Most often symptoms resolve after treatment with antibiotics. However, some patients will have "smoldering" disease that only partially improves and is marked by continued symptoms of left sided abdominal pain and low grade fevers.[169] Patients will often have crampy pain associated with a partial obstruction secondary to a continued phlegmon or stricture. Other patients with smoldering disease have more elusive symptoms of pain without fever or leukocytosis or imaging findings and this may be difficult to differentiate from irritable bowel syndrome.

When diverticulitis is associated with a colovesicular fistula, the infection or abscess is essentially drained by decompression into the urinary bladder and symptoms are marked by cystitis, pneumaturia, pyuria, or fecaluria.[170] Laboratory evaluation often reveals an abnormal urinalysis and polymicrobial urine culture. Similarly, colovaginal or uterine fistulae

EMERGENCY SURGERY

may present with vaginal discharge, passage of air or stool per vagina.

Differential Diagnosis. The differential diagnosis for patients with diverticulitis includes appendicitis, colorectal cancer, bowel obstruction, inflammatory bowel diseases, ischemic colitis, gynecological disease, and irritable bowel syndrome. Other diagnoses may include pyelonephritis, ureteral calculi, endometriosis, stercoral ulcer, or colonic volvulus. The use of CT as a diagnostic adjunct to history and physical can often confirm the diagnosis of diverticulitis or distinguish among the other potential diagnoses. Following the initial presentation of diverticulitis, the importance of endoscopy to exclude an underlying malignancy must be underscored; this is critical. Colonoscopy or sigmoidoscopy is most often performed at least 6 weeks after the episode of diverticulitis due to concerns of exacerbating microperforations secondary to intraluminal insufflation associated with performing these procedures.

Diagnostic Imaging. Although multiple imaging modalities are of potential use to diagnose suspected diverticulitis, none are as useful as CT.[171–173] Plain films are of limited value in confirmation of the diagnosis of diverticulitis, but may identify free intraperitoneal air as a nonspecific finding. Contrast enemas may be of utility to diagnose diverticulosis or strictures/mucosal abnormalities associated with diverticulitis. Water-soluble contrast should be used if an urgent operation or perforation is suspected, whereas barium should be avoided in this setting. Additionally, water soluble contrast may be of use in relieving partial obstruction secondary to the "slippery" nature of these agents and because high osmolarity may decrease tissue edema. It has been shown that ultrasound can demonstrate wall thickening, extraluminal air, and abscesses. However, ultrasound has not played a major role in the clinical diagnosis of diverticulitis in the United States.[174]

CT is both widely available and accurate. CT can accurately determine the diagnosis of diverticulitis, its complications, as well as other diagnoses (Fig. 35.16). Furthermore, severity-staging systems based upon CT findings in diverticulitis have been developed and are useful for determination of the morbidity and mortality, as well as the clinical course.[173,175] Moreover, CT severity scoring also correlated with recurrence in patients who were managed nonoperatively.[176] The scoring system that has gained the most wide spread acceptance is the Hinchey classification system (Fig. 35.17).

Management. Uncomplicated diverticulitis is treated with antibiotic therapy.[157,168] Based upon the common culture

FIGURE 35.16. CT scans of the colon revealing changes of acute diverticulitis.

results in patients with diverticular abscesses or perforations, most isolates are polymicrobial. The most common aerobic gram negative is *Escherichia coli*, aerobic gram positive is *Enterococcus*, and anaerobic is *Bacteroides fragilis*. Antibiotic regimens for the treatment of diverticulitis should have: (1) activity against these common bacteria, (2) good tissue penetration, (3) minimal toxicity, and (4) clinical efficacy.[168] There are a number of single or combination regimens that will satisfy at least the first three of these criteria (Table 35.6). Recommendations have been put forth by multiple societies including the American Society of Colon and Rectal Surgeons and the American College of Gastroenterology.[159,177] Additionally, the Surgical Infection Society and the Infectious Disease Society of America have also put forth applicable antibiotic regimens for complicated intraabdominal infections. However, these guidelines also involve source control (drainage procedures or surgical resection) and may not be as applicable to patients with uncomplicated diverticulitis who are treated with antibiotics alone.[168] The ideal regimen(s) has not been determined. Piperacillin/tazobactam or carbapenems are often used in hospitalized or higher risk patients based upon their broad spectrum of activity. Fluoroquinolones plus metronidazole are often used in uncomplicated diverticulitis based upon the ability to convert to oral therapy without need to change the antibiotic. Oral regimens include amoxicillin/clavulanic acid, moxifloxacin, ciprofloxacin and metronidazole, or trimethoprim/sulfamethoxazole and metronidazole. The ideal duration of antibiotic therapy in uncomplicated or complicated diverticulitis is not defined.

Patients with minimal symptoms and mild clinical findings on exam are often treated as outpatients on oral regimens for 7–14 days. Patients who present with more severe tenderness, fever, systemic symptoms, or inability to tolerate oral intake are most often hospitalized. These patients most often will undergo laboratory evaluations as well as CT. Patients with uncomplicated disease (Hinchey stages 0 or I) are generally treated with bowel rest and a parenteral regimen and then transitioned to an oral regimen following clinical improvement.

Some studies have demonstrated a benefit of immunomodulatory agents in the treatment of diverticulitis that does not require source control.[168,178–180] These have included 5-ASA products and mesalamine. Because of the inflammation involved in diverticulitis, these agents may prove to have a role in treating diverticulitis, particularly to decrease future recurrences. Additional therapies under investigation include rifaximin or probiotics.[181]

Diverticular abscesses are present in approximately 15% of patients with diverticulitis who have undergone CT. These abscesses can be mesocolic or pericolic (Hinchey stage I) or pelvic or retroperitoneal (Hinchey stage II). Patients with diverticular abscesses that are larger and have a radiologic window (accessible) are treated with percutaneous drainage as a means of source control, in addition to antibiotic therapy.[182] "Large" is a subjective term and usually is an abscess larger than 4 cm.[183] Percutaneous drainage may be more successful in patients with simple, nonloculated abscesses, or patients with mesocolic or pericolic abscesses. Transabdominal drainage is generally preferable, however, transgluteal, transperineal, transvaginal, or transrectal drainage are alternatives.

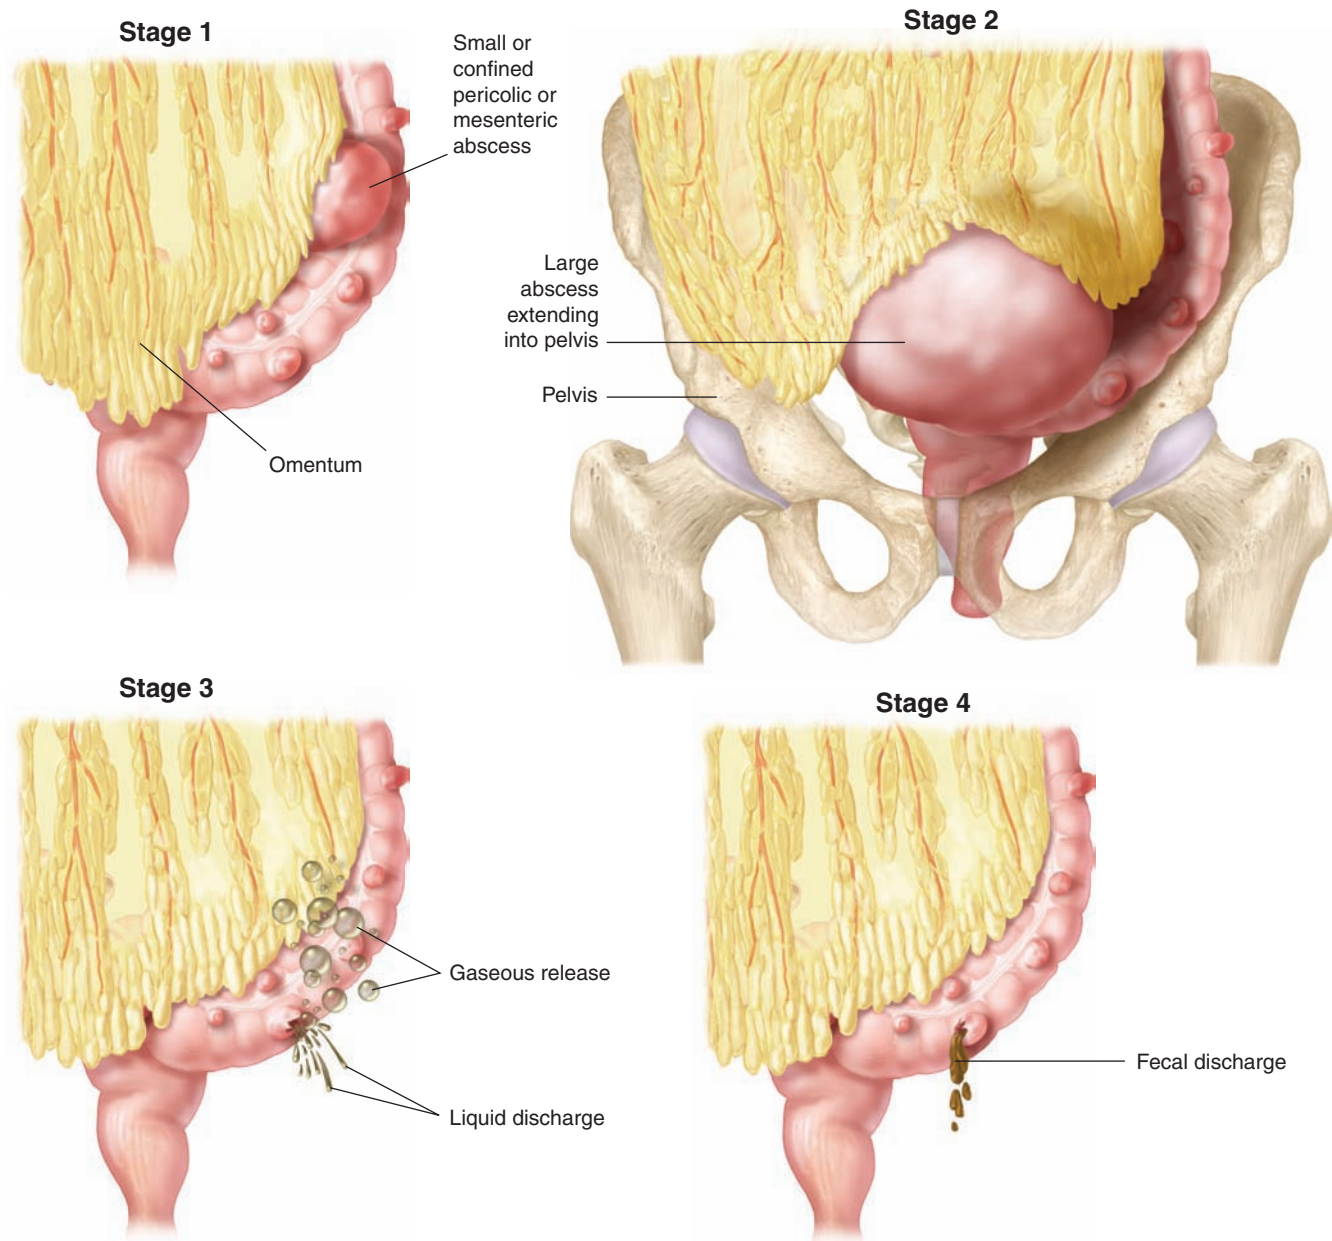
The ideal therapy for patients with diverticular abscess is actively debated. In general, percutaneous drainage is added as an adjunctive therapy in patients with larger abscesses that have a radiologic window.[183–186] The decision for operation in these patients is made on a case-by-case basis. Clinical response is followed. If the patient fails to improve or the clinical condition worsens, repeat CT to evaluate for recurrent or persistent abscesses is often performed or operation is recommended. Although the role and timing for elective surgical resection is also debated, patients with Hinchey stage 0, I, and


FIGURE 35.17. Representative Hinchey staging of diverticulitis. Stage 0 (not depicted) is mild diverticulitis without abscess formation. Stage I disease consists of small, pericolic of mesenteric abscesses, whereas stage II disease has abscesses that are either pelvic or distant intra-abdominal sites. Stage III consists of purulent peritonitis, while stage IV represents fecal peritonitis.

II ideally can be treated with antibiotics with or without percutaneous drainage and elective surgical resection offered in the future if indicated. As suggested, patients with complicated diverticulitis should undergo elective laparoscopic sigmoid resection after resolution of the acute episode.

When and if to operate on the patient with repeated bouts of uncomplicated diverticulitis is far more controversial. Traditional teaching until recently was that colon resection was offered for patients with two or more bouts of uncomplicated diverticulitis (inflammation limited to the colon) or any patient under age 50 with an episode of diverticulitis. The rationale was that these patients had high risk of recurrent disease, with concern for perforation. More recent data have disproven this assumption. In fact, 70% of patients with free

perforation from diverticulitis have no prior episode of symptomatic disease. The 2006 recommendation by the Society of Colorectal Surgeons states, "the decision to recommend elective sigmoid colectomy after recovery from acute diverticulitis (uncomplicated) should be made on a case by case basis as the number of attacks is not necessarily the overriding factor in defining the appropriateness of surgery."[159] On the other hand, diverticulitis in immunosuppressed patients, specifically transplant patients, does seem to be more virulent. Elective sigmoid resection should be considered after the first episode of diverticulitis.

Patients with free perforation and purulent peritonitis or feculent peritonitis (Hinchey stage III or IV) should be treated with surgical management. Only 1% of patients will develop

ANTIMICROBIAL THERAPY OPTIONS FOR ACUTE DIVERTICULITIS

Single agent regimens
Cephalosporin
Cefoxitin[a]
Penicillin/beta-lactamase inhibitor combinations
Ampicillin/sulbactam[c]; Ticaricillin/clavulinic acid;
Piperacillin/tazobactam
Carbapenem
Imipenem/cilastatin; Meropenem; Doripenem; Ertapenem
Glycylcycline
Tigecycline
Fluoroquinolone
Moxifloxacin

Combination regimens
Aminoglycoside[c] + an antianaerobic agent[d]
Tobramycin; Gentamicin
Cephalosporin + an antianaerobic agent[d]
Cefotaxime; Ceftriaxone; Ceftazidime; Cefepime
Monobactam + an antianaerobic agent
Aztreonam
Trimethoprim/sulfamethoxazole[e] + an antianaerobic agent[d]
Fluoroquinolone + an antianaerobic agent
Ciprofloxacin
Levofloxacin

Oral regimens
Moxifloxacin
Amoxicillin/clavulanic acid
Ciprofloxacin + metronidazole
Trimethoprim/sulfamethoxazole + metronidazole

[a]Not recommended because of increased resistance of *B. fragilis*.
[b]Not recommended as first line therapy because of increased resistance of *E. coli*.
[c]Not recommended as first line therapy because of toxicity concerns.
[d]Metronidazole or clindamycin have been used; however the utility of clindamycin is questioned because of increased resistance of *B. fragilis* and the association with *Clostridium* difficile colitis.
[e]Not FDA approved for intra-abdominal infections.

free perforation, and this is most often the initial attack of diverticulitis. Historically, surgical therapy was performed as a three stage operation (upstream diversion, followed by resection and colorectal anastomosis, and finally restoration of continuity). The mainstay of surgical treatment for perforated diverticulitis or complicated diverticulitis requiring urgent operation has been the Hartmann procedure. This involves resection of the involved disease segment, end colostomy and a blind pouch at the rectum. This procedure eliminates the septic focus, but has the disadvantage of requiring a second major operation. Studies have demonstrated that a high number of patients (up to 35%), particularly those of advanced age or with severe comorbidity never undergo reversal of their end colostomy.[187,188] Retrospective review has illustrated that Hartmann's procedures were associated with an 18.8% mortality, a wound infection rate of 24.2%, and stoma complications in 10.3%.[189] For this procedure, resect the minimal amount of colon necessary for source control, with limited pelvic mobilization or mobilization of the splenic flexure, essentially performing a "perforectomy" with margins only as extensive to allow creation of an ostomy and closure of the Hartmann stump. This approach makes the subsequent operation less difficult and facilitates dissection of the rectal stump and mobilization of the splenic flexure for anastomosis.

A wide mesenteric resection is not necessary. Identification of the ureter is preferred. It should be noted that additional resection of the distal sigmoid colon down to the site of splaying of the tenia coli is advocated at the time of second operation, that is, do not leave the sigmoid colon distally. Proximal resection is usually still limited to soft pliable colon without diverticula at the site of anastomosis. If proximal colon contains diverticula and the colon is otherwise grossly normal, this is left in place.

There is increased interest in alternative surgical treatment other than the Hartmann procedure. Several studies have suggested that in select patients with Hinchey stages III or IV diverticulitis, resection with primary anastomosis is superior to Hartmann resection.[190–192] In these studies, there is a selection bias in patients who underwent resection with primary anastomosis. Several clinical and patient-related issues should be considered as contraindications to this approach, including hemodynamic instability, diffuse peritonitis, significant bowel wall edema, ischemia, immunocompromised state, and ischemia.

An additional alternative that is being utilized for the acute presentation is laparoscopic exploration with peritoneal lavage.[193–199] Laparoscopic exploration is performed; if feculent peritonitis is found, the patient is converted to a laparotomy and a resection is performed. However, if the finding is purulent peritonitis, the patient's sigmoid colon is not mobilized or resected and the peritoneum is lavaged laparoscopically and a drain is left. Early studies demonstrate this approach to be promising. In a review of 213 patients from 8 studies with a 38-month follow up, 3% of cases were converted to an open procedure.[193] Ten percent of patients had complications and thirty-one percent of patients went on to have an elective resection with primary anastomosis.

Colovesical fistulae often require surgical treatment, however an urgent operation is rarely required, as the fistula usually serves to "drain" or decompress the infection.[170,200]. If a patient is highly symptomatic with symptoms of cystitis, then suppressive antibiotics are utilized. Management of a colovesical fistula at the time of operative exploration infrequently requires resection of the bladder. The fistula is usually "pinched off" the colon and the fistulous tract often may not be identified. A suture repair is necessary in few cases. We advocate an indwelling foley catheter with a cystogram prior to removal of the catheter, usually after 7–10 days postoperatively. When managed electively, as in all cases of diverticulitis, colonoscopy or sigmoidoscopy should be performed preoperatively to exclude a malignancy, in addition to cystoscopy to exclude primary bladder neoplasm.

Diverticular strictures can result in partial or complete bowel obstruction. Most often this is associated with repeated attacks of diverticulitis. The management of obstruction is covered in more detail in Chapter XX).

Infectious Colitides

There are a number of infections which can result in colitis. These include *C. difficile*, *Campylobacter*, *Salmonella*, *Yersinia*, *Shigella*, and *E. coli*. Additionally, CMV can result in colitis, particularly in immunosuppressed patients. Additional infections include amebic colitis from *Entamoeba histolytica* and toxic megacolon in Chagas disease from *Trypanosoma cruzi*. This chapter will focus on CDAD as this bacterium is now considered the leading nosocomial infection.

C. Difficile Associated Disease

C. difficile is a gram positive, spore forming anaerobe. *CDAD* affects over 3 million patients annually, causing 15%–35% of

antibiotic-associated diarrhea, and 70% of cases of antibiotic-associated colitis.[201] *C. difficile* colitis was initially identified in the 1970s and has since gained increasing notoriety due to its associated high morbidity (30%–80%) and mortality (4%–10%).[202] The reported incidence of "fulminant" or "severe, complicated" *CDAD*, defined as the most severe manifestation of *CDAD* with concomitant systemic toxicity and organ dysfunction is increasing. Additionally, recurrence is common, occurring in approximately 25% of patients.[203]

Pathophysiology. *CDAD* is acquired through the oral ingestion of *C. difficile* spores, which are resistant to gastric acidity and thus able to germinate into the vegetative form in the small intestine. Kyne et al. demonstrated that 31% of patients who received antibiotics in the hospital were colonized with *C. difficile*, and 56% of these patients developed symptomatic disease.[204] With colonization and depletion of competitive flora the *C. difficile* is free to overgrow and produce exotoxins (principally toxins A and B), which induce mucosal death and inflammatory changes. Essentially, this is a disease of colonic bacterial overgrowth. Most often, the consequences of toxin production are limited to the colon, resulting in the stereotypical diarrhea associated with this infection. In that small subset of patients with severe and fulminant disease, the consequences of the toxemia become systemic.[203]

Why only a subset of patients exposed to antibiotics become colonized, why only a fraction of these patients develop symptomatic disease, and why some patients suffer more severe disease compared to others is largely unknown. Some authors suggest that differing humoral antibody responses to the toxins are largely responsible for both the development of infection/colitis and the varying severity of disease.[205–207] Major risk factors for the development of *CDAD* are antibiotic exposure, hospitalization and advanced age (Table 35.7).

Symptoms/Clinical Manifestation. The severity of symptoms from *CDAD* ranges from mild diarrhea to sepsis. The most common clinical presentation is diarrhea associated with history of antibiotic use (either a few days after the antibiotic is started up to 12 weeks after the termination of antibiotics). Patients with diarrhea may have cramps, fever, and fecal leukocytes. Bowel movements are usually watery, with a characteristic foul smell. Fever, high leukocytosis, and abdominal pain usually localized to the lower quadrants accompany the diarrhea. Hypoalbuminemia often occurs as a result of large protein losses and is a sign of severe disease. For most mild cases, diarrhea is usually the

only symptom. However, there are rare occasions, especially in toxic patients with ileus, during which diarrhea may be absent.

Diagnosis. Having an index of suspicion is the most important component to making the diagnosis of *CDAD*. The diagnosis of *CDAD* is based on a combination of clinical and laboratory findings: symptoms, almost always diarrhea, plus a stool test positive for *C. difficile* toxins or toxigenic *C. difficile*. Visual or pathologic evidence of pseudomembranous colitis is also diagnostic. A careful history will usually confirm exposure to antibiotics; abatement of diarrhea in response to medical therapy supports the diagnosis. There are multiple laboratory tests available, however, the clinically most useful test with greatest sensitivity and specificity is cell cytotoxicity assay, which relies on the cytotoxic effects of toxin from stool samples on cells in culture.[208–210]

CT, with or without contrast, is a useful adjunct for evaluation of the colon in a patient with suspected *CDAD*. It is far less sensitive than stool toxin assays, and the changes seen are rarely diagnostic. The sensitivity and specificity of CT to identify colonic abnormalities in these patients is 52%–85% and 48%–93%, respectively.[211] In cases in which surgical consultation is desired, fulminant colitis characteristically features colonic-thickening, pericolonic-stranding, and the "accordion sign" (oral contrast material with high attenuation in the colonic lumen alternating with an inflamed mucosa with low attenuation). A "double-halo sign"/"target sign" is often seen with IV contrast representing varying degrees of attenuation of the mucosa secondary to hyperemia and submucosal inflammation). Most severe *CDAD* will show changes throughout the entire colon (pancolitis) and moderate quantities of ascitic fluid (Fig. 35.18). In one series, CT predicted the operative findings in 94% of cases.[212]

Management. In all cases, standard hospital isolation precautions must be instituted to reduce the spread of the disease. If possible, the antibiotics previously employed for the treatment of systemic infections should be discontinued, a goal which cannot always be accomplished because of persistent systemic infections. The recommended oral medications (metronidazole or vancomycin) must be given into the digestive tract so that the highest concentrations reach the colon. The two drugs are equally effective for mild or moderate disease, but metronidazole is less expensive.[213–215] Mild or moderate disease in adults usually responds to oral metronidazole 500 mg three times per day or 250 mg four times per day for 10–14 days. Severe disease, most often characterized by fever, leukocytosis [15–20,000 cells/mm³], cramps, and diarrhea but without hypotension, ileus, or megacolon is better treated with vancomycin 125 mg four times per day for 10–14 days.[203] First recurrences can be successfully retreated with either drug regimen but second and subsequent recurrences require a course of vancomycin with a taper of therapy over time. Patients who cannot tolerate oral antibiotics may be treated with intravenous metronidazole 500 mg IV every 8 hours. Parenteral metronidazole achieves therapeutic concentrations in the colon via biliary secretion but only in patients with diarrhea. It is important to remember that neither oral nor parenteral metronidazole reaches therapeutic concentrations in normal stool; thus continuing its administration more than 14 days in patients whose diarrhea resolves has no therapeutic value. Oral vancomycin, on the other hand, achieves effective concentrations in both normal and unformed stool so that recurrences are best treated with oral vancomycin. Vancomycin by the intravenous route is totally ineffective against *CDAD* because it does not reach the intestinal lumen.

EMERGENCY SURGERY
FIGURE 35.18. CT scans showing colitis in CDAD. CT scan findings of CDAD include colonic wall thickening, often involving the entire colon (pancolitis), pericolonic edema and mesenteric fat stranding, and ascites.

These therapeutic guidelines require amplification when patients do not respond or deteriorate during treatment. In any patient with severe disease, whether presenting initially with fever and leukocytosis complicating the diarrhea or these findings develop during medical treatment, early surgical consultation is required so that concurrent medical/surgical treatment planning can proceed for the unusual case in which operative intervention will be required. Surgical treatment has been demonstrated to improve outcomes in severe complicated *CDAD*, that is, in patients admitted to intensive care units with organ failure, or the need for vasoactive agents or ventilatory assistance. Although successful in many patients, the timing of operative intervention is difficult. Total abdominal colectomy, for example, the standard treatment of severe complicated disease, often referred to as "fulminant" *CDAD*, carries considerable morbidity and mortality (35%–85%).[203,216] The fear of these complications of treatment can lead to excessive deferral of surgical consultation, and an even less favorable outcome.

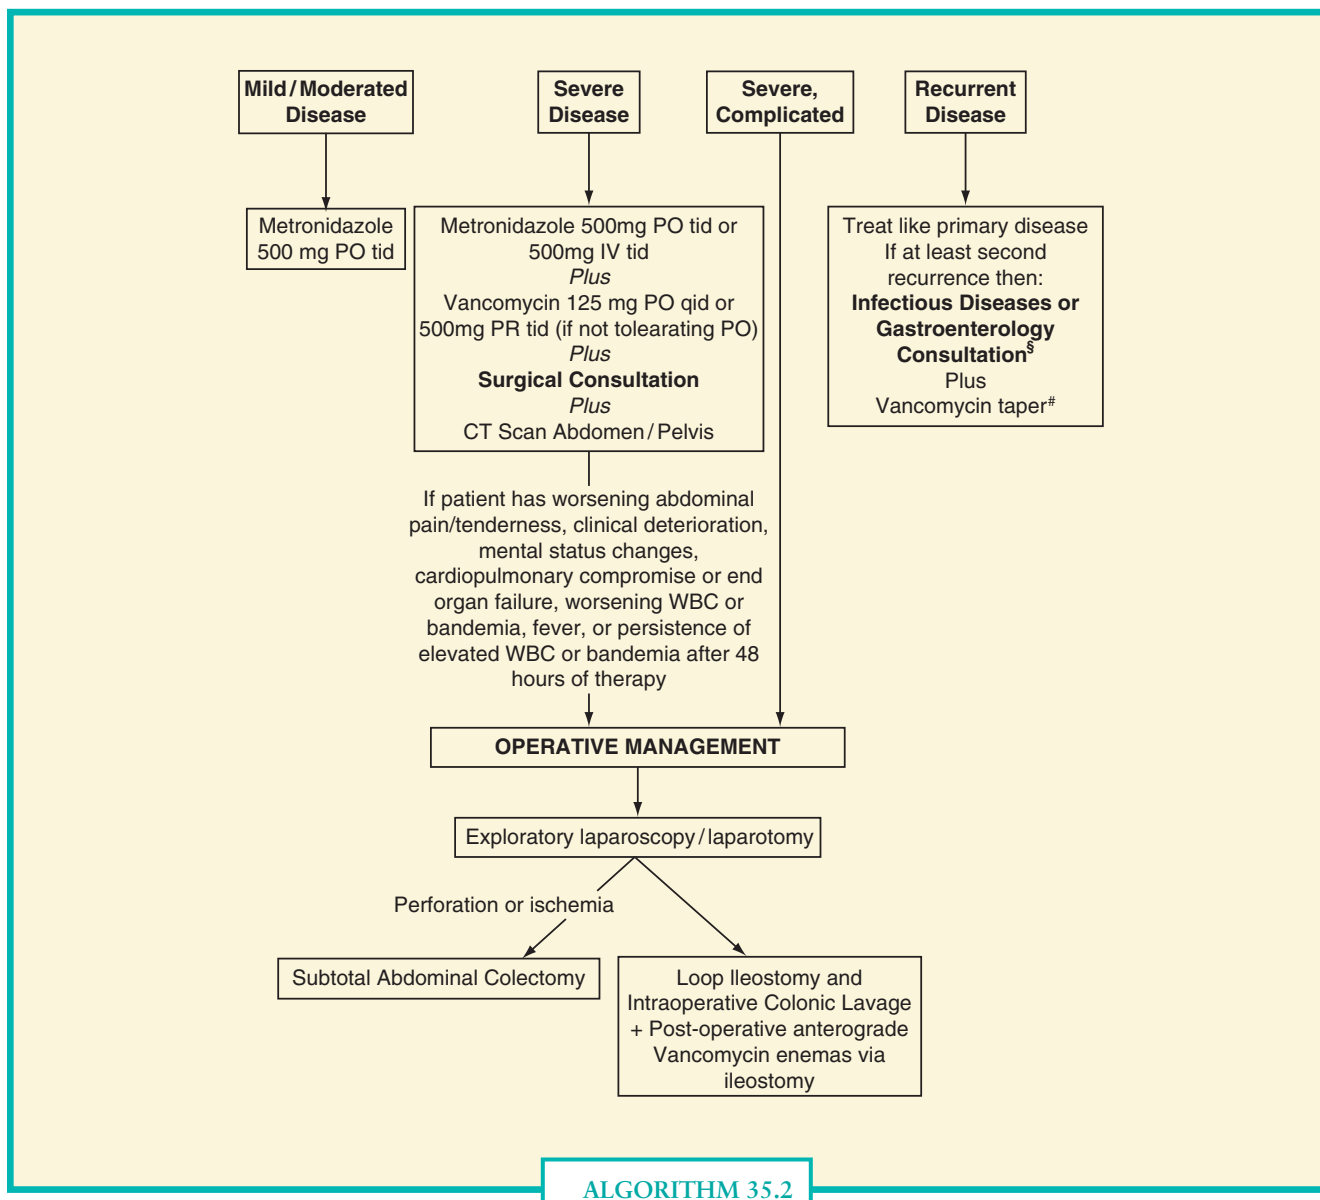
Early experiences from our group suggest that severe, complicated CDAD can be treated operatively (avoiding colon resection) with creation of a loop ileostomy and intraoperative colonic lavage, followed by antegrade vancomycin flushes of the colon via the ileostomy (in print). Using this approach, mortality has significantly decreased at our institution. Ileostomy can be reversed 3 months after the initial operation if the patient's clinical condition allows. This approach has the hypothetical advantages of improved short-term and long-term outcomes and avoidance of colectomy. However, it remains to be validated as an alternative to colectomy for the treatment of severe, complicated CDAD. Algorithm 35.2 highlights a recommended treatment strategy for patients with CDAD.

Bacterial Enterocolitides

A number of bacterial infections can cause enterocolitis. These include *E. coli*, *Campylobacter*, *Salmonella*, *Yersinia*, and *Shigella*. The most common symptom from these infections is diarrhea. The care is mainly supportive from a fluid and electrolyte standpoint. Additionally, treatment with antibiotics can hasten recovery. Typically, fluoroquinolones are first line antibiotics. The nonabsorbable rifamycin-based antibiotic rifaximin can be used for noninvasive *E. coli* infections. Although these infections can be quite serious, they typically do not require surgical consultation or treatment.

Cytomegalovirus Colitis

CMV is a double stranded DNA herpes virus. Although 50%–80% of the world's population is seropositive for CMV, generally, only immunocompromised patients develop invasive CMV infection. In an immunocompetent host, the CMV virus stays in a chronic latent state in the host's cells and viral proliferation is prevented by host cell-mediated immunity.[217] Although, there are reports of CMV causing colitis in older patients without obvious immunodeficiency, it is generally limited to patients with immunodeficiency.[218] CMV colitis is seen in 2%–16% of patients with solid organ transplants and 3%–5% of patients with HIV/AIDS.[219,220] Another population prone to CMV colitis is the group of patients with ulcerative colitis. CMV colitis has been reported in 27.3% of patients with steroid refractory colitis and 9.1% of patients with nonrefractory colitis.[221] Symptoms usually involve watery diarrhea, fever, and weight loss. However, there may be little diarrhea and blood per rectum in up to 30% of patients.

CMV colitis may be difficult to discern from other forms of colitis. When the colon becomes affected by tissue-invasive CMV, ulcerative changes can be seen. As ulcers increase in depth, erosion into blood vessels can cause profuse bloody diarrhea. Over time, inflammatory polyps may develop, which, rarely, may obstruct the colon. Colonoscopy and biopsy should diagnose CMV infection. Histological findings include giant cells (25–35 μm) with cytomegaly and large ovoid or pleomorphic nuclei containing basophilic inclusions (owl's eyes, halo rim). Culture for CMV may be positive, but testing for viral antigens using immunofluoresecent antibodies increases the sensitivity for detection of CMV.[222] CMV infection of the colon causes a vasculitis that may cause severe pain. Initially, because of the severe pain and peritonitis that can be found on exam, exploratory laparotomy and surgical resection


ALGORITHM 35.2

ALGORITHM 35.2 Treatment algorithm for *CDAD*. This protocol lowers what has been the standard threshold for operative therapy when compared to typical strategies that utilize operative management as a salvage type of procedure. Severe and severe complicated CDAD as defined by Society for Healthcare Epidemiology of America (SHEA) and the Infectious Diseases Society of America (IDSA). (Cohen SH, Gerding DN, Johnson S, et al. Clinical practice guidelines for Clostridium difficile infection in adults: 2010 update by the society for healthcare epidemiology of America (SHEA) and the infectious diseases society of America (IDSA). *Infect Control Hosp Epidemiol.* 2010:31(5):431–455.) §For second or more recurrent episodes we recommend consultation and management in conjunction with either the Infectious Diseases or Gastroenterology Divisions, depending on local practices. #Second recurrences are most often treated with a vancomycin course in which the frequency of dosing is decreased over multiple weeks.

was common. Additionally, if left untreated the severe inflammation and vasculitis may lead to ischemia and transmural necrosis of the bowel, resulting in perforation and peritonitis. With increased awareness of CMV infection in immunocompromised patients and treatment with antivirals, the need for operation is now rare. However, a continued challenge exists in patients with ulcerative colitis, where CMV colitis is also prevalent and can result in toxic megacolon. Antiviral therapy may resolve this condition, but if the diagnosis is not considered in patients with ulcerative colitis and therapy is initiated late in the course, colectomy may be necessary. First line antiviral therapy is ganciclovir, with foscarnet used as a second line therapy in most cases.[223]

Amebic Colitis

Amebic colitis, also known as amebiasis, is caused by invasion of the intestine by the protozoan parasite, *E. histolytica*. Although primarily a disease found in underdeveloped countries, this condition may exist in patients who have recently traveled outside the United States.[224,225] An accurate history, including travel and sexual history, is crucial to make the diagnosis. *E. histolytica* is found worldwide, but is most prevalent in Africa, Central and South America, and Asia. Symptoms usually include fever, crampy abdominal pain and diarrhea that may be bloody. Physical exam is not specific.

EMERGENCY SURGERY

Fecal examination usually does not show leukocytes, and the presence of leukocytes should suggest other infections. Ameba may be visualized in stool samples. Diagnosis is most reliably made by enzyme-linked immunoassay testing for *E. histolytica* antigens. Treatment is primarily supportive care plus the addition of metronidazole. Oral dosing of the aminoglycoside paromomycin is added after completion of metronidazole if symptoms resolve to destroy the cysts in the lumen. Loperamide is avoided in the treatment of amebiasis. In the case of fulminant amebic colitis, broad-spectrum antibiotics should be given in addition to metronidazole. If a patient clinically deteriorates or perforation is suspected the treatment involves surgical exploration and subtotal colectomy.

Ischemic Colitis

Ischemic colitis is the most common form of GI ischemia. There are numerous etiologies for ischemic colitis, but all result in decreased blood supply that is injurious to the colon.[226–228] Ischemic colitis can range from limited injury to the colonic mucosa to full thickness injury with colonic necrosis and the development of sepsis. The diagnosis of ischemic colitis can be challenging, and often the exact etiology is not determined. The outcome from ischemic colitis depends upon the severity of the injury, the duration of the ischemia, and the rapidity of diagnosis and treatment.

Pathophysiology. An understanding of the pathophysiology of ischemic colitis requires an understanding of the vascular supply (Fig. 35.15).[151,229–231] The SMA gives off direct branches (ileocolic, right colic, and middle colic arteries) to the ascending colon and the proximal two thirds of the transverse colon. The IMA gives off branches (left colic and sigmoidal arteries) to the distal transverse colon, the descending colon, and the sigmoid. Additionally, the IMA gives rise to the superior hemorrhoidal artery to supply the upper and middle rectum. The lower and middle rectum are also supplied by direct branches of the paired internal iliac arteries (middle and inferior hemorrhoidal arteries). The SMA and IMA collateralize primarily through a connection in the left branch of the middle colic artery and the ascending branch of the left colic artery. This connection may be inadequate leaving the splenic flexure relatively prone to ischemic insult. This is referred to as a "watershed" area or "Griffiths" point'.[232] Another region that may be prone to ischemic insult is the area of the colon between that supplied by the distal sigmoid branches and the superior hemorrhoidal artery.[229,231]

Blood flow to the colon can be decreased secondary to changes in perfusion that affect the systemic vasculature or local changes in blood flow in the mesenteric vasculature. The etiologies are often classified as occlusive or nonocclusive (Table 35.8).[233] Examples of *occlusive* include embolic phenomena, thrombosis, atherosclerosis, or small vessel disease. Examples of *nonocclusive* include shock states, medication effects, or colonic obstructions. Nonocclusive ischemia results in a low flow state to the colon or mesenteric vasoconstriction. Interestingly, systemic low flow states often affect the right colon, whereas localized nonocclusive ischemia tends to affect watershed areas. Specific clinical situations that can precipitate ischemic colitis include aortic surgery that compromises flow to the IMA, as well as angiographic embolization to treat GI bleeding.[234–236]

Symptoms/Clinical Manifestation. Although there are varied etiologies, the clinical presentation of ischemic colitis is quite uniform. Often, the onset is sudden, crampy abdominal pain that is poorly localized. Pain from ischemia of the left sided colon often is appreciated vaguely in the left lower quadrant or flank, and that of right sided ischemia is appreciated centrally. After the onset of abdominal pain, patients will

ETIOLOGIES OF ISCHEMIC COLITIS

■ OCCLUSIVE CAUSES	■ NON-OCCLUSIVE CAUSES
Arterial occlusion	Systemic hypoperfusion
Embolus	Shock
Thrombosis	Major cardiovascular surgery/bypass
Trauma	Snake venom
Postaortic surgery	Anaphylaxis
Colectomy with IMA ligation	Long-distance running
Small vessel disease	Colonic obstruction
Atherosclerosis	Volvulus
Vasculitis	Colon cancer
Rheumatoid arthritis	Strangulated hernia
Amyloidosis	Fecal impaction
Radiation injury	Pseudo-obstruction
Venous occlusion	Medications
Prothrombotic states	Digoxin
Mesenteric venous thrombosis	Cocaine NSAIDs Vasopressors Pseudoephedrine Interferon-ribavirin Diuretics

often experience the need to defecate and will pass bloody or maroon stools. This is secondary to mucosal ischemia. The quantity of blood is usually not significant, and if there is more substantial bleeding, other etiologies should be suspected. If ischemia is significant enough to progress to full necrosis of the colon, which can result in inflammation of the parietal peritoneum, the pain tends to become more localized and significant.

Physical examination generally reveals mild tenderness that may be more pronounced over the ischemic segment. Peritonitis is present when there is transmural necrosis. Depending upon the etiology of the ischemic colitis, the patient may have hemodynamic instability. The majority of patients who develop ischemic colitis in nonhospitalized settings present with normal hemodynamics and mild tenderness as the only findings.

Laboratory evaluations are nonspecific. Patients with more substantial ischemia may have an elevated white blood cell count. Electrolytes may be abnormal if a patient is dehydrated. If there is more significant ischemia, patients may have a metabolic acidosis, an elevated base deficit on arterial blood gases, as well as an elevated lactate; all are nonspecific. D-Lactate may be a more useful value to follow, as D-Lactate is produced by bacterial fermentation in the colon.[237] In the setting of mucosal ischemia, D-Lactate levels can increase in the systemic circulation secondary to increased mucosal permeability to this stereoisomer. D-Lactate levels have a sensitivity of 82%–90% and a specificity of 77%–87% in prediction of early colonic ischemia.[237,238]

Diagnosis. Diagnosis of ischemic colitis is made by history and physical examination in combination with radiologic

studies and colonoscopic inspection. Plain films of the abdomen are of limited utility and not sensitive, but may demonstrate thickened colon wall, thumbprinting on the colon wall, and rarely pneumatosis coli. Some advocate air contrast enemas, which may enhance visualization of thumbprinting.[239,240] Contrast enemas are generally avoided in the acute setting of ischemic colitis as they do not offer much information and can worsen ischemia if the colon is over distended. These studies may have a role in the follow up on the consequences of ischemia such as stricture.

CT with intravenous contrast is useful to assess acute mesenteric ischemia, as well as other pathology. Intravenous contrast allows visualization of the mesenteric arteries as well as the mesenteric venous system. CT angiography or conventional angiography may be indicated if mesenteric ischemia is suspected. Findings of ischemic colitis on CT scan are nonspecific, including colon thickening and ascites.[241] Ultrasound and Doppler flow studies are not reliable to consistently make a diagnosis.[242]

Colonoscopy is the most sensitive and specific diagnostic test. Early ischemia is visualized as changes in the mucosa. It will appear pale and edematous, and there may be hyperemic appearing patches. Advancing ischemia can be visualized as blackish nodules protruding into the lumen. These occur as a result of submucosal hemorrhage. If there are areas of mucosa that are gray-green or black, this suggests more advanced ischemia and should raise concern for transmural ischemia. Colonoscopy also allows biopsy to help differentiate inflammatory, ischemic, and infectious causes of colitis if these are in the differential diagnosis. Colonoscopy should be performed with caution as to not over distend the colon, which may exacerbate ischemia or precipitate perforation.

Management. In the absence of signs of colonic gangrene or perforation, ischemic colitis is managed nonoperatively.[243] Most patients with colonic ischemia have mucosal limited disease and fall into this category. Intravenous fluids are started and patients are resuscitated if there is evidence of volume depletion. Patients are placed on bowel rest and should not eat or drink. If patients have significant ileus or bowel distension then a nasogastric tube is placed for suction. Cardiac function is optimized and drugs which can impair mesenteric blood flow are limited if possible. Although there is little data to support this practice, most patients are placed on broad spectrum antibiotics to cover the usual colonic anaerobic and aerobic bacteria. Other pharmacologics that can improve mesenteric blood flow such as glucagon and papaverine have not been studied rigorously enough to support their use. Bowel preps or enemas are typically avoided as this may worsen ischemia. Patients are monitored for signs of deterioration, including fever, tachycardia, worsening exam, leukocytosis, or sepsis.

If transmural colonic necrosis, infarction, or perforation is suspected, prompt operative exploration is indicated. The ischemic colon is resected. Margins of resection should be based upon any evidence of ischemia and most would advocate resection to points with normal mucosa. This may be difficult to assess by inspection of the serosal surface of the colon and may be aided by direct mucosal inspection, either by colonoscopy or opening the resected specimen to evaluate mucosa at the margins for variability. Exploratory laparotomy allows assessment of colonic blood flow via visible inspection and palpation of pulses. If ischemia involves multiple segments or is more advanced, a subtotal colectomy may be performed. The decision to perform an end colostomy or ileostomy depends upon the etiology of the ischemic colitis. Anastomosis is usually avoided in patients with hemodynamic instability

or immunocompromised patients. If the ischemic segment is focal, the bowel margins are clearly viable and healthy, and there is no ongoing pathology to precipitate further ischemia, anastomosis can be performed. The adjunct of intraoperative colonic lavage or the addition of upstream fecal diversion, usually with a diverting loop ileostomy should be contemplated when an anastomosis is being performed.

The prognosis of patients with ischemic colitis is generally good if disease is limited to the mucosa, as in most patients.[233,244] Long-term consequences may be ulcerating segmental colitis or stricture formation. Strictures are seen in 10% of patients who recover and may require an elective segmental resection.[245] If the patient develops a segmental colitis, which can manifest as persistent diarrhea and rectal bleeding, this too may be treated with elective resection. Patients who require urgent exploration and operation for more substantial ischemia have a worse prognosis, with mortalities approaching 40%. This may be secondary to associated comorbidities in this patient population.

Acute Presentation of Inflammatory Bowel Disease

Severe acute ulcerative colitis can be defined as >6 bowel movements per day plus one of the following: (1) Temperature >37.8°C, (2) large amounts of rectal bleeding, (3) heart rate >90 beats per minute, (4) hemoglobin <10.5 g/dL, or (5) an erythrocyte sedimentation rate >30 mm/h.[246–248] Historically, untreated severe ulcerative colitis was associated with a mortality of 24%, but this has decreased to <1% using a combination of corticosteroids and immunomodulatory drugs and timely surgical intervention. The approach should be multidisciplinary and surgical therapy reserved as a salvage therapy. Toxic megacolon is a general term for an acute form of colonic distension associated with significant inflammation and colonic failure, and can lead to sepsis. Toxic megacolon can develop from inflammatory bowel disease and is an emergency that requires surgical therapy. Although approximately 10% of patients will satisfy criteria for severe colitis upon initial presentation for ulcerative colitis, most often patients who present with severe colitis from inflammatory bowel disease will already have a diagnosis or have sought medical care prior to the acute presentation. Therefore, we will not focus on the pathophysiology and initial diagnostic workup of inflammatory bowel disease, but rather the management of patients with acute severe colitis.

Diagnosis. Patients with criteria for severe colitis should be admitted to the hospital. It is important in patients who do not have an established diagnosis of inflammatory bowel disease to consider alternative diagnoses including infectious and ischemic colitis. In patients with a diagnosis of inflammatory bowel disease, it is also important to specifically consider CMV infection, as well as *C. difficile* infection.[249–252]

Sigmoidoscopy or colonoscopy is useful to evaluate the severity of an attack of colitis.[246,253,254] The extent of mucosal inflammation and ulceration can be determined. Biopsy can also be performed to diagnose CMV. Biopsy and inspection may also help diagnose ischemic colitis or Crohn's colitis. It should be noted that differentiation of inflammatory disease limited to the colon as Crohn's disease or ulcerative colitis may be difficult; in addition, 15% of patients will be given a diagnosis of indeterminate colitis. However, the management in acute severe colitis for each of these entities is similar. Inspection of the mucosa and stool samples can also be collected for analysis or culture to evaluate for *C. difficile* or other

infections, including, *Campylobacter*, *Salmonella*, *Yersinia*, *Shigella*, *E. histolytica*, and *E. coli*.

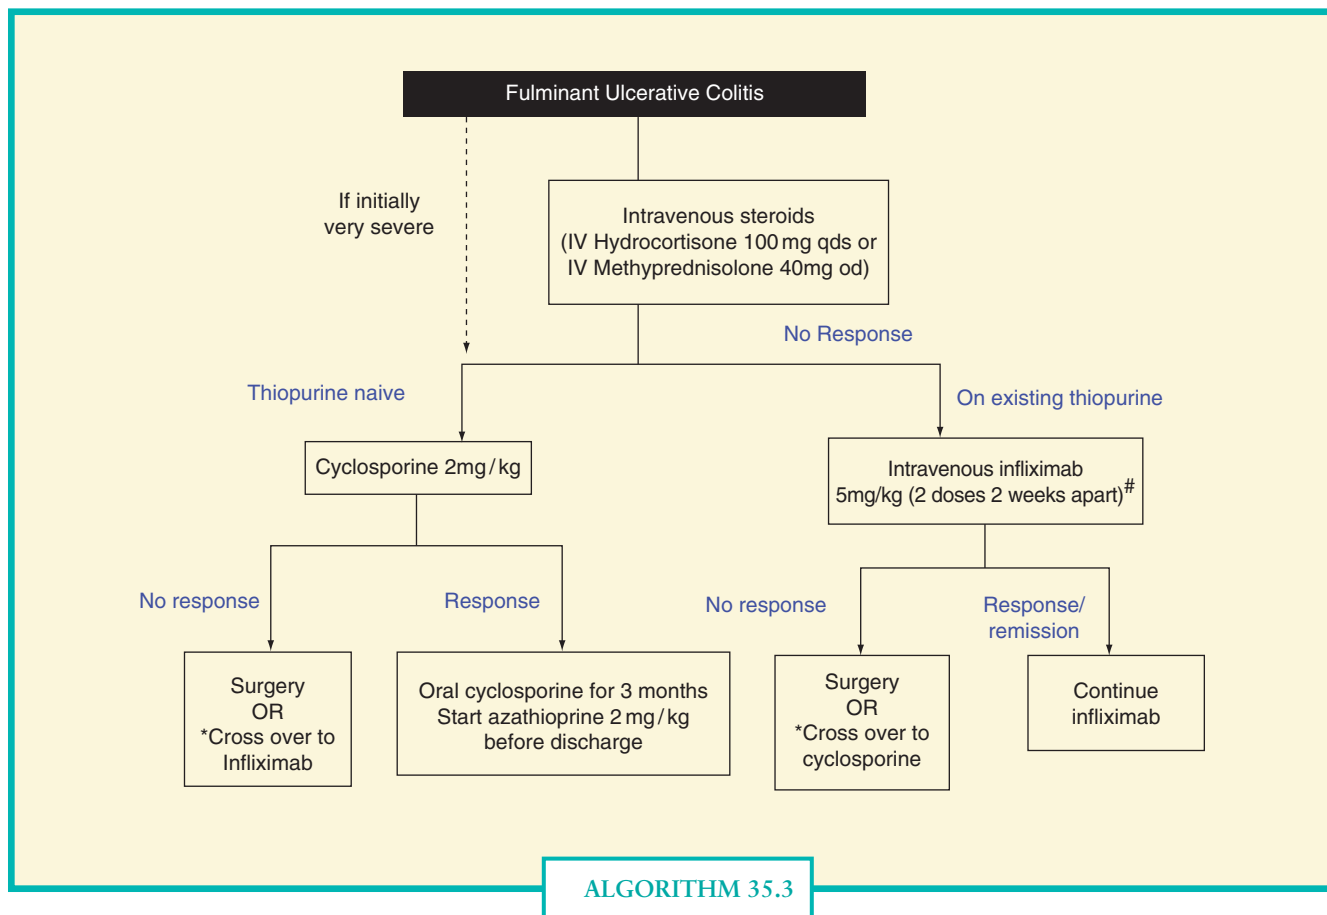
Plain films can evaluate for perforation, disease extent, or toxic megacolon. Modern day availability of CT makes this a diagnostic adjunct which can more accurately determine all of these features. However, it is not as easy to perform, is more costly, and exposes patients to more radiation compared to plain films. Plain films can be performed daily and used as an adjunct to clinical exam to help guide management. Physical exam findings may be masked by steroids and other immuno-modulatory treatments.

Laboratory examination for leukocytosis, blood counts, electrolytes, and inflammatory markers should be followed. Patients with severe colitis are prone to dehydration and electrolyte abnormalities, specifically hypokalemia. This may be exacerbated by corticosteroids.

Management. One of the most important facets of management is the multidisciplinary approach of gastroenterologist and surgeon. Patients should receive supportive care with intravenous fluids. Patients with severe colitis may be prone to venous thromboembolic disease secondary to protein losses and should receive prophylaxis against venous thrombosis even in the presence of bloody diarrhea. An algorithm for the treatment of severe colitis is highlighted in Algorithm 35.3.

The mainstay of treatment for acute severe colitis is corticosteroids.[247,248] Treatment is usually for 5 days but may extend up to 10 days. If a patient's clinical status improves, they are typically started on oral steroids, which are then tapered over time. Approximately 60% of patients do not respond completely to steroids.[246,247,255,256] There are multiple prognostic indices that can predict the outcome of patients with severe colitis and failure to respond to steroid therapy. If treatment failure seems likely, then additional "rescue" therapies should be considered earlier in the course. If the patient deteriorates, operation should be considered immediately. This underscores the importance of surgical consultation early in the hospitalization.

Cyclosporine is a calcineurin inhibitor that prevents T-cell activation and proliferation. It is used in an attempt to avoid surgery when corticosteroids fail.[256–258] Cyclosporine is often started on day 3 when steroids are failing, and converted to oral dosing once symptoms improve. Importantly, cyclosporine does not seem to increase the risk of perioperative complications in patients who do not respond and undergo surgery.

Infliximab is a monoclonal antibody that binds to TNFα. The use of infliximab was first established in Crohn's disease. Several smaller trials have supported the use of this antibody for the treatment of steroid refractory severe colitis.[259–262] The use of this agent is in evolution, but will likely prove to be of benefit. Infliximab has a good short term safety profile. However, the perioperative risks in patients who progress to


ALGORITHM 35.3

ALGORITHM 35.3 Clinical management strategy for severe/fulminant ulcerative colitis. #Infliximab has been associated with increased risk of infections. (Reprinted from Ng SC, Kamm MA. Therapeutic strategies for the management of ulcerative colitis. *Inflamm Bowel Dis*. 2009;15(6):935–950, with permission. Figure 4 p. 946.)

surgery may be more substantial, specifically for infectious complications. This remains to be determined.

Trials comparing infliximab to cyclosporine are underway.[263] Additional immunomodulatory agents are being investigated and show promise. These include immunoglobulin G2 against CD3 epsilon chains on T-cells, the calcineurin inhibitor tacrolimus, and leucocytapheresis to selectively remove populations of white blood cells.[264–268]

Surgery is still the definitive treatment. Failure of medical therapy in the acute setting, clinical deterioration, perforation, or toxic megacolon are indications for operation. In the setting of severe colitis, patients will generally undergo a subtotal abdominal colectomy, end ileostomy, and creation of a Hartmann's pouch. If the distal colon and rectum are severely inflamed and creation of a Hartmann's pouch does not seem possible, a mucous fistula can be created. Alternatively, the distal colon and rectum can be left as a Hartmann's pouch and the end can be secured above the fascia at the inferior extent of the midline wound. The fascia is not closed at this point. If the stump breaks down, it will manifest as a controlled mucous fistula. With either management, total proctocolectomy is usually avoided in this acute setting if a restorative procedure is contemplated in the management of the patient in the future. Not extending the resection down to the peritoneal reflection, thus leaving a longer Hartmann's pouch, will facilitate future dissection and creation of an ileal pouch with anal anastomosis in the future, if the patient is a candidate. Again, early surgical involvement and consultation with a stoma therapist will help guide management, as well as enhance patient understanding and acceptance of surgical management.

Colectomy is an effective treatment to manage this disease acutely. It can improve quality of life, and in the long term can decrease the need for immunomodulatory drugs and the risk of cancer. In patients who undergo a restorative procedure, complications from surgery are high, including anastomotic leak, stricture, small bowel obstruction, and pouchitis. This needs to be balanced with the long-term morbidity or mortality of medical therapy, which is still to be defined.

MISCELLANEOUS CAUSES OF COLONIC INFLAMMATION

Epiploic Appendagitis

Colonic epiploic appendages are fatty appendages on the peritoneal surface of the colon along its entire length. Torsion or spontaneous venous thrombosis of these appendages are rare, but diagnosed more commonly secondary to increased use of CT (Fig. 35.19). Symptoms manifest as localized abdominal pain. It most commonly occurs in the sigmoid or cecum, thus mimicking diverticulitis or appendicitis.[269,270] Laboratory findings are nonspecific. CT can diagnose this pathologic entity, although depending on the location, it can be difficult to discern epiploic appendagitis from early diverticulitis.[271–274] Ultrasound may aid in the diagnosis as well.[275,276] The disease is thought of as self limiting and treatment generally involves pain control and nonsteroidal anti-inflammatory medications. Some reports have demonstrated recurrence and would advocate, either in the primary setting or following recurrence, exploration (preferably laparoscopic if possible) with ligation and excision of the inflamed appendage.[277]

Neutropenic Enterocolitis

Neutropenic enterocolitis (also known as typhlitis) is a syndrome in neutropenic patients characterized most typically
FIGURE 35.19. CT scan showing appendagitis. Appendagitis may appear as an abnormality of the fat adjacent to the colon, with or without pericolonic fat stranding. White arrow points out a change in fat density of the colonic appendage adjacent to the sigmoid colon.

by fever and right lower quadrant pain. Patients may have distension, diarrhea, or lower GI bleeding. It can occur in patients with hematologic malignancies, myelodysplastic syndromes, AIDS, or in the setting of immunosuppressive therapies.[278–282] The etiology is uncertain but may occur as a result of mucosal injury from cytotoxic drugs and impaired host defense. Other diagnoses must be considered, such as appendicitis, ischemic colitis, CDAD, and other infectious colitis. CT can be useful to exclude other diagnoses. CT may demonstrate a dilated cecum, right lower quadrant inflammation, or pericecal inflammation or ascites. Treatment is usually supportive with intravenous fluids, bowel rest, and antibiotics. Immunosuppressive therapy should be stopped and consideration should be given to correct neutropenia using recombinant therapies, such as granulocyte colony-stimulating factor.[283] Operation is considered for patients with continued bleeding despite aggressive correction of hematologic abnormalities, perforation, or clinical deterioration. In this immunosuppressed population, most surgeons would advocate resection of the affected region (ileocecectomy versus right hemicolectomy) with end ileostomy and mucous fistula.

Radiation Proctitis

Radiation proctitis is characterized by injury to the distal colon or rectum following radiation therapy. Acute proctitis occurs within 6 weeks of therapy and is characterized by diarrhea, urgency, and rectal bleeding. These symptoms usually resolve spontaneously over time and therapy is aimed at prevention of perianal skin irritation and breakdown. Chronic radiation proctitis is delayed in onset and usually occurs at least 1 year after radiation therapy. It occurs as a result of radiation-induced obliterative endarteritis that results in mucosal ischemia.[284] This results in stricture formation and bleeding. The diagnosis is made by a history of radiation and endoscopic evaluation demonstrating mucosal edema, erythema, telangiectasias, ulcers, and strictures. Treatment should be based on the symptom complex. Sucralfate enemas have a low side effect profile and may be successful.[285,286] Ablative therapies, including argon plasma coagulation, lasers, and electrocautery can successfully treat bleeding.[287] Argon plasma coagulation has the advantage of being widely available, cheap, and having

EMERGENCY SURGERY

a minimal depth of penetration.[288–290] Some reports suggest that SCFA enemas or formaldehyde enemas can stop bleeding.[291,292] Surgery is reserved for recalcitrant bleeding, significant strictures, or pain.[293]

SUMMARY

Acute inflammatory processes of the intestinal tract may require urgent operation. The acute care surgeon must apply critical decision making to the management of patients presenting with inflammatory emergencies in an expeditious and well-thought-out manner. Surgeons must resist the temptation to do too much in the operating room during an emergency operation. The primary goals of the operation must remain the focus and a damage control approach may better serve some critically ill patients. Allowing the patient's health and hemodynamic status to guide decision making will generally lead to better outcome.

CHAPTER 36 ■ INTESTINAL OBSTRUCTION AND DYSMOTILITY SYNDROMES

LOUIS H. ALARCON

Few clinical conditions are as common yet potentially perplexing as intestinal obstruction. Intestinal obstruction is a frequent presenting problem and accounts for a large percentage of surgical consults for acute abdominal pain. As many as 15% of surgical admissions are for mechanical small bowel obstruction.[1]

Intestinal obstruction develops when gas and succus are prevented from passing distally through the gastrointestinal tract as a result of either intrinsic or extrinsic compression (i.e., mechanical obstruction) or gastrointestinal paralysis (i.e., nonmechanical obstruction, either ileus or pseudo-obstruction). Many different etiologies may account for this pathology. Ileus is the most common form of dysmotility, although not an obstruction *per se*. It frequently develops after abdominal surgery or in association with intra-abdominal or extra-abdominal inflammatory conditions.[2] Mechanical small bowel obstruction is slightly less common. Postoperative intra-abdominal adhesions account for the majority of mechanical small-bowel obstructions. Cancer and hernia account for the majority of the remaining cases of small-bowel obstruction. Mechanical colonic obstruction is less frequent than small-bowel obstruction, and accounts for 10%–15% of cases of mechanical bowel obstruction. The most common causes of mechanical large-bowel obstruction include obstructing carcinoma, diverticulitis, or volvulus. Acute colonic pseudo-obstruction occurs most often in elderly patients, in response to acute medical illness, or in the postoperative period.

PATHOPHYSIOLOGY OF INTESTINAL OBSTRUCTION

Mechanical small-bowel obstruction develops as gastrointestinal secretions and gas accumulate in the distended intestine proximal to an obstructed segment. As the distension progresses, the intraluminal hydrostatic pressure compresses the intestinal mucosal villus lymphatics, causing lymphedema of the bowel wall. With increasing intraluminal pressures, the hydrostatic pressure at the venous end of the postcapillary venules causes a shift in the Starling dynamics across the capillary bed, leading to the net filtration of fluids, electrolytes, and proteins into the bowel wall and lumen. This so-called "third spacing" can lead to the loss of massive amounts of intravascular volume, causing dehydration, hypovolemia, and end-organ hypoperfusion if untreated. Venous hypertension may also lead to arterial hypoperfusion and bowel ischemia in some cases, but, more often, direct arterial occlusion occurs due to the mechanical forces associated with a segment of bowel, which has twisted upon its mesentery (volvulus) or due to strangulation in an incarcerated hernia. If the bowel ischemia is not treated in a timely fashion, intestinal necrosis, perforation, and peritonitis ensue. Furthermore, the normal intestinal mucosal barriers are disrupted, theoretically allowing gut bacteria to translocate into the systemic circulation.[3,4] Enteric bacteria have been isolated in the mesenteric lymph nodes of approximately 60% of patients undergoing laparotomy for simple bowel obstruction (without strangulated intestine) compared to only 4% of patients undergoing laparotomy for conditions other than bowel obstruction.[5]

DIAGNOSIS AND EVALUATION

Patients with mechanical bowel obstruction or ileus often present with abdominal pain and distension, nausea, vomiting, and obstipation.[6] Several clinical features may help distinguish mechanical obstruction from ileus or pseudo-obstruction. The pain associated with mechanical obstruction is typically moderate to severe and crampy in nature, while patients with ileus tend to have less pain and in some cases no pain.

A detailed past surgical history must be obtained in all patients. Prior abdominal surgery places the patient at risk for the development of adhesive small-bowel obstruction. The lack of prior abdominal surgery or inflammatory conditions makes adhesive disease unlikely as the etiology of the patient's obstruction. Any prior history of malignancy must be taken into account, as recurrent cancer must be in the differential diagnosis.

PHYSICAL EXAMINATION AND INITIAL MANAGEMENT

The patient with bowel obstruction often requires simultaneous evaluation and initial resuscitation. It is important to rapidly assess the degree of physiologic impairment, and address it expeditiously. Common physiologic abnormalities include hypovolemia, electrolyte abnormalities, and prerenal azotemia. Establishment of intravenous access and fluid resuscitation are important parts of the initial management of these patients. Careful monitoring of urinary output with an indwelling Foley catheter may serve as an important endpoint of resuscitation. Nasogastric decompression may be necessary to reduce the incidence of vomiting and aspiration. The character of the nasogastric tube output may be useful as far as diagnosis is concerned. A nonbilious output implies a gastric outlet obstruction. Bilious but nonfeculent aspirate is usually seen in proximal small-bowel obstructions or colonic obstruction with a competent ileocecal valve. Distal small-bowel obstruction often presents with feculent nasogastric output.

It is also important to exclude other medical conditions, which may be associated with nausea, vomiting, and abdominal distention such as an acute coronary syndrome or pneumonia.

Examination of the abdomen proceeds in an orderly fashion: inspection, auscultation, palpation, and percussion. With the patient in the supine position, general inspection of the abdomen is performed. The degree of abdominal distension may vary with the level of the obstruction: proximal small-bowel obstruction may be associated with minimal abdominal

527

distension. Surgical scars from prior abdominal surgery should be noted. Visible peristaltic waves are often associated with mechanical small-bowel obstruction.

Auscultation with a stethoscope should be performed for at least 5 minutes to determine the presence and quality of bowel sounds. The typical bowel sounds in a patient with a mechanical small-bowel obstruction are high-pitched and hyperactive. Patients with ileus often have a silent abdomen. However, patients with long-standing intestinal obstruction or perforation associated with peritonitis may have a silent abdomen.

Palpation of the abdomen should start gently and become progressively deeper as the patient's pain is assessed. If the patient complains of pain in one discrete region area, it is useful to begin the palpation on the opposite side of the abdomen. Most patients with bowel obstruction have diffuse abdominal tenderness, but less than half will have mild tenderness, guarding, or rigidity.[6] Traditionally, many surgeons believe that the findings of localized tenderness, guarding, or rebound are indicative of underlying bowel strangulation and mandate operation. However, these findings are neither sensitive nor specific for the detection of underlying bowel ischemia[7] or obstruction.[6] Furthermore, patients with ileus may also have abdominal tenderness and may be difficult to distinguish from mechanical bowel obstruction in this regard. Gentle percussion should be performed to assess for tympany associated with underlying distended, gas-filled intestine; dullness, indicative of an underlying mass; or peritoneal irritation associated with ischemic bowel or peritonitis secondary to perforation.

A comprehensive evaluation for abdominal wall herniae must be performed in all patients. This includes careful inspection for inguinal, femoral, umbilical, incisional, and other abdominal wall herniae. Herniae should be assessed for the presence of incarcerated intestine. If local signs of infarcted intestine are present such as erythema or cellulitis, the patient should undergo immediate operation without attempt at reduction. Otherwise, careful reduction should be attempted, but care taken to avoid further injury to the intestine during this maneuver, or of reducing already ischemic bowel. Some herniae, such as obturator hernia or internal hernia, may not be readily detectable on physical exam and require imaging to detect. Digital rectal examination is performed to evaluate for masses, fecal impaction, and occult blood. Similarly, digital examination of any existing stoma is important to assess obstruction at a colostomy or ileostomy site.

DIAGNOSTIC STUDIES

Plain Radiographs

While abdominal radiographs should be obtained routinely on all patients suspected of having a bowel obstruction, plain films may be diagnostic in only half of such patients.[8,9] Plain films are more sensitive in the detection of high-grade obstruction but less sensitive to detect low-grade obstruction. A chest x-ray helps to exclude an acute pulmonary process such as pneumonia, as well as detect subdiaphragmatic air, indicative of hollow viscus perforation. Plain abdominal x-rays (upright, lateral decubitus, and supine) can distinguish between mechanical bowel obstruction and ileus in many cases and may establish the location of the obstruction (small vs. large intestine). Except for inguinal hernia or gallstone ileus, the cause of the obstruction is often not discernable on plain radiographs. It is helpful to distinguish between gas-filled loops of small and large intestine. The small intestine contains valvulae conniventes or plicae circulares, which
FIGURE 36.1. Abdominal radiograph of a supine patient with small-bowel obstruction. The stomach is markedly distended. There are several dilated small-bowel loops, which demonstrate prominent valvulae conniventes with bowel wall edema (*black arrow*). Scant gas is seen within the decompressed colon (*white arrow*).

encompass the entire lumen of the bowel. Colon, which contains gas demonstrates colonic haustral markings, which cross only part of the bowel lumen (Fig. 36.1). Normally, the small intestine does not contain visible gas, so the finding of substantial gas in the small intestine is abnormal. The presence of air–fluid levels is also indicative of either mechanical obstruction or ileus. Gas throughout the small intestine and colon is usually associated with ileus, but can also be seen in cases of distal (rectal) obstruction. The presence of distended, air–fluid-filled loops of small intestine with absent colonic gas suggests high-grade small-bowel obstruction. However, in the early stages of small-bowel obstruction or in cases of partial obstruction, some gas may remain within the colon. Patients with closed-loop obstruction or very proximal small-bowel obstruction may have few or no dilated loops of intestine. Massive distension of the colon is seen in cases of pseudo-obstruction or colonic volvulus. Thickened intestinal walls with mucosal thumbprinting occurs when the intestine is edematous or ischemic (Fig. 36.1). Also, pneumatosis of the intestinal wall and portal venous gas result from advanced cases of intestinal ischemia. Free intraperitoneal air indicates perforation of a hollow viscus.

Laboratory Studies

Patients with mechanical bowel obstruction often have fluid and electrolyte disturbances that should be corrected during the resuscitation phase and prior to surgical intervention. Likewise, patients with ileus often have an associated metabolic or infectious etiology that should be sought as part of the diagnosis and treatment of the condition. Serum electrolytes, creatinine, hemoglobin, and coagulation parameters should be checked routinely. Serum lactate may be elevated in cases of bowel ischemia. Patients with considerable physiologic impairment may need assessment of acid–base status with arterial blood gas. For patients with ileus, additional studies that should be obtained include serum magnesium, phosphate, ionized calcium, urinalysis, pancreatic enzymes, and a search for potential infectious sources.

ADJUNCTIVE TESTS

Computed Tomography

Many clinicians rely on computed tomography (CT) to determine the etiology and location of intestinal obstruction,[10–14] and CT has become the radiographic modality of choice for the diagnosis of intestinal obstruction.[9] The diagnosis of small-bowel obstruction on CT involves the identification of dilated loops of intestine proximally with normal or collapsed loops distally. A small-bowel caliber > 2.5 cm is considered dilated. If a transition point is identified, the diagnosis of obstruction is more certain. The transition point often resembles a bird's beak (Figs. 36.2 and 36.3), and this "beak sign" is present in 60% of cases of small-bowel obstruction.[9] The small-bowel feces sign, the presence of small-bowel particulate material in a dilated segment (Fig 36.4), is present in 56% of cases of small-bowel obstruction.[15] CT has a sensitivity of 81%–94% and specificity of 96% for diagnosis of high-grade bowel obstruction.[9] The accuracy of CT scan is reduced in cases of partial intestinal obstruction, although recent advances in CT technology are improving its accuracy in these cases. CT has several advantages over other imaging modalities: it can accurately determine the level, etiology, and degree of the obstruction and can readily indentify closed-loop obstruction and bowel ischemia. CT can detect extrinsic mass lesions or inflammatory processes not visible on plain radiographs.[16] CT is the most sensitive modality to detect intraperitoneal free air and pneumatosis intestinalis (Fig. 36.4C). CT is also the preferred modality to distinguish mechanical colonic obstruction from pseudo-obstruction.[17] Administration of oral contrast may not be tolerated by acutely ill and obstructed patients and is usually not essential for the CT identification of obstruction; luminal fluid and air can easily be distinguished within the bowel lumen. However, enteral contrast may be useful in discriminating partial from complete obstruction and the level of the obstruction. The use of intravenous contrast during CT is recommended so the bowel wall can be visualized in contrast to its luminal contents.[18–20] The most important information that CT can provide is whether strangulation (bowel ischemia) is present. The sensitivity of contrast-enhanced CT for diagnosis of intestinal ischemia is as high as 90%.[9] Signs of intestinal ischemia on contrast-enhanced CT include thickened bowel
FIGURE 36.3. Coronal CT scan demonstrating small-bowel obstruction with dilated proximal small intestine (*gray arrow*) and decompressed distal small intestine (*white arrow*) beyond the level of the obstruction.

wall, ascites, the target sign (trilaminar appearance of bowel wall from enhanced mucosa and muscularis with edematous submucosa in between), lack of contrast enhancement of bowel wall, pneumatosis intestinalis, gas in mesenteric or portal veins, and the "whirl sign" (twisting of mesenteric vessels in volvulus).

Other Radiographic Modalities

Given the limitations of plain abdominal radiographs described above, other adjunctive radiographic modalities have been advocated. Clearly, CT is the modality of choice given its availability and accuracy. However, in some instances, ultrasonography and magnetic resonance imaging (MRI) have been proposed. Both modalities are highly sensitive and specific for intestinal obstruction when performed and interpreted by experienced clinicians. Two prospective trials found that ultrasonography was as sensitive as and more specific than plain radiographs in the diagnosis of intestinal obstruction.[21,22] The accuracy of ultrasonography is operator dependent, and most surgeons are not yet comfortable in the interpretation of sonographic images for the diagnosis of intestinal obstruction. These reasons, plus the accuracy and widespread availability of CT, limit the clinical utility of ultrasonography in this setting. However, for patients who are hemodynamically unstable and not suitable candidates for transport to CT, bedside ultrasonography may be a useful modality.[21]

There is evidence suggesting that MRI is more sensitive and specific than contrast-enhanced CT in determining the etiology and location of bowel obstruction.[23] However, continuing evolution and technological advances in CT imaging, such as

FIGURE 36.2. CT demonstrating high-grade small-bowel obstruction with a transition point or "bird's beak" (*white arrow*) between distended and decompressed loops of small intestine. The decompressed descending colon is also seen (*black arrow*).
FIGURE 36.4. A: CT scan showing small-bowel obstruction with transition point at a focal area of wall thickening (*white ellipse*). B: proximal to the obstruction, there is marked dilation of the small bowel with small-bowel feces sign (*gray arrow*). C: pneumatosis intestinalis of a segment of ischemic, obstructed small intestine (*white arrow*).

multiphasic scanning, faster scanners, and 3D reconstruction, have increased the accuracy of this modality, further reducing the utility of ultrasonography and MRI.

Gastrointestinal contrast studies may be useful diagnostic modalities in some instances, but best used in the subacute or chronic setting. Oral contrast studies such as small-bowel follow-through can offer information about the location and degree of the obstruction and the bowel transit time. Limitations of the small-bowel follow-through include logistics, the length of time required to complete the study, the dilution of contrast as it travels distally, and the risk of contrast aspiration. Enteroclysis allows nondistensible segments of intestine to be more readily identified. Enteroclysis is performed by placing a catheter in the small intestine and infusion of contrast material. Enteroclysis is accurate at detection of low-grade and intermittent obstruction and can serve as an adjunct to CT in these cases; it has no advantage over CT in the diagnosis of high-grade obstruction.[9] The administration of contrast enemas may be useful in cases of colonic distension to evaluate for mechanical obstruction, for example, due to mass lesions or stricture.

Sigmoidoscopy

For patients with distal colon or rectal obstruction, sigmoid volvulus, or colonic pseudo-obstruction with massive colonic distension, flexible or rigid sigmoidoscopy may be both diagnostic and therapeutic. When the radiographs demonstrate distended colon with gas extending to the sigmoid or rectum, sigmoidoscopy will readily exclude a distal colon or rectal mass as the etiology of the obstruction. Care must be exercised to avoid instillation of a large amount of air during the sigmoidoscopy; this will increase the chances of iatrogenic perforation of the colon.

DETERMINATION OF THE NEED FOR SURGERY

For patients with suspected bowel obstruction, the decision to operate and the timing of surgery can be determined based on the history, physical exam, laboratory data, plain radiographs, and CT. It is important to distinguish mechanical obstruction from ileus. Patients with nonmechanical obstruction usually do not require immediate surgery. Early identification of patients with obstruction and bowel ischemia is critical. Also, in patients with mechanical obstruction, determination of whether the obstruction is complete (which requires immediate operation) vs. partial (which does not) is important. Similarly, determination of the level and etiology of the obstruction has important therapeutic implications. Patients with complete or partial bowel obstruction generally should be admitted to a surgical service as admission to nonsurgical service is associated with increased patient morbidity and mortality.[24,25] In one series of 166 cases of small-bowel obstruction, 20 patients underwent immediate surgery due to concern for bowel ischemia and 45% of these

proved to have ischemic bowel at laparotomy. Among those selected for conservative management, about two-thirds resolved without surgery, but 6% had strangulated bowel and 2% died.[26]

MECHANICAL OBSTRUCTION

There are many potential causes of bowel obstruction (see Tables 36.1 and 36.2). Patients with mechanical, complete bowel obstruction should undergo immediate surgery after expeditious correction of hypovolemia and fluid and electrolyte disorders. Nonoperative management of complete intestinal obstruction is associated with increased morbidity and mortality due to delayed recognition and treatment of strangulated bowel.[7] Immediate operation is also indicated for patients with bowel obstruction in the presence of peritonitis or signs of systemic toxicity, incarcerated or strangulated herniae, pneumatosis intestinalis, cecal volvulus, or sigmoid volvulus with systemic toxicity. CT will help identify the presence of these conditions in equivocal cases. Exceptions to this rule for immediate operation for these conditions include patients with terminal illness whose goals of care are palliation of symptoms, or those who have cardiopulmonary instability, which requires resuscitation prior to surgery.

ADHESIVE SMALL-BOWEL OBSTRUCTION

Postoperative adhesions are the most common cause of intestinal obstruction and account for 60% of cases of small-bowel obstruction.[29] Adhesive intestinal obstruction usually occurs in the small intestine. In the setting of colonic obstruction, an alternative etiology should be sought as adhesions rarely cause colonic obstruction. Intestinal obstruction resulting from adhesions may occur as early as days to as late as many years after surgery.[30] Adhesive small-bowel obstruction most frequently occurs after prior appendectomy, colorectal surgery, gynecologic procedures, or upper gastrointestinal surgery. One-fourth of patients with mechanical small-bowel obstruction had multiple prior laparotomies.[29] Laparoscopic surgery is associated with a lower incidence of postoperative bowel obstruction compared to comparable open surgery.[31] Initial treatment of adhesive small-bowel obstruction includes bowel rest, nasogastric decompression, intravenous fluids, correction of metabolic and electrolyte abnormalities, and analgesia.

TABLE 36.1

From Biondo S, Pares D, Frago R, et al. Large-bowel obstruction: predictive factors for postoperative mortality. *Dis Colon Rectum*. 2004;47:1889–1897.

In this setting, nonoperative management is associated with resolution of symptoms in approximately 90% of patients.[32–34] However, as many as half of these patients will experience recurrent obstruction.[34–36]

Some studies suggest that the probability of resolution of the bowel obstruction with conservative management can be predicted based on the nature of the prior abdominal surgery.[37–39] Procedures associated with a higher failure rate for conservative management of adhesive small-bowel obstruction include those which were performed through a midline laparotomy, those involving the aorta, colon, rectum, appendix or pelvic adnexa, and those done to alleviate previous obstruction due to carcinomatosis. In these cases, a shorter duration of observation during conservative management should be considered.

For patients with partial bowel obstruction due to adhesions, there is no clear consensus on how long such patients should be treated conservatively. However, beyond 48 hours of observation, the risks of complications increase substantially and the probability of nonoperative resolution decreases considerably.[40] In general, patients who are likely to resolve with conservative management begin to show clinical improvement in the first 12 hours. Consideration for surgical intervention should be made for patients who fail to show signs of improvement or who deteriorate in this time frame. Patients selected for conservative management must be examined serially and frequently, preferably by the same clinician. The degree of abdominal distension, amount and character of the nasogastric output (e.g., feculent output correlates with complete obstruction, necessitating surgery), the passage of flatus or bowel movement, and the development of new or worsening abdominal tenderness should be carefully assessed at frequent intervals. Follow-up plain radiographs may be useful to demonstrate persistence or resolution of the radiographic abnormality.

It should be possible to determine with a high degree of accuracy which patients will require surgery to address adhesive small-bowel obstruction within 24–48 hours of admission. Using CT, patients with complete bowel obstruction or closed-loop obstruction, that is, those who require urgent operation, can be readily identified and treated appropriately.[11–13] For those with partial obstruction, close clinical observation will identify those who are failing to progress and warrant surgical intervention. In addition, the success or failure of nonoperative management can be predicted by the time it takes for orally administered contrast to reach the right colon. Arrival

of contrast within 8–24 hours predicts success of conservative management with >95% sensitivity and specificity.[41–43]

SURGICAL ADHESIOLYSIS

Laparotomy with surgical adhesiolysis is the traditional surgical modality to treat patients with adhesive bowel obstruction who require operative intervention. The principles of this technique involve midline laparotomy with careful entry into the peritoneal cavity to avoid iatrogenic bowel injury, identification and sharp lysis of the adhesions that contribute to the obstruction, careful inspection of the intestine to identify injury or ischemia, repair or resection of perforated intestine, and resection of ischemic or gangrenous segments. When operative adhesiolysis is required for small-bowel obstruction, the mortality ranges from <5% for uncomplicated obstruction, to as high as 30% in cases where bowel resection is required for intestinal strangulation or gangrene.[30]

Laparoscopic lysis of adhesions relieves obstruction in the majority of patients and compares favorably to open surgery.[44–49] To reduce the chance of bowel injury during trocar placement, the first port should be placed using open technique under direct visualization and in an area away from prior surgical incisions.[50,51] In retrospective, case-control matched series, about half of patients treated with laparoscopic adhesiolysis required conversion to open surgery due to inability to complete the procedure laparoscopically or to manage complications.[49] Patients with two or more prior laparotomies had a considerably higher rate of intraoperative complication during laparoscopy. Despite the high conversion rate, the group of patients who underwent laparoscopic adhesiolysis experienced an overall reduction in postoperative complications. Other studies have also shown that patients explored laparosopically who required conversion to open laparotomy did not fair worse than those initially treated with laparotomy.[52]

One potential advantage of laparoscopic surgery for adhesive bowel obstruction over open surgery is that it results in a reduced risk of causing additional intra-abdominal adhesions, which may lead to subsequent adhesive bowl obstruction.[53,54] However, patients who undergo laparoscopic surgery for adhesive bowel obstruction may be at increased risk for early unplanned reoperation due to complications or incomplete relief of obstruction.[44] Another problem is that iatrogenic bowel perforation during laparoscopic adhesiolysis may not be detected during the initial surgery.[50] Thus, a low threshold to convert to open surgery is advocated when laparoscopic adhesiolysis fails to identify and treat an obvious point of obstruction or when the adhesiolysis is difficult or unsafe. Preemptive conversion to open laparotomy when there is poor visualization or dense adhesions is preferable to reactive conversion after an iatrogenic injury has occurred.[55] In addition, careful patient selection is also important; the laparoscopic approach may best be suited for patients who have undergone one or two prior abdominal operations, especially if they have undergone appendectomy only, and in whom the etiology of the obstruction is felt to be adhesive bands.[56] Patient selection for laparoscopic adhesiolysis is important. Indications for laparoscopic exploration include proximal obstruction, partial obstruction, anticipated single band, localized radiographic distension, and mild abdominal distension. Contraindications to laparoscopy for bowel obstruction include coagulopathy, inability to tolerate general anesthesia, severe abdominal distension, massively dilated loops of intestine, peritonitis, sepsis, hemodynamic instability, and dense adhesions with fused loops of intestine or multiple prior laparotomies. The surgeon's experience and advanced laparoscopic skills may also be an important factor in determining the safety and efficacy of laparoscopic adhesiolysis for bowel obstruction.[57,58]

INTESTINAL OBSTRUCTION IN THE EARLY POSTOPERATIVE PERIOD

A common surgical dilemma is the patient who develops abdominal distension, obstipation, nausea, vomiting, and pain early after abdominal surgery. It may be difficult to differentiate postoperative ileus from mechanical small-bowel obstruction in this patient population. As many as 10% of postoperative patients develop mechanical small-bowel obstruction,[59] and in 90% of these cases, the etiology is adhesive disease.[60,61] In most cases, plain abdominal radiographs will help differentiate between ileus and mechanical bowel obstruction in this patient population.[60]

Furthermore, it is imperative to exclude technical complication as the etiology of the patient's postoperative ileus or obstruction. Complications such as anastomotic leak, abscess, internal hernia, perforation, anastomotic stricture, or stomal obstruction must be identified and treated appropriately. These conditions are unlikely to resolve with nasogastric decompression and bowel rest. When plain abdominal radiographs are unrevealing, CT is the appropriate study in this situation.

In most patients without peritoneal irritation or systemic toxicity, intestinal obstruction in the early postoperative period can be managed safely with bowel rest, intravenous fluids, and nasogastric decompression.[59,60] Because the risk of intestinal strangulation in patients with early postoperative adhesive obstruction is lower (<1%)[60,62] than those who present with obstruction in a delayed fashion, these patients are usually managed conservatively for longer periods of time. Close to 90% of patients resolve spontaneously after 2 weeks of conservative management. Approximately 70% of those who will resolve with nonoperative management do so in the first week, with another 25% responding by the second week. Beyond 2 weeks, patients with persistent obstruction are unlikely to resolve spontaneously and should undergo operation to manage the obstruction.[60,61] Parenteral nutritional support should be initiated in patients who will be treated conservatively and with bowel rest and no enteral nutrition for >7–10 days.[63] In the past, long intestinal tubes were advocated to manage postoperative bowel obstruction.[33] However, a randomized trial of long intestinal tubes versus standard nasogastric tubes found no difference in time to resolution of obstruction, the need for operation, or the duration of postoperative ileus.[64]

BOWEL OBSTRUCTION IN PATIENTS WITHOUT PRIOR ABDOMINAL SURGERY

While adhesive disease is the etiology of intestinal obstruction in most patients with prior abdominal surgery, patients who have never undergone surgery and who develop intestinal obstruction should be carefully evaluated for an underlying etiology that requires surgical intervention. Such patients who have partial obstruction can be appropriately admitted for conservative management during this evaluation. These patients often have an external or internal hernia, tumor, malrotation, volvulus, or intussusception. Malignant tumors account for 20% of small-bowel obstructions, and is the most common cause of small-bowel obstruction after postoperative adhesions.[65] The most commonly utilized first-line test is CT, which will identify the etiology in the majority of cases. Once the obstruction resolves and if CT is unrevealing, a small-bowel follow-through may provide a diagnosis. In some cases, elective exploratory laparoscopy or laparotomy may be necessary to diagnose and treat the underlying etiology.

STRANGULATION AND CLOSED-LOOP OBSTRUCTION

The type, location, and etiology of intestinal obstruction will impact the likelihood of resolution without surgery as well as the morbidity and mortality. Strangulation occurs when blood supply to a segment of intestine is compromised, usually due to a loop of intestine trapped in an abdominal wall or internal hernia, a volvulus or intussusception. Venous flow is usually affected first, leading to bowel wall edema, which first affects the mucosa and submucosal layers. Decreased arterial flow and pressure to the affected segment follows. These factors contribute to reduced blood flow to the segment of intestine and increased permeability and edema of the involved bowel. Substantial fluid sequestration and systemic hypovolemia can result. As the local process progresses, inadequate blood flow leads to release of inflammatory mediators, the potential for bacterial translocation, intestinal gangrene, and perforation with peritonitis.

Strangulation occurs in approximately 10% of patients with mechanical small intestinal obstruction. While the mortality associated with uncomplicated intestinal obstruction is <5%, when strangulation develops, mortality increases to 10%–37%.[7,40,66] The goal of surgical intervention is to relieve the obstruction prior to the development of intestinal strangulation to reduce the associated morbidity and mortality. Patients at highest risk for strangulation are those who present with an incarcerated hernia, volvulus, closed-loop or complete intestinal obstruction. Early identification of these processes by careful physical exam and radiographs (plain abdominal radiographs or CT) is paramount to timely surgical management and are indications for immediate surgery. Unfortunately, physical exam alone has a poor sensitivity to detect early signs of obstruction with strangulation,[7] prompting many clinicians to recommend routine use of CT for patients with mechanical bowel obstruction admitted for a trial of conservative management. Contrast-enhanced CT can demonstrate compromised blood supply and intestinal wall edema in early cases of intestinal strangulation.[14,67,68] Radiographic evidence of pneumatosis intestinalis and free intraperitoneal air are late findings of gangrene and perforation, and indications for immediate operation; but the goal should be to intervene prior to the development of these findings.

Closed-loop obstruction is a specific type of obstruction in which two points along the course of the bowel are obstructed at a single location, thus forming a closed loop. Usually this is due to adhesions, volvulus, or internal herniation. Closed-loop obstruction is more likely to cause intestinal ischemia than obstruction due to simple adhesive disease, but may also be more difficult to diagnose on plain radiographs. CT often demonstrates a "whirl sign."[69]

INTESTINAL OBSTRUCTION DUE TO HERNIA

Hernia is the etiology of 10% of cases of small-bowel obstruction, and is more likely to be associated with strangulation than obstruction due to adhesions.[7,70] For patients without a history of prior abdominal surgery, hernia is the second leading cause of intestinal obstruction after neoplasm. Any hernia that is incarcerated, tender to palpation, is associated with skin changes such as erythema or induration, is an indication for immediate surgery. Ultrasonography and CT are appropriate diagnostic modalities in cases where the hernia is difficult to detect on physical examination.

Paraduodenal hernia, which is a congenital abnormality resulting from intestinal malrotation, has been recognized as an important cause of closed-loop obstruction in adults.[71,72] It may account for as many as half of internal herniae. Patients present with a spectrum of symptoms ranging from mild abdominal discomfort and nausea to catastrophic closed-loop obstruction with intestinal gangrene and perforation. The diagnosis is readily made by CT or upper gastrointestinal contrast study, and operation should be performed expeditiously to prevent strangulation and peritonitis.[71]

VOLVULUS

Intestinal volvulus is a closed-loop obstruction caused by twisting of the intestine on its mesentery, leading to obstruction and impaired blood supply to the segment of intestine. Patients present with acute colicky abdominal pain, nausea, vomiting, and distension. Small-bowel volvulus may not be readily apparent on abdominal radiographs because the closed-loop fills with fluid and air–fluid levels may be absent, but the fluid-filled loop is usually apparent on CT. The finding of small-bowel volvulus mandates surgical intervention.

Colonic volvulus can occur anywhere in the large intestine, but is most common in the sigmoid (Fig. 36.5) followed by the cecum. Plain abdominal radiographs are often diagnostic, usually making CT unnecessary. Patients with colonic volvulus who have signs of systemic toxicity, signs of peritoneal inflammation on physical examination, or bloody rectal output require immediate operation. For patients with sigmoid volvulus, in the absence of these indications for immediate surgery, endoscopic decompression is the most appropriate first-line treatment and is effective in approximately 95% of patients.[73] During sigmoidoscopy, careful navigation of the sigmoidoscope with minimal air insufflation should be performed to reduce the risk of perforation. The finding of mucosal gangrene during sigmoidoscopy is an indication to abort the procedure and proceed immediately for surgery. Plain abdominal radiographs should be obtained after the endoscopic decompression to exclude the possibility of perforation. After successful endoscopic decompression, the patient should be evaluated and prepared for definitive surgical therapy during the same hospital admission since the likelihood of recurrent volvulus is high; sigmoidectomy with primary anastomosis is the preferred operation in suitable candidates. Patients with colonic volvulus proximal to the sigmoid colon usually require surgical intervention; endoscopic decompression is usually unsuccessful and associated with a considerably higher rate of complications.

INFLAMMATORY CONDITIONS

Partial bowel obstruction secondary to inflammatory conditions such as inflammatory bowel disease, radiation enteritis, or diverticulitis usually resolve with conservative management: nasogastric decompression, bowel rest, intravenous fluids. Crohn's disease accounts for approximately 5% of all cases of small-bowel obstruction.[74] For patients with intestinal obstruction due to an exacerbation of Crohn's disease, the addition of antiinflammatory agents may reduce the duration of obstruction and the need for surgery.[75] Surgery may become necessary in some of cases of Crohn's disease if the patient has persistent obstruction, fails to improve with medical management, or develops peritonitis. Stricturoplasty and other nonresectional therapies are preferable to removal of segments of bowel in these patients due to the risk of short gut syndrome. Similarly, surgery is a last resort effort in patients with obstruction due to radiation enteritis. Radiation strictures with obstruction that does not resolve after a prudent course of conservative management may require operation. Resection to grossly normal sections of bowel may become necessary.
FIGURE 36.5. A: Abdominal radiograph of a patient with sigmoid volvulus, demonstrating massively distended sigmoid colon, which extends from the left lower quadrant to the right upper quadrant. B: CT scan of the same patient demonstrates a "beak sign" (*black arrow*) where the sigmoid colon twists upon itself, resulting in complete obstruction.

Patients with acute diverticulitis may also present with partial colonic obstruction in 20% of cases. CT should be obtained in most cases of diverticulitis which require hospital admission to detect complications such as an associated abscess, which may need percutaneous drainage or free perforation requiring laparotomy.[76] Partial colonic obstruction usually resolves with conservative management and intravenous antibiotics directed at the underlying diverticulitis. Surgery is indicated if the patient develops peritonitis, if the obstruction does not resolve after an appropriate period of observation, or if chronic diverticular stricture develops, causing recurrent obstruction. Full colonic evaluation to exclude colorectal neoplasm is indicated in cases where elective resection is contemplated.

PARTIAL COLONIC OBSTRUCTION

Common etiologies of partial colonic obstruction include cancer, diverticulitis, and strictures; adhesive disease is a rare cause of colonic obstruction. In the evaluation of patients with colonic obstruction, digital rectal examination and sigmoidoscopy are done to assess any rectal mass, fecal impaction, sigmoid volvulus, or stricture. If these tests are unrevealing, contrast enema should be performed to evaluate the more proximal colon. Failure to find an obstructing lesion in the patient with distension of the entire colon is usually associated with colonic pseudo-obstruction.

Patients with partial colonic obstruction should initially be treated conservatively, since the morbidity, mortality, and need for colostomy are all increased in the setting of emergency colonic resection for obstruction. Patients with distal sigmoid and rectal tumors causing partial obstruction may benefit from endoluminal colonic stenting. Approximately 90% of such patients will improve clinically within 96 hours of colonic stenting,[77] allowing patient preparation for one-staged open[77,78] or laparoscopic[79] colonic resection.

MALIGNANT BOWEL OBSTRUCTION

Bowel obstruction due to malignant disease may complicate the course of patients with abdominal and pelvic tumors, and occurs in 5%–43% of patients with advanced primary or metastatic intra-abdominal malignancy.[80] Some of these patients will have advanced, unresectable disease, and the goal of care is palliation of symptoms. The etiology of malignant bowel obstruction may be multifactorial, and can involve extrinsic compression of the bowel by tumor, infiltration of the mesentery, luminal obstruction by tumor, as well as impaired intestinal motility due to opioids, electrolyte disorders, certain medications, and adrenal insufficiency.[81] The rate of benign intestinal obstruction in patients with known malignancy ranges between 3% and 48%,[80] so a benign etiology must be considered in these patients. Regardless of the etiology of the obstruction, it may be desirable to avoid surgery in this population of patients. Bowel rest and early pharmacologic therapy with analgesics, antiemetics, and antisecretory drugs are the mainstays of treatment and have been shown to be effective at controlling gastrointestinal symptoms.[82] Octreotide has been

shown to reduce the severity of abdominal pain and vomiting, and the duration of nasogastric decompression needed in patients with inoperable malignant bowel obstruction in randomized controlled trials.[83–85] Intraluminal stents may be deployed endoscopically in patients with malignant bowel obstruction and are associated with improved quality of life and avoidance of laparotomy and colostomy in patients with inoperable malignant colorectal obstruction.[86–89] Palliative percutaneous endoscopic gastrostomy may be effective for long-term gastric decompression in terminally ill patients with gastric or proximal small-bowel obstruction.[90]

INTESTINAL DYSMOTILITY DISORDERS

Ileus

Ileus is a hypomotility state defined as the disruption of normal gastrointestinal propulsive activity in the absence of mechanical bowel obstruction. Implicit in this definition is that mechanical obstruction has been excluded. Ileus is fairly common immediately after abdominal surgery; however, it can also occur in association with a number of metabolic, inflammatory, or infectious processes in the abdomen, chest, or systemically. A common clinical mistake is failure to identify and treat the underlying etiology. The pathophysiology of ileus is complex and poorly understood, but involves the following factors: spinal–intestinal neural reflexes, local and systemic inflammatory mediators, sympathetic hyperactivity, and other exacerbating factors such as endogenous and exogenous opioids, intraperitoneal surgery and bowel manipulation, electrolyte and metabolic abnormalities.[91,92]

Postoperative ileus usually occurs after major abdominal surgery and manifests as atony of the stomach, small and large intestines. Under normal circumstances, intestinal motility returns at about 24 hours in the small intestine, followed subsequently by the stomach and colon. Perhaps contrary to traditional teaching, the duration of postoperative ileus can be shortened by the early removal of nasogastric tubes,[93,94] early initiation of enteral nutrition,[95–97] use of multi-modality pain prevention techniques, including: minimization of opioids, use of nonsteroidal anti-inflammatory agents[98] and regional blocks,[99] and the chewing of gum.[100,101] A comprehensive protocol of controlled rehabilitation with early ambulation and diet shortens the duration of postoperative ileus and reduces hospital length of stay after laparotomy with bowel resection.[102] The theory in support of early feeding is that it stimulates gastrointestinal hormones, elicits gut propulsive activity, and thus coordinated gut motility. Concern over an increased incidence of anastomotic leak with early feeding is unfounded.[103] In addition, studies have shown that laparoscopic surgery is associated with a shortened duration of postoperative ileus compared to open surgery.[104–106]

Treatment of persistent postoperative ileus must include a search for potentially contributing etiologies such as electrolyte disturbances (hypokalemia, hyponatremia, hypocalcemia, hypomagnesemia), offending medications (opioids, anticholinergics, calcium channel blockers, certain antiemetics), and other medical conditions such as infection (urinary tract infection, pneumonia, bacteremia, intra-abdominal abscess, peritonitis), uremia, pancreatitis, hypothyroidism, and low cardiac output state (myocardial infarction). Failure to identify and treat these underlying etiologies will result in increased morbidity and length of stay. Patients with established postoperative ileus may require nasogastric decompression, intravenous fluids, and bowel rest until the underlying etiology has been addressed and peristalsis returns. Diagnostic evaluation usually involves CT, which can help distinguish between ileus and mechanical obstruction in most patients, and identify the underlying etiology in some cases. A randomized, controlled trial demonstrated the efficacy of a peripherally acting μ-opioid receptor antagonist, alvimopan, in reducing the duration of postoperative ileus after laparotomy with bowel resection without compromising pain control in these patients.[107]

Pseudo-obstruction

Intestinal pseudo-obstruction is a motility disorder similar to ileus, which may develop in the small or large intestine, but is most common in the colon, where it carries the eponym of Ogilvie's syndrome. Acute colonic pseudo-obstruction develops classically in elderly hospitalized or institutionalized patients, and has many of the same risk factors as ileus. Patients usually present with abdominal distension, discomfort, nausea, vomiting, and obstipation.[108] It is important to exclude mechanical bowel obstruction, as the etiology and treatment of these entities is very different. Radiographs usually demonstrate dilated colon with no clear transition point. Usually, the cecum is the most distended portion of the colon, and is most at risk for perforation. Despite frequent assertions to the contrary, there is no clear linear relationship between cecal diameter and perforation. Some patients have recovered after reaching a cecal diameter of 25 cm,[109] while others have perforated at <10 cm.[110] The risk of perforation may also be associated with the duration of colonic distension.[111] The risk of spontaneous perforation is between 3% and 15% and is associated with a mortality of 50%.[110]

Treatment of acute colonic pseudo-obstruction is directed at the underlying etiology. Patients with signs of peritonitis or systemic toxicity require operation, and may need total abdominal colectomy. Otherwise, a trial of bowel rest, decompression, management of fluid, electrolyte and metabolic disturbances should be initiated. These measures alone will result in resolution of symptoms in 33%–100% of patients, with a mean response time of 3 days.[109] Colon decompression with rectal tube or sigmoidoscopy may be therapeutic and help identify underlying colonic ischemia. Colonoscopic decompression is effective in 70% of patients, with a 40% recurrence rate, 3% complication rate, and 1% mortality rate.[112] More recently, pharmacologic management has replaced endoscopic decompression in appropriate candidates. The potent parasympathomimetic agent, neostigmine, has been shown to be effective and safe in a randomized controlled trial of patients with acute colonic pseudo-obstruction. Neostigmine administration leads to prompt colonic evacuation and resolution of symptoms in most patients within minutes, with a low rate of recurrence (11%).[113,114] Contraindications to neostigmine include mechanical bowel obstruction, colonic ischemia or perforation, bradycardia, reactive airway disease, recent coronary occlusion, vagotonia, hyperthyroidism, and cardiac arrhythmias. Neostigmine should be used with caution in elderly patients with coronary artery disease, and should be administered in a cardiac monitored setting. Colonoscopic decompression or operation should be reserved for patients with a contraindication to, or who fail to respond to, neostigmine.

EMERGENCY SURGERY

CHAPTER 37 ■ APPENDICITIS

D. PATRICK BRYANT AND HEIDI FRANKEL

In the time of Leonardo da Vinci, the appendix was ascribed a function as an organ capable of expanding and contracting, to deal with excessive wind and prevent perforation of the cecum. Over the ensuing years, others have recognized that the appendix served an immune function as well, namely, in the lymphocyte response. This is particularly true in ruminators.[1] Bollinger et al.[2] theorize that the appendix is responsible for maintaining homogeneity in the flora of the colon.

EMBRYOLOGY

The appendix is an organ derived from the midgut. It begins as a outpouching of the embryonic cecum and then lines up at the confluence of the taeniae. The vermiform appendix becomes visible in the eighth week of gestation (when fetal length is 10–12 cm), and the first accumulations of lymphatic tissue develop during the 14th and 15th weeks directly below the epithelium. Some lymphocytes penetrate into the epithelial layer of the vermiform appendix that distinctly contains fewer goblet cells than the other colic mucosa. The vermiform appendix, tonsils, and Peyer's patches possess no draining lymphatic vessels.

ANATOMY

The appendix varies in size, but on average it is generally 6–9 cm in length and may be in a retrocecal, pelvic, retroileal, or right pericolic position, and at times within the wall of the cecum. The blood supply is from the appendiceal artery; the terminal branch of the ileocolic artery. It is an end artery and the ischemia that is part of the process in acute appendicitis is the result of no collateralized flow. Occasionally, the artery itself becomes thrombosed as part of the inflammatory process, resulting in a gangrenous appendix with perforation.

HISTORY

Perityphlitis was a diagnosis without a known causative factor until Dr. Reginald Fitz published his work in 1886 demonstrating that perityphlitis and perforated appendicitis were one and the same disease. In 1889, Dr. Charles McBurney presented his report on the early surgical intervention of appendicitis to the New York Surgical Society. In 1894, he presented his paper on the muscle splitting incision that bears his name. The procedure for appendectomy was largely unchanged for almost a century.

The first laparoscopic appendectomy was performed by Dr. Kurt Semm in May of 1980.[3] Currently, well over half of the approximately 250,000 appendectomies performed annually in the United States are laparoscopically done. In addition to laparoscopy, the major advances in the care of appendicitis included the introduction of broad spectrum antibiotics, the improvement in preoperative diagnostic testing, and the use of interventional radiology to perform drainage procedures for periappendiceal abscesses.

EPIDEMIOLOGY

The incidence of appendicitis peaks in the mid to late teens with a slight male predominance (~1.3: 1). The incidence of 84 per 100,000 patients has remained stable over time.[4] The overall mortality of appendicitis is 0.5%, 1.7% in cases with perforation, and over 20% in patients over the age of 70.[5]

PATHOPHYSIOLOGY

Acute appendicitis is the most common surgical emergency treated in the acute care setting. Its classic presentation remains relatively unchanged over time; present in about 80% of those who present with lower abdominal pain. The standard presentation in a relatively young person is a result of luminal obstruction of the appendix. This obstruction may be related to hyperplasia of the germinal follicles or from a fecalith impacted in the appendiceal orifice. The capacity of the appendix is about 0.5 mL. With the orifice obstructed, the pressure in the lumen quickly rises above 60 mm Hg and ischemia results. The ensuing distension stimulates the visceral afferent nerves, leading to the nausea and emesis, as well as the periumbilical pain, which is emblematic of early disease. As the inflammatory process continues, the pain localizes to McBurney's point when the inflamed appendix comes in contact with the peritoneum and the somatic afferent nerves are stimulated. As the pressure increases, vascular compromise develops and along with it, bacterial overgrowth, after which, perforation can be expected.

Perforation is clearly more of a problem in the pediatric population. Nearly one-half of young pediatric patients with acute appendicitis present to care after perforation.[5,6] Perforation is associated with vomiting, prolonged illness, and higher body temperatures. Perforation is also an important factor in morbidity and mortality, including prolongation of the hospital stay, development of a secondary abscess (pelvic, psoas, hepatic, tubo-ovarian), urinary retention, hematuria, and subacute and delayed bowel obstruction. Alternatively, patients with acute appendicitis who perforate may develop a "contained" abscess.

The entity of chronic appendicitis describes a disease process with symptoms over 7 or more days. The pathology tends to show more lymphocytic or eosinophilic infiltration. These patients have a greater diversity of abdominal complaints as well; pelvic, back, and bilateral lower abdominal pain, which makes diagnosis more difficult.

DIAGNOSIS

The "classic" history for appendicitis involves the patient presenting with periumbilical pain, which subsequently localizes to the right lower quadrant. At this point, the pain character changes from a dull ache or vague discomfort to a sharp "finger point" pain. This change is due to the change in the neurologic pathway involved. Periumbilical pain is due to

the distenson of the appendix sending nociceptive signals via the celiac pathway through visceral afferents. Localized right lower quadrant pain develops from the irritation of the parietal peritoneum that corresponds to the dermatomal distribution of the somatic afferent nerve roots at McBurney's point. Patients generally have a low-grade fever; it is rare for them to have a very high fever. They will invariably have malaise and lethargy. After the pain starts, patients often have some degree of nausea and emesis. These symptoms transpire over a 12–24 hours period; however, that can be variable as well.

On physical exam, the patient will often delineate the area of maximal tenderness (McBurney's point). Rovsing's sign is a peritoneal sign elicited by pressing on the left lower quadrant with resultant pain in the right lower quadrant. The psoas sign pertains to irritation of the psoas muscle that is described as pain in the pelvis after the patient extends his/her right thigh while lying on the left side. The obturator sign is demonstrated with the patient in the supine position and rotating a flexed right lower extremity medially.

A child with acute retrocecal or retroileal appendicitis (appendix deep to distal ileal bowel loops) may walk with exaggerated lumbar lordosis and have a slightly flexed right hip as a result of right psoas muscle spasm. Pain with extension of the right hip with the patient in left lateral decubitus position (psoas sign) and with internal rotation of the thigh (obturator sign) may be found with retrocecal appendicitis. If present, this indicates peritonitis.

Symptoms are contingent on the location of the appendix. For those patients with a retrocecal appendix, the pain is often posterior radiating to the groin, simulating the pain of renal colic. The patient may have associated microscopic hematuria. The anterior abdominal findings of tenderness and localized rebound are often less impressive in the patient with a retrocecal appendix. Those patients with an appendix lying in the pelvis can have pelvic pain with urinary symptoms.

LABORATORY DATA

The most diagnostic laboratory value for most patients with acute appendicitis is an elevated white blood count. This finding is most reliable in young persons, but less so in the elderly. If the WBC is normal without left shift, then the diagnosis of acute appendicitis should be reconsidered, although a normal WBC occurs in up to 30% of those with appendicitis. Of course, a markedly elevated WBC should raise the possibility of perforation. Urinalysis should be obtained to exclude nephrolithiasis. The presence of microhematuria may be caused by ureteral or bladder irritation from the adjacent appendicitis. In females of child-bearing age, a serum pregnancy test should be obtained. Additionally, a liver panel with amylase and lipase levels can be useful; pancreatitis should be considered in the differential diagnosis. Another marker that may be helpful is the C-reactive protein level. A normal C-reactive protein level has been associated with the absence of acute appendicitis.[6]

RADIOLOGY

An abdominal x-ray series (flat and upright) is a mainstay of the workup for abdominal pain, but generally will be unrevealing in appendicitis, with the rare exception of the radioopaque fecalith. The other benefit of the plain radiograph is when it suggests bowel obstruction in a patient without a hernia or previous surgery. This can be the sign of a perforated appendicitis in someone with an atypical presentation.

The accuracy **of ultrasound (US)** depends upon the skill level of the sonographer. US findings suggestive of acute appendicitis include a noncompressible appendix of at least 6

mm in diameter. US has become a mainstay of diagnosis in the pediatric population. US does have its limitations, and while the ranges of reported specificity (88%–99%) and accuracy (82%–99%) for US have been acceptable, sensitivity (50%–100%) has varied considerably. Furthermore, US is relatively inexpensive and safe. Its biggest drawback is that negative findings do not exclude appendicitis with a high degree of confidence unless a normal appendix is visualized. However, appendiceal visualization rates in normal individuals without appendicitis vary widely in the published literature, from a high of 98%,[7] to a low of 22%.[8] A meta-analysis of three United States and three European studies with varied prevalence of acute appendicitis indicated that US was inferior to **computed tomography (CT)** in all instances.[9]

CT has become the diagnostic test of choice in many emergency departments and primary care facilities. CT findings of acute appendicitis include a visualized appendix >6 mm in size with periappendiceal stranding or wall thickening. A fecalith can be visualized in one quarter of cases of acute appendicitis. A contrast-filled appendiceal lumen without other abnormalities on CT essentially eliminates the diagnosis of acute appendicitis. If the appendix cannot be visualized on CT, the diagnosis cannot be excluded. Current generation high-resolution scanners produce sensitivity rates of 91%–97% and specificity rates of 91%–93%[10] (Fig. 37.1). Particularly in centers where OR access is at a premium, utilization of CT to eliminate the negative appendectomy appears prudent. Further, a recent review suggests that a noncontrast CT compared to CT with contrast may provide equivalent diagnostic accuracy, expediting the workup.[11] Mere introduction of CT into a care algorithm in and of itself does not lower the published 10%–20% negative appendectomy rate. However, integrating its use into a management strategy that uses senior surgeon consultation early in the workup can dramatically lower this rate as reported by Antevil et al.[12] Clearly, the best use of this technology is in the premenopausal female, where Wagner and colleagues have demonstrated a nearly two-thirds reduction in the negative appendectomy rate.[13] On the other hand, liberal use of CT does not appear to affect the rate of perforation. As a general rule, however, with a reliable history and physical exam, there is little reason for an adjunctive CT scan.[14] The benefit of CT is
FIGURE 37.1. Pelvic CT with 16-slice scanner showing the obstructing fecalith at the base of the appendix.

EMERGENCY SURGERY

in the patient with an unreliable exam or the inconsistent story. In addition, in elderly populations where other surgical conditions are common (ischemic colitis, *Clostridium difficile* colitis, colon cancer), CT may provide essential information. There is certainly concern for exposing the pediatric population to unnecessary radiation. This must be balanced with the morbidity of delaying the diagnosis in this population, one with a high perforation rate—20% in recent study.[15]

SPECIAL SITUATIONS

Approximately 5% of patients with appendicitis present in a delayed fashion, well after rupture. Patients with *perforated appendicitis* and a contained abscess can undergo percutaneous drainage and subsequent interval appendectomy after 8–12 weeks. There are some who question whether this delayed appendectomy is necessary.[16] The risk for recurrence appears higher in the presence of an appendicolith[17] and, certainly, an interval appendectomy can address the issue of an incidental finding, albeit rare. Invariably, the procedure can be performed laparoscopically when done in a staged fashion, even as an outpatient.[18]

Of course, if the perforation is encountered in the process of the initial operation, then the procedure should carry forward; understanding the risk of postoperative abscess formation is increased. It may be prudent to place a drain and abort further surgery if dense adhesions are present and the anatomy is unclear.[19] Although acute or gangrenous appendicitis without perforation may be treated with 24 hours or less of antibiotics, perioperatively, those with perforation and abscess formation warrant longer therapy. Regimens should cover common aerobic and anaerobic enteric flora without concern for enterococcus. Both single agent and combination intravenous therapy are appropriate and may be completed with an oral regimen of either ciprofloxacin/metronidazole or amoxicillin/clavulanic acid in those able to tolerate an oral diet.[20]

In patients with a history of *inflammatory bowel disease*, it is incumbent on the treatment team to exclude an active flair prior to surgical intervention. However, in a new presentation for Crohn's disease, the diagnosis process should proceed as is prudent. If the diagnosis of Crohn's is made at the time of surgery, if the patient is not obstructed, perforated or bleeding, then the operation should end and medical treatment begun. Many favor appendectomy at this operation, if the cecum at the base of the appendix is normal.

In *female patients*, the differential diagnosis includes many other entities (ovarian cyst, torsion, tubo-ovarian abscess, pelvic inflammatory disease, endometriosis, ectopic pregnancy, and Mittelschmerz), that CT would be reasonable, provided that the pelvic exam, ultrasound, and lab results were equivocal. In **pregnancy**, the application of the CT exam becomes more problematic, although still useful, and in this scenario the addition of MRI becomes helpful. The diagnosis of acute appendicitis is always difficult during pregnancy due to blunting of signs and symptoms, and the change in the relative position of the appendix. However, the correct diagnosis and prompt treatment in pregnancy is of great importance. Delay in intervention with perforation or unnecessary intervention increases mortality and morbidity for both the fetus and the mother. The rate of perforation has been reported as 25%–40% during pregnancy and increases the rates of spontaneous abortion, preterm labor, perinatal morbidity, and mortality. Mortality (combined miscarriage and infant mortality) increases from 7% to 20% with appendiceal perforation.[21,22] The laparoscopic approach may be safe in most; however, there is a lack of high-grade evidence to unequivocally support this approach. In the most recent large series, the rate of fetal loss is doubled (from 3.1% to 5.6%) with the laparoscopic technique; however, the rate of preterm delivery (2.1% vs. 8.1%) is substantially lower.[23]

The accurate diagnosis of appendicitis in *children* is often difficult, particularly with reluctance to utilize CT with the attendant risks of ionizing radiation. In children with abdominal pain, either the presence of a fever or of rebound tenderness triples the likelihood of appendicitis.[24] Symptoms and signs are most useful in combination, especially for identification of patients who require no further evaluation or intervention, and have been incorporated into several scoring systems.[25,26] The antibiotic management of both simple and complicated appendicitis in children should be similar to that in adult patients.[27]

In the *elderly*, the need for CT might only be limited by the comorbidities of the patient, especially, renal failure or use of certain medications. The elderly are another group where increased utilization of CT due to unreliability of exam or history may be appropriate (Algorithm. 37.1).

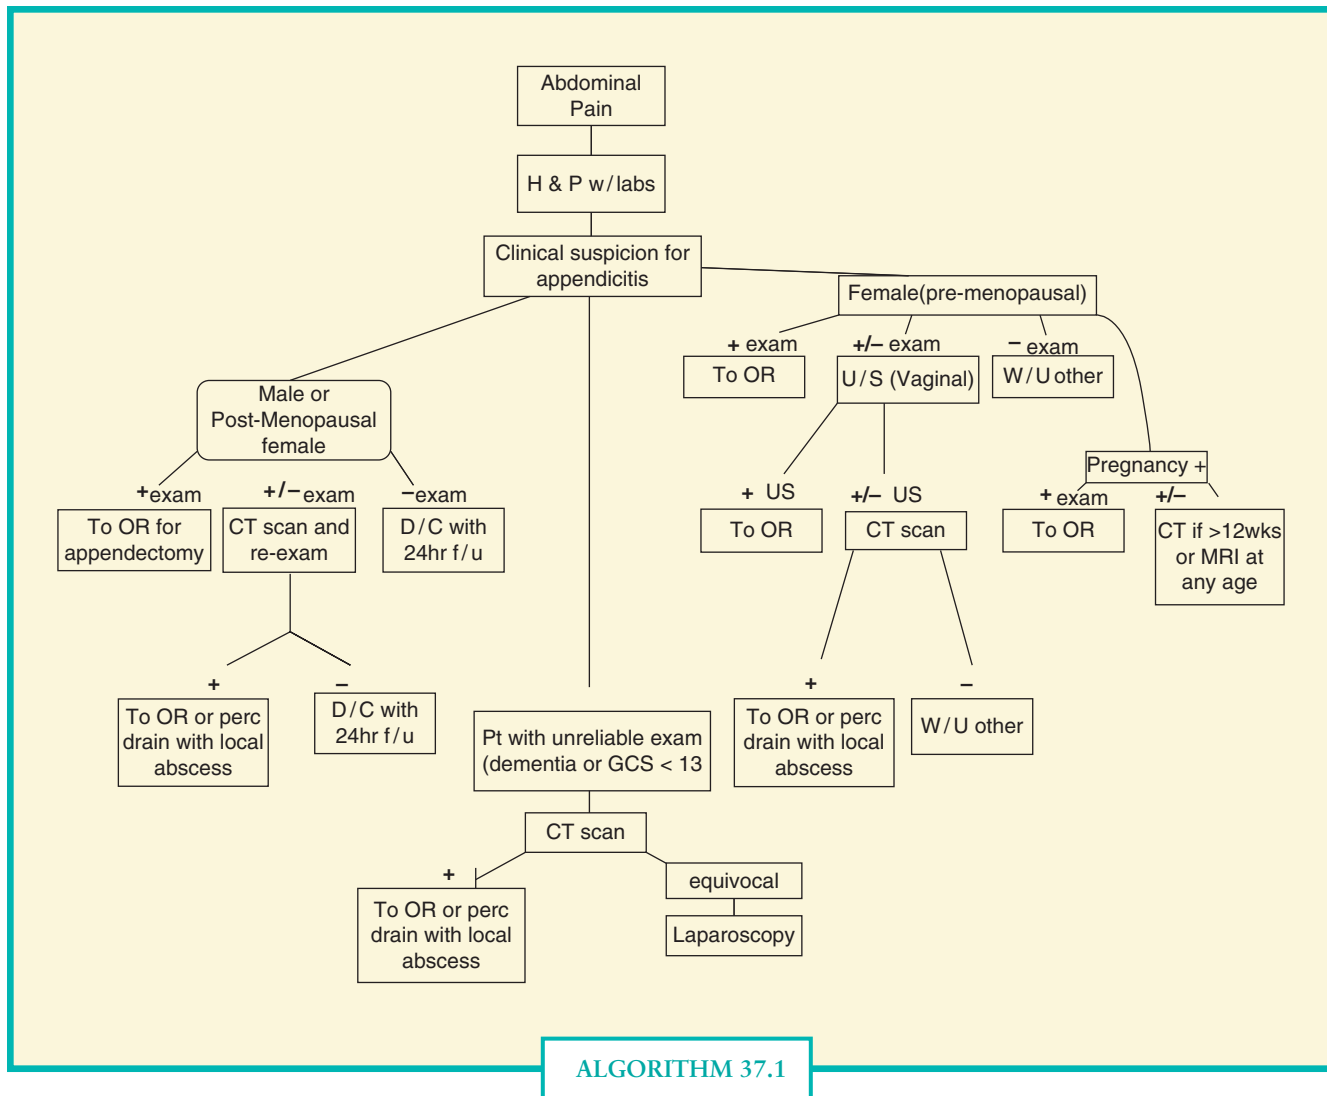
Immunosuppressed patients, particularly children, may develop acute appendicitis. The diagnosis may be difficult and CT may be warranted. The distinction between appendicitis and typhlitis is challenging and CT may not be definitive. The disease usually presents in complicated form and outcome is poor in the face of neutropenia.[28] Acute appendicitis may occur at a higher incidence in HIV-infected patients than in the general population, particularly in those with a high viral load or on a medication regimen that does not include highly active antiretroviral therapy. Presentation is often complicated as well.[29]

The incidence of *carcinoid* in the appendix at the time of appendectomy is 0.3%.[16] Currently, appendectomy for carcinoids <2 cm is adequate. Carcinoids over 2 cm in size require a right hemicolectomy for definitive management, with dissection to the root of the mesentery for lymphatic control. There is some recent literature to support the adequacy of a simple appendectomy for some carcinoids over 2 cm.[30]

For *appendiceal adenocarcinoid* (goblet cell carcinoma), the current management also includes right hemicolectomy for tumors over 1 cm in diameter.[31] Appendiceal adenocarcinoma is also a rare finding, with an incidence of 1 per 10 million cases. Those with stage I or II disease are treated with a simple appendectomy, whereas a right hemicolectomy should be performed for those with advanced disease.[32]

Another pathology that may be seen in the appendiceal specimen is a **mucocele or mucinous cystadenoma**. These are generally benign but should be removed early when found. If the base is uninvolved, then they can be removed via a standard appendectomy. For those that involve the cecum, a right hemicolectomy is indicated. The possibility to remove them laparoscopically is also available as long as the involved segment of the appendix is not grasped, to avoid the risk of perforation and spillage of epithelial tissue. Spillage could lead to the devastating condition of pseudomyxoma peritonei.[33,34] Pseudomyxoma can lead to chronic and acute bowel obstruction that often leads to mortality.

OPERATIVE PROCEDURE

As previously mentioned, the procedure for removal of the appendix had not changed substantially for 100 years, until the advent of laparoscopy. Currently, the debate continues as to which is the better modality. The most recent review shows that although laparoscopic appendectomy is becoming more prevalent, it is more costly and has unique complications. Laparoscopic appendectomy does have a slight advantage in earlier hospital discharge, decreased postoperative wound infection rate, and earlier return to activities. However, there is some question as to whether these benefits outweigh the initial increase in cost.[35]


ALGORITHM 37.1

ALGORITHM 37.1 Algorithm for the diagnosis of acute appendicitis.

There is also discussion about laparoscopy being advantageous in the ability to view the whole abdomen when the appendix seems normal, as well as the ability to irrigate and aspirate into the pelvis to prevent postoperative abscess.

Regardless, the procedure itself starts with a patient who has been evaluated with a decision to proceed to the operating room. Depending upon the duration of illness or suspicion of perforation, preoperative resuscitation should occur, with early use of antibiotics. Informed consent should address the appropriate risks involved and also be clear in regard to the risk of more extensive surgery, including the possibility of an ileocecectomy or right hemicolectomy. There should also be a clear communication about the post-op risks of abscess, urinary retention, bleeding, wound infection, bowel obstruction, and potential hernia.

There is some debate as to whether surgery for a patient with a known diagnosis of acute appendicitis can "wait until the morning" if this diagnosis is established at nighttime. The practice does appear reasonable provided the delay is <6 hours.[36,37] The abdominal landmarks are noted and having established the point of maximal tenderness prior to induction, the choice of incision is determined. The use of a transverse Rocky-Davis incision versus an oblique McBurney incision is surgeon preference. The skin incision is carried down to the external oblique and continues in the direction of its fibers. Muscle splitting through the internal oblique and the transversus abdominis muscles in the direction of their fibers is accomplished until the peritoneum is reached. The peritoneum is opened and the use of self-retaining retractors is considered. The cecum is identified and followed to the confluence of the taeniae so that the base of the appendix can be identified. Depending upon the level of inflammation, the appendix is delivered into the wound. The amount of fibrinous attachment will dictate how easy or difficult this may be.

There is no benefit from routinely culturing peritoneal fluid as >10 organisms are typically identified.[38] The most commonly isolated bacteria include *Escherichia coli, Bacteroides fragilis*, streptococcus species, and *Pseudomonas*. These are generally well treated with any third-generation cephalosporin or fluoroquinolone, with the addition of metronidazole or clindamycin for anaerobic coverage.

As the appendix is brought up into the wound, the decision to approach the mesoappendix versus the appendix first is addressed. If the mesoappendix is manageable, then serial

ligation between clamps is ideal. This should be ligated with minimum of 2-0 absorbable suture. The base of the appendix is clamped and a heavy absorbable suture is used to tie off the base. A clamp is placed distal to the sutures and the appendix is transected above the ties and removed from the patient. The protruding mucosa is fulgurated to prevent mucocele. Alternatively, the stump may be invaginated with a purse-string or Z-stitch as per surgeon preference. There is no evidence to support the invagination of the appendiceal stump. The area is copiously irrigated and the attempt to include the pelvis in the irrigation is made. The wound is closed in layers and the skin may be closed if the appendix was not perforated. Antibiotic therapy is then based on the guidelines. Non-perforated appendicitis requires only 24 hours of IV antibiotic therapy, whereas perforated appendicitis requires therapy until there are no clinical signs of infection.[27]

Those patients who have diffuse peritonitis after free spillage after a perforated appendix may be best served with a lower midline incision to deal with the diffuse contamination and prepare for the possibility of doing an ileocecectomy or right hemicolectomy should the cecum be considerably inflamed.

The laparoscopic approach is also adequate and is used often preferentially due to the potential benefit of shorter hospital stay and improved pain control. Additionally, it may be the procedure of choice for obese patients. The laparoscopic approach begins with the same previous initial resuscitation and antibiotic administration. The camera port is placed first; we prefer an open technique with the placement of a Hassan trocar. The 5 mm port for grasping the appendix can be in the suprapubic position or the right upper quadrant. The dissection port can be a 12 mm left lower quadrant port, as is our preference, or a 5 mm left lower quadrant port. The dissection of the window between the mesoappendix and the appendix is usually performed with the Maryland dissector. The mesoappendix can then be controlled with the harmonic scalpel, the LigaSure device, or a division with the GIA stapler with a vascular load, which requires a larger port. The appendix may then be divided at its base with the same stapler, or with an endoloop. The appendix is then removed in an endocatch bag and the area and pelvis irrigated with saline. After final inspection of the appendiceal stump and mesoappendix, the trocars are removed under direct inspection and the fascial defects closed with a figure eight fascial stitch. The skin closure is by subcuticular suture. The recent Cochrane analysis suggests that laparoscopic surgery for suspected appendicitis has diagnostic and therapeutic advantages compared to conventional "open" surgery. However, due to small differences, it does not advocate one therapy over the other. The advantages noted in the analysis of 67 studies were reduced pain, wound infection, and hospital length of stay.[39] Another recent meta-analysis of laparoscopic versus open appendectomy for complicated appendicitis suggests that the former has a reduced incidence of surgical site infection but no difference with regard to intra-abdominal abscess occurrence.[40]

For both the open and the laparoscopic approach, the patient is kept on IV fluids until a diet is tolerated. Treatment with antibiotics is as described above. Diet is started by postoperative day one and patients prepared for discharge.

Finally, because some patients may recover from an episode of acute appendicitis without operative intervention, there has been some interest in nonoperative management of this disease. However, a high readmission rate ranging from 14% to 35% was associated with antibiotic therapy alone.[41] Certainly, this strategy is fraught with danger in children and elderly patients and not the approach that we advocate.

THE ROLE OF THE ACUTE CARE SURGEON IN THE MANAGEMENT OF APPENDICITIS

Two studies address the role of the in-house acute care surgeon (ACS), also covering trauma patients, in caring for patients with appendicitis. They reach conflicting conclusions. The group from the University of Pennsylvania note that after adoption of an ACS model, the time to the operating room was shortened by 4 hours, the complication and rupture rate decreased by 10%, and length of stay was lessened by a day[42] compared to a traditional staffing model. The group from Wright State reports an identical time to the operating room and perforation rate, but a greater usage of the laparoscopic technique (that may be a function of evolution).[43]

SUMMARY

Acute appendicitis is the most common surgical emergency for the ACS. With advanced imaging and early intervention, the risk of mortality today is related to the patient's comorbidities. Current best practices lead to early surgery and treatment of abscess with surgery or drainage, given the presentation. The use of percutaneous drainage is a major advance in the care of these patients and allows a staged approach to complicated appendicitis.[44] Laparoscopy has added an important diagnostic and therapeutic tool for the management of appendicitis; particularly in females of childbearing age. The use of antibiotics should follow established practice guidelines. A problem yet to be solved is the substantial difference in the early diagnosis and treatment of the youngest of the population, who often are already perforated prior to the intervention of the medical staff.

EMERGENCY SURGERY

CHAPTER 38 ■ ACUTE PANCREATITIS

PATRICIO POLANCO AND STEVEN J. HUGHES

Acute pancreatitis (AP) is an inflammatory process readily diagnosed by the combination of epigastric abdominal pain, abnormal elevation of pancreatic enzymes (amylase or lipase) in the serum, or computed tomography evidence of pancreatic inflammation.[1] In 75% of affected patients, AP is a self-limited process presenting as mild pain with rapid, spontaneous resolution. However, AP is a severe, life-threatening condition in the remaining quartile of patients, characterized by a systemic inflammatory response syndrome (SIRS) associated with the potential of multiple organ system failure (MOSF) and other complications including death. Thus, optimal treatment varies considerably, driven by accurate assessment of the severity of the disease, determination of the underlying etiology, and identification of potential complications such as pseudocyst, necrosis, infection, hemorrhage, and abdominal compartment syndrome (ACS).

EPIDEMIOLOGY

The annual incidence of AP varies among populations, ranging between 4.9 and 35 per 100,000 persons per year.[2] Russo et al[3]. reported 218,188 patients admitted in the United States for AP, with an overall mortality rate of 1.8% in the year 2000. In fact, the incidence of AP is increasing in western countries, resulting in an increasing rate of outpatient visits and admissions for acute and chronic pancreatitis (Fig. 38.1) in the United States. This is attributed to increasing alcohol consumption, and an increased incidence of gallbladder disease and obesity in this population.[4] AP can occur at any age, but the mean age for the first attack is the sixth decade.

ETIOLOGY AND PATHOGENESIS

Calculus biliary tract disease is the most common cause of AP and when combined with ethanol alcohol abuse as the second most common causative factor, these etiologies account for over 80% of the cases. The other etiologies of AP are rare and can be difficult to definitively diagnose. Table 38.1 summarizes these various etiologies.

Mechanical

The most common cause of AP is the passage of biliary tract precipitates in the form of crystalline sludge or frank gallstones from the gallbladder into the common bile duct, leading to temporary or persistent obstruction of the pancreatic duct at the level of the ampulla of Vater. Data are inconclusive as to whether the ensuing AP is due to a chemical injury from reflux of bile or enteric contents or an increase in hydrostatic pressure. Biliary AP is more common in females.

The second most common mechanical etiology of AP is endoscopic retrograde cholangiopancreatography (ERCP). Asymptomatic hyperamylasemia is observed following ERCP in 35%-70% of patients. However, clinical symptoms consistent with pancreatitis occur in fewer than 5% of the cases,[5,6] and the current frequency of pancreatitis following ERCP is considerably lower through efforts to avoid pancreatic duct injection when unnecessary and avoidance of vigorous injection of contrast when the duct does need to be visualized.

Anatomical abnormalities of the pancreas can also lead to mechanical causes of AP. Periampullary neoplasms or diverticuli, and duodenal duplication cysts may rarely lead to AP. *Pancreas divisum* is a relatively common anatomic variant of the pancreas seen in 5%-7% of the healthy population and is due to failure of the dorsal and ventral ducts to fuse during embryogenesis. This abnormality is thought to result in a relative stenosis of the lesser ampulla, resulting in ductal hypertension and subsequent AP. Annular pancreas is often associated with aberrant ductal anatomy, but rarely presents with pancreatitis.

Finally, AP occurs in 5% of patients with blunt abdominal trauma; hyperamylasemia without frank AP is present in a substantial percentage of other blunt trauma patients. Penetrating trauma involving the pancreas also causes AP; the energy distribution of a firearm missile places this mechanism at considerably higher risk for pancreatitis than that of relatively low-energy stab injuries.[7]

Toxic

Alcohol-induced pancreatitis is more common among men and is the second most common cause of AP, but only a small percentage of alcoholic subjects develop pancreatitis. This disparity is thought to be due to a combination of environmental and genetic factors which are poorly understand. Alcohol-induced pancreatitis may present as AP or as chronic pancreatitis. Not all alcoholic pancreatitis patients progress to chronic pancreatitis; even with continued alcohol abuse, some patients have nonprogressive, repetitive AP.[8]

Pharmacologic

Certain pharmacologic agents cause AP in idiosyncratic fashion due to poorly understood pharmacogenetic factors (e.g., aminosalicylates, 6-mercaptopurine) or direct, dose-related toxic effects (e.g., diuretics, sulfonamides). Table 38.1 lists the most common agents associated with drug-induced AP. The estimated incidence of drug-induced pancreatitis is 0.1%-2%. Balani et al.[9] described certain subpopulations who may be at higher risk such as children, women, the elderly, and patients with advanced HIV infection or inflammatory bowel disease. Most cases of drug-induced pancreatitis are mild and self-limiting, and the diagnosis of the etiology is usually implied rather than proven.

Metabolic

Hypertriglyceridemia and hypercalcemia are the two most common metabolic disorders associated with AP, but account for fewer than 3% of AP cases. Serum triglyceride concentrations must be markedly elevated, above 1,000 mg/dL to provoke AP. Thus, this etiology of AP is usually associated with
FIGURE 38.1 Age-adjusted rates of ambulatory care visits and hospital discharges with Pancreatitis in the United States of America 1979–2004. Source: National Ambulatory Medical Care Survey and National Hospital Ambulatory Medical Care and National Hospital Discharge Survey. With permission from Everhart JE et al., *Gastroenterology,* 2009;**136**:1134–1144.

type I, II, and V hyperlipidemia, but elevated triglycerides secondary to obesity, diabetes, estrogen or tamoxifen therapy, or nephrotic syndrome can also provoke AP. Triglyceride concentrations need to be measured at admission; after fluid resuscitation, the serum values may reduce considerably and thus prove misleading. Hypercalcemia of any etiology can occasionally cause AP, representing <1% of cases, and not clearly correlating with the degree of hypercalcemia. This disorder is usually a manifestation of hyperparathyroidism, but can also be seen in patients with excessive doses of vitamin D, familial hypocalciuric hypercalcemia, metastatic cancer, and total parenteral nutrition (TPN).

Infectious

Although several infectious agents can cause AP, this etiology accounts for <1% cases of AP.[10] The viruses, Mumps, Coxsackievirus, Hepatitis B, Cytomegalovirus, Varicella-Zoster and Herpes simplex can induce AP. More recently, HIV infection has been related to AP. Although it is hypothesized that AP can be caused by HIV itself, most commonly it is associated with opportunistic infections or medications (e.g., didanosine). Bacterial infections including Mycoplasma, Legionella, Leptospira and Salmonella, and fungal infections (Aspergillus) and parasites (Toxoplasma, Cryptosporidium, and Ascaris) have been reported as agents causing AP.

Hereditary Pancreatitis

Some genetic mutations are associated with AP, most notably mutations of the *serine protease 1* (*prss*1) and *serine protease inhibitor Kazal 1* (*spink*1) genes. SPINK1 is described as disease modifier and can promote AP in combination with alcohol abuse. Also, at least one mutant variant of the *cystic fibrosis transmembrane conductance regulator* (*cftr*) gene has been identified in some patients with idiopathic chronic and acute recurrent pancreatitis. These possible inherited forms of AP should be suspected when the following criteria are

present: Idiopathic recurrent pancreatitis, relatives with pancreatitis-associated mutations or family history of recurrent pancreatitis, idiopathic chronic pancreatitis, or pancreatitis in childhood.[11] Genetic testing and counseling are recommended for this group of patients.

Autoimmune

Autoimmune pancreatitis is poorly understood, but is often associated with elevations in serum IgG4 concentrations, and resection specimens stain strongly for IgG4 expression. The process can be localized, or involve the entire gland. These patients typically present with a constellation of symptoms and findings consistent with pancreatic cancer including pancreatic and biliary strictures and low-attenuation masses by CT, rather than AP.

Vascular

AP secondary to ischemia is a very rare event but it has been described as a complication of lupus and other etiologies of vasculitis, atheroembolic events, intraoperative hypotension, and hemorrhagic shock. This etiology of AP needs to be particularly considered in patients that develop AP following cardiopulmonary bypass status.

PATHOGENESIS

The inflammatory processes that occur with AP are extraordinarily similar regardless of the etiology, and include both structural and biochemical changes. Early events are characterized by changes in secretion, intracellular activation of enzymes, and generation of inflammatory mediators. Intraacinar activation of trypsinogen, uncontrolled by endogenous antagonists such as SPINK 1, alpha-1 antitrypsin, and alpha-2-macroglobulin, leads to activation of other enzymes such as

TABLE 38.1

ETIOLOGIC FACTORS OF ACUTE PANCREATITIS

▪ ETIOLOGIC CATEGORY	▪ SPECIFIC ITEM
Mechanical	Gallstones or biliary sludge Neoplastic process Periampullary diverticulum Sphincter of Oddi dysfunction Blunt or penetrating trauma Post ERCP
Toxic	Alcohol Scorpion toxin
Drugs	Azathioprine Sulfonamides Thiazides Furosemide Pentamidine Didanosine Methyldopa Tetracycline Estrogens Valproic acid Sulindac 5-aminosalicylic acid 6-mercaptopurine L-Asparaginase
Metabolic	Hypertriglyceridemia Hypercalcemia Hyperuricemia
Infectious	Viral Parasites Mycoplasm
Vascular	Circulatory shock Ischemia–reperfusion Embolic Hypothermia Malignant hyperthermia Autoimmune vasculitis
Hereditary	Serine protease 1 (*prss1*) mutation Serine protease inhibitor Kazal 1 (*spink1*) mutation Cystic fibrosis transmembrane conductance regulator (*ctfr*) mutation
Autoimmune	IgG4

proelastase, procarboxypeptidase, prophospholipase A2 and other cascades including kallikrein–kinin, complement components, and fibrinolysis. Pancreatic digestion characterized by necrosis, apoptosis, and autophagy ensues. Microcirculatory injury and leukocyte chemoattraction with release of cytokines further mediate these processes.

The release into the circulation of activated pancreatic enzymes and cytokines (phospholipase, elastase, TNF, IL-2, platelet-activated factor—PAF, complement, etc.) mediate the SIRS seen in patients with severe pancreatitis. In these patients, these mediators affect distant organs, leading to increased vascular permeability, vasodilation, liver injury, pulmonary injury, myocardial depression, and acute kidney injury. Thus, severe AP can lead to MOSF.[12] Why a subset of individuals develop severe AP with SIRS is poorly understood and is an area of intense investigation.

CLINICAL FINDINGS

The most consistent symptom of AP is severe epigastric pain, often extending through or with band-like radiation to the back. Anorexia, nausea, and vomiting are also reported by the majority of patients. Systemic findings such as fever, tachycardia, dehydration, and in severe cases, shock and coma subsequently may be present. The typical, temporal history of biliary pancreatitis is onset of pain within 2 hours of a large meal, usually high in fat content. The onset of symptoms from alcohol-induced AP typically ensues 1–3 days after a drinking binge.

Importantly, findings on the initial physical exam are rarely indicative of the severity of the disease. Hemodynamic changes or signs of pulmonary, hepatic, or renal injury should not be expected at presentation, nor should their absence suggest the patient is likely to follow a self-limited clinical course. Epigastric tenderness is a constant finding. Guarding, abdominal distension, decreased bowel sounds, and even rebound tenderness may be present. The mucous membranes may appear dry and the urine typically appears concentrated.

Later in the disease course, if the AP process is caused by choledocholithiasis or liver injury leading to cholestasis has occurred, jaundice or scleral icterus may be noted. Similarly, physical findings of pulmonary injury will develop in severe AP including rales and decreased breath sounds, usually in left base associated with a pleural effusion. Without adequate volume replacement or in the setting of severe renal injury, oliguria or anuria may be observed. Although classically described, Grey-Turner sign (ecchymotic discoloration of flank) and Cullen sign (ecchymotic discoloration of periumbilical region) are seen in only 1%-2% of patients and indicate severe AP with retroperitoneal hemorrhage dissecting into these areas. These findings have been associated with a mortality rate of 37%.[13]

DIAGNOSIS OF AP: BIOCHEMICAL MARKERS AND IMAGING

The diagnosis of AP is first suspected clinically then confirmed by biochemical or radiologic evidence. According to guidelines published by the American College of Gastroenterology, the diagnosis of AP requires two of the following three features: (1) abdominal pain characteristic of AP, (2) serum amylase or lipase ≥3 times the upper limit of normal, and (3) characteristic findings of AP on CT scan.[14]

Biochemical Markers

Amylase and lipase are the most accepted confirmatory biomarkers in AP. Serum amylase concentrations rise within 6–12 hours of the onset of pain and with a half-life of approximately 10 hours. Serum lipase concentrations more slowly elevate, typically peaking 24 hours after the onset of pain, and then normalize over 2–3 weeks. In episodes of mild and uncomplicated pancreatitis, serum amylase should normalize within 3–5 days. Elevated serum amylase is considered a sensitive but nonspecific test for AP. Hyperamylasemia can be found in diseases that affect other organs, which produce amylase, such as salivary glands (e.g., parotiditis, trauma, calculi) and fallopian tubes (ectopic pregnancy and salpingitis). Hyperamylasemia can be observed in chronic renal failure patients or found in almost any peripancreatic inflammatory process including intestinal ischemia or a perforated viscus. In contrast, elevated serum lipase is both sensitive (85%-100%) and specific for the diagnosis of AP. Thus, it is ultimately a superior diagnostic tool except early in the clinical course;

additional, later sampling may be necessary.[15] Importantly, the level of pancreatic enzyme elevation does not correlate with severity of disease and has no value in the assessment of clinical progress or prognosis; therefore, daily measurement of amylase and lipase is not recommended.

Several other biochemical tests or biomarkers have been forwarded as having merit in the diagnosis of AP, but for a variety of reasons, none have been routinely employed. Urine amylase and clearance of amylase can be diagnostic tools for AP, but are only used to diagnose macroamylasemia (in which urine amylase is normal). The serum elevation of other pancreatic enzymes (phospholipase A, trypsin, carboxipeptidase A, colipase, and carboxylester lipase) currently lacks clinical utility. Pancreatitis-associated protein, Trypsinogen activation peptide (TAP), and Trypsinogen-2 are nonenzymatic pancreatic peptides that are elevated in AP. Serum concentrations of TAP have been described as a predictor of disease severity.[16]

IMAGING

Recent advances in imaging have led to significant progress in the diagnosis, assessment, prognostication, and treatment of AP and associated complications. Of historical interest, a series of abdominal roentgenograms was once the only option for imaging patients with abdominal pain and suspicion of AP. Classically, the findings of AP are localized or may be only a segmental ileus called the "sentinel loop sign" and the "colon cut-off sign." In severe cases, a generalized ileus can be observed.

Contrast-enhanced Computed Tomography (CT) is currently the preferred imaging tool for the diagnosis of AP and assessment of severity. CT at the initial evaluation of a patient with abdominal pain can exclude pancreatitis and many other acute intra-abdominal processes. However, CT is not necessary to implement appropriate initial treatment for a patient with even severe AP, and CT is not cost-effective when patients present with clear clinical and biochemical features of mild AP. If CT is obtained in a patient with self-limited AP, the findings range from a normal appearing pancreas without peripancreatic abnormalities to diffuse enlargement of the gland with heterogeneous attenuation of the parenchyma and stranding of the peripancreatic fat.[17] Focal involvement of the gland can be seen in up to 18% of patients and this pattern is commonly seen in patients with chronic alcohol abuse.[18]

If a patient presents with clinical features predictive of a severe episode or the patient's clinical condition deteriorates despite adequate initial medical management, a dynamic, contrast-enhanced CT should be obtained. In severe AP, all the findings described above can be observed, but the true value of dynamic contrast administration is the potential identification of regions of the gland that lack arterial enhancement representing an area(s) of necrosis. Beger *et al.* showed an overall accuracy of 87% for detection of necrosis (confirmed by surgical intervention) with 100% sensitivity for the detection of extended pancreatic necrosis, but only 50% sensitivity for the detection of minor necrotic areas identified at surgery; the specificity of CT for necrosis was 100% in this series.

The normal pancreatic parenchyma attenuates x-rays to 40–50 Hounsfield units (HU) on unenhanced CT images; this increases to 100–150 HU during the arterial phase of contrast administration. Typically, delineation of necrosis by dynamic, contrast-enhanced CT becomes identifiable 24–48 hours after the initiation of symptoms (Fig. 38.2). Thus, early CT (within 12–24 hours of initial presentation) may be equivocal or may underestimate the amount of necrosis and severity of disease, and more informative results are obtained with a dynamic, contrast-enhanced CT 48–72 hours after the onset of an acute attack of pancreatitis.[19] This timing also allows intravascular
FIGURE 38.2 Computed tomography of pancreatic necrosis. **A:** Arterial phase image of the pancreas from a dynamic, contrast-enhanced CT shows lack of enhancement of nearly the entire pancreas, suggesting necrosis of more than 80% of the Gland. **B:** CT of the same patient after open debridement and external drainage demonstrating control of peripancreatic fluid collections.

resuscitation prior to the administration of intravenous contrast, thus reducing the risk of contrast-induced renal injury. If contrast cannot be given due to severe allergy or tenuous renal function, the criterion of pancreatic parenchyma displaying attenuation <30 HU correlates to regions of ischemia, and the development of necrosis has been described.[19]

CT also plays an essential role in the identification and management of AP complications, such as focal fluid collections, abscess, and pseudocyst. Throughout the course of severe AP, repeated CT studies may be needed according to clinical evolution or anticipation of complications. However, routine serial CT scan is not recommended unless there has been a change in the patient's clinical condition.

Ultrasound (US) evaluation is appropriately obtained in patients with AP when cholelithiasis is a possible etiology. A diffusely enlarged pancreas with hypoechoic areas are distinctive ultrasonographic findings of AP. However, in almost a third of the patients, the interposition of bowel gas obscures the pancreas. For this reason, US has a limited role in diagnosis and assessment of the severity of AP.[20] US is helpful in the assessment of the intra- and extrahepatic biliary tree. A dilated common bile duct may suggest impaction rather than spontaneous passage of the biliary and pancreatic duct obstruction, and should prompt evaluation for the appropriateness of ERCP.

Magnetic Resonance Imaging (MRI)/Magnetic Resonance Cholangiopancreatography (MRCP) is similar in accuracy to contrast-enhanced CT in diagnosis and staging the severity of AP. MRI/MRCP is not the standard imaging technique for AP and its use will depend on availability, local expertise, and institutional algorithms. MRI is a good alternative when intravenous contrast cannot be administered and necrosis is suspected. Purported advantages of MRI include no radiation exposure, lack of nephrotoxicity of gadolinium, superior tissue characterization, and potential ability to detect pancreatic duct disruptions.[21] Disadvantages include patient intolerance or ineligibility, significantly longer durations of image acquisition, and variability in technique and access. MRCP is the only noninvasive method to assess the pancreatic duct and is appropriate when delineation of biliary and pancreatic duct anatomy is important or to identify the potential etiology of AP such as biliary calculi and pancreas divisum, or there is clinical need to assess the pancreatic duct for evidence of disruption or stricture (Fig. 38.3). If pancreatic stricture is suspected, the sensitivity of the technique is dependent upon imaging before and after the administration of secretin.
FIGURE 38.3 Disrupted pancreatic duct. Pancreatitis can result in disruption and/or stricture of the main pancreatic duct, complicating care. **A:** MRCP suggests a stricture or disruption of the pancreatic duct near the neck of the gland. **B:** Subsequent ERCP confirms disruption with an abrupt termination of filling and inability to visualize the proximal duct with contrast injection.

Endoscopic Ultrasound (EUS) is an increasingly important imaging tool in evaluation of the pancreas and biliary tree. However, knowledge of the value of EUS in AP is in evolution and access to this modality is currently limited for the most part to academic institutions. EUS may prove valuable in minimally invasive approaches to management of AP complications, including drainage or debridement of peripancreatic fluid collections, pseudocysts, and focal necrosis. Although not commonly used in AP, it could be useful in patients with recurrent pancreatitis with uncertain etiology since it has a high sensitivity for calculi, small pancreatic duct tumors, and duct abnormalities.[18] EUS criteria for chronic pancreatitis have been defined, but remain controversial versus traditional approaches of secretin stimulation and ERCP.

CLASSIFICATION AND PROGNOSIS OF ACUTE PANCREATITIS

Once the diagnosis of AP has been made, it is essential to determine the probable severity of the disease. Based upon the Atlanta Criteria established during a consensus conference in 1992, AP can be categorized in mild and severe cases. Mild AP is associated with minimal organ dysfunction and an uneventful recovery, and occurs in more than 75% of the patients. These patients usually experience rapid normalization of symptoms and laboratory values in response to the conservative measures of bowel rest, pain management, and crystalloid administration. Failure to improve within 48–72 hours should prompt investigation for complications or another diagnosis. In contrast, severe AP is associated with organ dysfunction or local complications, such as necrosis, abscess, or pseudocyst. Severe AP can be anticipated upon initial presentation by the identification of three or more Ranson's criteria, an APACHE II score >7, or Glasgow prognostic criteria (Table 38.2).

The Ranson's prognostic criteria, initially described in 1974, include 11 parameters, five of which are evaluated at admission, and six which are assessed after 48 hours. In the original report, the sensitivity of three or more criteria to predict severe disease was 65% with a specificity of 99%, yielding a positive predictive value (PPV) of 95% and a negative predictive value (NPV) of 86%. More recently, a meta-analysis that included 1,307 patients revealed an overall sensitivity for predicting severe AP of 75%, specificity of 77%, a PPV of 49%, and an NPV of 91%. These data reveal the fact that there is a high false-positive rate of Ranson's criteria and many patients with a score more than 3 will not develop clinically severe pancreatitis.[22] Preferentially used in the United Kingdom, the Glasgow's prognostic criteria examine eight factors.

The acute physiology and chronic health evaluation (APACHE), initially developed in 1981, included 34 factors, thus complicating its use. It was subsequently simplified to 12 factors in APACHE II (1985). This assessment is widely used and accepted today for critically ill patients. The APACHE II score produces comparable accuracy to Ranson's criteria in distinguishing mild from severe pancreatitis, with an accuracy of about 70%-80%. Later modifications of the score, APACHE III (1991) and APACHE O-Obesity (1996), have been proposed but are not broadly used.

CT can predict the severity of AP. Balthazar et al[23]. described a grading system based upon findings of unenhanced CT (Table 38.3). This initial grading system described five distinct groups based on pancreatic and peripancreatic inflammation with presence of fluid collections and/or free air. This was subsequently modified to include findings of contrast-enhanced CT that included the amount of necrosis (<30%, 30%-50%, and >50%) to create a CT severity index (CTSI).[24] Several studies have shown that the amount of necrosis strongly correlates with organ failure and mortality. A recent series of 276 patients

SEVERITY SCORING SYSTEMS FOR ACUTE PANCREATITIS

■ RANSON'S CRITERIA		■ GLASGOW'S CRITERIA	■ APACHE (0–4 POINTS EACH)
On admission	*Within 48 h*	Age >55 y	Temperature
Age >55 y	Hemoglobin ↓ below 10 mg/dL	White cell count > 15×10^9/L	Mean arterial pressure
WBC >16,000/mm³	Blood urea Nitrogen ↑ >5 mg/dL	PaO_2 <60 mmHg (8 kPa)	Heart rate
LDH >350 U/L	Calcium ↓ <8 mg/dL	LDH >600 U/L	Respiratory Rate
AST >250 U/L	PaO_2 <60 mmHg (8 kPa)	AST >200 U/L	Oxygenation
Glucose >200 mg/dL	Base deficit >4 mEq/L Fluid sequestration >6 L	Albumin <32 g/L Ca <2 mmol/L Glucose >10 mmol/L Urea >16 mmol/L	Arterial pH HCO_3^- Na^+ K^+ Creatinine Hematocrit White blood count Glasgow Coma Scale

TABLE 38.3

COMPUTED TOMOGRAPHY SEVERITY INDEX

GRADE	CT FINDING	POINTS	NECROSIS PERCENTAGE	ADDITIONAL POINTS
A	Normal pancreas	0	0	0
B	Pancreatic enlargement	1	0	0
C	Pancreatic inflammation and/or peripancreatic fat	2	<30	2
D	Single peripancreatic fluid collection	3	30–50	4
E	Two or more fluid collections and/or retroperitoneal air	4	>50	6

reported that organ failure occurred in 5%, 20%, and 50% of the patients with <30% necrosis, 30%-50% of necrosis, and >50% of necrosis, respectively.[25] Furthermore, a statistically significant correlation between the incidence of morbidity and mortality and the CTSI score has been established. Patients scoring 0–1 point had no morbidity or mortality, while those with a score of 2 have a morbidity of 4% without mortality. In the group of patients with CTSI scores of 7–10, mortality was 17% and 92% had complications.[26] Thus, the CTSI score has been validated as one of the most reliable prognostic factors of severity, morbidity, and mortality.

Finally, other immunologic markers of inflammation including C-reactive protein, IL-6, IL-8, IL-10, TNF, procalcitonin, and PMN elastase can be assayed from the serum and have been forwarded as predictors of AP severity. C-reactive protein is an acute-phase reactant, largely studied as a marker of inflammation and severity in AP. Concentrations of C-reactive protein above 150 mg/dL at 48 hours discriminate mild from severe AP.[20] Procalcitonin is another acute-phase reactant that has not only been described as a marker of severe AP with organ failure (when concentration >0.5 ng/mL at 24 hours after admission),[27] but also as a discriminator of infected pancreatic necrosis (when concentration >1.8 ng/mL).[28] Although the utility of these immunologic biomarkers has been reported, a positive impact on the clinical management of patients with AP remains unproven, and as such, few clinicians utilize them.

MANAGEMENT

Mild Acute Pancreatitis

The majority of the AP cases (>75%) can be classified as mild according to the Atlanta criteria. These patients usually recover in 3–5 days and only require conservative, supportive medical management. This consists of bowel rest, fluid resuscitation, pain control, and correction of electrolytes and metabolic disorders. Vigilance must be maintained to identify early signs of SIRS and organ dysfunction. Even in mild cases, considerable redistribution and subsequent loss of intravascular volume can occur. In addition to exacerbating potential renal injury, inadequate resuscitation can result in further pancreatic injury and pancreatic necrosis.[29] Thus, aggressive fluid resuscitation with close monitoring of hydration status, urine output, and vital signs is recommended for all patients with AP. Typical electrolyte abnormalities include hypokalemia, hypocalcemia,

hypomagnesemia, and hyperglycemia. These electrolytes should be evaluated daily and corrected as indicated.

In mild AP, there is no role for antibiotics. Analgesia is essential and should be administered parenterally to ensure adequate delivery. Opioids, typically via patient-controlled analgesia, are appropriate. Hydromorphone is the pharmacologic agent of choice. While morphine and meperidine have historically been used, morphine increases the sphincter of Oddi pressure, a theoretically undesired effect. However, there is no clinical evidence that morphine can worsen or exacerbate AP.[30] Meperidine has fallen out of favor due to its known potential to induce neuromuscular irritation and seizures due to accumulation of a neurotoxic metabolite (normeperidine).

Since the inflammation in mild AP subsides within a week, nutrition is not usually a concern. Bowel rest should be prescribed until the pain has resolved and the patient has return of appetite. Initial intake is restricted to water or clear liquids with advancement to a low-fat diet as tolerated. If symptoms recur, CT evaluation of potential complications is warranted. If complications are absent, in addition to the resolution of pain, delaying a second challenge to oral intake until there has been normalization of serum pancreatic enzymes is reasonable.

Cholecystectomy for Biliary Pancreatitis

If biliary pancreatitis is confirmed by US, laparoscopic cholecystectomy during the same hospitalization is safe and cost-effective. Even a 2-week delay in operative intervention is associated with a 13% rate of recurrent pancreatitis.[31] Furthermore, two prospective studies showed that laparoscopic cholecystectomy can be done safely in mild AP, even before normalization of amylase and lipase, and resolution of pain.[32,33] A recent randomized trial in mild AP compared this approach versus delaying intervention until serum enzymes normalized and abdominal pain had resolved. This study showed shorter length of stay in the early group without an increase in perioperative morbidity or technical difficulty.[34]

Inherent to the diagnosis of biliary pancreatitis is that particulate matter has been and may remain within the common bile duct. There is consensus that ERCP should not be performed prior to cholecystectomy in cases of mild, biliary pancreatitis unless data such as an elevated conjugated bilirubin or dilated common bile duct suggests persistent occlusion. Even then, some authors argue that intraoperative cholangiography is safer and more cost-effective than ERCP, noting that it has been shown that recent cholecystectomy

does not increase the risks of ERCP. However, debate continues as to the appropriateness of routine intraoperative cholangiography. The incidence of retained stones is approximately 9%, but the incidence of subsequent symptoms in patients who do not undergo cholangiography is only 1%.[35] Once a retained stone is identified, it should be addressed. Thus, routine intraoperative cholangiography in the setting of AP will result in a significant number of common bile duct explorations or ERCPs that do not provide clinical benefit.

Other Causes of Acute Pancreatitis

Patients with alcohol-induced pancreatitis should receive assessment for alcoholism and other addictions, and referral to therapy if appropriate. It is most cost-effective to make the assumption of essential nutrient deficiency, and thiamine and folate should be administered. These patients should be carefully monitored for signs of acute withdrawal from alcohol, and prophylaxis against seizure using benzodiazepines implemented immediately if such symptoms arise.

Management of hypercalcemia or hypertriglyceridemia etiologies should be addressed prior to discharge from the hospital. If the AP is drug-induced, the causative agent should be permanently withdrawn and listed as an allergy. Evaluation and management of other etiologies can be pursued after discharge in the outpatient setting.

Severe Acute Pancreatitis

The natural history of severe AP follows two distinct phases. The first phase is characterized by SIRS and varying organ dysfunction or failure with subsequent clinical stabilization or improvement, and the second phase occurs in patients who develop infectious complications, most typically occurring 3–6 weeks from the onset of symptoms.

Early Phase Interventions. When severe AP is probable (Ranson's criteria > 3, APACHE > 7), the patient should be admitted and monitored in an intensive care unit for aggressive fluid resuscitation with continuous surveillance of vital signs and pulmonary, renal, and other organ functions in preparation for the probable need to subsequently support failing organs systems. If SIRS does ensue, central venous and arterial pressure monitoring is warranted. This monitoring is critical in the setting of a severe capillary leak to minimize the risk of inadequate crystalloid replacement leading to inadequate tissue perfusion, shock, altered mental status, acute tubular necrosis and acute renal failure, and worsening pancreatic necrosis, or conversely, excessive resuscitation, exacerbating pulmonary edema, worsening ARDS, or intra-abdominal hypertension and subsequent ACS.

Abdominal Compartment Syndrome

ACS is a severe complication of AP that requires emergent surgical intervention. The etiology of ACS in severe AP is due to retroperitoneal and peripancreatic inflammation that results in large fluid shifts, leading to visceral and abdominal wall edema in addition to ascites, and the ileus that often accompanies severe pancreatitis. Spontaneous hemorrhage can also increase retroperitoneal and intra-abdominal contents. ACS can be a devastating complication of AP, and the related mortality is estimated to be between 50% and 75%.[36,37] Treatment for ACS is emergent, decompressive laparotomy to relieve intra-abdominal hypertension. ACS occurs early in AP, most often within the first week and potentially within the first 24 hours of presentation. Urgent decompressive laparotomy results in immediate improvement in hemodynamics and ventilator requirements, and can save a subset of these patients. Importantly, decompression does not mandate future pancreatic debridement in all patients; exploration of the pancreas during release of an ACS is unwarranted, thus this procedure can be performed in the ICU to avoid transfer of these critically ill patients.

Nutrition in Severe AP

Patients with severe AP should be anticipated to be at high risk for the development of malnourishment during their illness. Enteral nutrition (EN) via nasojejunal feeding access is superior to TPN for patients with severe AP. Several randomized controlled trials and subsequent meta-analysis have consistently showed that EN significantly reduces infections, surgical interventions, and mortality in patients with severe AP.[38-40] The use of EN instead of TPN has the notable advantages of prevention of catheter-related infections and preservation of the intestinal barrier, preventing bacterial translocation from the intestines, likely the major source of bacteria that lead to infected necrosis. When elemental or semi-elemental supplements versus complex polymeric formulas are delivered distal to the ligament of Treitz, the stimulation of the pancreas is reduced by 50%. Importantly, the presence of gastric ileus, peripancreatic fluid collections, necrosis or elevated pancreatic enzymes are not contraindications for enteral feeding.

Antibiotic prophylaxis in Severe AP

Infection is the leading cause of morbidity and mortality in severe AP and complicates the disease in 20%-40% of patients with necrotizing pancreatitis.[41,42] The extent of necrosis is predictive of the subsequent risk of infection. This complication usually occurs 3–6 weeks after the onset of symptoms. The risk of mortality increases to 40% if initially sterile pancreatic necrosis becomes infected. The majority of cases represent monomicrobial infections with *Escherichia coli, Pseudomona, Klebsiella, Enterococcus,* and *Bacteriodes* species. With the increasing use of antibiotic prophylaxis, polymicrobial infections and other organisms including *Staphylococcus* and *Candida* species have been increasingly observed.

Based on controlled and uncontrolled trials, the use of antibiotic prophylaxis was suggested as part of the conservative medical management of necrotizing pancreatitis. Initial meta-analyses further suggested that mortality and morbidity can be reduced through the administration of prophylactic, broad-spectrum antibiotics.[43] Imipenem–cilastatin, meropenem and the combination of ciprofloxacin and metronidazol (in penicillin-allergic patients) were the antibiotics recommended due to their better penetration into the necrotic material. Subsequently, superiorly designed and controlled studies failed to demonstrate such a benefit.[42,44-46] The most recent Cochrane Database Review (2010)[47] of seven randomized, controlled trials that compared antibiotics versus placebo in CT-proven pancreatic necrosis failed to demonstrate a statistically significant difference between the two groups with respect to mortality, rates of infected pancreatic necrosis, need for surgical intervention, fungal infection, and nonpancreatic infection. Despite these data, antibiotic prophylaxis in necrotizing pancreatitis is an unsettled topic of discussion and some guidelines and experts still recommend this practice.

ERCP and Sphincterotomy in Severe Biliary Pancreatitis

Initial studies of the potential benefit of ERCP in patients with severe AP provided disparate results, with some suggesting ERCP actually worsened the disease. In fact, the most recent meta-analysis by Petrov et al.[48] that included three trials encompassing 405 patients showed that early ERCP in patients with either mild or severe acute biliary pancreatitis without concomitant acute cholangitis did not lead to a substantial reduction in the risk of overall complications and mortality.[48] However, approximately 10% of patients with severe biliary pancreatitis present with persistent occlusion of the ductal systems. Multiple studies and meta-analyses suggest that early ERCP and papillotomy benefits the course of the disease in this setting, leading to a substantial reduction in complications.[49,50] When there is high suspicion of persistent bile duct stones (i.e., jaundice, dilated bile duct) or evident choledocholithiasis on noninvasive imaging (US, CT, MRCP), ERCP should be performed within 72 hours. If a patient presents with concomitant cholangitis, ERCP should be performed within 24 hours.

Medical Approaches to Modulate the Severity of Acute Pancreatitis

Multiple agents have been investigated in hope they can prevent the development of severe AP. A noninclusive list includes probiotics, somatostatin analogs, antiproteases, drotrecogin alfa (Xigris), and lexipafant. Many of these agents modulate the severity of AP in animal models that typically administer the agent prior to the pancreatic insult; a timing scheme that cannot be duplicated clinically. However, clinical trials of these agents have failed to demonstrate benefit to placebo. In fact, lexipafant did not reduce ERCP-induced pancreatitis even when given prior to the procedure, and the use of probiotics has recently been found to be associated with worse outcomes. Thus, there are no current proven strategies/agents that prevent or reduce severe AP.

Late-Phase Interventions

Late-phase interventions are required when complications of AP occur, including infected pancreatic necrosis, hemorrhage, and pseudocyst or other fluid collection. Disruption of the pancreatic duct and persistent pancreatic fistula may also occur and are briefly addressed.

Infected Pancreatic Necrosis. Infectious complications of pancreatic necrosis usually occur 3–6 weeks after the onset of symptoms, and the mortality without surgical intervention can reach 100%. The reported mortality of infected necrosis with surgical management ranges between 15 and 28%.[51] The diagnosis of infected pancreatic necrosis is suspected by worsening abdominal pain, fever, and leukocytosis. The presence of gas within the pancreas by CT is considered highly suggestive of infected necrosis. Alternatively, infected necrosis can be confirmed by CT-guided fine needle aspiration.

Open surgical debridement and external drainage was once the predominant surgical approach to management of pancreatic necrosis in the United States. This typically included serial laparotomies to facilitate further debridement of evolving peripancreatic necrotic tissues. Unfortunately, this approach is associated with an approximately 20% enteric fistula rate and near-universal abdominal wall hernia. Given that several other less invasive techniques have been reported to successfully drain the infected pancreatic bed including percutaneous, laparoscopic, or retroperitoneal approaches with or without continuous lavage, many large-volume centers have abandoned this approach for an incremental treatment ladder, or step approach. This approach tries to delay or even avoid surgical intervention.

Delayed intervention has proven to reduce mortality to 27%[52] from 65% compared to early surgical intervention.[53] One of the advantages of delayed intervention is that the demarcation of necrotic tissues and subsequent liquefaction facilitates the use of nonsurgical approaches such as percutaneous or endoscopic drainage that can temporize or even prevent the need for surgery. In fact, endoscopic techniques of pancreatic drainage via transgastric or transduodenal approaches that eliminate the risk of persistent pancreaticocutaneous fistula are becoming increasingly common in carefully selected patients. Percutaneous necrosectomy has also been described in small series of patients in this setting with good clinical success, but typically require repeated drainage or procedures to upsize the catheters.[54,55] Reported failure rates for this approach are highly variable (31%-87%). Nonetheless, should these approaches fail, they do not typically complicate subsequent surgical intervention.

Minimally invasive pancreatic debridement and external drainage have been reported with encouraging results. A retroperitoneal approach to debridement and drainage of infected pancreatic necrosis was initially described by Gambiez *et al.* in a series of 20 patients with clinical success in 75% of patients, but a transperitoneal laparoscopic approach mimicking the traditional open procedure with either retrocolic or antecolic access of the lesser sac is the most commonly reported. A combined approach of percutaneous drainage followed by use of these catheters to guide laparoscopic trochars into the cavity and then perform an intracavitary, laparoscopic debridement has been successfully employed at our institution. Other authors have described various alternatives and combined percutaneous techniques with retroperitoneal approaches. Thus, there are multiple approaches to the management of infected pancreatic necrosis, but no studies have prospectively compared them. The favored approach continues to be driven by institutional experience and expertise.

Pancreatic Pseudocyst and Peripancreatic Fluid Collections. Extravasation of pancreatic secretions from ductal structures into the parenchyma or surrounding structures resulting in pseudocyst or persistent peripancreatic fluid collection(s) complicates approximately one-third of severe AP cases. Such collections of either pancreatic juice or transudate range dramatically in size, location, and clinical significance. In half of these patients, multiple collections are present. Pseudocysts typically expand over the first week following the onset of symptoms, and then evolve over the ensuing 4–12 weeks, although this process can be further prolonged in some patients (Fig. 38.4). Once contained by anatomic planes, the ensuing inflammatory response eventually produces a fibrous capsule that lacks an epithelial lining. As above, the evolution of these collections over time also includes liquefaction of particulate and necrotic material. Intervention should be delayed until this process has matured. The likelihood of spontaneous resolution is related to the size, but not strongly enough to produce a clinically reliable rule relating size, location, and symptoms to the need for intervention. When present, these collections pose the risk of becoming infected, and often produce mass effect that leads to symptoms of pain, early satiety, nausea, or biliary obstruction.

Surgical management is reserved for the relief of symptoms or infection. The potential for pancreatic duct stricture or disruption must be considered as these conditions alter the

EMERGENCY SURGERY
FIGURE 38.4 Evolution of pancreatitis. **A:** MRI of patient with acute pancreatitis 24 hours after the onset of symptoms demonstrates pancreatic edema without signs of necrosis. Gallstones and sludge were also identified, confirming the etiology. **B:** CT of the same patient obtained at 48 hours. **C:** CT of the same patient 1 week after presentation demonstrates areas of necrosis. **D:** CT of the same patient 3 weeks after presentation demonstrates the development of peripancreatic fluid collections.

surgical procedure of choice. MRCP is preferred over ERCP given the potential of infecting a previously sterile collection with ERCP. If a pancreatic duct stricture or disruption is identified, distal pancreatectomy rather than enteric drainage is typically indicated. However, in select circumstances, ERCP and placement of a pancreatic stent may subsequently be appropriate, but must be performed as part of a collaborative plan that is prepared to address subsequent infection or treatment failure.

In the majority of cases, enteric drainage is the surgical treatment of choice. The size, location, and complexity of the pseudocyst determine whether cyst gastrostomy or cyst Roux-En-Y is performed. Minimally invasive and endoscopic approaches for both of these procedures have been reported with similar success compared to open techniques. Biopsy of the pseudocyst wall is indicated for intraoperative assessment of an epithelial lining suggestive of a neoplastic rather than inflammatory process. Even with removal of debris and septations, and creation of a large communication between the collection and the intestine, most series report about a 20% failure rate with persistent fluid collection following the surgical procedure.

Hemorrhage

AP-associate hemorrhage is a rare but lethal complication. If pancreatic secretions are exposed to retroperitoneal structures due to necrosis or peripancreatic fluid collections, the potential for life-threatening hemorrhage exists. The hemorrhage can be retroperitoneal, intraperitoneal, or hemosuccus pancreaticus. When hemorrhage occurs, the splenic artery is the most frequently involved named vessel, followed by the

gastroduodenal artery. Diagnostic and treatment modalities include endoscopy, angiography including embolization, and surgical exploration and ligation, and are dependent upon clinical scenario, expertise, and availability. Operative approaches include opening the causative fluid collection with control and ligation of the involved artery, packing if control cannot be obtained because the source is diffuse or venous, or distal pancreatectomy if warranted and technically feasible. The potential for hemorrhage is particularly significant when fluid is identified by CT to be tracking into the splenic hilum and under the capsule of the spleen, and most experts agree this is an indication for urgent surgical intervention of splenectomy, debridement, and external drainage.

EMERGENCY SURGERY

CHAPTER 39 ■ CHOLECYSTITIS, CHOLANGITIS, AND JAUNDICE

UMUT SARPEL AND H. LEON PACHTER

Disorders of the biliary tract often demand the attention of the acute care surgeon. These disorders can run the gamut from the benign attack of biliary colic, to the rapidly fatal entity—suppurative cholangitis. However, attention to key features in the history and physical exam, when coupled with the appropriate labs and imaging tests, allows an accurate diagnosis and treatment plan in most instances.

ANATOMY

Simplistically, the biliary system can be thought of as the plumbing of the liver, providing drainage of bile into the intestines. Most surgical disorders of the biliary tract are secondary to an obstruction along this drainage tract. As such, the diagnosis and treatment of biliary disorders requires a thorough understanding of biliary anatomy.

Biliary Anatomy

The intrahepatic bile ducts course alongside their arterial and portal venous counterparts to form the portal triads of the liver parenchyma. These ducts coalesce into the right and left hepatic ducts. The caudate lobe has its own system of small ducts which drain directly into both the right and left main ducts. As the right and left hepatic ducts exit the liver, they remain sheathed in Glisson's capsule, hiding them from direct view. The right duct has a short course outside the liver, whereas the left duct has a long extrahepatic course as it travels along the undersurface of the left lobe to the hilum. The point of biliary convergence into the main hepatic duct is variable; in some individuals the bifurcation is well outside the liver, while in others it is practically intraparenchymal.

The gallbladder is nestled along the undersurface of the liver at the junction of the right and left lobes. It is separated from the liver parenchyma by the cystic plate, which is a continuation of Glisson's capsule. A common mistake during cholecystectomy is to dissect the gallbladder en bloc with the cystic plate off the liver bed, which leads to unnecessary bleeding. The true plane for cholecystectomy is found close to gallbladder wall, leaving the whitish cystic plate intact on the liver.

The cystic duct empties into the common hepatic duct, forming the common bile duct (CBD). The length of the cystic duct may be short, or it may run along the hepatic duct for some distance before joining it. This anatomical variability is of paramount significance during cholecystectomy when extreme care should be taken to avoid inadvertent injury to the CBD while ligating the cystic duct.

The main bile duct runs vertically in the hilum, anterior to the portal vein and lateral to the hepatic artery. The normal diameter of the CBD is approximately 5 mm, although it can be slightly wider in the elderly.[1] A useful rule of thumb is that the diameter of the bile duct increases 1 mm for every decade of life. While an 8 mm CBD could be a normal finding in an 80-year-old, it should be considered dilated in an otherwise healthy 30-year-old. The cystic duct usually measures 3 mm in diameter. Thus, any difficulty in ligation of the cystic duct with a 5-mm clip applier should be a red flag to the surgeon that the structure in question may in fact be the CBD.

When dealing with the biliary tree, anatomical variations are common and unpredictable. If appropriate vigilance is not exercised, an elective cholecystectomy can become a disaster with injury to the bile ducts, arteries or both. It cannot be stressed enough that the possibility of anomalies in biliary anatomy must be foremost in the mind of any surgeon performing a hepatobiliary procedure. Moreover, awareness of these variations is essential for the proper interpretation of an intraoperative cholangiogram.

A relatively common and potentially critical variation is the low-inserting posterior sectoral duct. In most individuals, this duct, which drains segments VI and VII of the liver, joins the anterior sectoral duct to form the right hepatic duct. However, in some individuals, this duct travels independently to enter the common hepatic duct, the cystic duct, or even the CBD as a separate structure. This low-inserting posterior duct may be injured during cholecystectomy leading to a persistent bile leak or atrophy of intrahepatic liver segments.

Arterial Anatomy

In most instances, the hepatic artery arises from the celiac trunk. However, the right hepatic artery (or even the entire hepatic) may originate from the superior mesenteric artery. In these cases, the hepatic artery will lie posterior to the CBD for its entire length. As a result, the cystic artery's position within Calot's triangle will be altered, which may lead to confusion during cholecystectomy.

Another common variant is the accessory left hepatic artery. Instead of arising from the common hepatic artery, this vessel arises from the left gastric artery. In most cases, this is actually an accessory artery which supplies segments II and III, while a smaller branch off the common hepatic still supplies segment IV.

After the hepatic artery bifurcates, the right hepatic artery dives behind the CBD where is becomes vulnerable to injury during cholecystectomy. The right hepatic artery sometimes curves near the cystic duct in its course towards the liver; this has been termed "Moynihans' hump."[2,3] In these cases, the cystic artery is short, and attention must be paid to avoid either injury to the right hepatic artery or ligation when mistaken for the cystic artery. Anterior and posterior branches of the cystic artery are often identifiable; these can originate from the main cystic artery or may arise independently from the right hepatic artery.

When an injury to the CBD occurs in the course of a cholecystectomy, it is often a paired injury; that is, the common duct is mistaken for the cystic duct and as part of the illusion and the right hepatic artery is mistaken for the cystic artery. Therefore, in all cases of iatrogenic bile duct injury, it is important to investigate the patency of the right hepatic artery.[4,5]

Venous Anatomy

The venous drainage from the gallbladder is directly into the liver parenchyma. Variations in hepatic venous and portal venous anatomy are common, but rarely clinically relevant to the acute care surgeon. However, special mention of the anatomy of the middle hepatic vein is warranted. The course of the middle hepatic vein within the hepatic parenchyma becomes quite superficial as it nears the gallbladder fossa. The vein can be injured during cholecystectomy if the surgeon veers off the correct plane and violates the liver parenchyma. Dark venous blood quickly fills the field, and can turn an ambulatory case into one with major blood loss. Direct pressure applied to the liver bed usually allows temporary hemostasis while assistance is en route. Depending upon the degree of injury, definitive control can be obtained with either argon beam coagulation, clipping, or with a parenchymal suture.

PHYSIOLOGY

Hepatocytes import unconjugated bilirubin from the plasma and conjugate it with glucuronic acid to make it water soluble. Conjugated bilirubin is then excreted into the bile canaliculi, and is eventually emptied into the duodenum. Through this process, approximately 1 L of bile is produced per day.[6] The function of bile is (1) to deliver bile salts to the intestines to aid in digestion of fats, (2) to excrete bilirubin, which is an oxidative product of heme, resulting from the destruction of senescent red blood cells, and (3) to excrete toxins.

Jaundice is the physical manifestation of hyperbilirubinemia, and usually becomes noticeable when the bilirubin level exceeds 3 mg/dL. Jaundice can result from an aberration anywhere along the process from bile production through excretion. The etiology of jaundice can be determined by whether the hyperbilirubinemia is predominantly unconjugated or conjugated. Unconjugated hyperbilirubinemia is seen with overproduction of bilirubin, impaired uptake of bilirubin, or impaired conjugation of bilirubin. Conjugated hyperbilirubinemia is seen with impaired excretion or obstruction of the biliary tree.

A conjugated hyperbilirubinemia can also be seen in cholestasis. In this clinical scenario, the ratio of total to direct bilirubins will mimic an obstructive pattern, although no downstream obstruction is present and biliary dilatation will accordingly be absent. Any systemic inflammatory process can affect bile secretion and result in cholestatic jaundice. This is often the case in the chronically ill or septic intensive care unit (ICU) patient whose labs demonstrate direct hyperbilirubinemia and otherwise unimpressive liver function studies. This cholestatic jaundice may be profound and will not resolve until the underlying process is controlled.

Surgical emergencies of the biliary system are usually due to acute obstruction of the biliary tree. Obstructive jaundice has several physiologic consequences which have relevance to surgeons, including aberrations in cardiac output, coagulation, renal function, wound healing, and the immune system. These issues should be considered for any jaundiced patient on the surgical service.

Cardiac Physiology

Obstruction of the biliary system can cause hemodynamic disturbances including decreased peripheral vascular resistance and depressed cardiac contractility.[7,8] Jaundiced patients display more labile blood pressure and are more susceptible to shock. Obstructed patients who undergo biliary decompression can become acutely hypotensive. It is unclear if this is due to cardiac lability, or secondary to instrumentation-induced bacteremia.

Coagulation

In patients with obstructive jaundice, impaired vitamin K absorption from the gut occurs due to a lack of intestinal bile, and is evidenced by a prolonged prothrombin time.[9] The effect is reversible with parenteral administration of vitamin K. There is little risk to vitamin K administration, therefore any jaundiced patient undergoing an operation should receive preoperative supplementation.

Renal

The decreased cardiac function associated with jaundice leads to renal hypoperfusion and acute renal failure. Hepatorenal syndrome is well-known in advanced cirrhotics, but renal insufficiency can also occur in patients with obstructive jaundice. When undergoing surgery, special attention needs to be paid to maintenance of intravascular volume. The mortality rate of patients with obstructive jaundice who develop renal failure is close to 70%.[10]

Wound Healing

Delayed wound healing and a high incidence of wound dehiscence have been reported in patients undergoing surgery to relieve obstructive jaundice. This may be related to decreased activity of the enzyme prolyl hyrdoxylase, which is required for normal collagen synthesis, in the skin of jaundiced patients. Levels of this enzyme return to normal following relief of the obstruction.[11] Accordingly, meticulous wound closure technique must be used in this group of patients.

Immune System

Jaundiced patients have numerous defects in cellular immunity which make them prone to infection; including impaired T-cell proliferation, decreased neutrophil chemotaxis, and defective phagocytosis.[12–14] In addition, bacterial translocation from the gut is increased when bile is absent the intestinal lumen. Jaundiced patients should be considered immunocompromised.

IMAGING OF THE BILIARY TREE

Ultrasound

Ultrasound is inexpensive, fast, and noninvasive making it the ideal method for visualization of the gallbladder and intrahepatic bile ducts. Views of the more distal CBD are usually obscured by overlying bowel gas and cannot be adequately examined by ultrasound. In addition, it is of limited use in obese patients and in cirrhotics because of the poor image quality caused by these conditions. Lastly, it is important to keep in mind that sonography is highly user-dependent, and thus only as reliable as the skill of the user.

Stones and sludge in the gallbladder are hyperechoic and cast an acoustic shadow. The sensitivity of ultrasound in the detection of stones is high, and the lack of stones on an ultrasound should bring into question the diagnosis of biliary colic or cholecystitis in an otherwise healthy patient.

Sonographic findings suggestive of acute cholecystitis are: (1) the presence of stones or sludge, (2) gallbladder wall thickening >4 mm, (3) pericholecystic fluid, and (4) a sonographic Murphy's sign, or tenderness elicited when the sonographer presses the ultrasound probe onto the visualized gallbladder.

When making a diagnosis of cholecystitis, it is important to note that bilirubin levels should be normal and on imaging the CBD should be of normal size. If jaundice or a dilated CBD is seen in a patient with abdominal pain, cholangitis must be suspected instead. Rarely, a markedly edematous gallbladder or a large stone impacted within the gallbladder can cause external compression of the CBD; a process known as Mirizzi's syndrome. In this case, intrahepatic biliary dilatation may be seen on ultrasound; however the CBD distal to the gallbladder (downstream from the obstruction) should not be dilated.

Computed Tomography

Computed tomography (CT) is not the initial test of choice for evaluation of the biliary system since approximately one-third of stones are not dense enough to be seen on CT.[15] In addition, the cost and radiation exposure make CT undesirable as first-line imaging. Nevertheless, in reality, CT is often the first test performed on patients with abdominal pain.

In acute cholecystitis, CT will demonstrate a thickened gallbladder; streaking and edema may be present in the pericholecystic fat. However, the CT appearance of the gallbladder can be misleading: the gallbladder may become slightly thick-walled due to other intraabdominal processes (e.g., ascites) which can mislead the clinician. Alternatively, the CT appearance of the gallbladder may be underwhelming even in genuine cases of acute cholecystitis. The absence of stones on CT scan should never be used in clinical decision making, since stones may be missed on CT.

Despite its limitations in stone-related disease, CT is well-suited to identify tumors and other non-stone sources of obstruction of the biliary tree. CT is also useful in patients with postoperative complications, since it can demonstrate the presence of a bile collection (biloma), hematoma, or vascular injury. When present, pneumobilia is easily seen with CT. While this is a normal finding following biliary enteric bypass or sphincterotomy, in patients who have not been instrumented, pneumobilia may indicate the presence of a biliary enteric fistula or may be a manifestation of suppurative cholangitis.

Scintigraphy

Hepatobiliary scintigraphy involves the intravenous injection of a radiopharmaceutical tracer (e.g., technetium-iminodiacetic acid compound) which is taken up by the liver and excreted into the bile. Sequential images show activity in the liver, then in the bile ducts and gallbladder, and eventually in the small bowel. The gallbladder is seen within 30 minutes, and the intestines within 60 minutes in most subjects. Nonvisualization of the gallbladder implies obstruction of the cystic duct and, in the appropriate clinical setting, confirms the presence of cholecystitis. Scintigraphy is the most accurate test for acute cholecystitis and sensitivity rates exceed 95%.[16] Specificity rates are also high, but false positives can be seen during prolonged fasting, and when acute pancreatitis hypoalbuminemia is present. Scintigraphy can be a useful tool for the confirmation of biliary tract pathology in patients where the clinical picture is unclear. It is particularly useful to confirm *acalculous cholecystitis*, where ultrasound findings may be equivocal.

Cholangiography

Direct cholangiography can be obtained by injection of contrast (1) percutaneously through the liver, (2) retrograde via the ampulla during endoscopic retrograde cholangiopancreatography (ERCP), or (3) directly into the biliary tree during surgery. Cholangiography provides the highest resolution imaging of biliary anatomy. The technique of intraoperative cholangiography is discussed later. Noninvasive imaging of the biliary tree can be obtained by magnetic resonance cholangiopancreatography (MRCP). However, unlike ERCP, MRCP does not provide the opportunity for a concomitant therapeutic component.

DISORDERS OF THE GALLBLADDER

Surgical pathology of the biliary tree usually results from physical obstruction of bile drainage; most often due to stones. Treatment depends upon the site of obstruction and whether there is concomitant infection.

Asymptomatic Cholelithiasis

Bile is maintained in a liquid state by the delicate balance of bile salts, lecithin, and cholesterol. Cholelithiasis results when these factors become unbalanced. The vast majority of gallstones are cholesterol stones which form in the gallbladder. Pigment stones, which form secondary to hemolysis, are fairly unusual. Results from autopsy studies and ultrasound screening studies suggest that cholelithiasis is present in 10%-20% of the population. Surveillance of individuals with known gallstones suggests that only 15% of patients ever develop symptoms.[17,18] Gallstones are often detected incidentally on an ultrasound or CT obtained for other reasons. These asymptomatic stones do not require any surveillance or surgical follow-up.

Biliary Colic

Gallstones may intermittently obstruct the cystic duct, causing pain known as biliary colic. This term is actually a misnomer, since within each attack the pain is constant, not colicky. When the cystic duct is obstructed, the patient usually experiences right upper-quadrant or epigastric pain that typically lasts for 4–6 hours. The pain may radiate to the back, shoulder or the subscapular area. Nausea is usually present, and vomiting may occur, but is not the dominant symptom. Classically, the pain starts after a fatty meal, due to cholecystokinin release. The resulting contraction of the gallbladder against an obstructed cystic duct causes intense pain. The pain often subsides without treatment when the offending stone slips back into the gallbladder, thereby resolving the obstruction.

Some patients with biliary colic will develop intractable pain with a crescendo of symptoms. These patients may experience symptoms with nearly every meal and often present with documented weight loss or dehydration. Cholecystectomy should be performed expeditiously in these cases.

It is important to note that in biliary colic, while obstruction of the cystic duct is present, infection is not. Accordingly, the treatment is does not require antibiotics, only bowel rest with IV hydration, pain control, and elective cholecystectomy. Once infection develops, right upper-quadrant tenderness, leukocytosis and fever invariably follow. With these findings, biliary colic has now evolved into acute cholecystitis. Careful physical examination and the use of ultrasonography will usually distinguish between these two entities.

Acute Cholecystitis

Acute cholecystitis occurs when obstruction of the cystic duct is accompanied by infection of the bile and gallbladder. These patients will present with complaints of pain and nausea similar to biliary colic; however the pain of cholecystitis will persist for 1–2 days if left untreated. On physical examination, right upper quadrant tenderness will be present due to inflammation of the gallbladder. A classic Murphy's sign describes the focal gallbladder tenderness that is elicited when, upon taking a deep breath, the patient abruptly halts inspiration due to the sudden pain that occurs when the descending gallbladder hits the examiner's hand, which is pressed into the right subcostal margin. Fever and mild leukocytosis are typically present, consistent with infection. Liver function tests should be normal, except in rare cases of Mirizzi's syndrome described below.

The treatment of acute cholecystitis generally consists of antibiotics, bowel rest with IV hydration, pain control, and cholecystectomy. Common biliary pathogens are the enteric gram-negative organisms including *Escherichia coli* and *Klebsiella*.[19] Bile is normally sterile; the sphincter of Oddi prevents enteric bacteria from entering the biliary system, and the flow of bile helps prevent infection with its mechanical flushing action. However, when cystic duct obstruction occurs, as in cholecystitis, stasis of bile within the gallbladder allows bacterial proliferation and infection.

The definitive treatment of cholecystitis is cholecystectomy. In the past, delayed cholecystectomy was advocated as safer than cholecystectomy performed during the acute inflammatory phase. However, a meta-analysis of 12 prospective, randomized trials showed that prompt cholecystectomy does not result in higher rates of CBD injury, and actually results in substantially lower length of stay and decreased hospital costs.[20,21] Therefore, unless there are medical contraindications, early cholecystectomy should be performed.

Variations of Cholecystitis

Routine cholecystitis is relatively straightforward in its diagnosis and treatment. However, certain types of cholecystitis can be more challenging to identify and manage.

Mirizzi's Syndrome

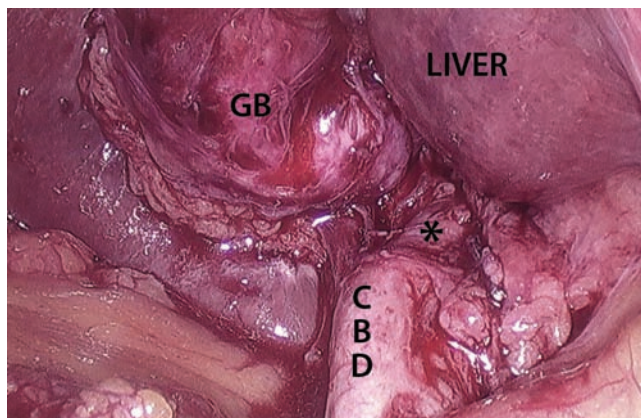
Mirizzi's syndrome, occurs when an inflamed gallbladder causes external compression of the CBD, thereby leading to obstructive jaundice (Fig. 39.1).[22] The compression may


FIGURE 39.1. Mirizzi's syndrome. *Asterisk* marks area of CBD compression by the infundibulum of the gallbladder.

be due to an enlarged and inflamed gallbladder, or from a large stone impacted in the gallbladder neck. Mirizzi's syndrome is rare, one study states that it occurs in approximately 0.1% of patients with gallstone disease[23]; therefore, Mirizzi's syndrome is diagnosis of exclusion. Direct hyperbilirubinemia should never be attributed to Mirizzi's syndrome unless other causes of obstructive jaundice have been excluded, since the consequences of a missed cholangitis can be severe.

Acalculous Cholecystitis

Acalculous cholecystitis occurs almost exclusively in patients with severe comorbidities, and is classically seen in hospitalized patients who are septic, receiving parenteral nutrition, on vasopressors, or who have suffered major trauma or burns. The precise etiology of this entity is unknown, but theories include gallbladder ischemia and presence of inspissated bile.[24,25] Since the cystic artery is a small terminal vessel, global hypoperfusion is thought to result in gallbladder wall ischemia and eventually necrosis. The diagnosis of acalculous cholecystitis is challenging because, by definition, it occurs in patients who are ill, have confounding histories, and are usually unable to verbalize their symptoms. Acalculous cholecystitis is often found as the result of a CT done for fever of unknown origin in a patient in the ICU. Gangrene and perforation occur commonly, due to the frequent delay in diagnosis.

Often, ultrasound or CT show only a distended, mildly thickened gallbladder. Diagnosis can be difficult since gallbladder distension may simply be due to a prolonged NPO status with total parenteral nutrition, and not cholecystitis. Nuclear scintigraphy (e.g., HIDA scan) can be useful in unclear cases of acalculous cholecystitis. Since many patients with acalculous cholecystitis are quite ill, often immediate cholecystectomy is not possible or prudent. In this setting, imaging-guided percutaneous drainage of the gallbladder allows drainage of bile and release of the infection. This treatment is sufficient in most cases, less commonly a cholecystectomy may be required if tissue necrosis has set in. If the patient resolves the episode of acalculous cholecystitis with percutaneous cholecystostomy, cholecystectomy is seldom necessary at a later time.

Gangrenous Cholecystitis

Gangrenous cholecystitis occurs when infection and inflammation cause thrombosis of the cystic artery; this leads to ischemia and gangrene of the gallbladder wall, eventually resulting in liquefaction necrosis and perforation of the gallbladder. Gangrene occurs first at fundus of the gallbladder because this is the most distant site from the blood supply of the cystic artery. In patients with free perforation, bile stained ascites may be present. Gangrenous cholecystitis is more common in diabetics due to their underlying small vessel disease.[26] Once gangrene has developed, a cholecystostomy tube will most likely be insufficient to halt the process. The problem that arises is ascertaining which patients can be managed with a tube cholecystostomy and which cannot. If the patient with acute or gangrenous cholecystitis has not improved within 24 hours of placement of the tube, it is possible that tissue necrosis is present, for which the patient should undergo urgent cholecystectomy. Other causes for the lack of response to cholecystostomy include malposition or dislodgement of the catheter or incorrect diagnosis of cholecystitis.

Emphysematous Cholecystitis

The imaging appearance of gas within the gallbladder wall is pathognomonic of emphysematous cholecystitis and indicates the presence of gas-forming bacteria such as clostridia species, *E. coli*, or *Klebsiella*.[27] The infection progresses in stages from the presence of gas in the gallbladder lumen, to within the gallbladder wall, and ultimately into pericholecystic tissues.[28] The presence of gas can obscure ultrasound imaging of the gallbladder, however the diagnosis is easily made with CT (Fig. 39.2). Emphysematous cholecystitis occurs more commonly in elderly or diabetic males, and is more frequently associated with acalculous cholecystitis.[29] Expeditious cholecystectomy is warranted if the patient will tolerate the operation.

Hydrops of the Gallbladder

The normal physiologic function of the gallbladder is to take up and store the bile excreted from the liver. In long-standing cases of cystic duct obstruction the bile within the gallbladder is slowly resorbed. Continuing secretion from the mucosa of the gallbladder results in its filling with a clear mucoid fluid termed "white bile". This is known as *hydrops* or a mucocele of the gallbladder. Typically, these patients have a distended gallbladder that cannot be grasped during laparoscopic cholecystectomy. The diagnosis is usually made when the surgeon aspirates the gallbladder to decompress it and clear mucous is returned.

Cholecystitis During Pregnancy

Cholecystitis is the second most common nongynecologic process to complicate pregnancy, following appendicitis.[30] Estrogen through its negative effect on smooth muscle activity is thought to be responsible for the increased rate of cholecystitis in women, and in pregnancy in particular. Although the pathophysiology of cholecystitis is the same as in the non-pregnant state, the natural hesitancy of clinicians to image and treat a pregnant patient can lead to a delay in diagnosis and intervention (see Chapter 44). This delay can be more harmful to the mother and fetus than cholecystitis itself. While straightforward attacks can be treated with antibiotics,
FIGURE 39.2. Emphysematous cholecystitis on CT.

recurrent cholecystitis can lead to maternal dehydration and malnutrition, with obvious deleterious effects to the fetus. In these cases, cholecystectomy may be necessary during pregnancy. If possible, the procedure should be performed during the second trimester; surgery during the first trimester is associated with increased fetal loss, and surgery during the third trimester may induce premature contractions. As a general rule, all attempts should be undertaken, if possible, to bring the patient to term and then perform an elective cholecystectomy. The approach is similar for biliary pancreatitis in pregnancy.

Gallstone Ileus

Gallstone ileus is another misnomer of medical terminology. Whereas ileus implies the absence of mechanical obstruction, in gallstone ileus there is a physical obstruction of the GI tract by a gallstone. Long-standing, recurrent attacks of cholecystitis eventually lead to erosion of a gallstone through the gallbladder wall into a neighboring loop of bowel. Cholecystoduodenal fistulization is most common, but cholecystocolic fistulae may also develop. The fistula itself is asymptomatic; gallstone ileus occurs when the offending stone occludes the bowel lumen leading to obstruction. Classically, the gallstone erodes into the duodenum and travels to the narrowest point in the GI tract, the ileocecal valve, where it causes small bowel obstruction in the terminal ileum. An abdominal x-ray showing dilated loops of small bowel along with a pneumogram of the biliary tree is pathognomonic for gallstone ileus. At operation, an enterotomy is performed to remove the obstructing stone (Fig. 39.3). If possible, the stone should be milked proximally so that the enterotomy can be performed through normal, nondilated bowel, rather than at the site of obstruction which is typically edematous. A full examination of the small bowel is necessary to detect additional nonobstructing stones which may be present.[31] Once the patient recovers from surgery, elective cholecystectomy and the division of the cholecystoenteric fistula may be considered, but is usually unnecessary. Cholecystectomy should absolutely not be attempted during the acute presentation since the right upper quadrant is hostile due to the inflammation caused by the recent fistulization.[32,33] If later cholecystectomy is contemplated an open approach should be undertaken to minimize inadvertent injury to the CBD and to have maximal exposure for repair of the bowel fistula.

DISORDERS OF THE COMMON BILE DUCT

Choledocholithiasis

In studies where routine intraoperative cholangiography is performed, approximately 6% of asymptomatic patients are found to have incidental CBD stones.[34] However, unlike asymptomatic cholelithiasis, the discovery of asymptomatic choledocholithiasis should prompt intervention due to the potentially severe consequences of jaundice, gallstone pancreatitis, or cholangitis.

The presence of stones in the CBD should be suspected in any patient with:

- direct hyperbilirubinemia
- intrahepatic biliary dilatation seen on preoperative imaging
- dilated CBD seen on imaging or by intraoperative visualization
- history of gallstone pancreatitis, or with elevated amylase or lipase levels
FIGURE 39.3. Gallstone ileus. **A:** CT showing Inflammation of the gallbladder and duodenum. **B:** Gallstone obstructing distal small bowel, after enterotomy with extraction of gallstone.

In these patients, the CBD must be imaged by either preoperative MRCP, ERCP, or by intraoperative cholangiography. at the time of cholecystectomy Preoperative ERCP is usually the method of choice, since it is therapeutic as well as diagnostic. In addition, if a preoperative ERCP is unsuccessful, a CBD exploration can then be performed at the time of cholecystectomy.

Cholangitis

Cholangitis occurs when the flow of bile from the liver is obstructed and the static column of bile proximal to the obstruction becomes infected. Cholangitis rarely ensues when the biliary obstruction occurs gradually over a period of time, as with tumors or strictures. Choledocholithiasis or the sudden clogging of a biliary stent is the usual etiology.

The presentation of cholangitis is described by *Charcot's Triad*: fever, jaundice, and right upper-quadrant pain. On examination, the liver is diffusely tender, as opposed to the focal gallbladder tenderness seen with cholecystitis. This finding can be elicited by palpation in the epigastrium where the liver is not shielded by the rib cage. *Reynaud's Pentad*, the addition of hypotension and mental status changes, heralds the onset of septic shock. Laboratory values demonstrate marked leukocytosis and direct hyperbilirubinemia, often accompanied by mildly elevated transaminases; which reflect the hepatotoxic effect of the infection. The predominance of conjugated bilirubin points to obstruction as the cause of the jaundice, as opposed to acute hepatitis.

Ultrasonography will typically reveal intrahepatic biliary dilatation and a dilated CBD due to downstream obstruction. However, due to the presence of overlying gas in the duodenum, the offending stone itself, which is lodged at the ampulla, will not be seen on sonography. The ultrasound can determine if there are stones in the gallbladder; if gallstones are present, the clinician can reasonably assume that the cause of the cholangitis is stones; although it is possible to have had a single gallstone, which traveled into the CBD, which then left the gallbladder empty, this is decidedly unusual.
FIGURE 39.4. Intrahepatic biliary dilatation.

FIGURE 39.5. Recurrent pyogenic cholangitis due to chronic intrahepatic stone formation. Note the biliary dilatation, pneumobilia, and parenchymal atrophy of the left lobe, while the right hepatic lobe is spared. The left lobe is thought to be more commonly affected due to the sharper angle of insertion of the left duct into the CBD.

CT will also demonstrate biliary dilatation (Fig. 39.4), although ultrasound is the first imaging that should be obtained since many gallstones are not apparent on CT. It is important to point out that the CBD diameter may be normal during the early stages of cholangitis this finding can mislead the clinician. In the setting of sudden obstruction, it may take 24–48 hours for appreciable biliary dilatation to develop. Therefore, the absence of biliary dilatation on initial imaging studies should not exclude the diagnosis of obstructive cholangitis. If uncertainty exists, an MRI/MRCP can both identify the presence and location of stones, or reveal if a tumor or other process is responsible. Scintigraphy will demonstrate lack of bile flow into the small bowel, although the poor image resolution and logistic difficulties with arranging a HIDA scan make it less commonly used in the setting of cholangitis.

Bile in its natural state is golden-brown in color and does not contain bacteria. In contrast, infected bile becomes bright green secondary to bacterial metabolism of bilirubin. As the infection progresses further, the obstructed bile becomes purulent, and is known as suppurative cholangitis. The most common isolated pathogens are *E. coli*, *Klebsiella*, *Enterobacter*, and *Enterococci*; anaerobes are also present in a minority of cases.[19] Intravenous antibiotic therapy for cholangitis must provide excellent gram-negative coverage. Patients with long-standing biliary obstruction may also have *Pseudomonas* and *Candida* in their systems.

Antibiotic treatment for cholangitis is necessary but not sufficient for its treatment. It is critical to underscore that the urgently needed treatment for cholangitis is decompression.[35] This is especially true for suppurative cholangitis, where the mortality is 100% if not promptly drained. Similar to lancing an abscess, drainage is absolutely necessary; antibiotics alone are insufficient to treat the infection. Patients with an obstructed duct may develop post-decompression shock following CBD instrumentation.[36] It is not unusual for patients to become transiently bacteremic with fevers and rigors following decompression. A short duration of vasopressor support may be required in these cases. Once the acute cholangitis has resolved, cholecystectomy is indicated during the same admission to prevent further attacks.

Recurrent Pyogenic Cholangitis

This entity is characterized by repeated bouts of cholangitis as a result of stones and strictures in the intrahepatic bile ducts. The exact etiology of this disease is still unknown, although a causal relationship with *Chlonorchis sinensis* infection has
been implicated.[39] While biliary strictures and intrahepatic stones are at the root of the disease, it remains unclear which is the initial event. Strictures lead to biliary stasis and stone formation, and alternately stones cause biliary strictures, thus resulting in a vicious cycle. Over the years, these patients develop progressively severe biliary dilatation and eventually atrophy of the involved hepatic segments. The left hepatic lobe is more commonly affected than the right lobe, perhaps due to the angle of insertion of the left duct into the CBD.[38] Over time, the involved liver atrophies into a thin, fibrotic parenchyma containing dilated bile cisterns packed with columns of stones (Fig. 39.5). In addition, years of irritation of the bile ducts can lead to malignant degeneration, resulting in cholangiocarcinoma.

Patients usually report multiple previous attacks of abdominal pain and frequently have already undergone cholecystectomy. However, since these stones form within the intrahepatic bile ducts, cholecystectomy is not curative, and the cholangitic attacks continue. ERCP is typically unsuccessful at biliary decompression since the affected bile ducts are usually packed with large stones. Percutaneous transhepatic biliary drainage is necessary if antibiotics are unsuccessful in treating the infection.

Once the acute cholangitis resolves, the patient needs to be evaluated for definitive treatment. Simple stone extraction or destruction with laser lithotripsy is not effective. Since the ducts themselves are abnormal and strictured, new stone formation and infection invariably occur. If anatomically feasible, the most definitive therapy is resection of the affected liver. Bile duct resection and hepaticojejunostomy are commonly required in complex cases.

LAPAROSCOPIC CHOLECYSTECTOMY

Identification of Anatomy

Laparoscopic cholecystectomy, when uncomplicated, results in little physiologic insult to the patient, and allows outpatient surgery or discharge home within 24 hours. The guiding

principle of safe cholecystectomy is the clear identification of the gallbladder-cystic duct junction. The use of laparoscopic cholecystectomy allows much faster patient recovery, but has resulted in a higher rate of injury to the CBD (compared to open cholecystectomy) ranging from 0.3% to 0.6%.[39] The lower rate of injury in open surgery is likely due to the anterograde, or fundus-down, approach which allows definitive identification of the CBD before any structures are ligated. However, in laparoscopic cholecystectomy, initial dissection in the hepatocystic triangle can create visual ambiguity, leading to confusion of the CBD for the cystic duct.[40]

One method to assure correct anatomy is to always obtain the *critical view* before ligation of any structure. In this approach, the fat in the hepatocystic triangle is dissected away until the liver bed can be seen with only two structures traversing it; by definition these structures can only be the cystic duct and cystic artery (Fig. 39.6).[39]

Universal intraoperative cholangiography is another method to confirm correct anatomy. Advocates of universal intraoperative cholangiography point out that this method can also identify unsuspected CBD stones. Opponents state that the discovery of small asymptomatic stones, which would probably pass on their own, leads to transcystic duct exploration or the necessity of a postoperative ERCP, which have their own inherent risks and complications.

The Difficult Cholecystectomy

In patients with chronic cholecystitis, repeated attacks lead to fibrosis of the gallbladder and bile ducts, making identification of anatomy challenging. Interestingly, difficult cholecystectomy occurs more often in males than females,[41] perhaps because cholecystitis is less often suspected as the diagnosis in men. It is important for the general surgeon to have several different approaches to cholecystectomy in his/her armamentarium.

The "dome-down" anterograde technique of open surgery, whereby the gallbladder is taken off the liver bed from the fundus downward, can be used in laparoscopic surgery as well. This approach allows the surgeon to dissect down to the vital structures before ligating them. However, this method can be challenging since the liver retraction normally provided by the gallbladder is lost.

In severe cases of inflammation, when the cystohepatic triangle cannot be recognized or dissected, a subtotal or partial
FIGURE 39.6. The critical view of safety for laparoscopic cholecystectomy. Note that only 2 structures are seen traversing the liver bed: the cystic duct and the cystic artery.

cholecystectomy may be the most prudent course of action. In this technique, the gallbladder is filleted open to the level of Hartmann's pouch and the anterior wall is excised. Any stones are removed, including any impacted in the neck of the gallbladder. The posterior wall of the gallbladder is left *in situ* and the mucosa is cauterized; a drain is left behind in the liver bed. Closure of the cystic duct is not needed and should not be attempted, since inadvertent injury to the CBD may result.

Spillage of stones is not uncommon during laparoscopic cholecystectomy. However, every reasonable attempt should be made to retrieve them since several long-term complications have been reported from retained stones. Frequently the stone acts as a nidus for infection, leading to the formation of an intraperitoneal abscess.[42] Less commonly, gallstones have been reported to fistulize into the bronchial tree, the bladder, and through the skin.[43,44]

Conversion from laparoscopic to open cholecystectomy is indicated in the setting of a difficult cholecystectomy. However, an open approach does not guarantee an easier operation. Clear identification of anatomy and strict adherence to surgical principles is necessary to avoid injury to the biliary tree.

For patients with severe comorbidity or those who are hemodynamically unstable, an ultrasound-guided, percutaneous cholecystostomy tube can be used to decompress an infected gallbladder.[45] Percutaneous cholecystostomy is especially useful in severely ill patients who develop acalculous cholecystitis. Once the acute infection has resolved, cholecystectomy can be performed. Alternatively, in patients who are poor operative candidates if contrast injected into the cholecystostomy tube shows flow into the CBD and duodenum, the cholecystostomy tube may be removed with no further intervention.

Intraoperative Cholangiography

Various techniques can be used to perform intraoperative cholangiography. Typically a clip is first applied high on the cystic duct at the level of the gallbladder. The anterolateral wall of the cystic duct is incised to create a small "ductotomy." The cystic duct can be gently milked to deliver any stones within. A cholangiography catheter is then introduced either percutaneously across the abdominal wall or via a cholangiography clamp, and is then guided into the ductotomy and secured in place. The smooth insertion of the catheter may be impeded by stones impacted in the cystic duct, or by the valves of Heister, the spiral mucosal folds of the cystic duct. Great care should be taken not to force the catheter into position; this can lead to an unrecognized injury to the back wall of the cystic duct, resulting in a bile leak postoperatively.

To be complete, cholangiography must demonstrate filling of bilateral hepatic ducts, the full length of the CBD, and flow into the duodenum. If the hepatic ducts do not fill, placing the patient in Trendelenburg position and administering morphine may be effective. Gentle compression of the CBD may also be needed in patients with dilated, compliant ducts to force dye to fill the proximal system. On the other hand, if the duodenum does not fill, the administration of glucagon to relax the sphincter of Oddi can be attempted. A filling defect may represent a stone, or may be a bubble of air inadvertently introduced into the tubing. Bubbles will tend to float into a different position if the table is tilted.

Common Bile Duct Exploration

The natural history of stones in the CBD is not certain, and has not been studied prospectively. Incidentally discovered

EMERGENCY SURGERY

small stones will likely pass into the duodenum without clinical impact. However, since cholangitis and gallstone pancreatitis are potentially lethal, it is generally advisable to remove CBD stones upon discovery. If suspected preoperatively, ERCP is the method of choice for clearing the CBD. However, if CBD stones are discovered during the course of cholecystectomy, the surgeon has the choice of an immediate laparoscopic CBD exploration or a postoperative ERCP.

Laparoscopic CBD exploration is a technically challenging procedure, particularly if the duct is normal sized. The surgical team and nursing staff need to be well-versed in the use of the choledochoscope and various methods of stone extraction. Open CBD exploration is now rarely necessary; however, it is a vital technique for all general surgeons to possess. A wide Kocher maneuver is necessary to be able to palpate the distal, retroduodenal CBD. A longitudinal, choledochotomy is made in the distal portion of the CBD, keeping in mind that the blood supply of the CBD is at 3 o'clock and 9 o'clock. The duct is held open with stay sutures on either side, and can then be atraumatically swept with a Fogarty's balloon or stone clamp.

Following laparoscopic or open CBD exploration, a T tube is left within the common duct. This allows egress of bile during the immediate postoperative period when distal ampullary edema or spasm may occur. In addition, the T tube allows access for postoperative cholangiography to assess for retained stones or bile leak. Stone extraction can be performed by interventional radiology via a 14 French T tube if the stones are ≤5 mm in size.[46]

Following CBD exploration, a biliary-enteric anastomosis may be needed, such as in patients with retained intrahepatic stones, or in those with a stone impacted at the ampulla. Patients in whom a large number of stones are retrieved should be presumed to have a retained stone even if none is seen, and bypass should be considered. Finally, any patient with multiple large should undergo biliary-enteric bypass, since ERCP can generally only retrieve stones < 1 cm in size. A side-to-side choledochoduodenostomy is the easiest type of bypass to perform, since the duodenum has already been mobilized and can usually be easily rolled upwards to meet the CBD.

Complications of Biliary Surgery

Complications from biliary surgery generally result from either bleeding from the hepatic parenchyma or injury to the biliary tree.

Hemorrhage

Bleeding during cholecystectomy can occur from (1) injury to the cystic or hepatic artery, (2) oozing from the hepatic parenchyma, or (3) laceration of the middle hepatic vein.

During laparoscopic dissection of the hepatocystic triangle, the cystic artery may be damaged or inadvertently transected before control is obtained. Typically, a fine-tipped instrument can be used to grasp the bleeding stump and a clip can be applied under direct vision. Under no circumstances should clips be placed blindly in this region. Although the brisk, pulsatile bleeding from the cystic artery stump can be visually impressive, gentle pressure will usually allow temporary hemostasis until the camera is cleaned and the instruments are prepared. It is important to ascertain whether the injured vessel is indeed the cystic artery. Injury to the right hepatic artery is not uncommon, and if suspected should prompt conversion to open surgery for close inspection and repair. Ligation of the hepatic artery generally does not cause any immediate ramifications since the hepatic parenchyma will continue to

receive blood supply from the portal vein. However, since the bile ducts are fed predominantly by the hepatic artery, biliary strictures may occur over time.

During cholecystectomy, oozing from the liver bed commonly occurs from dissection in the wrong plane. When removing the gallbladder, the cystic plate, a whitish extension of Glisson's capsule, should be left intact on the liver bed. The correct plane is usually closer to the gallbladder than initially suspected; visualization of the yellow-brown hepatic parenchyma indicates that the dissection has gone too deep. A useful method to control bleeding from the liver bed is argon beam coagulation. Alternatively, electrocautery on a high setting can be used to paint the bleeding liver surface for hemostasis. Although not immediately hemodynamically significant, if this oozing is not controlled a hematoma in the liver bed can result. Postoperatively, this hematoma may become infected or cause compression of the bile duct.

Sudden, massive, dark-colored hemorrhage from the liver bed indicates laceration of the middle hepatic vein. This major vessel lies just below the bed of the gallbladder, and is vulnerable to injury during cholecystectomy.[47] Fortunately, the hepatic veins are a low pressure system, and direct compression of the site will tamponade the bleeding. Depending upon the degree of injury, definitive control can be obtained with either argon beam coagulation, clipping, or a parenchymal suture.

Bile Leak

Bile leak following cholecystectomy is discovered when bile is seen in a drain either left at surgery, or in one placed by interventional radiology upon discovery of a fluid collection. The source of the bile may be from (1) the liver bed, (2) the cystic duct stump, (3) the CBD, (4) a posterior sectoral duct, or (5) a duct of Luschka. The most important first step in the treatment of a bile leak is to ascertain whether the leak is controlled. The following step is to determine whether there is downstream obstruction; either from a retained stone or from iatrogenic injury.

Most cases of bile leak are from the cystic duct stump; these are typically low volume and well controlled by a drain. Patients with an uncontrolled bile leak despite drainage likely have a severe injury or transection of the CBD. Bile is extremely irritating to the peritoneum, and if the leak is uncontrolled, biliary peritonitis will result. Patients with an uncontrolled bile leak will have marked abdominal tenderness and manifest signs of sepsis. It is important to note, that even patients with severe bile leaks may have normal bilirubin levels since there is no obstruction to the flow of bile out of the liver. Once the sepsis is controlled, these patients must be reexplored by an experienced hepatobiliary surgeon. The irritation of the peritoneum caused by bile can make reexploration challenging, particularly if the bile leak was initially unrecognized and drainage delayed.

On the other hand, if the bile leak is well-controlled by a drain, the patient will be asymptomatic with normal hemodynamic parameters. A minor bile leak from the gallbladder bed will result in trace amounts of bile within the drain which resolves within 1–2 days without intervention. However, the patient with more substantial amounts of bile in the drain, or with abdominal pain, should be evaluated with ERCP. The most common site of bile leak is from the cystic duct stump,[48] either due to a dislodged clip or due to increased pressure caused by a retained stone downstream. Injection of contrast during ERCP can demonstrate the source of the bile leak, confirm that extravasation is controlled by the drain, and exclude distal obstruction as the cause of the leak. In addition, sphincterotomy and insertion of a biliary stent can be performed to change the pressure gradient, allowing flow of bile out of the

ampulla rather than through the site of injury. Typically, the bile leak will resolve immediately following ERCP and the patient can be safely discharged.

While a bile leak which originates from the cystic duct or the CBD will be clearly seen on ERCP, other sources of leak may not be visualized. For example, if the leak is from a transected posterior sectoral duct, the liver side may continue to leak bile and no leak of contrast will be apparent from the biliary stump. In this case however, close inspection of the cholangiogram will reveal failure of the posterior right sector to fill with contrast, indicating the true diagnosis. Similarly, a duct of Luschka may not retain a connection to the main biliary tree, and therefore may not be seen on ERCP.[48] These etiologies should be suspected when there is bile in the drain, but the ERCP is nondiagnostic. Minor bile leaks will resolve over time, although several weeks of drainage may be required. However, a leak from transected posterior sectoral duct may persist and reoperation may be necessary.

Injury to the Common Bile Duct

While injury to the CBD is a serious complication, the sequelae of the injury can be greatly diminished if the injury is recognized at the time of surgery. During cholecystectomy, the surgeon must always be attentive to possible anatomical variations, and should maintain a degree of suspicion even in apparently straight-forward cases. Unclear anatomy can create an optical illusion where the surgeon mistakes one structure for another.

During cholecystectomy, the cystic duct and the cystic artery must be clearly identified before any structure is ligated. If there is any doubt as to the anatomy at hand, a cholangiogram should be performed, or the case should be converted to open. If bile is seen leaking into the operative field, the anatomy must be reexamined and a cholangiogram performed. If an unexpected ductal structure is encountered while taking the gallbladder off the liver bed, this should alert the surgeon that a biliary injury may have already occurred, as often the second structure is the cystic duct and the initially ligated structure is the CBD. In short, every attempt should be made to ascertain the correct anatomy, and any level of doubt should lead to an investigation.

If a CBD injury is recognized at the time of surgery, it is wise to recruit the assistance of a hepatobiliary surgeon to aid in the reconstruction. A limited, sharp injury to the CBD may be possible to repair over a T tube. However, most laparoscopic bile duct injuries result in complete discontinuity of the biliary tree and require Roux-en-Y hepaticojejunostomy. Cautery and crush injuries should categorically not be repaired primarily since the area of damage extends beyond what is immediately apparent.

Most instances of injury to the biliary tree are not recognized at the time of operation.[49] Postoperative manifestations of injury are bile leak, biliary obstruction, or both. The most important initial step in management is to determine the exact anatomy of the injury and to ascertain whether a bile leak is controlled. A detailed classification of biliary injuries by Strasberg et al.[5] and Bismuth[50] outline the varieties of biliary tree injuries that occur during cholecystectomy.

Any patient who develops abdominal pain, fever, or jaundice following cholecystectomy has a biliary injury until proven otherwise. Imaging is the first step in the evaluation of these patients. A CT of the abdomen may reveal the presence of intrahepatic biliary dilatation or a fluid collection in the liver bed. While a small hematoma can be managed expectantly, a biloma should be drained percutaneously by interventional radiology. If a biliary leak is present it should be managed with a drain and ERCP as detailed in the previous section.

Biliary obstruction following cholecystectomy is either due to a retained stone, or inadvertent ligation of the CBD. ERCP is necessary to delineate the etiology. Occasionally, a hematoma compressing the CBD causes biliary obstruction, and a biliary stent is sufficient treatment until the hematoma resorbs. When CBD injury has occurred, reconstruction with Roux-en-Y hepaticojejunostomy is necessary to restore biliary-enteric continuity. Over 90% of these patients will do well,[51] but some may suffer from anastomotic stricture and bouts of cholangitis over their lifetime.

Late Stricture of the Common Bile Duct

The development of a biliary stricture following cholecystectomy is usually the result of iatrogenic injury to the CBD. This may be the result of direct compression of the bile duct by a surgical clip which was placed too close to the CBD. Another common mechanism of injury results from or overly aggressive dissection near the junction of the cystic duct with the CBD, leading to a delayed ischemic stricture. Similarly, the use of cautery too close to the CBD can result in a thermal injury with delayed stricture. Lastly inadvertent ligation of the right hepatic artery can result in delayed biliary stricture formation from ischemic insult. ERCP with balloon dilation and stent can be attempted for stricture of the CBD; however the stricture usually recurs over time. Roux-en-Y hepaticojejunostomy may be necessary for long-term relief.

CONCLUSION

Diseases of the biliary tree are seen frequently by the acute care surgeon, and cholecystectomy is one of the most commonly performed operations, therefore a thorough understanding of the pathology and treatment of these disorders is vital. While cholecystectomy is relatively straightforward in some patients, in others the surgery can be fraught with danger. Major hemorrhage from injury to the hepatic artery or the middle hepatic vein can occur; severe biliary injury may result from misinterpretation of the anatomy or ischemic injury to the CBD. In addition, variations in anatomy are relatively common and further increase the complexity of surgery on the biliary tract.

CHAPTER 40 ■ GASTROINTESTINAL TRACT FOREIGN BODIES

ROBERT A. IZENBERG, ROBERT C. MACKERSIE

The ingestion or insertion of foreign bodies (FBs) into the gastrointestinal (GI) tract, whether accidentally or deliberately, represents a common problem for emergency medicine physicians and gastroenterologists, and a less common problem for general and acute care surgeons. The earliest reports of an ingested GI FBs date back to 1692 when a young (age 5) Frederick William I, the future King of Prussia, swallowed a shoe buckle. The buckle passed uneventfully several days later, aided by the oral administration of several grains of rhubarb. So celebrated was this event that the actual buckle was displayed in Berlin for many years afterwards.

Similar to King Frederick's shoe buckle, 80%-90% of ingested food boluses and FBs will pass spontaneously.[1] Studies have suggested that 10%-20% of patients will require nonoperative (generally endoscopic) removal, and approximately 1% will require surgical intervention.[2] The true incidence of FB obstruction is unknown, but a recent study by Longstreth, reported an estimated annual incidence rate of food impaction at 13 episodes per 100,000 in a Health Maintenance Organization (HMO) population with a 1.7:1 male to female ratio.[3] This same study ranked it as the third most common nonbiliary endoscopic emergency, ranking only behind acute upper GI hemorrhage and acute lower GI hemorrhage in its frequency. Although deaths from FB ingestions and insertions are rare, a recent review noted an estimated 1,500–1,600 deaths annually in the United States from FB ingestion/insertion.[4]

The following discussion of GI FBs will review general considerations in the surgical treatment of GI ingestions and insertions, followed by a more specific review of the management options for FB ingestions (upper GI) and insertions (colorectal).

GENERAL CONSIDERATIONS

The GI tract has a remarkable ability to pass indigestible material to which is attributed the (relatively) low incidence of problems created by FB ingestions. The tendency for peristaltic flow to be centered axially and to slow down as a result of irritating (FB) stimuli may facilitate the passage of foreign material. This same smooth muscle activity may also contribute to pushing the more easily passed blunt or smooth end of an object forward ahead of the less easily passed sharp or rough end.

With respect to impedance to forward motion, the GI tract is not created uniformly and several areas may create additional obstacles. The cricopharyngeal sphincter, for example, is anatomically the narrowest point in the GI tract, and the cervical esophagus has been the most common site of FB impaction in some series. Those objects which remain in the pharynx are usually sharp or slender such as fish or chicken bones, tacks, pins or toothpicks. These sharp objects can become trapped in the faucial or lingual tonsil, the tonsillar fossa, or lateral pharyngeal wall behind the posterior pillar. Occasionally, they are impaled between the base of the tongue and the surface of the

epiglottis. Open safety pins can be caught in the hypopharynx with one end engaged in the piriform sinus.[5]

Other areas of anatomic esophageal narrowing are the lower esophageal sphincter (LES), and the levels of the aortic arch and left mainstem bronchus,[6] with the LES a more common point of obstruction. Areas where ingested FBs may be entrapped further downstream are the pyloric muscle, the duodenal sweep/ligament of Treitz and the ileocecal valve. In addition to these normal areas of FB impedance, pathologic changes to the GI tract may produce sufficient narrowing to entrap even smaller ingested material. Peptic stricture of the lower esophagus or duodenum, anastomotic stricture from previous GI surgery, fundoplication of the lower esophagus, Schatzki rings, scleroderma, Crohns strictures, and even achalasia may contribute to FB entrapment.

Two obvious factors to be considered with all upper GI ingestions or rectal insertions are size and contour of the FB (sharp/pointed/rough vs. blunt/smooth). In regard to size, while no precise cutoff can be used to absolutely determine which ingested objects will pass and which will not, as a general rule an object length of over 5 cm (~3 cm in children) and a diameter over 2 cm will typically be trapped at either the pylorus or ileocecal valve. The distinction between sharp/pointed and blunt/smooth ingested FB is important due to the increased risk (estimated at 15%-35%) of perforation with the former.[1,7]

Although seemingly straightforward, one of the more difficult challenges in the management of FB ingestions and insertions can sometimes be simply making the diagnosis. The majority of FB ingestions occur in young children who may or may not be able (or refuse) to give a reliable history and present with seemingly unrelated symptoms. Patients with recognized psychiatric illness may intentionally or unintentionally ingest FBs and present with a nonexistent or misleading history. Findings on physical examination, in the absence of complications, may be limited, and a high degree of suspicion is often needed leading to imaging studies and the correct diagnosis.

Surgical intervention for ingested or inserted FBs is generally reserved for either complications (perforation, obstruction, major hemorrhage, local/systemic toxicity), or intractability (failure to pass an otherwise benign FB). Given the enormous variety of ingested objects, (buttons, coins, beads, toothpicks, toothbrushes, pens, pins, hair, jewelry, hardware, fishhooks, razorblades, paperclips, silverware, toys, keys, crayons, rocks, dentures, batteries, drugs, bones, etc.), the diagnostic challenges, and the profile of the "at-risk" patient populations, management is often highly individualized. Well coordinated multidisciplinary management involving radiology and gastroenterology services can help minimize both the incidence of surgical intervention and complications.

FOREIGN BODY INGESTION (per os)

There are only two ways a FB can end up in the GI tract: ingested via the mouth (os), or inserted via the rectum. While there is some epidemiologic crossover, these two mechanisms

generally are associated with different patient populations, different foreign objects, and a different approach to the diagnosis and management. As such, the following discussion distinguishes between the two.

Patients who have ingested FBs present in several ways: (1) Without symptoms following a recognized ingestion, in order to be "evaluated," (2) With symptoms referable to a recognized ingestion, (3) With symptoms, but following an unrecognized, unwitnessed, or unacknowledged ingestion. These patterns maybe associated with distinct demographic groups. Group 1 includes the "worried well," the legitimately concerned, and sometimes prisoners who deliberately swallow objects for secondary gain. Group 3 is comprised mostly of young children, psychiatric patients, and very elderly adults.

Approximately 80% of the patients with ingested FBs are under 15 years of age[6] with the peak incidence occurring between the ages of 3 months and 3 years.[8] Adults are also at risk, especially those with preexisting anatomic or motility disorders in the case of unintentional food bolus ingestion, and those with psychiatric and behavioral disorders or dementia in cases of intentional or accidental ingestions of objects other than food. Edentulous adults are at particular risk of FB ingestion whether it is a food bolus or swallowing of dentures. The wearing of dentures decreases the normal oral tactile sensitivity making it difficult to sense the size of a food bolus or the presence of bones. Prisoners may also purposefully ingest/insert FBs into the GI tract, seeking secondary gain by movement from their place of incarceration to a medical facility for treatment. Purposeful ingestion of FBs to facilitate drug trafficking also occurs, and FB impactions have also been reported as part of hazing rituals in the past and also in college students playing the game of "quarters."[9]

Elements of a careful history include the object ingested (if known), past episodes of dysphagia, food impaction, previous abdominal operations, gastroesophageal reflux disease, known structural esophageal disease, and the contents of any associated meal. Symptomatic patients will often report sudden onset of dysphagia during the meal, which may be accompanied by chest pain, or odynophagia and an inability to tolerate secretions. In children and adults unable to give a history, any sudden refusal to eat, drooling, or respiratory symptoms such as a cough or wheezing due to aspiration are reasons to suspect FB ingestion. Often the patient's localization of the pain is unreliable as a means of identifying the location of the retained FB. As a general rule, pain/discomfort symptoms are referred more proximally in the esophagus and pharynx than the actual site of retention/impaction.[10]

Physical examination, to assess the patient's stability and to assess any complications of the impaction, is often unrevealing. Airway compromise, ventilation, and the risk of aspiration should first be assessed. The inability to handle secretions and drooling suggests a complete or near-complete obstruction of the esophagus by the object. Subcutaneous crepitus, swelling of the neck or chest, or peritoneal signs is suggestive of perforation and should trigger rapid diagnostic measures to confirm and localize the site of perforation or, in the case of frank peritonitis, immediate operation.

The use of radiographic imaging is mildly controversial, particularly for esophageal FBs. In patients symptomatic for an esophageal FB who are likely to be referred for endoscopic evaluation and FB extraction regardless of imaging results, plain imaging or computed tomography (CT) imaging may only add to the cost and delay definitive management. For those patients deemed to be candidates for imaging studies, plain film radiographs of the neck, chest and abdomen are the fastest and simplest means of detecting radio-opaque objects such as metal or larger bones. Most fish bones, chicken bones, plastic, and small pieces of glass however cannot be easily visualized on plain radiographs. Contrast studies using Gastrografin or thin barium will usually allow visualization (with or without the addition of cotton fiber), but the contrast agents themselves may create problems. Barium hinders visualization during any subsequent endoscopy and should not be used in the setting of suspected esophageal perforation. Gastrografin can cause pulmonary edema and severe pneumonitis if aspirated.

CT of the neck, chest and abdomen may be helpful if perforation abscess or fistula is suspected, or to visualize an object not seen with other modalities. In a 1999 study by Eliashar et al.,[11] helical CT was found to have sensitivity and specificity of 100% and 93.7%, respectively, for detecting esophageal bone impactions. CT imaging of the abdomen may also be used to characterize the location and extent of bowel obstruction for larger and more distal FB.

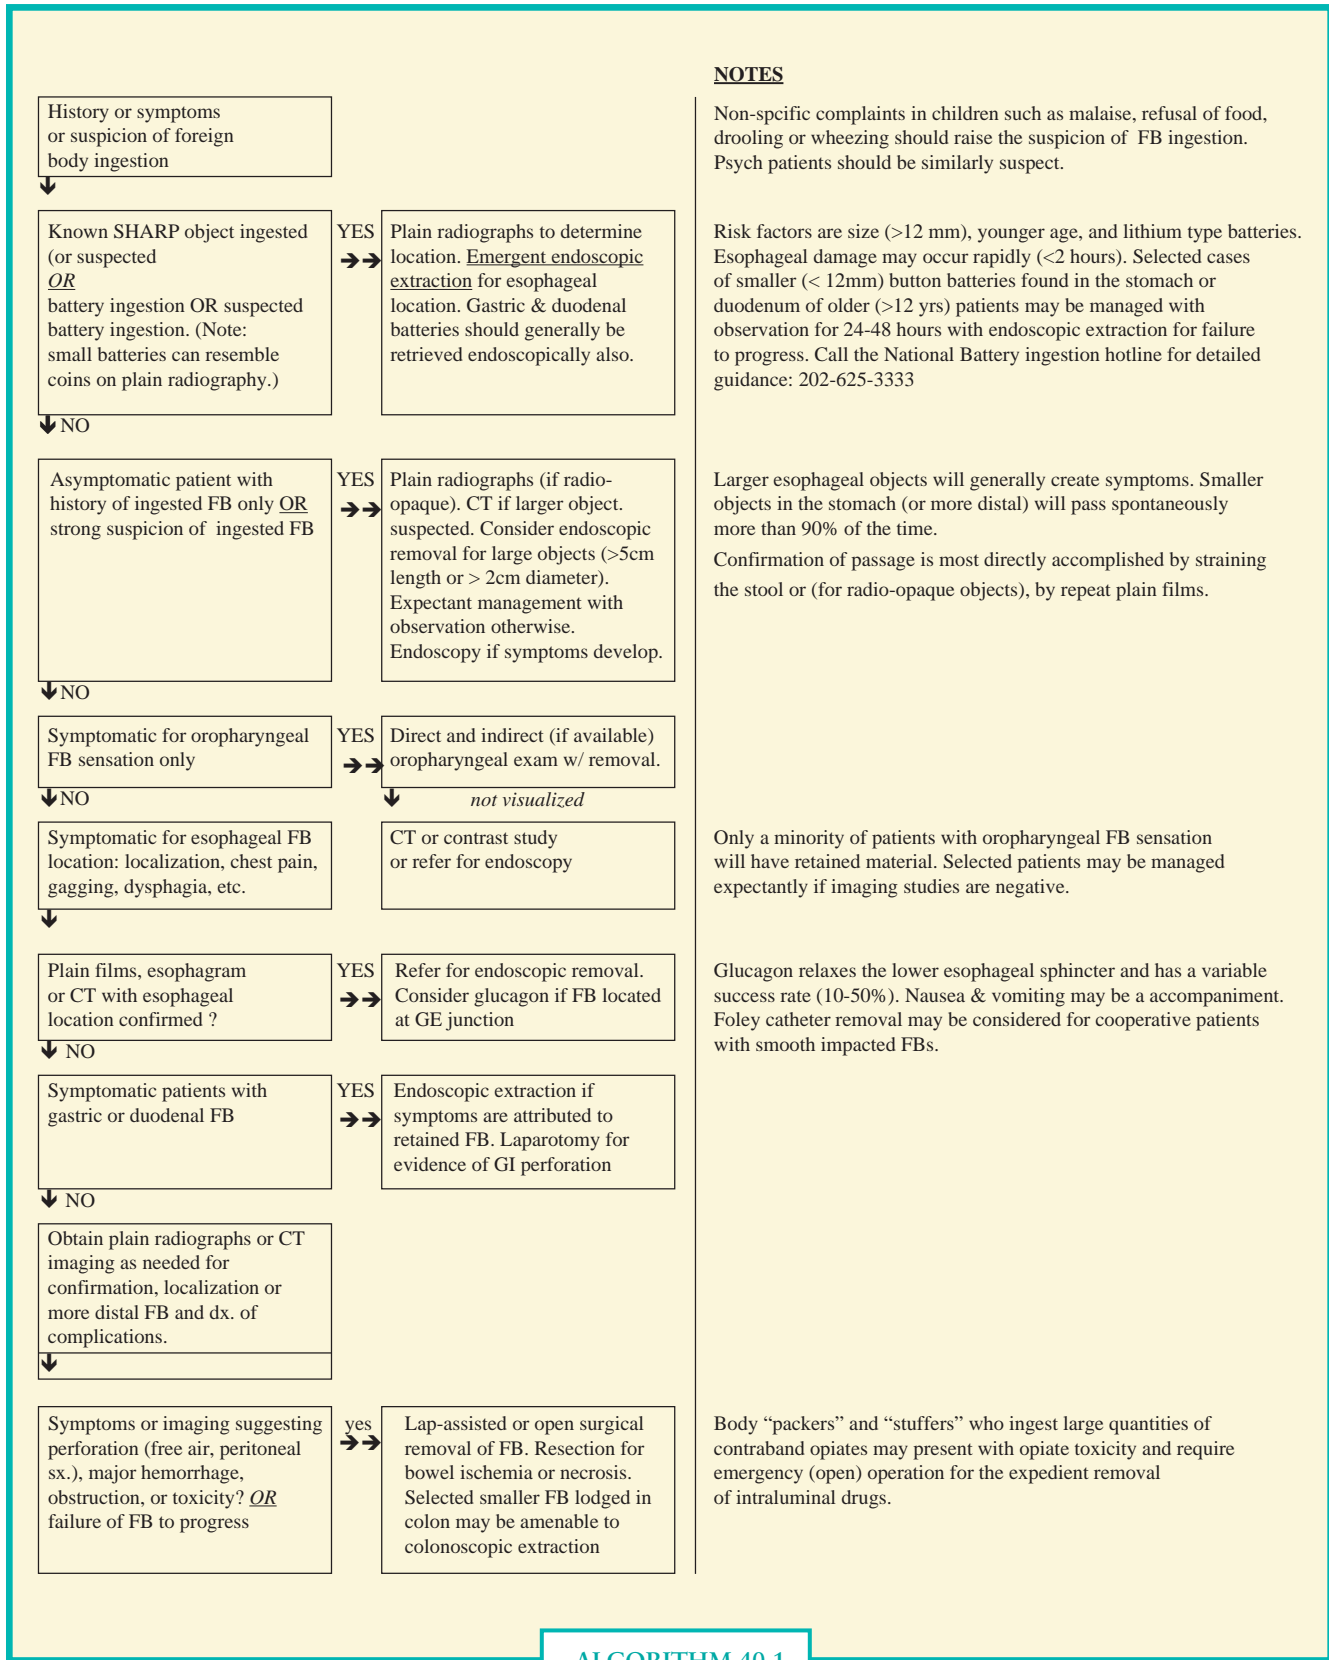
Flexible esophagogastroduodenoscopy is often both diagnostic (of the type and location of the impacted FB) as well as therapeutic (removal). Upper GI endoscopy has the additional advantage of diagnosis of the underlying pathology (e.g., web or stricture) which led to the impaction and to assess the degree of associated mucosal damage.

Clinical Management of Upper GI Foreign Bodies

Recognizing that the management of many cases of FB ingestion needs to be individualized, a general proposed management scheme is outlined in Algorithm 40.1. The discussion that follows roughly corresponds to the sequence outlined in the Algorithm 40.1.

Regardless of symptoms, there are two categories of FB ingestion that mandate early endoscopic retrieval: sharp or pointed objects in any accessible location (oropharynx, esophagus, stomach, duodenum), and small batteries often ingested by young children. As previously noted, the incidence of GI perforation with sharp/pointed objects is sufficiently high to justify pre-emptive retrieval.

In the case of battery ingestions, multiple mechanisms of injury are involved including electrical discharge and mucosal burns (that may occur very quickly), pressure necrosis with larger batteries, mercuric oxide toxicity, and caustic injury from leakage in a moist saline-rich environment. Most significant battery-related injuries occur in younger (age < 4 years) children ingesting cylindrical or larger (>18 mm) lithium type batteries. Liquefaction necrosis and perforation may occur rapidly (<2 hours) after the ingestion of these devices when they become lodged in the esophagus. Following radiologic confirmation of location and of battery versus coin ingestion, the former should be immediately removed via endoscopy to avoid serious or even fatal complications. If the battery cannot be extracted from the esophagus, an alternative is to push it into the stomach where it can be retrieved with a basket more easily. Batteries that have passed beyond the esophagus at presentation usually do not require removal unless the patient exhibits signs and symptoms of injury to the GI tract or a large diameter battery (those larger than 2 cm in size) remains in the stomach for greater than 48 hours as determined by repeat radiographs.[8]

In patients completely devoid of symptoms in whom a FB ingestion is known or suspected, plain radiographs may be obtained to verify ingestion, size, and location of radio-opaque objects. For non-radio-opaque objects, CT is usually necessary for visualization. Most patients with FB lodged in the esophagus will be symptomatic and will require endoscopic extraction. For those asymptomatic patients with gastric or duodenal FB, the decision to perform endoscopic extraction may be made on the basis of length (>5 cm for adults, 3–4 cm for children) or diameter (>2 cm). Asymptomatic patients ingesting smaller (nonsharp, nonpointed) objects may be managed expectantly and observed for the development of any symptoms.


NOTES

Non-spcific complaints in children such as malaise, refusal of food, drooling or wheezing should raise the suspicion of FB ingestion. Psych patients should be similarly suspect.

History or symptoms or suspicion of foreign body ingestion		

Known SHARP object ingested (or suspected *OR* battery ingestion OR suspected battery ingestion. (Note: small batteries can resemble coins on plain radiography.) **YES** ➔➔ Plain radiographs to determine location. <u>Emergent endoscopic extraction</u> for esophageal location. Gastric & duodenal batteries should generally be retrieved endoscopically also.

Risk factors are size (>12 mm), younger age, and lithium type batteries. Esophageal damage may occur rapidly (<2 hours). Selected cases of smaller (< 12mm) button batteries found in the stomach or duodenum of older (>12 yrs) patients may be managed with observation for 24-48 hours with endoscopic extraction for failure to progress. Call the National Battery ingestion hotline for detailed guidance: 202-625-3333

↓NO

Asymptomatic patient with history of ingested FB only <u>OR</u> strong suspicion of ingested FB **YES** ➔➔ Plain radiographs (if radio-opaque). CT if larger object. suspected. Consider endoscopic removal for large objects (>5cm length or > 2cm diameter). Expectant management with observation otherwise. Endoscopy if symptoms develop.

Larger esophageal objects will generally create symptoms. Smaller objects in the stomach (or more distal) will pass spontaneously more than 90% of the time.

Confirmation of passage is most directly accomplished by straining the stool or (for radio-opaque objects), by repeat plain films.

↓NO

Symptomatic for oropharyngeal FB sensation only **YES** ➔➔ Direct and indirect (if available) oropharyngeal exam w/ removal.

↓NO   ↓ *not visualized*

Symptomatic for esophageal FB location: localization, chest pain, gagging, dysphagia, etc. | CT or contrast study or refer for endoscopy

Only a minority of patients with oropharyngeal FB sensation will have retained material. Selected patients may be managed expectantly if imaging studies are negative.

↓

Plain films, esophagram or CT with esophageal location confirmed ? **YES** ➔➔ Refer for endoscopic removal. Consider glucagon if FB located at GE junction

Glucagon relaxes the lower esophageal sphincter and has a variable success rate (10-50%). Nausea & vomiting may be a accompaniment. Foley catheter removal may be considered for cooperative patients with smooth impacted FBs.

↓ NO

Symptomatic patients with gastric or duodenal FB **YES** ➔➔ Endoscopic extraction if symptoms are attributed to retained FB. Laparotomy for evidence of GI perforation

↓ NO

Obtain plain radiographs or CT imaging as needed for confirmation, localization or more distal FB and dx. of complications.

↓

Symptoms or imaging suggesting perforation (free air, peritoneal sx.), major hemorrhage, obstruction, or toxicity? <u>OR</u> failure of FB to progress **yes** ➔➔ Lap-assisted or open surgical removal of FB. Resection for bowel ischemia or necrosis. Selected smaller FB lodged in colon may be amenable to colonoscopic extraction

Body "packers" and "stuffers" who ingest large quantities of contraband opiates may present with opiate toxicity and require emergency (open) operation for the expedient removal of intraluminal drugs.

ALGORITHM 40.1

ALGORITHM 40.1 Suggested Management for FB ingestion (upper GI).

Patients symptomatic for FB sensation only in the oropharynx should undergo direct and indirect (if available) examination with extraction of any identified objects. For patients with a negative exam, imaging studies may be obtained (contrast swallow or CT) to stratify patients in need of endoscopic evaluation and extraction. As only a minority (<25%-30%) of these patients will have a retained FB, some authors advocate expectant management for those patients with negative examination and negative imaging studies of the oropharynx.

Retained esophageal FB typically produces symptoms including dysphagia, odynophagia, gagging, excessive salivation, chest pain or heartburn, and patients usually seek early medical attention. While the majority of these patients will require endoscopic FB retrieval, there are less invasive techniques that may obviate this approach. Glucagon has been administered in this setting in an effort to relax the esophageal smooth muscle and promote passage of smaller FB or food boluses. Glucagon is known to relax GI tract smooth muscle and has been reported to relax the LES (lower esophageal sphincter) by 60% in normal subjects after IV administration.[12] Despite its promise, results with glucagon have been mixed with its success rate being reported at anywhere from 12% to 50%.[12] Some authors have attributed this to the inability of glucagon to relax the fixed stenosis of esophageal strictures. Contraindications to the use of Glucagon include insulinoma, pheocromocytoma, Zollinger-Ellison syndrome, and known hypersensitivity to the drug.

Foley catheter extraction is another technique used in the emergency departments (EDs) with success reported at over 85%. It requires a cooperative patient, <72 hours since ingestion, and the absence of respiratory symptoms or underlying esophageal disease. Contrast esophagography is first performed to confirm location, size, and "smoothness" of the FB and to exclude significant esophageal disease or the presence of multiple ingested objects. The Foley catheter is passed through the nose past the FB and the FB is then displaced up into the mouth using a (distally inflated) balloon much like an embolectomy catheter removes a clot.

At this point in the management scheme, asymptomatic patients and those with more proximal impactions have already been managed, leaving symptomatic patients with ingested objects located in the stomach, duodenum, or more distally. As previously mentioned, larger objects (>5 cm length or >2 cm diameter) and sharp or pointed objects should
FIGURE 40.2. Obstructed small bowel. (Courtesy of Dr. Michael West.)

generally be extracted if endoscopically accessible in the esophagus, stomach, or duodenum. Past the duodenum, the next major anatomical obstacle is the ileocecal valve, but sharp or larger objects may hang up anywhere in the GI tract (Figs. 40.1–40.3). Management at this stage should be individualized based on the nature of the ingested object, symptom complex, and patient risk factors (including previous abdominal surgery). Indications for surgery include evidence of perforation such as free air on diagnostic studies or peritoneal signs, obstruction, major hemorrhage (rare), or the failure of the ingested object to progress through the GI tract after a "reasonable" period of time (typically 2–3 days). Surgery may also be indicated for the removal of higher risk FBs (particularly large or sharp) that cannot be extracted endoscopically or are not expected to pass.

An interesting but uncommonly encountered condition occurs exclusively in younger females who ingest substantial quantities of their own hair. These hair balls (trichobezoars), are highly resistant to GI peristalsis and usually accumulate in the stomach but may extend into the duodenum and even into the jejunum, constituting a condition known as the Rapunzel

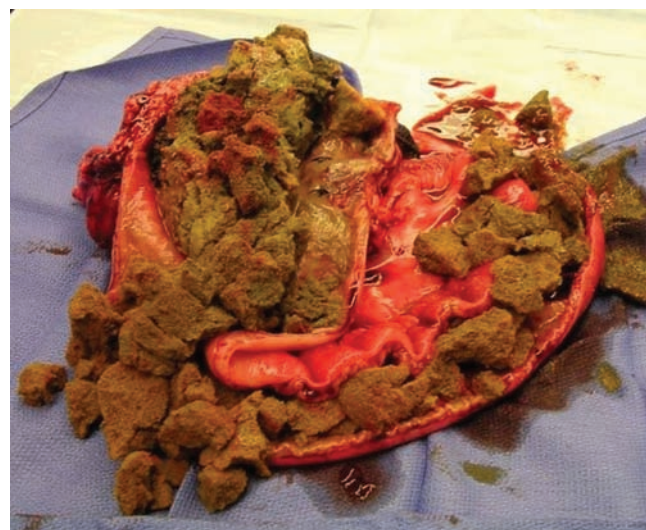
FIGURE 40.1. CT of small bowel bezoar. (Courtesy of Dr. Michael West.)


FIGURE 40.3. Bezoar containing furniture foam. (Courtesy of Dr. Michael West.)

syndrome. Most patients have associated psychiatric or eating disorders including trichotillomania (pulling out one's own hair), trichophagia (eating same), anorexia neverosa, depression, or pica. Complete endoscopic removal of large trichobezoars has proven difficult and most patients will require open surgical intervention for complete extraction.

The surgical procedures performed in the setting of complicated FB ingestions vary with regard to the level of the lesion and the severity of damage to the adjacent bowel. The variability of entrapped ingested objects and the limited number of cases requiring surgery do not allow any meaningful guidelines to be developed. In most cases the surgical approach is an extrapolation from management techniques applicable to other diseases or conditions.

As a general rule, larger FBs lodged in the GI tract may be identified and removed using laparoscopic assist techniques. Surgical options include simple enterotomy and extraction and repair or extraction and oversew of a small perforation with abdominal washout. Segmental ischemia or severe inflammation may require primary resection with anastomosis. More severe ileocecal lesions may require cecectomy or limited right colectomy. In most cases, a primary ileocolic anastomosis may be safely performed. Large, severely inflamed duodenal perforations, often more distal, may be the most troublesome, requiring complex or augmented repair (using small bowel loop or Roux-Y) with or without duodenal diversion. The morbidity of operation after perforation from a FB has been reported as high as 57% with mortality as high as 6%.[13]

One unique indication for surgical intervention pertains to the removal of wrapped packets of drugs, typically heroin, cocaine, or other opiates, that are swallowed and do not pass on their own causing obstruction or leak with systemic toxicity. This may occur with "body stuffers" or "body packers." These street slang terms denote users who more abruptly ingest quickly prepared packets of drugs to conceal them to avoid arrest and prosecution ("stuffers") and drug traffickers ("mules") who ingest more carefully wrapped packets of drugs for purposes of concealed transport. In addition to obstruction, these packets of drugs may leak or rupture, leading to GI absorption and overdose toxicity.

Risk factors for complications arising from ingested drug packets include: 1) a large number (>50) of packets, 2) large size packets, 3) signs of systemic toxicity, 4) bowel obstruction, 5) passage of disrupted packaging. Asymptomatic "stuffers" or "packers" may be managed expectantly with careful monitoring for laboratory of clinical evidence of drug absorption. Extraction of drug packets is indicated for obstruction, failure to pass, or evidence of systemic toxicity. Due to the greater likelihood of tearing the drug packets during retrieval, endoscopic removal is usually avoided. The preferred approach has been (open) laparotomy for both its speed and the lesser likelihood of inadvertent packet rupture.

FOREIGN BODY INSERTION (PER RECTUM)

Colorectal and lower GI tract FBs are approached and managed differently from those of the upper GI tract. Although one of the earliest case reports was published in 1919,[14] and Haft and Benjamin[15] referred to a case as long ago as the 16th century, retained rectal FBs were thought to be an uncommon occurrence in the past and more of a curiosity or a source of humor than a medical problem.[16]

Today, rectal FBs are no longer viewed as a medical oddity and have been reported with greater frequency in recent years. The vast majority of FBs ingested from above that are capable of making it past the esophagus, pylorus, duodenum, and ileocecal valve will rarely become lodged in the colon or rectum.

As a result, the great preponderance of rectal FB encountered by physicians are inserted from below.

The transanal introduction of FBs has been observed in penitentiary prisoners, psychiatric patients, in association with homicide and suicide attempts, as an accompaniment to various erotic acts including sadomasochistic practices, in cases of sexual aggression or rape, in people under the effects of drugs or alcohol, and in drug "mules."[17] Objects can be inserted for diagnostic or therapeutic purposes, or self treatment of anorectal disease, by criminal assault, by accident, or most commonly for sexual purposes. One recent systemic review found that 48.7% of cases were reportedly for sexual stimulation followed by personal care or self treatment of constipation, hemorrhoids or pruritis ani (25%), assaults (11.8%), and accidents (9.2%).[19] While there appears to be more reports of retained rectal FBs in the western literature, it occurs worldwide, with a consistent male predominance.[19] A very strong male predominance is supported by reports from Kurer et al., who observed a male: female ratio of 37:1 in their review of the literature in 2009,[16] and by Busch and Starling,[20] who reported it to be 28:1.

A wide variety of retained rectal FBs have been reported, ranging from glass bottles to household tools, dildos, vibrators, vegetables and fruits, and many more[20,21] (Fig. 40.4). Kurer et al.,[16] found that the most commonly retained FBs in their review were household objects (42.2%) and that they were generally bottles of various shapes and sizes and drinking glasses.

While a detailed history should of course, be taken, it is often the case that the patient will present to the ED only after multiple prior attempts have been made to remove the object. The circumstances and even timing of the FB insertion may change due to general embarrassment on the part of the patient. The presenting complaint may be rectal bleeding, diarrhea, constipation, or obscure abdominal pain[22] in the majority of patients, with the denial of the rectal insertion of a FB.[16] The history should include the size and character of the device and the time lapse between insertion of the object and presentation to the hospital. Symptoms such as nausea, vomiting and abdominal pain are very significant and may point to complete obstruction or perforation, especially if coupled with fever, tenderness or peritoneal signs on abdominal examination.

Despite the fact that most rectal FBs are inserted knowingly or with consent, the potential for assaultive mechanisms, including rape and domestic violence (DV) must be considered. Suspicious cases are best managed in conjunction with appropriate investigative process and with the involvement of sensitive rape or DV counseling. In some cases, patients may not be aware of the presence of a retained rectal FB and present with other complaints.

EMERGENCY SURGERY

Clinical Management of Rectal Foreign Bodies

As with upper GI FBs, cases of retained rectal FB are highly individualized, and a considerable degree of flexibility and even creativity may be useful in successful extraction and management. A general scheme for the management of rectal FB is presented in Algorithm 40.2.

General, acute care, and colorectal surgeons are the specialists most commonly consulted when a patient presents with a retained rectal FB as many of these patients will require FB extraction in the operating room, with some patients requiring more extensive colorectal procedures. The major initial

---

NOTES

History or symptoms consistent with rectal insertion and possible retained rectal foreign body	Rectal instrumentation in the absence of a retained FB may require imaging and/or sigmoidoscopic evaluation if significant damage or perforation of the colon or rectum is suspected.
↓	
Signs of sepsis or peritonitis — **YES** → → CT imaging if needed, resuscitation and immediate surgery for presumed colo-rectal perforation	Surgical management includes removal of FB, repair of the perforation, abdominal wash-out, and diverting colostomy if indicated. Resection for ischemia or irreparable perforation.
↓ NO	
Verification of retained FB: rectal exam (mandatory). Imaging studies if (-) exam or to characterize lesion as needed	
↓ NO	
Smaller object, very distal object, or one likely to be easily extractable — **YES** → → Moderate sedation, rectal local anesthesia as needed, attempted manual extraction (usually in ED).	Smaller (<5-6cm length, < 3-4 cm diameter), smooth FB may be managed expectantly in patient without symptoms. Endoscopic removal may be attempted for more proximal, small objects unlikely to pass spontaneously
↓ NO	↓
Large, more proximal, or unlikely to be easily extractable objects, *OR* unsuccessful attempted removal in ED, clinic, or ward	Successful removal ?
↓	
Transport to the OR for general or regional anesthesia. Exam and attempted extraction using various instrument & techniques — **YES** → → Post-removal sigmoidoscopy for evaluation distal colon & rectum	Full thickness lacerations seen on post-extraction exam mandate immediate surgery. Contrast studies may be used to further evaluate questionable perforations. Superfical mucosal lacerations may be managed expectantly.
↓ NO	
Successful ? — **YES** → → Post-removal sigmoidoscopy or colonoscopy w/ period of observation.	
↓ NO	
Laparotomy (limited initially) with intraabdominal manipulation & attempted removal via rectum. Successful ? — **YES** → → Intraoperative, post-removal sigmoidoscopy or colonoscopy. Routine post-operative care if no major injury to colon or rectum	
↓ NO	
Colotomy for intraabdominal removal of FB. Primary repair if colon is undamaged. Intraoperative sigmoidoscopy or colonoscopy.	Proximal diverting colostomy may be necessary for colo-rectal ischemia, rectal resections, or complicated repairs.

ALGORITHM 40.2

ALGORITHM 40.2 Suggested management for retained rectal FBs.

decision to be made is whether a given patient is best managed in the operating room or can potentially be managed in the ED or other treatment area. Evidence of colo-rectal perforation based on physical examination (peritonitis) or imaging (free air, rectal contrast extravasation, bowel ischemia, etc.) mandates operative exploration with or without a retained rectal FB. Other relative indications for using the OR as the venue for attempted FB extraction include large, sharp, pointed, or more proximal FBs, or those of a nature likely to make simple manual extraction difficult.

A digital rectal examination will often identify the presence of an object in the distal rectum. However, an object lodged at or above the rectosigmoid junction will not be palpable. Huang described these objects lying above the rectosigmoid junction (>10 cm above the dentate line in average sized adults) as high lying FBs, and reported that in his series, 33% of patients presented in this fashion.[18] Occasionally, objects will be palpable on abdominal examination either in the right or left lower quadrants.

Special attention should be paid to the condition of the anal sphincters on rectal exam. This is particularly important in patients who present without a previous history of FB placement or in those who are victims of assault. Many patients with retained rectal FBs will have lax anal sphincters from repeated anal penetration, however in patients without sphincter injury, the sphincters may have increased rectal tone secondary to muscle spasm. The examination and documentation of anal resting and squeeze tone along with perianal sensation is an integral part of the rectal evaluation.

Laboratory studies including white blood count can be used to assess the potential for occult perforation. Other lab values include an arterial blood gas or serum lactate suggestive of occult injury such as mucosal ischemia from pressure necrosis, or an extraperitoneal perforation which may not be immediately obvious on examination.[23]

Radiographic studies, specifically plain films of the abdomen (flat plate to include the kidneys, ureter and bladder, upright abdomen, and chest x-ray) will often demonstrate the size, shape and position of the object in the colon or rectum. Small air bubbles seen along the psoas muscle suggest a retroperitoneal rectal perforation but this sign is subtle and may not be appreciated. An upright chest radiograph may be obtained looking for free air under the diaphragm signifying an intraperitoneal perforation of the colon or rectum.[21]

In a stable or asymptomatic patient, an abdominal and pelvic CT scan will provide more detailed information regarding the size, character and location of the rectal FB as well as increasing the sensitivity for detection of extraperitoneal colorectal perforation. Rectal wall thickening, mesorectal air, fluid collections, and fat stranding all indicate a full-thickness injury and should be taken as evidence of perforation until proven otherwise.[23]

In the absence of colorectal perforation and for rectal FBs more likely to be extractable without general anesthesia, an attempt at transanal extraction of the FB in the ED or other treatment area may be undertaken. Some authors have further limited the patient population eligible for ED extraction to those whose FBs are narrow and made of either wood or latex rubber,[21] presumably because the ability to gain a purchase on the object with a tenaculum or Kocher clamp is easier when dealing with these substances.

Transanal Removal

If extraction in the ED is attempted, positioning and relaxation must be optimized. The patient may be positioned either in lithotomy on a pelvic exam table, in high lithotomy using candy cane stirrups, or in left lateral Sims position with the knees flexed to the chest making sure the buttocks are well off the bed. For relaxation and analgesia, a rectal field block may be administered subcutaneously, intersphincterically, and submucosally using either 0.5% or 1% Lidocaine (Xylocaine) mixed 50:50 with 0.5% Bupivicaine (Marcaine) both with epinephrine. A pudendal nerve block may also be used, infiltrating deeper tissues approximately 1 cm medial to the ischial tuberosities in the posterolateral location bilaterally.[23] Moderate sedation, typically with fentanyl and versed is usually necessary in addition to local anesthesia to ensure the patient's comfort during the procedure. Only after the patient has been sufficiently relaxed should attempts be made to remove the object.

If the object can be palpated lower in the rectum, the anal canal should be gently dilated to accommodate three fingers.[23] Attempts can then be made to deliver the object using any number of clamps or devices to extract the object. As previously mentioned, if the object cannot be palpated, or if aggressive actions are necessary to deliver the object, then the patient should be transferred to the operating room where more definitive anesthetic care can be delivered (deeper relaxation general or spinal anesthesia) before attempting to remove the object.

Lake et al.[24] noted that approximately one-third of the patients with rectal FBs had had an attempt at removal by the emergency medical service prior to the surgical service being summoned. This lead to successful removal of the object, in 16% of those patients, but in additional delay to treatment in the remaining 84%.

Whether the extraction is performed in the ED or the operating room, a rigid sigmoidoscopy should then be performed to evaluate the rectal mucosa, to ensure that there are no further objects within the colon, that there is no active bleeding and also to make sure there is no full-thickness injury to the bowel mucosa.

Extraction Methods

Multiple techniques have been proposed for removal of the myriad of objects that may be found as retained rectal FB, and a high degree of inventiveness is often helpful in devising "object-based" solutions.[25] For blunt or solid objects, most authors favor trying to manually remove the object and if that fails to use a Kocher clamp or ring forceps as graspers. The ability to use the surgeon's hand will depend on the laxity of the anal sphincters and also the density of the anal block (and the size of the hand). Patients treated under local or conscious sedation, may be asked to perform a Valsalva maneuver, to assist in the delivery of the object. Smooth objects such as bottles, jars, fruits and vegetables, dildos and vibrators often cannot be easily grasped, and care must be taken not to fragment the object *in vivo*. For glass objects this may lead to disaster, however, in the case of fruits and vegetables, fragmentation may actually assist in removal of the object, or in allowing the object to pass spontaneously. Schecter and Albo report using plaster of Paris powder mixed with water and inserted into the open end of the jar. As the plaster begins to harden, a ring forceps is introduced into the soft plaster and allowed to harden in place. The forceps can then be used to apply traction to extract the jar.[21]

Some smooth objects create a vacuum seal with the rectum making their removal more difficult. Several authors have reported the use of a Foley catheter, which is passed proximal to the object and followed by inflating the balloon. The inflation of the balloon and subsequent insufflation of the bowel proximal to the object can assist in breaking the vacuum, and the catheter can then be used as a handle to deliver the object thus manipulating it from both above and below. Other authors have reported using a Sengstaken-Blakemore or Minnesota tube in a similar manner to remove impacted jars.[23]

Obstetrical forceps and obstetrical vacuum devices have also been employed to break the vacuum seal, widen the canal and extract foreign objects. Graspers however, should not be used to extract drug packets found in body packers (see previous section). Instead, these patients should be admitted, hydrated and observed for spontaneous passage. If the patient remains stable without signs of perforation, then the packets will invariably descend to a level where they can be manually extracted. If signs of perforation or systemic toxicity occur the patient should be taken to the operating room and the packets should be rapidly removed via the rectum or through laparotomy with colotomy.

More recently, flexible endoscopy has been advocated as an adjunct to the extraction process. This approach has been reserved for those objects which are in the proximal rectum or in the distal colon.[24] Of patients presenting with retained FBs, 55% of those within the sigmoid required laparotomy versus only 24% of those in the rectum.[24] Endoscopy has been advocated as a possible way to avoid open surgery, by extracting the object using a polypectomy snare or by using the scope to break the vacuum seal of objects further in the anorectal canal and distal colon thereby removing objects that would otherwise not be amenable to transanal extraction.[23]

Surgical Management

As stated previously, there are several occasions where surgery for a retained rectal FB is necessary. The first is the failure of transanal extraction in the ED using moderate sedation, whether from inadequate relaxation or from position or composition of the object. If the patient requires deeper anesthesia, further transanal extraction attempts may be made in the operating room using the same or similar techniques employed in the ED. In addition, abdominal pressure applied to the left lower quadrant may help to propel an object caudally to allow for transanal extraction[22]—a maneuver usually too painful to be performed in a sedated patient in the ED.

The complete failure of all efforts at transanal extraction generally mandates a laparotomy to remove the obstructing object. Once inside the abdomen, manual "milking" of the object into the distal rectum may aid in the extraction transanally. If this is not successful, then a colotomy may be made and the object removed from the colon. In the absence of any significant colon or rectal damage, the colotomy may be repaired primarily. Fecal diversion is generally not necessary in these patients.

Patients presenting initially with sepsis and peritoneal signs, as previously mentioned, require aggressive resuscitation, broad spectrum antibiotics, placement of appropriate monitors, and emergent abdominal exploration. The decision as to what specific procedure to perform on this group of patients is dependent on the location of the perforation, the duration of the perforation and the delay to presentation, the degree of surrounding tissue injury, the amount of fecal contamination in the area, and the patient's physiologic condition. As a general rule, patients with established peritonitis, fecal contamination, and hemodynamic instability should be treated as any other unstable perforated colorectal patient with washout, FB removal, closure or resection of the site of perforation, and a "damage control" laparotomy with temporary abdominal closure and staged proximal diversion.

Management Post Removal and Potential Complications

Major complications following the extraction of rectal FBs are rare but can be life threatening if missed. All patients are observed for some period of time to assess their clinical stability prior to discharge. The length of this period of observation depends on the clinical stability of the patient, the length of delay to presentation, as well as how difficult the extraction was and whether it was transanal or via laparotomy. Patients undergoing transanal FB removal should undergo post extraction endoscopy, and serial abdominal examinations with follow-up radiograph as needed.[24,26] Bleeding from laceration of the rectal mucosa is usually self-limiting; however, on occasion these patients may require repeat examination under anesthesia and suture ligation of the bleeding vessel. Delayed perforation from occult colorectal injury following FB extraction is a more serious problem that can require emergent laparotomy and possible colostomy. Sphincter problems may also be encountered post extraction especially if the FB was the result of an assault. Repair of these injuries should be delayed until adequate evaluation of the symptoms and defects can be performed. Referral to a colorectal surgeon experienced in complex rectal sphincteric reconstruction is sometimes necessary.

SUMMARY

FBs of the GI tract continue to present a challenge to physicians and surgeons. Although the vast majority of ingested FBs will pass spontaneously, those >2 cm in size, or 5 cm in length are at increased risk of impaction. Button batteries and narcotic packets pose additional risks because of their potentially fatal consequences. Endoscopy is the preferred method of retrieval for most impacted, orally ingested objects. Surgical intervention is reserved for complications of upper GI FBs and for objects requiring removal beyond the duodenal sweep.

With regard to rectal FBs, an attempt at transanal extraction either under local, sedation or general anesthesia will often be successful. Patients require sigmoidoscopic or colonoscopic examination of the involved colon or rectum and observation for delayed complications. Failed transanal extraction mandates open surgical intervention for either augmented transanal or direct (colotomy) FB extraction.

EMERGENCY SURGERY

CHAPTER 41 ■ ANORECTAL ABSCESS AND INFLAMMATORY PROCESSES

HERAND ABCARIAN

ANORECTAL ABSCESS

Anorectal abscess is by far the most common colorectal disease requiring acute care and surgery. The overwhelming majority of anorectal abscesses originate from infection in anal glands, which drain into the crypts of Morgagni at the dentate line. Occlusion of the draining channel in bacteria-rich environment produces an abscess in the intersphincteric space before spreading to adjacent spaces (Fig. 41.1).

Other causes of anorectal abscess include Crohn's disease, rare specific infections such as tuberculosis, actinomycosis, and pinworm infestation in children. Trauma with external (penetrating) injuries or internal perforation of anorectum (from ingested sharp objects such as toothpicks, fish or chicken bones) may cause an abscess, which can also appear acutely or as a smoldering infection, often difficult to diagnose.

The presenting symptoms of anorectal abscess vary depending upon the extension of infection in perianal or perirectal spaces and whether the abscess is located proximal or distal to the anorectal ring (Fig. 41.2). *Low abscesses*, that is, those located distal to the anorectal ring, include intersphincteric, perianal or ischiorectal, depending on the anatomic site of the purulent collection between the sphincters, at the anal verge or in the ischiorectal fossa. These abscesses are associated with intense localized symptoms such as pain, swelling, erythema, cellulitis, tenderness, and fluctuation later in the disease process. In intersphincteric abscesses, the pain is aggravated with Valsalva maneuver (coughing, sneezing, laughing) On the other hand, the patient may have little or no systemic symptoms of fever, chills, and malaise, probably because of earlier diagnosis and intervention. The *low abscesses* are easier to diagnose, with the exception of posterior midline intersphincteric abscesses in male patients where the infection is sequestered in the intersphincteric or deep postanal space. The only way to reliably make the diagnosis is a careful bidigital examination, which may need to be done under anesthesia if the patient is in too much pain to tolerate examination otherwise. With the index finger, gently pushing posteriorly and the thumb pressing between the coccyx and the anus, the warm, tender swelling and induration can be easily palpated. The more superficial perianal or ischiorectal abscess can be drained urgently in the office, clinic, or emergency department with liberal use of local infiltration anesthesia.

High abscesses, that is, those located proximal to the anorectal ring (e.g., high intermuscular/submucosal or supralevator), often present with minimal local symptoms such as pelvic or rectal pressure on sitting or defecation. However, they may be associated with more systemic symptoms of fever, chills and malaise, and ketoacidosis in diabetics. These patients often identified as having "fever of unknown origin" are subjected to unnecessary laboratory and imaging studies and ineffective nonoperative treatment with oral or intravenous antibiotics. A high index of suspicion and a careful gentle rectal examination is all that is needed to arrive at the correct diagnosis. If the patient does not tolerate the examination in the outpatient setting, then he/she should be examined under anesthesia where proper and expeditious surgical procedure can be performed at the same time.[1]

The principle of surgical therapy of anorectal abscess is early, adequate, and dependent drainage. Small superficial abscesses may be drained under local infiltration anesthesia. A cruciate incision is preferable to a simple incision because its edges retract and the corners can be excised with a scalpel or iris scissors to create a small opening and prevent premature sealing of the incision with the thick proteinaceous pus. The incision should be made on the prominent point of the abscess and it must be placed as close to the anus as possible to shorten the length of a subsequent fistula should one develop postoperatively. Packing or placement of mushroom drains is usually unnecessary and may cause undue pain at insertion and removal.

Larger abscesses must be drained in the operating room under regional or general anesthesia. This allows exploration of adjacent spaces to drain the abscess thoroughly and also to probe and identify an associated fistula tract. If the abscess is very large, multiple openings (unroofing) is preferable to a long anteroposterior incision. Smaller (1–2 cm) openings can be connected with Penrose drains looped around the intact skin bridges and sutured to itself to maintain postoperative drainage as long as necessary. These openings heal within 4–6 weeks of removal of Penrose drains while a long anteroposterior, circumanal incision undergoes a step-off deformity (due to retraction of sphincter mechanism medially) and may take months to heal, leaving significant postoperative scarring.[2] Contrary to popular belief, there is no septation in an abscess cavity to be broken up. Exploration of cavity is only indicated to exclude extension to adjacent spaces.

If infection spreads bilaterally (horseshoe abscess), the patient should be taken to the operating room for adequate drainage. A horseshoe abscess always originates from an infection in the deep postanal space. If the surgeon is adequately trained to deal with the primary source, a midline sphincterotomy should be done. Otherwise, bilateral abscesses should be drained to deal urgently with sepsis and leave the fistula to be dealt with subsequently and in more experienced hands if necessary.

High abscesses need to be drained in the operating room under anesthesia for good exposure. If the submucosal or high intermuscular abscess bulges into the rectal lumen, it should be drained into the rectum. A small (1 × 1 cm) window overlying the abscess should be excised for biopsy as well as for prolonging drainage and to delay premature healing of the incision. A supralevator abscess pointing into the rectum may be drained in a similar fashion. But if it has tracked caudad into the ischiorectal fossa, as it often does, it should be drained through ischiorectal space, providing it with dependent drainage. A supralevator abscess should never be drained both through the rectum as well as externally as this will result in an extrasphincteric fistula, which is extremely difficult if not impossible to cure later on.[3]

The natural history of anorectal abscesses after early drainage is as follows: (a) It may heal and never recur; (b) It may heal and recur at the same area, months or years later; or (c) It may never heal and remain as a persistent draining sinus. The latter two scenarios signify the presence of a fistula. Therefore,
FIGURE 41.1. Left: Anal glands opening in anal crypts. Right: Extension of abscess to adjacent spaces: *1*. Submucosal; *2*. High intermuscular; *3*. Supralevator; *4*. Ischiorectal; *5*. Perianal; *6*. Intersphincteric.

in select cases when a fistula is identified at the time of abscess drainage and the portion of the sphincter mechanism overlying the fistula tract is very small, the surgeon may elect to perform a primary fistulotomy. This will treat the fistulous abscess definitively, shorten sick days, minimize morbidity, and prevent recurrences.[4] However, primary fistulotomy in inexperienced hands may result in unintended extensive sphincterotomy and subsequent fecal incontinence. Therefore, when a fistula is identified but the surgeon is uncertain about its extent and complexity, it is best to place a nonabsorbable braided suture (No. 1 or 2 silk) or silastic (vessel) loop into the tract, tying it loosely as a draining Seton. This will provide long-term drainage, prevent recurrence of abscess, and allow the definitive treatment of the fistula to be postponed to a later date or referral to a more experienced surgeon.[5,6]

FOURNIER'S GANGRENE

Fournier's gangrene or synergistic perianal or scrotal gangrene was first described in 1883. The symptoms and tissue necrosis may evolve rapidly, within a few hours in young men, or follow a more insidious course lasting 2–3 days in the elderly. Enriquez et al.,[7] in a retrospective comparison of Fournier's gangrene, found that those secondary to GI causes had slower onset than those related to GU causes.

The illness typically begins with perianal, scrotal or penile pain, swelling, fevers, chills, and urinary retention. Symptoms may be present for a few days but the patient may present with septic shock without anorectal or urogenital complaints. A careful history must be taken to elicit presence of comorbidities, especially instrumentation, unusual sexual practices, HIV, and most importantly, diabetes mellitus which is present in over 50% of the patients.

Physical examination reveals gross swelling of perineum, penis, scrotum, and gluteal regions (Fig. 41.3). Overlying skin may show purpura, necrosis (black spots), and is often associated with crepitus. In extreme cases, these signs may extend to thighs, groins, lower abdominal wall, and anterior or posterior chest wall. The area may be exquisitely tender but necrotic skin is often anesthetic. Spontaneous drainage from watery brown liquid to frank pus may occur and is associated with characteristic feculent odor. Signs and symptoms of systemic toxicity such as fever, tachycardia, hypotension, or altered mental status may be present.

In a compilation of 164 cases of Fournier's gangrene from the literature, Cataldo found 41% to be of GI and 30% from GU sources. In 36% of patients, the cause was not identified.[8] Given the frequency of GI causes, that is, abscess–fistulas, it is easy to picture the spread of infection penetrating Colles fascia, leading to scrotal gangrene. On the other hand, if Fournier's gangrene is a result of subclinical urinary extravasation (e.g., instrumentation), the infected urine spreads to corpus cavernosum and penetrates tunica albuginea, leading to involvement of Buck's fascia. Once Buck's fascia is transgressed, involvement of Dartos fascia follows. Dartos fascia is an extension of Colles fascia, which itself is an extension of Scarpa's fascia of the abdominal wall. Thus, infection may easily spread to the buttocks, thighs, groins, and along the abdominal wall.[9]

In cases of GI origin, gram-negative bacteria and Bacteroides species predominate; whereas in cases due to GU origin, *Escherichia coli* and Streptococcus species are most common.

EMERGENCY SURGERY

FIGURE 41.3. Fournier's gangrene involving bilateral ischiorectal fossa and scrotum.

In trauma-related cases, Staphylococcus and Streptococcus predominate. Irrespective of the source, bacterial synergism results in recovery of multiple types of organisms in over 80% of the cases, which includes Clostridial species as well. Pseudomonas is the most common pathogen found in gangrene associated with hematologic malignancies.[10,11] Just as there is no need for imaging studies to diagnose Fournier's gangrene, detailed, time-consuming bacterial cultures are often unnecessary as long as the treatment plan includes broad antibiotic coverage.

Treatment of Fournier's gangrene includes systemic resuscitation and support, broad-spectrum antibiotics, wide surgical excision, and debridement with delayed wound closure. Hyperbaric oxygen (HBO) therapy can be used as an adjunct but not in lieu of the above measures.

Systemic support includes administration of fluids and electrolytes, glucose control, and, in cases of septic shock, placement of central lines and pressors, as indicated. Broad-spectrum antibiotics to provide coverage for gram-negative rods, anaerobes, and clostridial species are essential. Surgical therapy includes debridement and excision of all necrotic areas. Lithotomy position allows access to perianal, perineal, external genital regions, as well as both groins and thighs. Debridement should be carried out to bleeding tissue. Anal sphincters and testicles are usually spared and need not be excised (Fig. 41.4).

In general, it is good policy to return to the OR in 24 hours to explore for further necrotic tissue left behind especially in questionable areas. If the patient remains febrile with elevated WBC, ESR, or CRP, a reexploration in 24–48 hours is mandatory. Suprapubic cystostomy is indicated for gross urinary leak (e.g., ureteral rupture 2° dilation of a stricture). Diverting colostomy should be reserved for patients in whom fecal contamination is a major problem. After initial aggressive debridement, the patient should be maintained on broad-spectrum antibiotics. Nutritional support is essential to aggressively combat the catabolic state.

HBO therapy has been used in the management of Fournier's gangrene. Even though the use of HBO is logically justified, no prospective randomized trials have been performed to study the efficacy of HBO. Published reports have dealt with small patient groups. HBO may be beneficial as bactericidal by increasing subcutaneous neovascularity, enhancing phagocytosis, inhibiting the production of Clostridial alphatoxins, bacteriostatic effect on many anaerobes (Bacteroids, Peptococcus, Peptostreptococcus) and actual bactericidal effect on Clostridium spores.

FIGURE 41.4. Same patient after third surgical intervention. Note scrotal debridement and multiple ischiorectal fossa counterincisions.

Fournier's gangrene remains a potentially lethal disease. Presence of advanced age, diabetes, alcoholism, and malignancy are associated with higher mortality.[12] Higher mortality in Fournier's gangrene of GI origin (28%) versus those secondary to GU disease (10%) has been reported.[6] Therefore, every effort must be made to control the spread of infection through wide debridement, supported with broad-spectrum antibiotics, nutritional support, and HBO. The survivors may undergo plastic and reconstructive operations, often in multiple stages, to provide skin coverage and preserve function.

ANAL FISSURE

The role of acute care and surgery in anal fissure is usually in two separate and distinct phases of the disease.

1. Acute anal fissure causes severe pain, which may last for hours following bowel movement and can be quite disabling. Gentle eversion of the anal canal by lateral traction on the buttocks generally helps in the diagnosis of midline anal fissure. In its acute stage, the base of this fissure is quite pink (corrugator ani muscle). Digital rectal examination is very painful, totally unnecessary, and must be avoided. Acute anal fissure will respond to bowel management (softening the stool), warm sitz baths, and use of "chemical sphincterotomy," a term used often to describe use of nitroglycerine, calcium channel blockers, and botulinum toxin in reducing the spasm and contracture of the internal sphincter which is the source of prolonged pain after defecation. 2% Diltiazem gel, 0.3% Nifedipine ointment, and 0.2% nitroglycerine ointment applied on anal surface two to three times daily often provides rapid pain relief. The main problem with all medications used to lower internal sphincter pressure is that even though temporarily effective, none is durable and the symptoms of fissure will recur in over 50% of the cases, necessitating surgical management.[13,14]

2. Chronic anal fissure can be just as painful as acute anal fissure. Gentle examination reveals that the midline fissure is lined with white fibers of the internal sphincter. It is unlikely for the medical management to succeed in such cases and elective lateral internal sphincterotomy is often necessary. Long-standing anal fissures may be associated with low intersphincteric abscess caused by infection undermining the posterior midline internal sphincter. Swelling, erythema, purulent drainage, or fluctuations are signs that mandate urgent surgical intervention. A minimal posterior midline internal sphincterotomy is all that is needed to unroof the abscess and lower the internal sphincter pressure permanently, allowing the fissure to heal. "Conservative" care using antibiotics, sitz baths, and analgesics are usually ineffective and delay the inevitable surgical procedure needed for permanent cure. There is minimal risk of fecal incontinence in conservative posterior midline fissurotomy and intersphincteric fistulectomy.

HEMORRHOIDS

Pelvic sepsis following rubber band ligation of hemorrhoids is a serious and potentially lethal complication if not diagnosed early and treated aggressively. Russell and Donahue originally described this complication in four patients. The warning signs of incipient pelvic sepsis are increasing pain after banding and dysuria or urinary retention. Spread of infection in perirectal tissues and pelvis is usually followed by septic shock and death.[15] If a patient complains of increasing pain after rubber band ligation of internal hemorrhoids, which is usually a

painless procedure, he/she needs to be immediately examined, especially if worsening pain is associated with dysuria. Examination under anesthesia shows the necrotic hemorrhoid often with the rubber band still in place, surrounded by an irregular grayish area, which is the spreading submucosal infection. The band must be removed, the necrotic tissue debrided to bleeding tissue at depth and periphery, leaving the wound open to heal by secondary intention. Intravenous broad-spectrum antibiotics should be administered and the patient monitored for signs and symptoms of sepsis.[16] Colostomy is unnecessary but repeat debridement is indicated if the patient remains septic. In the absence of aggressive therapy, death from septic shock may result.

Uncomplicated hemorrhoids generally do not cause infectious complications except when there is circumferential, prolapsed internal and thrombosed external hemorrhoids. These set of findings have been coined "acute hemorrhoidal disease" by Salvati.[17] This can be seen after severe traveler's diarrhea or in women who had undergone a prolonged, difficult vaginal delivery with instrumentation. Erosion of thrombosed hemorrhoids or pressure necrosis of the skin from large thrombosis may lead to a superficial abscess. The abscess must be drained but the remainder of circumferential hemorrhoids need not be excised acutely to avoid excessive excision of anoderm and postoperative anal stricture. It is best to inject the edematous hemorrhoids with a mixture of lidocaine, epinephrine, and hyaluronidase. The latter chemical breaks down tissue barriers and causes immediate spread and dissipation of the edema with resolution of symptoms.[17]

PILONDIAL CYST/ABSCESS

Is an acquired condition unrelated to the anorectum. However, when acutely infected, it required expeditious incision and drainage to prevent spread of infection. Waiting for the abscess to "point," results in the infection spreading through normal uninvolved skin. Large pilonidal abscesses should be drained and not excised primarily because there is a tendency to excise the edematous area of cellulitis, leaving wounds two to three times larger than if the same cyst is excised when quiescent. Infected cysts, especially in cases of hirsute patients, recurrent infections, free drainage of pus, and lateral extension of the abscess must be treated with only excision and not subjected to a variety of plastic surgical closures due to high failure of wound closures.[18]

EMERGENCY SURGERY

ABDOMINAL WALL HERNIAS: EMERGENCIES AND RECONSTRUCTION

TIMOTHY C. FABIAN AND MARTIN A. CROCE

INTRODUCTION

There are few conditions that test the combination of a surgeon's critical care skills, technical ability, and judgment more than a patient with an open abdomen. Successful management depends on appropriate initial operative intervention, temporary abdominal wall coverage (depending upon the etiology for open abdomen), delivery of surgical critical care, management of complications, and definitive abdominal wall reconstruction (AWR). The current chapter will address these issues. We will discuss acute abdominal wall coverage as it relates to the etiology of the defect and methods for temporary closure. Different options for definitive abdominal wall management will be presented, including technical points for reconstruction. Finally, data regarding outcomes for AWR will be presented.

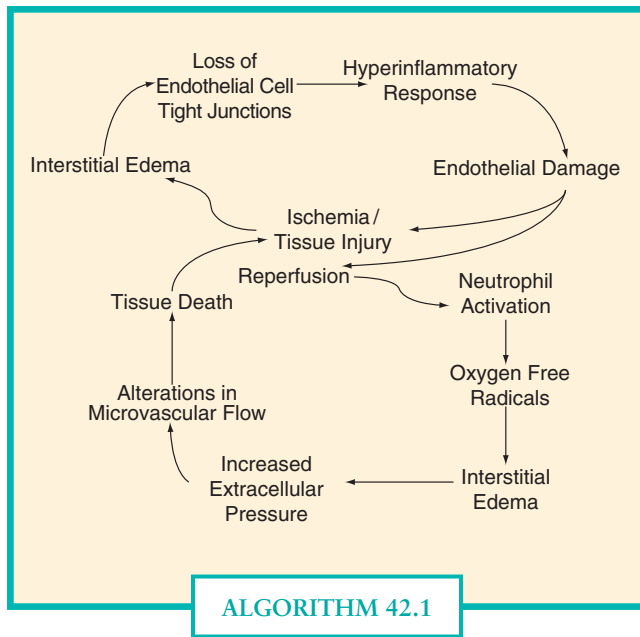
Acute Coverage: Etiology

Abbreviated Laparotomy for Trauma. The concept of abbreviated laparotomy for critically injured patients was described by Stone et al.[1] in 1983. They described the concept of addressing life threatening hemorrhage quickly followed by immediate closure of the abdomen without definitive management of the hollow organ or other abdominal injuries. Ligation of injured bowel segments to control contamination was recommended. Gauze packing of major hepatic injury or other areas of the abdomen with "nonsurgical bleeding" was used to control hemorrhage. Patients later returned to the operating room when hemodynamically stable for definitive management—bowel resection and anastomoses, ostomy creation, omental packing of hepatic wounds, etc. These investigators demonstrated improved survival in patients who had laparotomy terminated as rapidly as possible to avoid further hemorrhage and its sequelae—particularly coagulopathy. The concept of traumatic coagulopathy was subsequently expanded upon by Moore[2] who referred to the "bloody vicious cycle" of metabolic acidosis, hypothermia, and progressive coagulopathy. Subsequently, the term "damage control" was introduced by Rotondo et al.[3] to describe the abbreviated laparotomy as initially reported by Stone.

While the concept of abbreviated laparotomy undoubtedly has saved numerous lives, it was not without its own problems; we have in some sense traded morbidity for decreased mortality. Some patients had temporary abdominal closure with prosthetic material. Usually, this material was polypropylene mesh. Contact with the underlying bowel sometimes led to fistula formation, especially if the mesh was left long enough to allow ingrowth of granulation tissue.[4] If the skin was simply closed over the mesh, the mesh frequently became infected.[5-7] Other patients still underwent attempts at abdominal closure, with the hope that abdominal closure would allow the gauze packing to effectively tamponade exsanguinating hemorrhage. The packing was effective, but the increased abdominal pressure led to a series of physiologic perturbations. Profound respiratory failure, renal failure, and subsequent cardiovascular collapse were observed, leading to the recognition of the entity "abdominal compartment syndrome" (ACS).

Abdominal Compartment Syndrome. While compartment syndrome may occur anywhere in the body, it is more likely to develop in anatomic compartments with low compliance.[8] Common anatomic sites are extremities, the intracranial vault, and the abdomen. Regardless of location, the most likely final common pathway is an ischemia/reperfusion injury (Algorithm 42.1). Endothelial damage from ischemia/injury initiates a series of inflammatory cascades resulting in the loss of endothelial cell tight junctions and subsequent interstitial edema and cellular swelling. Continued ischemia further exacerbates the hyperinflammatory response, resulting in continued ischemia. Reperfusion, with its attendant neutrophil activation and oxygen-free radical production, further accelerates the cellular damage and interstitial edema. This causes dramatic increase in interstitial edema, resulting in alterations in microvascular blood flow. Typically, pressures around 25 mm Hg are necessary for reduction in microvascular flow. Left untreated, this cascade of events usually leads to cellular death in the compartment. It is important to realize that the detrimental edema and microvascular flow alterations require reperfusion; that is, resuscitation from shock. This phenomenon is most evident following revascularization of the lower extremity following vascular injury. If four compartment fasciotomies are performed prior to vascular repair, minimal swelling of the muscle is seen. However, when fasciotomies follow vascular repair, the muscle typically will bulge.

The pathophysiology of the ACS is similar. ACS may be viewed as a global ischemia/reperfusion injury, resulting in significant visceral edema. The three characteristics of ACS are respiratory insufficiency, decreased splanchnic flow, and diminished renal function. In a series of experiments in dogs, Richardson and Trinkle[9] created a model of progressive intra-abdominal hypertension (IAH). This linear pressure increase resulted in a dramatic increase in peak inspiratory pressures, decreased cardiac output, and venous hypertension in both the inferior vena cava and renal veins; all at an abdominal pressure of 25 mm Hg. These findings were confirmed in a porcine model by Diebel et al.[10] They demonstrated that increased abdominal pressures reduced cardiac output (without alterations in pulmonary artery occlusion pressures), decreased superior mesenteric arterial flow, and decreased mucosal pH.

The three types of ACS are primary, secondary, and recurrent. *Primary ACS* typically follows injury, shock and resuscitation, and laparotomy (either abbreviated with or without gauze packing); this type is most commonly seen. *Secondary ACS* is typically seen in patients who receive massive fluid resuscitation following severe injury,[11] burns, or resuscitation from sepsis.[12] Secondary ACS was originally described by Maxwell et al.[11] in seven patients who developed ACS without previous laparotomy. All patients had dramatic improvement


ALGORITHM 42.1

ALGORITHM 42.1 Ischemia/reperfusion injury.

following abdominal decompression. *Recurrent ACS* (formerly called tertiary ACS) is ACS, which recurs after initial treatment; likely due either to inadequate initial treatment or ongoing tissue ischemia.

In suspected cases with the clinical scenario of ACS, the diagnosis may be confirmed by measurement of the bladder pressure, which reflects abdominal pressure. There are many ways to measure bladder pressure,[13-16] and there are currently commercially available kits that allow continuous measurements. The World Society of the Abdominal Compartment Syndrome (www.wsacs.org) has offered standard definitions of IAH based on the intra-abdominal pressure (IAP) and standard methods of pressure measurement.[17] There are four proposed grades of IAH:

Grade I:	IAP 12–15 mm Hg
Grade II:	IAP 16–20 mm Hg
Grade III:	IAP 21–25 mm Hg
Grade IV:	IAP >25 mm Hg

Abdominal perfusion pressure (APP), which is analogous to cerebral perfusion pressure, may also be calculated:

$$APP = \text{mean arterial pressure} - IAP$$

Some have suggested that the APP is an accurate predictor of abdominal visceral perfusion.[18,19] A target APP of at least 60 mm Hg is associated with improved survival in patients with IAH and ACS.[18] ACS may be defined as sustained IAP > 20 mm Hg (with or without an APP < 60 mm Hg) that is associated with new organ dysfunction.[17] The management of patients with ACS is the same as for patients with compartment syndrome of any other body area; decompression. This, of course, results in a patient with an open abdomen. In less severe cases, nonoperative therapy may be beneficial.[20,21]

Severe Intra-abdominal Infection. There are instances when adequate source control may not be possible with a single laparotomy. Diseases such as perforated diverticulitis and necrotizing pancreatitis may result in diffuse suppurative peritonitis. Leaving the abdomen open in such instances allows easier access for repeat laparotomy for irrigation, debridement of nonviable tissue, and ultimately, source control. This

practice of repeat laparotomy has not been shown to improve patient outcome in controlled trials.[22,23] Nonetheless, it has its proponents and may be performed in the operating room or at the bedside in the ICU in selected cases.[24-26] More importantly, repeat laparotomy is frequently required to obtain effective source control, and the open abdomen can avoid the development of ACS in these critically ill septic patients.

Mesenteric Ischemia. The management of patients with acute mesenteric ischemia is facilitated by use of the open abdomen. The "second look" procedure allows assessment of bowel viability and resection of ischemic or necrotic segments, if necessary.[27] Ward et al.[28] demonstrated improved outcome in patients with delayed bowel anastomosis and repeat laparotomy. Park et al. demonstrated improved survival with bowel resection at either the first or second look procedure.[29] By leaving the abdomen open, even in the patient deemed low risk for development of ACS, the fascial edges are spared repeat fascial closures and necrotic fascial edges.

Abdominal Wall Loss. Necrotizing soft tissue infections of the abdominal wall are devastating disease processes. Adequate source control requires prompt diagnosis and operative intervention, which may necessitate debridement of large portions of the abdominal wall.[30,31] Interestingly, this problem has decreased in frequency with more liberal uses of the open abdomen. Leaving the abdomen open avoids tight fascial closure. This tight closure may result in strangulation of the fascia, which can serve as a nidus for infection in contaminated wounds.

Other causes of abdominal wall loss include shotgun blasts and high-velocity gunshot wounds. It is imperative to adequately debride these wounds. In the case of shotgun injuries, the shell and wadding are frequently imbedded in the tissue and must be removed. In the case of high velocity injuries, the missile tract should be debrided of nonviable tissue. The kinetic energy imparted to the tissue will cause more extensive injury, and these wounds frequently result in significant tissue loss. These wounds should be reexamined frequently, because they often will require further debridement.

Acute Coverage: Options. The primary goal of acute, temporary coverage of the open abdomen is protection of the underlying viscera. This should be accomplished without compromising the fascia in anticipation of subsequent abdominal closure or reconstruction. Effective temporary closure allows control of fluid losses and helps reduce the catabolism associated with large wounds. To these ends, there are a number of options for temporary closure. The primary options are plastic, absorbable mesh, a vacuum device, skin, and nonabsorbable mesh (Fig. 42.1).

Plastic Closure. One of the easiest devices to use for temporary abdominal closure is a sterile 2-L IV infusion bag. Surgeons in Colombia described its use years ago for temporary abdominal closure; hence the term "Bogotá bag." Another plastic device for acute coverage is the x-ray cassette cover. These are inexpensive, readily available, and can cover a large area if necessary. Plastic temporary closure is a short-term method for coverage since it is not particularly durable. The plastic is typically sewn to the skin edges allowing for a fairly rapid closure. Another advantage to using plastic for acute coverage is it allows the underlying viscera to be visually inspected. Plastic closure is generally during the first 48–72 hours postinjury as ongoing resuscitation is necessary. If the patient survives this initial phase after injury, a more durable method of temporary abdominal closure will be necessary.

Absorbable Mesh. The use of absorbable mesh for acute coverage affords more durability for temporary closure than

EMERGENCY SURGERY

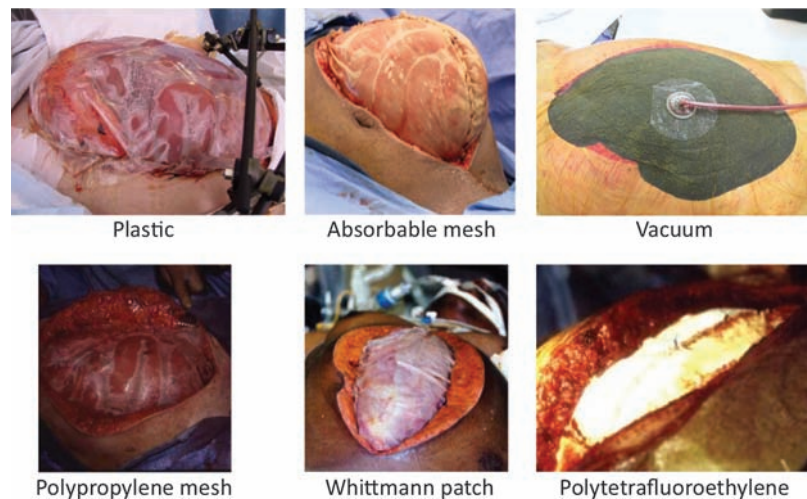
Polypropylene mesh   Whittmann patch   Polytetrafluoroethylene


does plastic. These meshes, polyglycolic acid (Dexon), and polyglactin 910 (Vicryl) may be sewn to the fascia and will prevent the progressive loss of abdominal domain that may be seen when the closure material is sewn to the skin. The authors' choice is woven polyglactin 910. It is not as elastic as polyglycolic acid or knitted polyglactin 910, but is similarly pliable. Since it does not stretch, it allows sequential pleating that can facilitate delayed fascial closure. It is important to note that pleating the mesh should be performed frequently to avoid adhesions between the viscera and abdominal wall. If the mesh is placed and no attempts are made to cinch and pleat it, adhesions will form, and the patient is destined for a planned ventral hernia. When the mesh is ready to be removed, it simply peels off the underlying viscera and early granulation tissue since there is a thin suppurative layer that forms under the mesh. In a small number of patients, there is rapid ingrowth of granulation tissue through the mesh. In these patients, skin graft may successfully be performed without attempts at mesh removal.

Vacuum Closure. Use of vacuum-assisted temporary abdominal closure is gaining in popularity due to its rapid placement and simplicity. There are also commercially available kits for vacuum-assisted closure of the abdomen. Since its original description by Brock et al.[32] in 1995, it has become one of the standards for acute coverage of the open abdomen. Whether the "homemade" vacuum device[32] or the commercial device is used, there are a number of real and theoretic advantages. Perhaps, the most important component is the sheet of plastic that is placed beneath the abdominal wall and superficial to the viscera. This sheet precludes adherence between the viscera and abdominal wall that may facilitate delayed fascial closure. Indeed, several investigators have reported high-delayed fascial closure rates for patients with vacuum-assisted acute coverage ranging from 65% to 100%.[33-35] However, only one prospective randomized study has been performed comparing vacuum with absorbable mesh for acute coverage of the open abdomen. Bee et al.[36] randomized 51 patients to either vacuum-assisted or polyglactin 910 coverage for patients with open abdomens.[36] There was no difference in delayed fascial closure rates (31% for vacuum and 26% for mesh). The lower delayed fascial closure rates occurred despite strict protocols with aggressive mesh pleating and repeated attempts at closure. It appears that the best predictor for delayed fascial closure is patient selection. It is unlikely that patients with massive visceral edema and hemorrhagic shock will undergo delayed fascial closure. On the other hand, patients without massive edema, or those left open for "second look" procedures, are excellent candidates for delayed closure. Regardless,

careful attention to the abdomen with repeated attempts at closure is required to optimize delayed facial closure rates.

Nonabsorbable Mesh. Early materials for temporary abdominal coverage included polypropylene mesh. This mesh was sewn to the fascia, preventing loss of domain. It was either removed when granulation tissue began to grow through the interstices or left in place. If removed, a split-thickness skin graft was placed over the wound. If left in place, full-thickness skin and subcutaneous tissue were typically mobilized and reapproximated. This method had the advantage of eliminating a large ventral hernia. There were two problems with this management; fistula formation and mesh extrusion. Fistula rates around 20% were reported, with progressive mesh extrusion even higher over time.[4,5,37] Since there are better alternatives available, there is little need for polypropylene mesh for acute coverage of the abdomen. Another nonabsorbable option is use of the plastic artificial burr (Wittmann patch). Velcro-type sheets are sutured to the fascial edges and allowed stepwise reapproximation of the fascia. Investigators have reported high-delayed fascial closure rates.[38] A modification described by Fantus involves placement of a plastic sheet beneath the abdominal wall, similar to the vacuum device, to prevent adhesions and facilitate closure.[39]

Skin Closure. In patients with relatively small fascial defects where delayed fascial closure cannot be accomplished, there are basically three options: allow the wound to granulate, place a split-thickness skin graft, or mobilize skin and subcutaneous tissue for approximation. The latter allows a better cosmetic result, but does not change the need for ultimate ventral hernia repair. Split-thickness skin grafting provides optimal coverage for large defects and is a key component in the staged management of AWR as described later. A subset of patients may benefit from immediate skin reapproximation with a series of towel clips or suture. This closure can be beneficial in patients without significant visceral edema and are at low risk for the development of ACS. For example, patients with acute mesenteric ischemia and a "second look" procedure may be ideal candidates for initial towel clip closure.

Complications. Given the fact that patients managed with an open abdomen are critically ill and injured, it is not surprising that complications are not uncommon. Most are related to the wound. Patients who have acute coverage material sewn to the skin may develop skin edge necrosis, a relatively minor problem. For those patients with the material sewn to the fascial edge, development of fascial necrosis may be a more serious issue. Both require debridement back to healthy, viable tissue.

Some patients have a persistent systemic inflammatory state, which precludes adequate mobilization of fluids. This results in persistent visceral edema along with an edematous, nonpliable abdominal wall. Regardless of the method of temporary abdominal closure, these patients will not undergo delayed fascial closure. Adhesions will develop between the viscera and abdominal wall, creating a "frozen abdomen." When this occurs, it is imperative to obtain biologic coverage of the open, granulating viscera. This is best accomplished with split-thickness skin grafting. Wound coverage will reduce the catabolic demand of the open abdomen[40] and reduce the incidence of formation of enteroatmospheric fistula.

An enterocutaneous fistula is an epithelialized communication between the gastrointestinal tract and the skin. An enteroatmospheric fistula is a hole in the bowel that is exposed in an open abdomen. Should such a fistula occur before the open abdomen has granulated, the management is resection; this is a rare occurrence and is usually the result of a technical failure. The new anastomosis should be buried beneath viable tissue (loops of bowel or the abdominal wall) so that none of the suture line is exposed. Unfortunately, most of the enteroatmospheric fistulae occur in patients with a frozen abdomen, making reoperation precarious at best.

In a prospective study on temporary abdominal closure, Bee et al.[36] noted an increased rate of fistulae in patients managed with vacuum closure. Further analysis identified the subgroup more prone to fistula development; patients with tube jejunostomies, placed either for nutrition or for management of duodenal injury. These fistulae were likely due to the plastic drape, which is effective in preventing adhesion formation. While adhesion prevention is advantageous when trying to gradually close an abdomen, adhesion formation between viscera and the abdominal wall is beneficial when patients have tube enterostomies. It is our current practice to avoid vacuum temporary closure in patients with tube enterostomies.

Prevention, of course, is the best course of action. The longer the granulating abdomen is left open, the greater chance for a fistula.[40,41] Jernigan et al.[40] demonstrated a significant association between a prolonged open granulating abdomen and fistula formation. In their series of 274 patients initially managed with an open abdomen, 129 patients either survived with an open abdomen or had fascial closure. Ten of these patients developed a fistula and had skin grafting almost 10 days later than those without a fistula. Thus, early grafting is important for fistula prevention.

Fischer et al.[42] evaluated 2,224 patients who had laparotomy for trauma and found 43 patients with fistulae (1.9%). The fistula rate for the 380 patients with an open abdomen was 8.4%; nearly 70% occurred prior to skin grafting. Of note, 37% of the fistulae closed spontaneously. Management of these patients is difficult; control of the enteric output and support of nutrition are paramount. Control may be obtained by various tubes placed in the fistula, but this is rarely completely successful and often enlarges the size of the enterostomy (Fig. 42.2).
FIGURE 42.2. Vacuum dressing for management of open abdominal wound.

The bowel is protected, and the sponge is cut around the fistula; this allows output control. Skin grafting may be possible around the fistula so that an ostomy bag may be placed. As long as nutrition can be maintained, these patients can then undergo fistula resection at the time of AWR.

DEFINITIVE ABDOMINAL WALL RECONSTRUCTION

There are several issues to consider in determination of the proper time for AWR following damage control operations. Ideally, secondary fascial closure can be undertaken during the initial hospitalization. Secondary closure eliminates the need for rehospitalization for reconstruction and its attendant morbidity and costs. Gradual pleating of the prosthetic bridge will permit secondary fascial closure in some patients. When negative pressure therapy has been used, secondary closure rates up to 90% have been reported.[33] Others have experienced much lower success, approximating 25%.[36] While all of the reasons for such disparity are not entirely clear, it is likely in part related to institutional biases for performing temporary abdominal closure. Those institutions that have liberal indications will perform temporary closure in less severely injured patients than in those centers with more conservative criteria. Less severely injured patients will develop less intestinal edema and will consequently have high-fascial closure rates following the index laparotomy. Other contributing factors might include fluid resuscitation protocols, and the degree of aggressiveness applied to fascial reapproximation.

Another approach to achieve abdominal closure during the initial hospitalization for those patients, in whom fascial reapproximation is not possible, is hernia repair with prosthesis prior to discharge. Since the wounds are heavily contaminated with ICU pathogens, the use of synthetic meshes is prohibited. Biologic meshes have been utilized for these reconstructions since they have been shown to be more resistant to infection than synthetics. Guy et al.[43] reported one of the initial experiences with that technique in 10 patients. Early results provided enthusiasm for that approach. Others series with limited numbers of patients and short follow-up have been reported.[44,45] While that technique has the appeal of eliminating future AWR, there are several drawbacks. Most of these patients are very early in their recovery from massive insults and hernia repair at that time adds further insult. They are relatively immunocompromised, and their healing ability is likely impaired. It would be anticipated that hernia repair failure rate will be high when long-term follow-up is achieved.

When the open abdominal wound cannot be closed during the hospitalization for injury, the patient becomes a candidate for delayed AWR. The intestinal contents are covered with skin during convalescence. Occasionally, full-thickness skin and subcutaneous fat are mobile enough to cover the open wound; more commonly, STSG is required. The length of the interval from hospital discharge to AWR must be carefully timed. Reconstruction should be delayed until the patients have recovered from their injuries and have resumed an anabolic state. If operation is done prior to resolution of dense adhesions and inflammation, results are significantly compromised and morbidity increased. Enterotomies are predictable and lead to infectious wound complications and failure of reconstruction. On the other hand, when reconstruction is excessively deferred, loss of abdominal domain progresses. Loss of domain puts more tension on the repair and increases hernia recurrence rates. AWR should generally be undertaken 6–12 months following initial wound coverage. It takes that time for dense adhesions and inflammation to resolve with the development of predominantly filmy adhesions. This process

EMERGENCY SURGERY

can be easily followed by examination of the wound when a STSG has been used. During the early stages, the abdominal contents can be determined by palpation to be primarily an indurated sheet with minimal ability to separate thickened bowel loops. As time passes, resolution of the induration can be appreciated on examination. Eventually, the STSG can be pinched between the examiner's fingers and loosed adhesions appreciated along with the separation of nonindurated small bowel loops. Those findings signal the correct time for AWR.

METHODS OF RECONSTRUCTION

Two basic types of procedures are employed for delayed reconstruction. AWR can be accomplished by either prosthetic hernia repair or autologous tissue transfer. Autologous repair of these defects is usually by a component separation technique. The majority of reconstructions in North American are done with prostheses. A major advantage of this approach is the relative simplicity of repair and the ready availability of material for fascial replacement. Significant disadvantages include prosthetic infection, gastrointestinal fistulae, and repair failure with hernia recurrence. Mesh infection and fistula formation essentially always require mesh removal, a generally unpleasant task. The subsequent, tertiary reconstruction adds another layer of difficulty and even higher failure rates. While there is less experience with components separation reconstruction, advantages of autologous tissue transfer include avoidance of implantation of foreign material with the potential for fewer septic complications and a lower fistula rate. However, autologous tissue procedures are more complex and have the potential for wound complications including skin necrosis, wound infection, and repair failure.

Prosthetic Reconstruction

A wide variety of techniques described for prosthetic hernia repair and a vast number of prosthetic materials are available. Prosthetic use has become routine over the past two decades. Prior to that, direct suture of the fascial edges resulted in a 54% failure rate for ventral herniorrhaphy.[46] Failure occurred primarily due to closure under tension. Nearly all hernias larger than 3 cm are now repaired with prostheses. In the early years of prosthetic utilization, ventral hernia repairs were most commonly done by a fascial "bridging" or "inlay" technique. Following mobilization of skin flaps and dissection and excision of the hernia sac, healthy fascial edges were defined circumferentially. The edges of the prosthetic material are sewn to the edges of the fascia with either running or interrupted suture technique. Reports with long-term follow-up revealed high recurrence rates. Failures occurred where the prostheses pulled away from the fascial edge. Those poor results paved the way for the investigation of other surgical techniques.

Initial advances were made by overlapping the prostheses 3–5 cm beyond the fascial edge. Stoppa and Rives[47,48] led the way in this innovation. They described extraperitoneal mesh placement between the rectus muscle and posterior fascia with the wide overlap. Mesh placement in such fashion leads to tension-free attachment with a large surface area for tissue incorporation. It has been subsequently demonstrated that polypropylene meshes contract up to 30% over time,[49] providing a rationale for the overlap and perhaps explaining the higher recurrence rate with bridging techniques. The Rives-Stoppa technique of overlapping mesh 3–5 cm or more beyond normal fascial edges has been deemed the "gold standard" for prosthetic repair by the American Hernia Society.[50]

Intraperitoneal foreign material carries the small but real risk of gastrointestinal erosion. Novitsky et al. have supported placement between the peritoneum and posterior fascia.[9] Placement of mesh in the retrorectus position is commonly referred to as an "underlay" technique. Using Stoppa's basic premise, others began placing mesh as an "onlay" anterior to the rectus fascia. Hence, the different techniques have been variously accompanied with peritoneal or posterior fascial closure to avoid direct bowel contact. A group from the Netherlands, led by de Vries Reilingh, has made many important contributions to the field of complex ventral hernia repair. They compared onlay, inlay, and underlay techniques (Fig. 42.3).[51] The underlay technique was associated with the lowest recurrence rate, 12% compared with 44% for inlay ($p = 0.03$) 23% for onlay (NS). The onlay technique had significantly higher wound complications compared with both of the others. The underlay technique has the greatest support at this time. Up to this point, only the basic components of mesh repair have been considered. A more confusing and controversial area is the type of mesh chosen for repair.

Mesh Types

A large array of mesh products are available for AWR. The surgeon is challenged to sort out the pros and cons of the varied materials. Unfortunately, there is little follow-up available to make truly informed decisions regarding mesh selection. Be that as it may, a general classification will follow in an attempt to highlight properties that merit consideration when considering mesh products for AWR.

Traditionally, the ideal fascial substitute was considered to possess the characteristics of strength, infection resistance, and being noncarcinogenic, and biologically inert. However, as we now know, the characteristic of being biologically inert has instead become a desirable feature that has attracted much attention and investment. There are currently three broad mesh categories: synthetic absorbable, synthetic nonabsorbable, and biologic. An excellent review of the available products was recently published.[52]

Absorbable meshes (glycolic acid and polyglycolic acid) are an important instrument in the toolbox of the acute care surgeon. They are a serviceable adjunct for temporary abdominal closure (discussed earlier in this chapter) and for coverage of defects associated with major abdominal wall loss from trauma or infection. However, they are not appropriate for definitive AWR since they will be totally absorbed between 3 and 6 months, and result in a 100% hernia recurrence rate.

Synthetics meshes have a long and interesting surgical history. While an in-depth historical discussion is beyond the scope of this chapter, a brief synopsis will aid in appreciation of the evolution of these products. A timeline for various materials is demonstrated in Figure 42.4. Prostheses for hernia repair were introduced in the late 19th century. The earliest materials were silver.[53,54] Silver is bactericidal and was associated with low recurrence; but the material fragmented over time and that deterioration was associated with fluid accumulations and sinus tracts. Nonetheless, it was the primary material used for half of a century. The chemical element tantalum (Ta) was introduced next.[55] Tantalum is a hard, corrosion resistant, inert material. Not surprisingly, it was associated with fistulae, and its use was relatively short-lived. Polyethylene terephthalate, a polyester fiber (Dacron), enjoyed another relatively short life for hernia repair,[56] but it has had a successful run as a vascular conduit since its introduction for that purpose by Michael DeBakey.[57] Polypropylene mesh was introduced in the late 1950s as Marlex. After a run similar to silver of
FIGURE 42.3. Reconstruction of a large incisional hernia using the (**A**) onlay, (**B**) inlay, and (**C**) underlay technique. PPM, polypropylene mesh; *1*, rectus abdominis muscle; *2*, the external oblique muscle; *3*, the internal oblique muscle; *4*, transverse muscle; *5*, peritoneum.

another half century, polypropylene has continued supremacy as the most common material used for ventral hernia repair today.[52] Polytetrafluoroethylene (PTFE) was introduced for hernia repair in 1970 and has remained the only real challenger to polypropylene as a synthetic prosthesis for hernia repairs. PTFE is a fluorocarbon that is extremely nonreactive and durable.

Polypropylene was first introduced in its heavyweight form (Marlex and Prolene) and is now also available as a lightweight mesh (Vypro). The heavyweight meshes have a tensile strength six times that of the abdominal wall, while the lightweight has strength similar to the abdominal wall.[58] Heavyweight meshes have been associated with chronic pain more frequently than those with lightweight mesh repair.[59] Data derived from implantation in animals suggest that there may be less inflammation associated with the lightweight materials and have less shrinkage and contraction over time.[60,61] However, there

is no clinical data that demonstrates clear superiority of any particular polypropylene product. It is widely accepted that polypropylene should not be placed in direct contact with the abdominal viscera.

Expanded polytetrafluoroethylene (ePTFE) provides the advantage of being biologically inert. This provides an appealing characteristic for intraperitoneal insertion. But that non-reactivity creates somewhat of a double-edged sword. ePTFE becomes incorporated to a lesser degree than polypropylene with less connective tissue ingrowth, contributing to higher recurrence rates at the mesh-fascial interface. Wound seromas are more commonly associated with ePTFE. For abdominal wall repairs, ePTFE is currently most commonly used in laparoscopic repairs or as a composite.

There are problems with both polypropylene and ePTFE meshes when used for AWR. A major drawback of polypropylene is when it is placed in the intraperitoneal surface and has potential contact with the gastrointestinal tract, there is a substantial risk for fistula to develop; fistula rates as high as 28% have been reported.[62] A disadvantage of PTFE is a tendency to not become incorporated well into the tissue. That may lead to hernia recurrences and to wound seromas. To surmount both of these shortcomings, products have been developed with coupled surfaces. The polypropylene surface is intended for use in contact with the abdominal wall fascia or muscles while the smooth PTFE side is intended for apposition to the bowel. While polypropylene is used in the major of these composite products, the undersurface has also been coated with various polymers including cellulose polymers instead of the PTFE. Another product, DualMesh, is a double-sided

Timeline of Mesh Introduction

ePTFE prosthesis with differing surface properties on each side to allow for tissue incorporation on one and a smooth surface to avoid bowel erosion on the intra-abdominal surface. Most reports on these composites are in animal models, with the majority supporting the dual concepts of increased incorporation and decreased risk for erosion. However, there is minimal data from clinical trials to prove their superiority.

Biologic meshes were clinically introduced 20 years ago. Initial applications were for the treatment of third-degree burns, breast reconstruction, bladder slings, and an assortment of occasional reconstructive applications. They are derived from human, bovine, and porcine sources. The tissues are chemically decellularized, which leaves a lattice of collagen, elastin, and laminin for neovascularization and tissue regeneration. The primary products that are available at this time are human acellular dermal matrix (HADM), porcine acellular dermal matrix (PADM), and porcine small intestinal submucosa (PSIS). As previously noted, HADM has been used for one-stage AWR following damage control laparotomy in a small number of patients. When used for primary hernia repair, HADM has resulted in high eventration rate related to stretching of the material and 20% hernia recurrence rate when used as a reinforcement of fascial repair.[63] Eventration has not been less problematic with the other biologic meshes. HADM is harvested from cadavers, and it might be anticipated that there would be substantial variability among sections as opposed to the uniformity of synthetic materials. The PADM would seem likely to have more uniformity than HADM, but there has been minimal clinical study. Laboratory studies demonstrated that biologic prostheses placed intraperitoneally resulted in neovascularization and attained tensile strength greater than the surrounding tissues.[64] Currently, the greatest advantage for the biologic meshes is their use in contaminated fields. They resist infection to much higher degrees than synthetics; HADM may be more resistant than PSIS.[65,66] When surgical site infections develop, wounds with exposed biologic meshes can usually be managed with negative pressure dressings and mesh salvage. After a period of several weeks, neovascularization produces granulation tissue, which will be a satisfactory bed for STSG. That cannot be accomplished with synthetic meshes; the wound may clean up and even allow for skin closure. But they always become reinfected, sometimes in a few days, sometimes in a few weeks. Infected synthetic mesh requires excision.

It is important for surgeons to understand financial impacts of our management strategies. The most expensive prosthesis is HADM averaging $26.00 per cm²; bovine and porcine-based material cost between $8.60 and $22.00 per cm²; absorbable mesh such as Vicryl and polypropylene cost $.20 per cm² and $1.00 per cm², respectively. A cost comparison of the different meshes demonstrated wide variation. The average size of defects resulting from temporary abdominal closure techniques that cannot be closed at the initial hospitalization has been reported from 600 to 960 cm.[36,41,67] Closure of those defects with biologic prostheses as inlays or fascial bridges would result in expenses of $15,600-$24,960.

Components Separation

Mesh reconstruction of the large abdominal wall defects resulting from damage control procedures is plagued by prosthetic infection and hernia recurrence. Intestinal contamination predisposes to those complications. Intestinal stomas and fistulas are common antecedents in these patients, and enterotomies

during dissection at the time of AWR occur in 30%.[69] In 1990, Ramirez et al. first described the components separation technique for AWR.[30] This method of reconstruction relies on autologous tissues with local myofascial tissue advancement rather than mesh. The concept is simple and based on "relaxing incisions."

Incision of the external oblique component of the anterior rectus fascia is done bilaterally. Incision is begun in the midabdomen approximately 1–2 cm lateral to the rectus sheath. The incisions are extended superiorly over the costal margin and inferiorly to the area of the pubis. The plane between the external oblique and internal oblique muscles is then bluntly dissected laterally to the region of the anterior axillary line. The posterior rectus fascia is mobilized from the rectus abdominus muscles. This completes mobilization of the anterior rectus fascia and rectus muscle. The anterior fascia and muscle are approximated in the midline. This procedure provides advancement of approximately 10, 20, and 6 cm in the upper, mid, and lower thirds of the abdominal wound.[69] This procedure works well for moderate size hernias, but the majority of defects resulting from damage control laparotomy cannot be closed in a tension-free manner and require mesh supplement for repair. To accomplish closure of these very large defects with a minimal need for adjunctive mesh, we developed a modification of the Ramirez technique.[70]

Modified Components Separation will be described as a series of steps (Fig. 42.5).

Step 1. STSG Removal. This begins in an area that has loose adherence of graft to viscera, usually in the midabdomen. The graft is sharply incised and with a combination of blunt and sharp dissection the graft is freed from bowel, omentum, and liver. Adhesions are usually filmy, but are dense in some locations. Small areas of intact skin may be left without sequelae. There are usually dense adhesions of the skin to the liver, and caution should be taken to avoid disruption of Glisson's capsule in order to avoid troublesome bleeding. Dense adhesions are also encountered at the musculofascial junction. The STSG is excised from the abdominal wall to preserve the skin edges. Following graft excision, lysis of adhesions of viscera to the anterior abdominal wall is performed laterally to expose the posterior fascia for tissue advancement, generally to the region of the anterior axillary line. Step 1 usually takes 45–60 minutes; if adhesions are dense, this may take hours. Be prepared for a long operation and proceed with patience. Ostomy reversal is done at this time.

Step 2. Full-thickness Skin Flaps. Dissection is begun in the anatomic plane just superficial to the fascia. This is avascular except for musculocutaneous perforators. These should be preserved whenever possible to avoid wound problems associated with skin necrosis, which is rare. The flaps are raised to the area between the anterior and midaxillary lines to gain mobilization for midline closure. Meticulous hemostasis should be established to minimize infection and seroma formation.

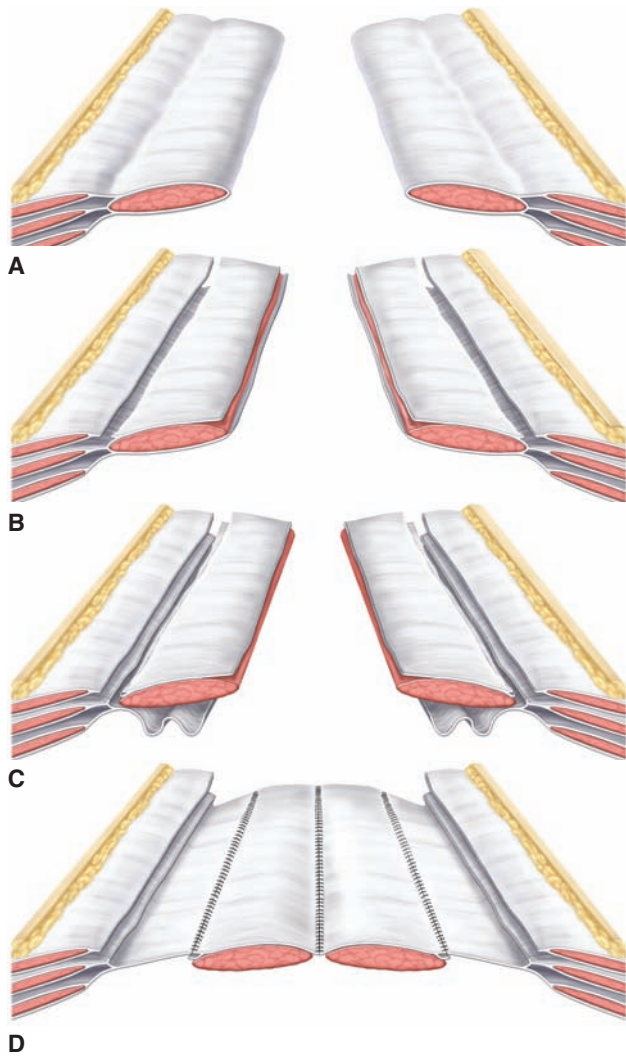
Step3. Release of External Oblique Component of Anterior Rectus Fascia. The lateral edge of the rectus muscle is easily identified and confirmed by placing a hand in the abdomen with the palmar surface in contact with the posterior rectus sheath and the thumb on the anterior rectus sheath. In this manner, rubbing the fingers and thumb easily identifies the lateral border of the rectus muscle. A nick is made 1–2 cm lateral to that, which incises the external oblique component of the anterior rectus sheath, leaving the


FIGURE 42.5. Modified components separation technique for AWR. (**A**) Normal anatomy above the arcuate line. (**B**) The posterior rectus sheath is mobilized from the rectus muscle, and the external oblique fascia is divided. (**C**) The internal oblique component of the anterior rectus sheath is divided down to the arcuate line. (**D**) Completed repair, suturing the medial border of the posterior sheath to the lateral border of the anterior sheath, with approximation of the medial portion of the anterior sheath in the midline.

interior oblique component intact. A hemostat is inserted, and the external oblique fascia is incised superiorly over the costal margin 5–7 cm, which results in division of some lower fibers of the serratus anterior muscle attachment. The external oblique fascia is incised inferiorly to the level of the pubis. The loose areolar tissue between the external and internal oblique muscles is then bluntly dissected to maximize medial mobilization.

Step 4. Dissection of the Posterior Rectus Sheath. The medial edge of the rectus sheath is incised for the entire length of the muscle. There is dense scar on the medial aspect that requires excision. This exposes the anterior and posterior fascia and muscle as three separate layers. The posterior sheath

is freed from the muscle, the length of the muscle. Just below the umbilicus, the arcuate line can be seen, below which there is peritoneum but no posterior fascial component. The inferior epigastric vessels enter around the arcuate line, and care is necessary to avoid injury since they provide the great component of the blood supply to the rectus mechanism. Steps 1–4 comprise the Ramirez components separation, and if the wound can be closed without tension, the procedure is complete. The remaining steps make up the Memphis modification for wounds under tension.

Step 5. Release of Internal Oblique Component of the Anterior Rectus Fascia. Following release of the posterior sheath, a hand is placed between the rectus muscle and posterior sheath. With the hand cupping the muscle, the index finer should be at the most superior portion of the sheath. The anterior fascia is sharply incised over the index finger. This opens the anterior portion of the internal oblique fascia, while protecting the posterior sheath. A finger can then be seen through this incision. Using electrocautery, an incision is made through the interior oblique component of the anterior rectus fascia, stopping at the arcuate line. Further division inferiorly would create a lateral hernia defect since there is no posterior rectus fascia below this point. The rectus muscle with the adherent anterior sheath will be free medially and laterally.

Step 6. Translocation of the Anterior Fascia and Muscle. After release of the internal oblique fascia, the rectus muscle and anterior fascia will be attached only at the most superior and inferior portions. The posterior sheath remains in continuity with the native abdominal wall laterally. The rectus muscle and anterior fascia can be pulled medially, and this provides the additional mobilization gained by the modification. The medial aspect of the posterior sheath is sutured to the lateral aspect of the anterior sheath.

Step 7. Wound Closure. The anterior sheath is sutured in the midline. This results in three separate suture lines. The most difficult portion to gain adequate length is in the epigastric area. If closure cannot be accomplished without undue tension, mesh adjuncts will be required. This is necessary in 10%-20% of cases and is currently done with biologic mesh placed as an underlay. Four closed suction drains are placed and the skin closed. Abdominal binders are used in the postoperative period.

Aggressive pulmonary toilet and early mobilization are necessary postoperatively. Heavy lifting should be avoided for several months. Wound infection and necrosis of the medial skin edges are the major complications. Patients with thin body habitus are at greatest risk for skin necrosis. When major wound complications result in an open wound, negative pressure dressings are employed.

In evaluation of any surgical procedure, and especially when evaluating the success and failure rates of ventral hernia repair and AWR, careful consideration must be given to follow-up. We recently evaluated our AWR results from a 15-year experience.[71] Figure 42.6 clearly demonstrates that patients will continue to develop hernia recurrences for up to 4 years, and recurrences appear to cease at that time. Few ventral hernia studies report that duration of follow-up, and it is nonexistent for AWR following damage control procedures. This same principle applies to those patients who have secondary fascial approximation during the same hospitalization as the temporary abdominal closure, or when biologic mesh repair is done during the initial hospitalization. It could be

EMERGENCY SURGERY
FIGURE 42.6. Time (months; horizontal axis) to hernia recurrence (14% rate) from 114 AWRs. The percentage of recurrence is represented on the vertical axis with the majority occurring within 48 months. From DiCocco JM, Magnotti LJ, Emmett KP, et al. Long-term follow-up of AWR after planned ventral hernia: a 15-year experience. *J Am Coll Surg* 2010;210:686–698.

expected that there will be a high-ventral hernia recurrence rate in those patients.

Over the past 15 years, most of the reconstructive techniques for AWR detailed in this chapter have been employed at our institution.[71] The hernia recurrence rate from this experience compares very favorably with other reports (Table 42.1).

With one of the largest series reported, and with the longest follow-up (mean 5.6 years), our recurrence has proven to be one of the lowest (14%). The modified component separation technique has evolved into the workhorse for AWR at our institution. With long-term follow-up, the hernia recurrence rate for this procedure has been 5%.[71]

TABLE 42.1

HERNIA RECURRENCE RATE AFTER AWR

■ FIRST AUTHOR	■ N	■ FOLLOW-UP (MO)	■ RECURRENCE (%)	■ DEFECT SIZE (CM²)	■ BMI	■ METHODS USED
De Vries[74]	43	15.6	28	234	27.3	CS

CHAPTER 43 ■ SURGICAL INFECTIONS OF SKIN AND SOFT TISSUE

VANESSA P. HO, SOUMITRA R. EACHEMPATI, AND PHILIP S. BARIE

Infections of skin and soft tissue (SSTI) encompass a diverse set of conditions and are a common cause of hospitalization and morbidity. For the purposes of clinical trials, the U.S. Food and Drug Administration (FDA) uses the term skin and skin structure infections (SSSI), further divided into "uncomplicated" and "complicated" subgroups.[1] Necrotizing tissue soft tissue infections (NSTIs) are studied separately and are therefore excluded from studies of complicated SSTI (cSSTI), although certainly not from the practices of acute care surgeons. The term "skin and soft tissue infections" is preferred and used herein as inclusive of the infections that may necessitate surgeon involvement.

New terminology has been proposed by the FDA for the study of antimicrobial therapy of SSTIs: "acute bacterial skin and skin structure infections (ABSSSI)."[2] This terminology, not in clinical use, describes infections of lesser severity that do not require surgical drainage or debridement, owing to the perceived difficulty of parsing whether it is the surgery or the antibiotic that is most important to achieve cure. For the purposes of this discussion of surgical therapy of SSSIs, the definition is irrelevant, and the question of efficacy is moot.

SSTI vary widely in severity; whereas some SSTIs can be treated non-operatively, others are life threatening and require radical surgical debridement in addition to broad-spectrum antibiotic therapy. Practice guidelines for treatment of SSTIs have been published by both the Infectious Diseases Society of America (Table 43.1)[1] and the Surgical Infection Society (Table 43.2).[3]

Uncomplicated SSTIs are superficial or self-limited. They may require only incision and drainage (without antibiotics) or oral antibiotics (without drainage) and rarely require hospitalization. Uncomplicated infections have historically been excluded from trials of antibiotic therapy for complicated SSTIs and vice versa, but may be included henceforth under the ABSSSI paradigm.

By contrast, cSSTIs involve deeper tissues or require major surgical intervention. An infection is also considered complicated if the patient has specific medical comorbidities, including chronic kidney disease, diabetes mellitus, or peripheral arterial disease. Examples of cSSTI include major abscesses, deep (organ/space) surgical site infections (SSIs), diabetic foot infections (DFIs), incisional SSIs with systemic signs of infection, infected decubitus ulcers, and NSTIs. Because clinical trials of drug therapy for cSSTI exclude NSTI, limited prospective data have been collected for their treatment.

UNCOMPLICATED SSTI

Uncomplicated infections include simple abscess, impetigo, furuncles, and nonnecrotizing cellulitis. Nonnecrotizing cellulitis is a diffuse, spreading skin infection without a suppurative focus, usually presenting as a complication from a breach of skin integrity.[4] The differential diagnosis of cellulitis includes both infectious and noninfectious entities, and serious underlying sources of infection should be ruled out. Cellulitis may

be a sign of a deeper infection (e.g., spread of subjacent osteomyelitis, thigh cellulitis following colon perforation into the retroperitoneum). Clinicians must be aware that early NSTIs can be confused for cellulitis if initial symptoms are modest.

Cellulitis is caused most commonly by gram-positive cocci, either streptococci (usually *Streptococcus pyogenes*) *or Staphylococcus aureus*.[5] In cases where patients are immunocompromised, causative agents can also include *Haemophilus influenzae* and *S. pneumoniae*.[3] Predisposing factors include alterations of skin integrity or venous or lymphatic drainage or alterations in host defenses, such as diabetes mellitus. The diagnosis of cellulitis is made clinically, based on history and the appearance of the lesion; neither imaging studies nor cultures of the lesion have a high diagnostic yield. Needle aspiration or punch biopsy also has low yield; an organism is isolated 5%–40% of the time.[6–8]

Simple cutaneous abscesses are well-circumscribed collections of purulent material within the dermis and subcutis. These lesions are usually painful, tender, and fluctuant, with a central pustule and surrounding erythema and edema. These infections are typically polymicrobial, with *S. aureus* isolated in only one-quarter of cases. Treatment of cutaneous abscesses is incision and drainage, with mechanical destruction of intracavitary loculations (Table 43.1).[1] Gram stain, culture, or systemic antibiotics are rarely necessary unless a patient has systemic signs or severe immune compromise. Antibiotic coverage is usually unnecessary unless the patient has surrounding cellulitis.

In cases where antibiotic treatment is warranted for uncomplicated SSTI, oral therapy is appropriate unless the patient has systemic signs (e.g., fever, chills), medical comorbidity, or a rapidly spreading lesion. Appropriate oral agents include dicloxacillin, cephalexin, cephradine, or cefadroxil. For moderate-to-severe infections, parenteral penicillins are the treatment of choice; however, treatment failures may occur in severe cases. Other possible regimens for initial empiric parenteral therapy of severe nonnecrotizing cellulitis are antistaphylococcal penicillins such as nafcillin or cephalosporins such as cefazolin or ceftriaxone (Table 43.1). If methicillin-resistant *S. aureus* (MRSA) is suspected or the patient is highly allergic to penicillin (i.e., anaphylactoid reaction), vancomycin, telavancin, tigecycline, or linezolid may be chosen. A new "fifth-generation" cephalosporin with activity against MRSA, ceftaroline (see below), has also been approved, specifically for ABSSSI. Minocycline or linezolid may be appropriate for oral therapy of hospital-acquired MRSA.

MRSA IN SSTI

MRSA in SSTI requires particular mention. Approximately 60% of hospital isolates of *S. aureus* are MRSA[9]; hospitalized or recently hospitalized patients who develop a SSTI must be considered for empiric therapy against hospital-acquired strains of MRSA. Community-acquired MRSA (CA-MRSA) SSTIs are being observed increasingly among patients with

589

SUMMARY OF RECOMMENDATIONS FROM PRACTICE GUIDELINE FOR DIAGNOSIS AND TREATMENT OF SKIN AND SOFT TISSUE INFECTIONS (SSTI)-INFECTIOUS DISEASES SOCIETY OF AMERICA

Level I	
Impetigo:	Mupirocin is the best topical agent and is equivalent to oral systemic antimicrobials when lesions are limited in number. Patients with numerous lesions or who do not respond to topical therapy should receive an oral antimicrobial agent. PCN or penicillinase-resistant PCN are TOCs for nonbullous lesions. PCN or 1-G cephalosporin is recommended for bullous lesions.
Erysipelas:	PCN is TOC for streptococcal infection. Penicillinase-resistant PCN or 1-G cephalosporin is recommended if staphylococci are suspected.
Cellulitis:	Penicillinase-resistant PCN or 1-G cephalosporin is the TOCs, unless resistant organisms are common in the community. Use clindamycin or vancomycin for PCN-allergic patients.
Cutaneous abscess:	Incision and drainage is the TOC.
Furunculosis:	Recurrent furunculosis may be treated with mupirocin to the anterior nares (for chronic staphylococcal carriers) or clindamycin 150 mg/d for 3 mos.
MRSA:	Linezolid, daptomycin, and vancomycin have excellent efficacy in SSTI in general and in particular those caused by MRSA.
NSTI:	Surgical intervention is the major therapeutic modality.
Type I NSTI:	Ampicillin–sulbactam plus ciprofloxacin plus clindamycin is TOC for community-acquired infection.
Type II NSTI:	Clindamycin/PCN combination therapy is TOC.
Level II	
Furunculosis:	Attempt to eradicate the staphylococcal carrier state among colonized persons.
Type I NSTI:	A variety of antimicrobials directed against aerobic gram-positive and -negative bacteria and anaerobes may be used in mixed necrotizing infection.
Type II NSTI:	Consider intravenous gamma globulin (IVIG) therapy. PCN/clindamycin combination therapy is the TOC for infections caused by *Clostridium perfringens*.
Animal bites:	Oral amoxicillin–clavulanic acid or intravenous ampicillin–sulbactam or ertapenem should be administered to non–PCN-allergic patients because of suitable activity against *Pasteurella multocida*. Acceptable alternative regimens include piperacillin–tazobactam, imipenem–cilastatin, and meropenem.
Level III	
Cutaneous abscess:	Gram stain, culture, and systemic antibiotics are rarely necessary.
Furunculosis:	Systemic antibiotics are usually unnecessary, absent fever, or extensive surrounding cellulitis.
Animal bites:	1-G cephalosporins, penicillinase-resistant PCN, macrolides, and clindamycin should be avoided as therapy because of poor activity against *P. multocida*.
Human bites:	Intravenous ampicillin–sulbactam or cefoxitin are the TOCs for non–PCN-allergic patients. A hand surgeon should evaluate clenched-fist injuries for penetration into synovium, joint capsule, or bone.

Suspicion of possible surgical site infection does not justify use of antibiotics without a definitive diagnosis and the initiation of other therapies, such as opening the incision. All infected surgical incisions should be opened.

1-G, first-generation cephalosporin; MRSA, methicillin-resistant *Staphylococcus aureus*; NSTI, necrotizing soft tissue infection; PCN, penicillin; SSI, surgical site infection; TOC, treatment of choice.

From Stevens DL, Bisno AL, Chambers HF, et al. Practice guidelines for the diagnosis and management of skin and soft-tissue infections. *Clin Infect Dis*. 2005;41:1373–1406

no prior contact with the health care system.[10] Molecular epidemiologic studies indicate that CA-MRSA is a genetically unique pathogen that has a distinct susceptibility pattern. The CA-MRSA clone likely arose from antibiotic selection pressure upon a commensal, saprophytic *Staphylococcus* sp. that is part of normal skin flora.[11] About 75% of CA-MRSA infections are SSTI, but this pathogen may cause pneumonia as well; either manifestation may be associated with tissue necrosis.[12] In many areas of the United States, CA-MRSA is now the predominant cause of SSTIs that present to emergency departments and should be considered when choosing empiric therapy.[13]

The antimicrobial susceptibilities of CA-MRSA differ from the hospital clones. CA-MRSA is similarly susceptible to vancomycin and linezolid, but CA-MRSA may also be susceptible *in vitro* to macrolides, clindamycin, and co-trimoxazole. Whereas the latter drug is most reliable for oral therapy,[14] severe infections usually require intravenous antibiotics.[15,16] Macrolide-inducible clindamycin resistance has

been associated with treatment failures; therefore, caution is advised with clindamycin therapy,[17] especially in the presence of macrolide resistance.

Outbreaks of CA-MRSA have been associated with groups of people in close contact, including prison inmates, amateur and professional sports teams, military recruits, and clients of day-care centers.[18–21] Direct contact with skin is a definite risk factor, as are shared personal hygiene items (e.g., towels, bars of soap). Also at risk are young children and people of lower socioeconomic status. SSTI infections caused by CA-MRSA have a characteristic appearance that may aid in diagnosis. The lesions are usually superficial and well-demarcated, often with central necrosis. If uncomplicated, incision and drainage alone or topical mupirocin ointment or chlorhexidine solution may be sufficient therapy. If antibiotic therapy is required, oral co-trimoxazole should be considered, but severe infections are at risk of treatment failure with this regimen and should be treated with a parenteral glycopeptide or linezolid.

TABLE 43.2

SUMMARY OF RECOMMENDATIONS FROM GUIDELINES FOR TREATMENT OF COMPLICATED SKIN AND SOFT TISSUE INFECTIONS FROM THE SURGICAL INFECTION SOCIETY

Non-necrotizing Cellulitis
- Most frequent causative agent is β-hemolytic streptococci; other agents are *Haemophilus influenzae* and pneumococcus
- Parenteral penicillin is TOC; treatment failures may occur in severe cases
- Protein synthesis-inhibitory agents alone or in combination with cell wall-active agents should be given in severe cases, but macrolide resistance is increasing
- Other regimens may include antistaphylococcal penicillins, cefazolin, or ceftriaxone

Complicated Skin and Soft Tissue Infections
- Involve a broad variety of pathogens; frequently polymicrobial
- *Staphylococcus aureus* is most common isolate; CA-MRSA increasingly common
- Simple abscesses may respond to incision and drainage alone
- Complex abscesses and abscesses with cellulitis require adjuvant antibiotics
- Empiric antibiotic therapy should be directed toward the most likely pathogens, including CA-MRSA in most settings
- Suspected polymicrobial infections should be managed with coverage of enteric gram-negative and anaerobic pathogens

Necrotizing Soft Tissue Infections
- Delays in diagnosis increase morbidity and mortality
- Presence of gas in soft tissue is specific for necrotizing infections
- CT and MRI improve the detection of soft tissue gas, but radiographic findings of tissue fluid and edema are not sensitive or specific
- Clinical features suggestive of NSTI are:
  - Pain disproportionate to findings at physical exam
  - Tense edema
  - Bullae
  - Skin ecchymosis/necrosis
  - Cutaneous anesthesia
  - Systemic toxicity
  - Progression despite antibiotic therapy
- Predictive laboratory values are:
  - White blood cell count >14 × 10^9/L
  - Serum [sodium] <135 mmol/L
  - [Blood urea nitrogen] >15 mg/dL
- Early antibiotic coverage of likely pathogens is indicated; this depends on the clinical setting, inciting pathophysiology, and previous exposure to antibiotics
- Timely and adequate surgical debridement of involved tissue improves outcome
- Frequent reevaluation or return to the operating room within 24 hours should be undertaken to ensure adequacy of debridement and lack of progression
- Necrotizing infections are more frequently polymicrobial; they may involve anaerobic and aerobic gram-positive and gram-negative pathogens
- Possible single-agent regimens include imipenem/cilastatin, meropenem, ertapenem, piperacillin/tazobactam, ticarcillin/clavulanic acid, or tigecycline

Diabetic Foot Infections
- May involve a wide variety of pathogens; separating colonizing bacteria from pathogens may be difficult
- Monomicrobial infections caused by gram-positive cocci are most common, but gram-negative bacilli and anaerobes may be involved. Chronic wounds may have resistant pathogens.
- Empiric therapy should take local sensitivity patterns, previous antibiotic exposure, and previous pathogens into consideration.
- Adequate tissue cultures should be obtained. Superficial surface swabs are not recommended.
- Possible antibiotic regimens include cefazolin, ceftriaxone, cefoxitin, ampicillin/sulbactam, piperacillin/clindamycin, piperacillin/tazobactam, imipenem/cilastatin, and ertapenem; daptomycin and linezolid can be used with the addition of gram-negative coverage
- For MRSA infections, vancomycin, daptomycin, and linezolid can be considered[a]

Adjunctive Therapies
- Data are insufficient for extracorporeal plasma treatment, HBO, and intravenous immunoglobulin.

[a]Note that telavancin is FDA-approved for the treatment of SSTI caused by MRSA, but was approved subsequent to publication of this guideline
CA-MRSA, community acquired methicillin-resistant *Staphylococcus aureus*; CT, computed tomography, FDA, U.S. Food and Drug Administration; HBO, hyperbaric oxygen therapy; MRI, magnetic resonance imaging; MRSA, methicillin-resistant *Staphylococcus aureus*; NSTI, necrotizing soft tissue infection; SSTI, skin and soft tissue infections, TOC, treatment of choice.

COMPLICATED SSTI

Complicated SSTIs involve deeper tissues or require major surgical intervention. Infection in the presence of chronic kidney disease, diabetes mellitus, or peripheral arterial disease also defines a cSSTI. Examples of cSSTIs include major abscesses, organ/space SSIs, some incisional SSIs (those with systemic signs of infection), DFIs, infected decubitus ulcers, and NSTIs. Clinical trials of drug therapy for cSSTI exclude NSTIs because of high mortality rates and the crucial contribution of timely surgical debridement to outcome. An evidence-based summary of recent clinical trials of antibiotic therapy is shown in Table 43.3.[1,15,22–34] Most trials are designed to demonstrate "non-inferiority" of the tested regimen against the comparator regimen, and so numerous regimens appear comparable despite widely divergent spectra of activity. Notably, comparable outcomes are achieved by agents that treat only gram-positive cocci (e.g., vancomycin, linezolid, daptomycin, telavancin), but the many options available to investigators (e.g., choice of comparator in "standard therapy" regimens, addition of aztreonam) make the literature a challenge to interpret.

Three meta-analyses have been published recently to assess the literature comparing linezolid with vancomycin for cSSTI ($n = 2$)[35,36] and daptomycin versus comparator agents (either vancomycin or semisynthetic penicillins[37]; Table 43.4). Despite considering different trials for inclusion, the two meta-analyses of linezolid versus vancomycin each concluded that resolution of cSSTI is more likely after linezolid therapy, albeit with more nausea, diarrhea, and myelosuppression (nephrotoxicity is more common with vancomycin). Differences in cure rates of infection were not observed for daptomycin versus comparators.

Diabetic Foot Infection

Patients with diabetes mellitus are at risk for considerable morbidity as a result of chronic foot ulceration and foot infection, including limb loss.[38,39] DIFs are usually a consequence of skin ulceration, either from ischemia or trauma to an insensate, neuropathic foot. One-third of patients presenting with a DFI have had a chronic foot lesion for more than 1 month beforehand. Two-thirds of patients with DFI present with peripheral arterial disease, and the prevalence of sensory neuropathy is about 80%. Although most DFIs remain superficial, as many as 25% spread contiguously to involve subcutaneous tissue or bone (osteomyelitis). The compartmentalized anatomy of the foot, with its various spaces, tendon sheaths, and neurovascular bundles, allows ischemic necrosis to affect tissues within a compartment or spread along anatomic planes. Recurrent infections are common, and 10%-30% of affected patients eventually require amputation.[40]

Diabetic patients are predisposed to DFIs not only because of the portal of entry and poor perfusion, but also because of defective innate immunity, including impaired neutrophil and monocyte/macrophage function, which appear to correlate with the adequacy of glycemic control.[41,42] Adaptive immunity may be impaired as well. Diabetic patients also have a higher prevalence of nasal carriage of *S. aureus*, which predisposes patients to SSTIs.

Infections affect the forefoot most commonly, especially the toes and the metatarsal heads on the plantar surface. Infection must be diagnosed clinically because, as with all skin wounds, polymicrobial flora is present, many of which are nonpathogenic. Systemic signs (e.g., fever, chills), purulent drainage, or at least two local signs of inflammation (e.g., calor [warmth], rubor [redness], dolor [pain, or tenderness], and tumor [induration]) are suggestive. Deep infections may have few surface signs. Chronic wounds may manifest discoloration, friability, delayed healing, or be malodorous. Signs of systemic toxicity are uncommon in DFI, even with limb-threatening infection, but metabolic abnormalities (e.g., hyperglycemia, ketoacidosis, hyperosmolar state) imply severe disease. Many patients do not complain of pain, and more than one-half of patients have neither fever, nor leukocytosis, nor an elevated erythrocyte sedimentation rate. Whenever the diagnosis of DFI is considered, aggressive management is indicated because these infections may progress rapidly.

Several severity scores have been proposed for DFI,[43] but none has universal acceptance. Severity may be determined clinically by assessment of the depth of the wound and tissue perfusion. Local wound exploration with a sterile surgical instrument is important to identify necrotic tissue or the presence of a foreign body (e.g., a needle that the patient stepped on, but did not feel at the time) or osteomyelitis.[44,45] Assessment of severity is essential for antibiotic selection (including route of administration) and to determine the need for hospitalization and the necessity and timing of surgical debridement or level of amputation. Systemic signs should raise suspicion of a deep infection. Indications for hospitalization include correction of hypovolemia or metabolic abnormalities, parenteral antibiotic therapy, or the need for surgery. Other reasons to hospitalize a DFI patient include an inability or unwillingness of the patient to provide local wound care or to maintain non–weight-bearing status or likely noncompliance with outpatient oral antibiotic therapy. Antibiotic therapy alone cannot overcome suboptimal wound care and inadequate glycemic control.

Acute DFIs are usually caused by gram-positive cocci; *S. aureus* is the most important pathogen in DFI. Whereas *S. aureus* is often present as a monomicrobial infection[42,46] (Table 43.5), it is also usually an important pathogen in polymicrobial infections. Chronic wounds, recurrent infections, and infections of hospitalized patients are more likely to harbor complex flora, including aerobes and anaerobes.[47] Among gram-negative bacilli, bacteria of the family Enterobacteriaceae are common. *Pseudomonas aeruginosa* may be isolated from wounds that have been treated with hydrotherapy or wet dressings. Enterococci may be recovered from patients treated previously with a cephalosporin. Anaerobic bacteria seldom cause DFIs as the sole pathogen, but they may be isolated from deep infections or necrotic tissue.[47] Antibiotic-resistant bacteria, especially MRSA, may be isolated from patients who have received antibiotics previously or who have been hospitalized or reside in long-term care facilities.

Antibiotic Therapy. Forty to sixty percent of diabetic patients who are treated for a foot ulcer receive antibiotics, but antibiotic therapy does not improve the outcome of uninfected foot lesions in diabetic patients.[39,48] Successful antibiotic therapy requires a therapeutic concentration of antibiotic at the site of infection. Intravenous antibiotics are indicated for patients with systemic illness, severe infection, intolerance of oral antibiotics, or pathogens that are not susceptible to oral agents. After the patient stabilizes and shows signs of improvement, a switch to oral antibiotic therapy may be appropriate. Slower delivery of antibiotic after an initial oral dose is inconsequential for non–critically ill patients, and so the main consideration is the bioavailability of the chosen agent. Among the potential choices of oral antibiotics for DFIs, clindamycin, linezolid, and fluoroquinolones have good oral bioavailability. Even parenteral antibiotics may not penetrate tissue adequately in the presence of peripheral arterial disease, even when serum concentrations are adequate.[49]

Initial empiric therapy should be directed at common pathogens (Table 43.5).[46,48–51] Mild infections may be treated more narrowly because disease progression is unlikely to

TABLE 43.3

RECENT PROSPECTIVE TRIALS OF ANTIBIOTIC THERAPY FOR COMPLICATED SKIN AND SKIN STRUCTURE INFECTIONS

■ STUDY	■ DRUG	■ COMPARATOR	■ RESULT	■ NOTES
Stevens, 2002[23]	Linezolid 600 mg IV QD	Vancomycin 1 g IV Q12H	73% vs. 73% Cure, E population 95% CI (−16.6, 16.8)	MRSA only Open-label 7 days of therapy Underpowered
Seltzer, 2003[30]	Dalbavancin 1 g IV day 1 and 500 mg day 8	Standard therapy	94% vs. 76% E population Only result fortwo doses of dalbavancin shown	Open-label Dose-ranging phase 2 trial
Arbeit, 2004[22]	Daptomycin 4 mg/kg IV QD	Standard therapy or vanco-mycin 1 g IV Q12H, oral switch to synthetic penicil-lin OK if MSSA	83% vs. 84% cure, E population 95% CI (−4.0, 5.6)	Combined report of two phase 3 trials Non-inferior treatment for 7-14 d
Wilcox, 2004[24]	Linezolid 600 mg IV/PO Q12H	Teicoplanin dose deter-mined by investigator	96% vs. 88% cure, ITT population 95% CI (2.5, 13.2)	Linezolid superior to teicoplanin, but dose of teicoplanin questionable
Giordano, 2005[25]	Moxifloxacin 400 mg IV/PO QD	Piperacillin–tazobactam 3.375 g IV Q6H, amoxicil-lin–clavulanate 800 mg PO Q12H	79% vs. 82% cure, E population 95% CI (−12.04, 3.29)	Non-inferior Treatment for 7-14 d
Ellis-Grosse, 2005[26]	Tigecycline 100 mg load then 50 mg IV Q12H	Vancomycin 1 g Q12H plus aztreonam 2 g IV Q12H	80% vs. 82% cure, mITT population 95% CI (−7,1, 2.8)	Combined report of two phase 3 trials Non-inferior
Jauregui, 2005[27]	Dalbavancin 1 g day 1, 500 mg day 8	Linezolid 600 mg IV/PO Q12H	89% vs. 91% E population 97.5% CI calculated, only lower limit of −7.28 reported	Randomized D:L 2:1 Treatment for 14 d
Weigelt, 2005[28]	Linezolid 600 mg Q12H IV/PO, aztreonam permitted	Vancomycin 1 g IV Q12H, switch to semisynthetic penicillin if MSSA, aztreonam permitted	92% vs. 89% cure, ITT population 95% CI (−0.11, 7.47)	Open-label Phase 4 Treatment up to 14 d Linezolid superior in MRSA subset 95% CI (6.08–25.70
Stryjewski, 2006[31]	Telavancin 10 mg/kg IV q24h	Standard therapy Antistaphylococcal penicil-lin or vancomycin 1g IV q12h	96% vs. 90% cure, in MRSA cases 92% vs. 78% (*p* = 0.07)	Randomized double-blind active-control phase 2
Fabian, 2005[29]	Meropenem 500 mg IV q8h	Imipenem–cilastatin 500 mg IV q8h	73% vs. 75% cure in mITT population 95% CI (−8.4, 4.7)	Randomized double-blind; imipemem–cilastatin underdosed?
Cenizal, 2007[15]	TMP-SMX 180/600 mg PO q12h for 7 days	Doxycycline 100 mg PO q12h for 7 days	79% vs. 100% cure (*p* = 0.283)	Randomized; underpow-ered
Stryjewski, 2008[32]	Telavancin 10 mg/kg IV q24h	Vancomycin 1 g IV q12h	88% vs. 87% cure 95% CI (−2.1, 4.6)	Pre-specified pooled analysis of two random-ized double-blind trials
Corey, 2010[33]	Ceftaroline 10 mg/kg IV q24h	Vancomycin 1g IV q12h plus aztreonam	86% vs. 86% cure, mITT population	Randomized double-blind Phase 3
Itani, 2010[34]	Linezolid 600 mg IV q12h	Vancomycin 15 mg/kg IV q12h	81% vs. 74% cure, mITT population	Open-label randomized trial of patients with MRSA. Aztreonam and metronidazole permis-sible in either arm

"Standard therapy" means that selection of the comparator agent was at the discretion of the investigator. Non-inferiority is defined statistically when the lower limit of the 95% confidence interval is >−15, and the confidence interval contains zero. A trial with a relatively narrow confidence interval is likely to have greater statistical power (or more homogeneous results) than one with a wider interval.
CI, confidence interval; E, evaluable patient group; ITT, Intention-to-treat patient group; IV, intravenous; mITT, modified intention-to-treat patient group; PO, oral administration; TMP-SMX, trimethoprim-sulfamethoxazole.

prevent modification of the regimen when microbiology data become available. For severe infections, regimens should utilize broad-spectrum intravenous antibiotics. Any regimen must account for allergy, renal function, recent antibiotic therapy, local susceptibility patterns, and the possibility of antibiotic-resistant pathogens. Empiric coverage for gram-positive bacteria (staphylococci and streptococci) is almost always required, and so the usual question is whether to broaden the regimen to cover gram-negative bacteria (Table 43.5).[46,50,51] Anaerobic coverage should be considered for necrotic or malodorous wounds. If the patient responds to empiric therapy, the regimen may be narrowed according to microbiology susceptibility testing. The possibility of fastidious organisms missed by culture should be considered among nonresponders, or surgery may be needed.

Agents with demonstrated efficacy in clinical trials of therapy for DFIs include cephalosporins, β-lactamase inhibitor combination antibiotics, fluoroquinolones, clindamycin,

TABLE 43.5

(50% of cases had only gram-positive cocci isolated).
Data from Lipsky BA, Itani K, Norden C, et al. Treating foot infections in diabetic patients: a randomized, multicenter, open-label trial of linezolid versus ampicillin-sulbactam/amoxicillin-clavulanate. *Clin Infect Dis*. 2004;38:17–24.

carbapenems, glycopeptides, and linezolid (Table 43.6). The optimal duration of therapy for DFI has not been determined; common practice is to treat mild infections for 1 week, whereas serious infections that do not involve bone may require therapy for 2 weeks. Adequate debridement, resection, or amputation can shorten the necessary duration of therapy. Blood stream infection is a rare complication, for which many experts recommend a minimum of 2 weeks of therapy. Therapy may be discontinued when all signs and symptoms of infection have resolved; incomplete wound healing is not an indication to prolong antibiotic therapy.

Adjuncts to Antibiotic Therapy. Hyperbaric oxygen (HBO) may improve wound healing and decrease the rate of amputation of DFI according to one double-blind, randomized trial.[52] However, most evidence of HBO effect in DFI is anecdotal[53] and difficult to interpret because of patient comorbidities that are poorly controlled for small sample sizes, and scant documentation of wound size and severity. Potential candidates for HBO therapy include patients at high risk for amputation (deep infections unresponsive to therapy). Objectively, HBO may be most beneficial when the transcutaneous oxygen tension is <40 mm Hg before therapy and increases to >200 mm Hg after therapy.[53]

Surgical revascularization may also be considered.[54] Improving blood flow to the ischemic, infected foot may be a crucial determinant of outcome. Initial debridement is undertaken in the presence of infection; revascularization is generally postponed until sepsis is controlled, but should not be postponed more than a few days lest there be additional tissue loss in the meanwhile. Successful revascularization of an ischemic, infected foot can result in 3-year limb salvage rates of up to 98%.[55]

A good outcome may be expected in 80%–90% of mild cases treated appropriately and 50%–60% for more advanced DFIs. Aggressive surgical debridement is often needed for infections of deep tissue or bone. Partial amputations (e.g., toe amputation, "ray" amputation of a metatarsal) may be foot-sparing and lead to effective control of infection in >80% of cases. Healing is facilitated when there is no exposed bone, absent tissue edema, a palpable popliteal pulse, ankle systolic blood pressure >80 mm Hg, and a white blood cell count <12,000 per mm[3]. Infection recurs in 20%–30% of cases and should increase the suspicion of underlying osteomyelitis.

TABLE 43.6

RECENT PROSPECTIVE TRIALS OF ANTIBIOTIC THERAPY FOR COMPLICATED SKIN AND SKIN STRUCTURE INFECTIONS OF THE FOOT IN PATIENTS WITH DIABETES MELLITUS

■ STUDY	■ DRUG	■ COMPARATOR	■ RESULT	■ NOTES
Lipsky, 2004[46]	Linezolid (L) 600 mg IV/PO q12h	Ampicillin–sulbactam (A-S) 3 g IV q6h then amoxicillin–clavulanate 875 mg q 12 h	Clinical cure 81% vs. 71% (p = NS) Linezolid superior in post-hoc foot ulcer and nonosteo-myelitis groups	Open label randomized L:A-S 2:1 Treatment for 7–28 d
Harkless, 2005[50]	Piperacillin–tazobactam 4.5 g q8h IV	Ampicillin–sulbactam 3 g IV q6h	Clinical cure 81% vs. 83% Confidence interval not reported	Open label vancomycin 1 g IV q12h optional for both groups
Lipsky, 2005[51]	Ertapenem 1 g QD	Piperacillin–tazobactam 3.375 g Q6H for 5 d Amoxicillin–clavulanate 1 g PO Q12h for up to 23 d	94% vs. 92% cure, E Population 95% CI (−2,9, 6.9)	Non-inferior Treatment for up to 28 d

Osteomyelitis. Osteomyelitis is a feared complication of DFI (incidence, 50%–60% in serious DFIs; 10%–20% in mild infections).[39] However, because diabetic patients may have destructive bone lesions caused by peripheral neuropathy (e.g., Charcot joint), distinguishing between neuropathic and infectious destruction of bone can be difficult. The likelihood of osteomyelitis is increased with foot ulcers that are chronic (>4 weeks), large (>2 cm diameter), deep (>3 mm), or associated with a marked elevation of ESR (>70 mm/h).[39] Wound exploration that "probes to bone" has a positive predictive value of >90% for the diagnosis of osteomyelitis.

The initial diagnostic test should be plain radiographs of the foot. Radiographic changes may take 2 weeks to become manifest, and so repeating an initially negative study of a stable patient may be a better tactic than proceeding immediately to more sophisticated and expensive imaging. If clinical and plain radiographic findings are nondiagnostic, technetium 99m bone scans are 85% sensitive, but only 45% specific. Leukocyte scans (e.g., ^{111}In) have similar sensitivity, but higher specificity (~75%). Magnetic resonance imaging (MRI) is usually the diagnostic test of choice because of high sensitivity (>90%) and specificity (>80%), but is expensive. A definitive diagnosis of osteomyelitis requires a bone biopsy for culture and histology. Bone biopsy must be obtained through a clean surgical incision that does not traverse an open wound to avoid contamination by colonizing organisms. Biopsy is indicated if the diagnosis remains doubtful after imaging studies, or if the etiologic agent(s) cannot be ascertained because of previous antibiotic therapy or confusing culture results. Most cases of osteomyelitis are polymicrobial; *S. aureus* is isolated most commonly (~40%), but *S. epidermidis*, streptococci, and Enterobacteriaceae are also common isolates.

Antibiotic therapy of osteomyelitis should be based on results of bone culture, because soft tissue culture results do not predict bone pathogens accurately.[39] Empiric therapy should always cover *S. aureus*; broader coverage should be administered based on history or results of cultures. Most antibiotics penetrate bone poorly, and leukocyte function is impaired in these patients, and so long-term (at least 6 weeks) parenteral (at least initially) therapy is required. Osteomyelitis complicating DFI can be arrested by antibiotic therapy alone in about two-thirds of cases, and so resection of infected bone is not always necessary. Oral antibiotics with good bioavailability (e.g., fluoroquinolones, clindamycin) may be useful for most of the therapeutic course. If all infected bone is removed, a shorter course of therapy (e.g., 2 weeks) may be appropriate. Clinical resolution may be documented by a decrease to normal of the ESR or loss of increased uptake on a leukocyte scan.

SURGICAL SITE INFECTION

Infections of surgical incisions are now referred to as SSIs,[56] a common surgical complication that occurs after about 3% of all surgical procedures.[57] Potential complications of SSIs include tissue destruction, failure or prolongation of wound healing, incisional hernias, and occasionally blood stream infection. Recurrent pain and disfiguring scars may also result. Surgical site infections result in substantial morbidity, prolonged hospital stays, and increased direct patient costs, creating a huge economic burden on healthcare systems.[58]

Infection may occur within the surgical site at any depth, from the skin to the intracavitary operative field. Superficial incisional SSI involves tissues down to the fascia (Fig. 43.1), whereas deep incisional SSI extends into fascia and muscle, but not intracavitary. Organ/space infections are intracavitary, but, if related directly to an operation, are considered to be SSIs.

Epidemiology

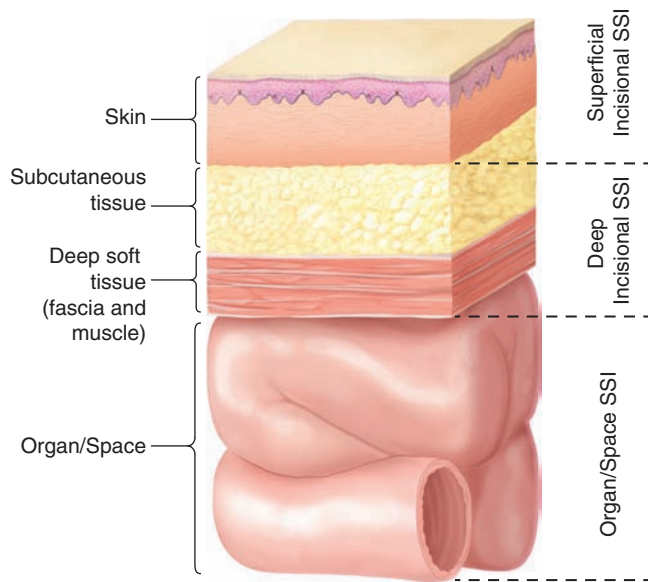
Numerous factors determine whether a patient will develop a SSI, including factors contributed by the patient, the environment, and the treatment (Table 43.7).[59] As described by the National Nosocomial Infections Surveillance System (NNIS)[59–61] of the U.S. Centers for Disease Control and Prevention (CDC) (Table 43.8), the most recognized risk factors for SSI are the wound classification (contaminated or dirty—see below and Table 43.9), American Society of Anesthesiologists (ASA) class ≥ 3 (chronic active medical illness; Table 43.10),


FIGURE 43.1. Cross-section of the abdominal wall depicting U.S. Centers for Disease Control and Prevention (CDC) classifications of surgical site infection.

TABLE 43.7

RISK FACTORS FOR THE DEVELOPMENT OF SURGICAL SITE INFECTIONS

Patient Factors
Ascites
Chronic inflammation
Corticosteroid therapy (controversial)
Obesity
Diabetes
Extremes of age
Hypocholsterolemia
Hypoxemia
Peripheral vascular disease (especially for lower extremity surgery)
Postoperative anemia
Prior site irradiation
Recent operation
Remote infection
Skin carriage of staphylococci
Skin disease in the area of infection (e.g., psoriasis)
Undernutrition

Environmental Factors
Contaminated medications
Inadequate disinfection/sterilization
Inadequate skin antisepsis
Inadequate ventilation

Treatment Factors
Drains
Emergency procedure
Hypothermia
Inadequate antibiotic prophylaxis
Oxygenation (controversial)
Prolonged preoperative hospitalization
Prolonged operative time

Adapted from Barie PS. Surgical site infections: epidemiology and prevention. *Surg Infect (Larchmt)* 2002;(3 suppl 1):S9–S21.

TABLE 43.8

NATIONAL NNIS RISK INDEX FOR SURGICAL SITE INFECTIONS

■ TRADITIONAL CLASS	■ 0	■ 1	■ 2	■ 3	■ ALL
Clean	1.0%	2.3%	5.4%	NA	2.1%
Clean/contaminated	2.1%	4.9%	9.5%	NA	3.3%
Contaminated	NA	3.4%	6.6%	13.2%	6.4%
Dirty	NA	3.1%	8.1%	12.8%	7.1%
All	1.5%	2.9%	6.8%	13.0%	2.8%

Adapted from National Nosocomial Infections Surveillance (NNIS) System Report, Data Summary from January 1992–June 2001, issued August 2001. *Am J Infect Control.* 2001;29:404–421.

and prolonged operative time, where time is longer than the 75th percentile for each such procedure. Clean surgical procedures (class I incisions; Table 43.9) involve only integumentary and musculoskeletal soft tissues (e.g., groin hernia, breast, thyroid). Clean-contaminated procedures (class II) open a hollow viscus (e.g., alimentary, biliary, genitourinary, respiratory tract) under controlled circumstances (e.g., elective colon surgery). Contaminated procedures (class III) involve extensive introduction of bacteria into a normally sterile body cavity, but too briefly to allow infection to become established (e.g., penetrating abdominal trauma, enterotomy during adhesiolysis for mechanical bowel obstruction). Dirty procedures (class IV) are those where the surgery is performed to control established infection (e.g., colon resection for complicated diverticulitis).

According to the NNIS classification, the risk of SSI increases with an increasing number of risk factors present, irrespective of the wound class and almost without regard for the type of operation (Table 43.11).[62] Laparoscopic abdominal surgery is associated with a decreased incidence of SSI under certain circumstances, which has required a modification of the NNIS risk classification.[61] For laparoscopic biliary, gastric, and colon surgery, one risk factor point is subtracted if the operation is performed via the laparoscope, so that the NNIS risk classification system grades risk from –1 to 3. Laparoscopy decreases the risk of SSI for several reasons, including decreased wound size, limited use of cautery, and a diminished stress response to tissue injury. Laparoscopic appendectomy, on the other hand, is a unique circumstance in that the risk of SSI is reduced by laparoscopy only if no risk factors are present (i.e., the patient is otherwise healthy, the appendix is not perforated, and the operation does not take more than 1 hour).

Outpatient surgery and early discharge protocols pose problems for surveillance of SSI.[63] Although many SSIs will develop in the first 5–10 days after surgery, a SSI may develop up to 30 days after surgery (1 year, if a prosthetic device was inserted); thus, SSIs do occur in the postdischarge setting. Therefore, estimates of the incidence of SSI after ambulatory surgery depend upon inherently unreliable voluntary self-reporting by surgeons. Therefore, the incidence of SSI reported by NNIS is almost certainly underestimated. Unfortunately, data reported by the NNIS also do not identify cases as incisional or organ/space SSIs.

Host-derived factors are important contributors to the risk of SSI that the ASA score may not capture. Increased age,[64] obesity, malnutrition, diabetes mellitus,[65,66] hypocholesterolemia,[67] previous radiation therapy, and other factors are

TABLE 43.9

SURGICAL SITE INFECTION WOUND CLASSIFICATION AND APPROXIMATE RATES OF INFECTION

■ CLASS	■ DEFINITION	■ EXAMPLES	■ RATE (%)
I: Clean	Atraumatic wound No inflammation No break in aseptic technique No entry of biliary, respiratory, GI, or GU tracts If drained, by closed drainage	Herniorrhaphy Excision of skin lesion Thyroidectomy	1–5
ID: Clean; prosthetic material implanted	Same as I, Clean	Vascular surgery with graft Cardiac valve replacement	1–5
II: Clean-contaminated	Atraumatic wound No inflammation Minor break in aseptic technique Biliary, respiratory, GI, or GU tract entered under controlled conditions with minimal contamination	Appendectomy without perforation Elective colectomy after bowel preparation Cholecystectomy	2–9
III: Contaminated	Traumatic wound with delay in therapy or exogenous contamination Acute non-purulent inflammation Major break in aseptic technique Entry of biliary, respiratory, GI, or GU tract with gross spillage of contents	Penetrating abdominal with hollow viscus injury Inadvertent enterotomy during adhesiolysis for mechanical small intestinal obstruction	3–13

GI, gastrointestinal; GU, genitourinary.

TABLE 43.10

AMERICAN SOCIETY OF ANESTHESIOLOGISTS (ASA) PHYSICAL STATUS SCORE

ASA 1
A normal healthy patient.

ASA 2
A patient with mild-to-moderate systemic disturbance that results in no functional limitations. Examples: hypertension, diabetes mellitus, chronic bronchitis, morbid obesity, and extremes of age.

ASA 3
A patient with severe systemic disturbance that results in functional limitations. Examples: poorly controlled hypertension, diabetes mellitus with vascular complications, angina pectoris, prior myocardial infarction, and pulmonary disease that limits activity.

ASA 4
A patient with a severe systemic disturbance that is life threatening with or without the planned procedure. Examples: congestive heart failure, unstable angina pectoris, advanced pulmonary, renal or hepatic dysfunction.

ASA 5
A morbid patient not expected to survive with or without the operative procedure. Examples: ruptured abdominal aortic aneurysm, pulmonary embolism, and traumatic brain injury with increased intracranial pressure.

ASA 6
Any patient in whom the procedure is an emergency. Example: ASA 4E.

not accounted for specifically by NNIS. In a study of 2,345 patients undergoing cardiac surgery, the incidence of SSI was 8.5% (199/2,345).[68] The relative risk (RR) of SSI among diabetic patients was 2.29 (95% confidence interval [CI] 1.15–4.54), and the RR among obese patients (body mass index >30) was 1.78 (95% CI, 1.24–2.55). Malone et al. found an incidence of SSI of 3.2% among 5,031 noncardiac surgery patients at a Veterans Affairs hospital. Independent risk factors for the development of SSI included ascites, diabetes mellitus, postoperative anemia, and recent weight loss, but not chronic obstructive pulmonary disease, tobacco use, or corticosteroid use.[69] Other studies have linked low-serum albumin concentration and increased serum creatinine concentration to an increased risk of SSI.[70]

Microbiology

Inoculation of the surgical site occurs during surgery, either inward from the skin or outward from the tissues being operated on. The microbiology of SSI depends on the type of operation, with an increased likelihood of gram-negative bacilli after gastrointestinal surgery or infrainguinal vascular surgery. However, most SSIs are caused by gram-positive cocci that are commensal skin flora (Table 43.12),[70] including *S. aureus*, coagulase-negative staphylococci (usually *S. epidermidis*), and *Enterococcus* spp. Head and neck surgery (if pharyngoesophageal structures are entered) and intestinal surgery may be associated with SSI caused by enteric facultative (e.g., *Escherichia coli*) and anaerobic (e.g. *Bacteroides fragilis*) bacteria. Properly administered antibiotic prophylaxis is an essential part of an ensemble of tactics to prevent surgical site infection and is discussed elsewhere (see Chapter 13).

TABLE 43.11

SURGICAL SITE INFECTION RATES AFTER COMMON
OPERATIVE PROCEDURES BY RISK CATEGORY

■ PROCEDURE	■ NUMBER OF RISK FACTORS			
	■ 0	■ 1	■ 2	■ 3
Appendectomy	1.15	1.15	3.47	3.47
Bile duct, liver, or pancreatic surgery	8.07		13.65	
Breast surgery	0.95	2.95	6.36	6.36
Colon surgery	3.99	5.59	7.06	9.47
Gastric surgery	1.72		4.23	
Herniorrhaphy (inpatient)	0.74	2.42	5.25	
Peripheral vascular bypass surgery	2.93	6.98		
Small bowel surgery	3.44	6.75

Healthcare Safety Network (NHSN) report: Data summary for
2006 through 2008, issued December 2009. *Am J Infect Control.*
2009;37:783–805.

Preoperative Preparation

The patient should be assessed prior to elective surgery for
modifiable risk factors. Open skin lesions should heal before-
hand if possible. The patient should be free of bacterial infec-
tions of any kind and should preferably quit smoking at least
1 month prior to surgery. The patient must not be shaved
the night before, considering that the risk of SSI is increased
by bacteria that colonize the inevitable small cuts and abra-
sions.[70] Particular attention should be paid to the patient's
nutritional status. Obese patients should lose as much weight
as is safely possible. Malnourished patients can reduce the risk
of SSI significantly with as few as 5 days of enteral nutritional
support.[71,72]

TABLE 43.12

INCIDENCE OF PATHOGEN ISOLATION IN SURGICAL
SITE INFECTION (COLLECTED SERIES)

■ ORGANISM	■ PERCENTAGE
Staphylococcus aureus	20
Coagulase-negative staphylococci	14
Enterococci	12
Pseudomonas aeruginosa	8
Escherichia coli	8
Enterobacter spp.	7
Proteus mirabilis	3
Streptococcus spp.	3
Klebsiella pneumoniae	3
Candida albicans	2

Diagnosis and Treatment

Specific criteria have been established by the CDC for the diag-
nosis of SSI (Table 43.13). Adherence to these diagnostic guide-
lines is important, because SSI can be misdiagnosed otherwise.
Proper surveillance requires the prospective involvement of
trained personnel, adhering to the aforementioned criteria, who
inspect incisions directly and in prospect. Retrospective stud-
ies of SSI are plagued by diagnostic inaccuracy and therefore
are inherently dubious. Likewise, voluntary self-reporting by
surgeons produces notoriously underestimated incidence rates,
because reporting does not occur; SSIs that become apparent
in the outpatient setting escape hospital-based surveillance
programs. Therefore, published data from NNIS (Table 43.8)
probably are at or near the lower end of the confidence interval.

TABLE 43.13

CRITERIA FOR DIAGNOSIS OF INCISIONAL
AND ORGAN/SPACE SURGICAL SITE INFECTIONS
(SSIs) WITHIN 30 DAYS OF ALL PROCEDURES
(1 YEAR IF PROSTHETIC MATERIAL IS IMPLANTED)

■ **INCISIONAL SSI**

Superficial—infection involves skin or subcutaneous tissue of
the incision *and* at least one of the following:
1. Purulent drainage from the superficial incision
2. Organisms isolated from an aseptically obtained
   culture from the superficial incision
3. One or more of the following: pain, localized swelling,
   erythema, or heat, and incision is opened deliberately
   by surgeon, unless incision is culture negative.
4. Diagnosis of superficial incisional SSI by surgeon

Deep—infection involves fascial or muscle layer of the
incision *and* at least one of the following:
1. Purulent drainage from the deep incision, excluding
   organ/space[a]
2. Incision that dehisces spontaneously or is opened delib-
   erately by a surgeon in the presence of fever (>38°C),
   or pain, unless site is culture negative
3. Evidence of infection is found on direct examination,
   during repeat surgery, or by histopathologic or radio-
   logic examination[b]
4. Diagnosis of deep incisional SSI by surgeon

■ **ORGAN/SPACE SSI**

Infection of any part of the anatomy (e.g., organs or sur-
gically created spaces) opened or manipulated during an
operation *and* at least one of the following:
1. Purulent drainage from a drain that is placed into the
   organ/space
2. Organisms isolated from an aseptically obtained
   culture from the organ/space
3. Evidence of infection is found on direct examination,
   during repeat surgery, or by histopathologic or radio-
   logic examination[b]
4. Diagnosis of an organ/space SSI by surgeon

For all classifications, infection is defined as occurring within 30 d
after the operation if no implant is placed or within 1 year if an
implant is in place and the infection is related to the incision
[a]Report infection that involves both superficial and deep incision
sites as a deep incisional SSI
[b]Report an organ/space SSI that drains spontaneously through the
incision as a deep incisional SSI
Adapted from Mangram AJ, Horan TC, Pearson ML, et al. Guide-
line for prevention of surgical site infection, 1999. Hospital Infec-
tion Control Practices Advisory Committee. *Infect Control Hosp
Epidemiol.* 1999;20:250–278.

Not all draining or erythematous incisions are infected. A superficial swab culture will likely become contaminated during specimen collection and be overinterpreted. Once a diagnosis of SSI is established, there is only one constant in the management: incise and drain the incision. Often, opening the incision and applying basic wound care (e.g., topical saline-soaked wet-to-dry cotton gauze dressings) is sufficient, provided that the incision is opened sufficiently to facilitate wound care and the diagnosis of associated conditions. An incision that is too small may fail to control the infection. Most nostrums other than physiologic saline applied to gauze dressings (e.g., modified Dakin solution, 0.25% acetic acid solution) actually suppress fibroblast proliferation and may delay secondary wound healing.

Opening the incision adequately is essential because it affords not only control of the infection but also an opportunity to diagnose and treat associated conditions such as skin, subcutaneous tissue, or fascial necrosis that requires debridement; fascial dehiscence or evisceration that requires formal abdominal wall reconstruction; or subfascial drainage that could signal an organ/space infection or an enteric fistula. Without control of complicating factors, a SSI will be difficult or impossible to control.

Antibiotic therapy is not required for uncomplicated superficial SSIs that are opened and drained adequately and that receive appropriate local wound care. If antibiotic therapy is unwarranted, then culture and susceptibility testing of wound drainage are of no value. In fact, routine swabs of drainage are not recommended because the risk of contamination by commensal skin flora is high. Rather, tissue specimens or an aliquot of pus collected aseptically and anaerobically into a syringe are recommended for analysis.

Antibiotics may be indicated if there is systemic evidence of toxicity (e.g., fever, leukocytosis) or cellulitis that extends more than 2 cm beyond the incision. Antibiotics are also indicated as adjunctive management of several of the complications mentioned earlier. The choice of antibiotic is defined by the operation performed through the incision and the likely infecting organism. Coverage against gram-positive cocci is indicated in most circumstances.

Wound closure by secondary intention can be protracted and disfiguring. Reports of vacuum-assisted wound closure (VAC) are proliferating. Putative benefits of VAC dressings include reduced inflammation, increased fibroblast activity, improved wound hygiene (fluid is aspirated continuously from the field), and more rapid wound contraction and closure.[73] However, these benefits remain conjectural in the absence of definitive class I data.

NECROTIZING SOFT TISSUE INFECTION

Necrotizing soft tissue infections (NSTIs) are dangerous because of rapid progression and much systemic toxicity, but fortunately also uncommon.[74] Bacterial proteases cleave tissue planes, facilitating rapid spread. Host defenses are overwhelmed, leading to hemodynamic instability and hypoperfusion. Ischemic tissue in turn is susceptible to progression of the infection, and organ dysfunction may result. Because NSTIs are uncommon and their initial manifestations are protean and can be subtle, clinicians must have a high index of suspicion in order to prevent diagnostic delay. Although most presentations are obvious, a NSTI must always be considered whenever a patient presents with severe pain, particularly of the perineum or an extremity, which is disproportionate to any physical findings. There may be no obvious portal. The presence of gas in the soft tissues (crepitus) on examination or by imaging study is helpful, but unreliable if absent.

Delayed definitive therapy (i.e., surgical debridement) is the major risk factor for mortality in cases of NSTI; therefore, familiarity is crucial for anyone (e.g., surgeon, emergency physician, primary care physician) who might encounter an early presentation. True NSTIs cannot be treated successfully with antibiotics alone (although broad-spectrum antibiotics are an essential adjunct to surgery), and so timely surgical consultation is mandatory.[75] Even with optimal therapy, mortality is approximately 25%–30%, and hospitalization is protracted, complicated, and expensive regardless of outcome.[75–77]

Although many names have been applied to these serious infections, such as synergistic gangrene and the eponymous Fournier gangrene (of the scrotum), it is most useful to characterize NSTIs based on the deepest tissue layer involved by necrosis. Involvement of the skin and subcutaneous tissue only is *necrotizing cellulitis*, whereas involvement of the fascia (most common) is referred to as *necrotizing fasciitis*, and involvement of underlying muscle is referred to as *necrotizing myositis* or sometimes myonecrosis. Some experts classify NSTIs further by the causative pathogen (e.g., clostridial myositis) or whether the infection is polymicrobial (type I) or caused by a single organism (type II). It is important to distinguish NSTI from nonnecrotizing SSTIs, because the latter may be treated effectively with intravenous antibiotics alone. However, only operative debridement can classify accurately the anatomic extent of NSTI; therefore, attempts to classify NSTIs preoperatively can only engender dangerous, even life-threatening delay.

Etiology

Necrotizing STIs can be primary or secondary events. Primary, or idiopathic, infections are less common and lack a portal of entry. Whether the source of bacteria in primary NSTIs is the blood stream or from epithelial disruptions too small to be apparent is debated; either mechanism is possible. One well-known example, the halophilic marine bacteria of the genus *Vibrio* (especially *V. vulnificus*),[78] can cause NSTIs after ingestion of raw seafood or skin trauma while wading in seawater. Another example is NSTI caused by *Clostridium septicum*, which is specifically associated with occult carcinoma of the colon and likely arises after a bacteremia.[79]

Much more common than primary infections are secondary infections, which may arise after burns or trauma, in recent surgical incisions, or as a consequence of unrecognized, neglected, or inadequately treated SSTIs. Other potential portals of entry include human, animal, or insect bites, and parenteral drug abuse.[80] Secondary NSTIs often have associated conditions that can predispose to tissue necrosis or impede containment by local host defenses. Inadequate treatment of SSTIs, such as decubitus ulcers,[81] ischemic leg ulcers, Bartholin cyst abscess, or perirectal or ischiorectal abscess, poses a high risk of progression to NSTI. However, for reasons that are unclear, SSTIs of the face, neck, or chest[82–85] progress less often to NSTI than infections of the perineum and lower extremity.

Microbiology

Necrotizing STIs are divided into two categories: polymicrobial (type I, 80%) and monomicrobial (type II, 20%). Monomicrobial NSTIs are caused most commonly by *S. pyogenes*, but *S. aureus* and *C. perfringens* can also be causative. Rare causes of monomicrobial NSTI include *V. vulnificus*, community-associated MRSA,[11] and *Bacillus cereus*.[86] *Pseudomonas*

aeruginosa rarely is a pathogen of NSTI; rarer still are the infections caused by *C. septicum*. Phycomycotic NSTI (mucormycosis) caused by *Rhizopus*, *Mucor*, or *Absidia* spp. may occur in profoundly immunosuppressed patients or after accidental burial by a landslide. Much more common are the polymicrobial NSTIs, which account for approximately 80% of cases. Aerobic gram-positive and -negative bacteria and anaerobes are usually all present, and the bacteria may act synergistically to promote dissemination and increase toxicity. *Escherichia coli* and *B. fragilis* are the most common aerobic and anaerobic isolates, respectively.[87] The most likely gram-positive coccus to be isolated depends on the clinical context. For example, enterococci are more likely to be isolated when the NSTI complicates a recent abdominal incision.

Pathogenesis. After inoculation of susceptible tissue, several factors determine the extent of infection, including the size of the inoculum, the invasiveness of the organism,[88,89] the presence of a foreign body or ischemic tissue, and impaired host responses. Inoculation can occur from delayed or inadequate treatment of an initially localized process, inappropriate closure of a contaminated surgical incision that should have been left open, or in the presence of an enterostomy or retention sutures. Inoculation may also be occult; for example, NSTI of the thigh can be the initial manifestation of a colon perforation into the retroperitoneum.

The hallmark of NSTI is rapid progression and a fulminant clinical course. Both monomicrobial and polymicrobial NSTIs are true emergencies that require rapid diagnosis and definitive treatment. Several bacterial enzymes cause tissue damage and promote bacterial invasiveness, including hemolysin, fibrinolysin, hyaluronidase, and streptokinase elaborated by *S. pyogenes*; collagenase elaborated by *P. aeruginosa*; and lecithinase elaborated by *C. perfringens*. Polymicrobial NSTIs are characterized by synergistic interactions of facultative aerobes and anaerobes. Tissue hypoxia and impaired neutrophil function create conditions favorable for the proliferation of facultative bacteria, which consume oxygen in the microenvironment and lower the tissue redox state, thereby creating conditions favorable for the growth of anaerobes.

Extensive tissue necrosis develops from direct tissue injury caused by bacterial toxins, inflammation and tissue edema, and vascular thrombosis. The subcutaneous fat and fascia are more likely than the overlying skin to develop necrosis. Thus, there may be little or no early cutaneous evidence of underlying infection, but the patient will complain of severe pain. As the infection progresses, thrombosis of the cutaneous microcirculation leads to the characteristic erythema, edema, bullae, and overt gangrene of advanced NSTI.

Soft tissue gas may or may not be present, depending on the pathogens involved, but develops as a result of anaerobic wound conditions that allow gas-forming organisms to proliferate, including *C. perfringens*, *B. fragilis*, *E. coli*, *K. pneumoniae*, *P. aeruginosa*, and *Proteus* spp. These bacteria produce insoluble gases such as hydrogen, nitrogen, and methane, which remain in the tissue to a variable degree. Gas in the tissue tends to be a late finding in nonclostridial polymicrobial infections and to be absent in NSTI caused by *S. pyogenes*.

Diagnosis

The diagnosis of NSTI is based primarily on the history and physical examination. One notable early characteristic is a complaint of severe pain that is disproportionate to local physical findings. Inspection of the overlying skin may yield few early clues as cutaneous stigmata may be subtle. Clinicians should consider NSTI for all soft tissue manifestations of inflammation signs and symptoms such as pain, swelling, rubor, increased temperature, and loss of function. Characteristic features to elicit include edema and tenderness that extend beyond the margin of erythema, skin vesicles or bullae, crepitus, and the absence of lymphangitis and lymphadenitis. Erythema limits should be marked with a pen and should be reexamined frequently; failure to improve with appropriate antibiotics should prompt further investigation. Crepitus is a specific indicator but not commonly present in early NSTIs. As infection progresses, cutaneous anesthesia and necrosis develop along with clinical manifestations of sepsis (fever, tachycardia, hypotension, and encephalopathy). Occasionally, patients with clostridial sepsis will present with anemia and jaundice secondary to hemolysis, and patients with myonecrosis will present with myoglobinuria, rhabdomyolysis, and acute renal failure.

Some common laboratory tests may point the clinician toward the diagnosis of NSTI in the appropriate clinical context. Wall et al.[90,91] showed that hyponatremia ($[Na]_{serum}$ < 135 mEq/dL) and leukocytosis (white blood cell count >14 × 10⁹/L) have good diagnostic accuracy (Table 43.14). Wong et al.[92] described the Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score (Table 43.15), which may be even more accurate. Although these observations have not been subjected to independent validation, they may be valuable to the extent that it *heightens* the suspicion of a clinician confronted with a possible NSTI.

If the diagnosis is not obvious by physical examination and laboratory testing, radiographic studies may be obtained, provided surgical exploration, which is the definitive diagnostic test as well as therapeutic intervention, is not unduly delayed. Plain radiographs can demonstrate gas in the soft tissues even in the absence of crepitus, but the absence of gas does not exclude the presence of NSTI. Computed tomography is sensitive for the presence of soft tissue gas, and it may also demonstrate asymmetric edema of tissue planes (a nonspecific finding). A CT scan may be helpful in the evaluation of the obese patient with a deep-seated infection, a circumstance where the physical examination can be unreliable. However, to the extent that obtaining any imaging study will delay the operative management of the patient, they should be avoided. Wheareas fine needle aspiration and incisional biopsy of questionably affected tissues may add information, these should only be used in the setting of operative debridement. Gram stain of the biopsy material can demonstrate causative organisms and an inflammatory cell infiltrate; frozen section demonstration of necrosis, thrombosis, or pathogens in tissue are diagnostic. The use of imaging or biopsy as "confirmatory" tests cannot be condoned. Clinical diagnosis alone is sufficient to begin broad-spectrum antimicrobial therapy and undertake surgical exploration and debridement.

Treatment

The management of NSTI is a true emergency. The elapsed time between the onset of symptoms and the initial operative treatment is the single most important factor influencing morbidity and mortality. Delay in diagnosis must be avoided at all costs, as the success of management depends on prompt recognition and operative debridement.[93–95] Once the diagnosis of NSTI is made, tissue salvage and patient survival can only be achieved by prompt, widespread debridement in the operating room. Operative debridement should not be delayed for resuscitation, as this may be performed in the operating room, and the patient may not respond to resuscitation until

TABLE 43.14

OBJECTIVE CRITERIA TO DISTINGUISH NECROTIZING SOFT TISSUE INFECTIONS
FROM NON-NECROTIZING INFECTIONS

■ **A. DIAGNOSTIC ACCURACY**

	■ SENSITIVITY (%)	■ SPECIFICITY (%)	■ POSITIVE PREDIC-TIVE VALUE (%)	■ NEGATIVE PREDIC-TIVE VALUE (%)
Tense edema	38	100	100	62
Gas on x-ray	39	95	88	62
Bullae	24	100	100	57
WBC > 14 × 10⁹/L	81	76	77	80
Sodium <135 mg/dL	75	100	100	77
Chloride <95 mg/dL	30	100	100	55
BUN > 15 mg/dL	70	88	88	71

■ **B. INCIDENCE OF POSITIVE LABORATORY PARAMETERS (UNIVARIATE ANALYSIS)**

	■ NECROTIZING FASCIITIS	■ OTHER INFECTION	■ *P* VALUE
WBC > 14 × 10⁹/L	17/21 (81%)	5/21 (24%)	0.0002
Sodium <135 mEq/L	15/20 (75%)	0/17 (0%)	0.0001
Chloride <95 mEq/L	6/20 (30%)	0/17 (0%)	
BUN > 15 mg/dL	14/20 (70%)	2/17 (12%)	0.0007

BUN, blood urea nitrogen WBC, white blood cell Data from Wall DB, de Virgilio C, Black S, et al. Objective criteria may assist in distinguishing necrotizing fasciitis from nonnecrotizing soft tissue infection. *Am J Surg*. 2000;179:17–21; Wall DB, Klein SR, Black S, et al. A simple model to help distinguish necrotizing fasciitis from nonnecrotizing soft tissue infection. *J Am Coll Surg*. 2000;191:227–231.

EMERGENCY SURGERY

the infected tissue is removed. Identification of the causative organism(s) and underlying pathology can wait. Antibiotics are a necessary adjunct and must be started immediately, but they are only an adjunct; the mortality of true NSTI managed nonoperatively is 100%.

The patient should have blood products available in the operating room and should have adequate IV access for resuscitation. The first surgical objective is a thorough wound exploration to confirm the presence and extent of NSTI. Debridement of all infected, devitalized tissue must be aggressive. The underlying tissue necrosis usually extends far beyond the boundary of the skin involvement; therefore, exposure must be wide and dissection must extend beyond the boundary of tissue viability. Considering that these infections spread rapidly, resection of a margin of viable tissue is prudent even at the cost of additional deformity or disability; certainly, all non-viable tissue should be removed at the initial operation. When the margin of viability is indistinct, frozen section examination of the limits of resection can occasionally be helpful. NSTIs are characterized by gray-brown fluid drainage, gray fascia, easy separation of subcutaneous fat from fascia, or dead muscle. Wound drainage must be submitted for comprehensive microbiologic testing. Fasciotomies should be performed if compartment syndrome is suspected or is a likely sequela of impending resuscitation. A temporary prosthesis may be necessary to reconstruct the abdominal wall to prevent evisceration in some cases. All open wounds are irrigated before loose packing with saline-moistened gauze.

Routine reexploration in the operating room is necessary at 24 hours to ensure that all necrotic tissue has been debrided. Patients with NSTIs are often unstable, so ICU management

must also be aggressive with mechanical ventilation, fluids, blood and blood products, and hemodynamic support as appropriate so that the crucial return trip to the operating room can occur on schedule. End-organ dysfunction such as acute kidney injury and coagulopathy should be treated supportively and aggressively so that return trips to the operating room are not delayed. Operative debridement is continued daily until the infection is controlled. Extremity amputation or colostomy may be necessary to manage severe infections of the extremity or perineum, respectively.

Empiric antibiotics must be effective against a broad range of potential pathogens (gram-positive cocci, gram-negative bacilli including *Pseudomonas*, and anaerobes), because the infecting organism usually cannot be discerned from inspection alone. Empiric antifungal therapy is unnecessary in most cases of NSTI. Antibacterial monotherapy can be achieved with a carbapenem or piperacillin–tazobactam. Current guidelines recommend ampicillin–sulbactam, but activity may be inadequate against *E. coli* and *K. pneumoniae*. Clindamycin in high dosage may be preferable to penicillin G for streptococcal infections, because of *in vitro* evidence that clindamycin inhibits toxin production. Clindamycin is also effective against MSSA. Metronidazole can be substituted for clindamycin for therapy for type I infections if better anaerobic coverage is needed. Gentamicin is best avoided because of the additive risk of acute kidney injury in patients who may be hypovolemic or hypotensive. However, gentamicin is an efficient microbicide when given in adequate dosage; single-daily dose administration provides an adequate peak serum concentration while also minimizing toxicity. Combination therapy that includes vancomycin is now popular, especially considering that nearly 60% of *S. aureus* strains are now MRSA. Vancomycin or other

TABLE 43.15

LABORATORY RISK INDICATOR FOR NECROTIZING FASCIITIS (LRINEC) SCORE

■ PARAMETER	■ POINT VALUE
C-reactive protein, mg/L	
<150	0
≥150	4
White blood cell count, mm^3	
<15	0
15–25	1
>25	2
Hemoglobin, g/dL	
>13.5	0
11–13.5	1
<11	2
Sodium, mEq/L	
>135	0
≤135	2
Creatinine, mg/dL	
≤1.6	0
>1.6	2
Glucose, mg/dL	
≤180	0
>180	1

The maximum LRINEC score is 13 points. A score of ≥6 points should raise the suspicion of a necrotizing soft tissue infection, whereas a score of ≥8 points is strongly predictive. The model was constructed retrospectively but has a positive predictive value of 92% at a cutoff score of 6 points, and a negative predictive value of 96%.

Adapted from Wong CH, Khin LW, Heng KS, et al. The LRINEC (Laboratory Risk Indicator for Necrotizing Fasciitis) score: a tool for distinguishing necrotizing fasciitis from other soft tissue infections. *Crit Care Med*. 2004;32:1535–1541.

agents that are active against MRSA can be added to piperacillin–tazobactam or a carbapenem if appropriate.

All identified pathogens should be treated. The duration of therapy must be individualized, but most NSTIs will require a minimum of 10 days of therapy. Once culture and sensitivity data are available, the empiric antibiotic regimen should be adjusted accordingly. Adjustment can be challenging when multiple pathogens are isolated from a polymicrobial infection, but an attempt must be made to narrow the antibiotic spectrum as appropriate in order to decrease the chance of superinfection by multidrug-resistant pathogens. Clostridial infections are best treated with penicillin alone, but many clinicians prefer high-dose clindamycin to penicillin for NSTIs caused by *S. pyogenes* because of its antitoxin properties. Anaerobic infections of the head, neck, and upper extremity tend to be caused by penicillin-susceptible anaerobes, whereas those of the trunk and lower extremity tend to include *B. fragilis*, against which penicillin is ineffective. Rare phycomycotic infections may require amphotericin B; fluconazole is ineffective.

Patients with traumatic wounds should receive tetanus toxoid or immune globulin, depending on their immunization status. Other therapy is supportive, including early nutritional support and prophylaxis against venous thromboembolic disease. HBO therapy has been advocated, especially for clostridial infections.[92–94] Among the putative benefits of hyperbaric oxygen are inhibition of exotoxin production, increased tissue oxygen tension, and improved neutrophil function. However, there are no randomized trials of HBO therapy of NSTI. A "dive" is time-consuming, and patients may be too unstable for this setting; priority should always be timely diagnosis and rapid transfer to the operating room for wide debridement.

CHAPTER 44 ■ OBSTETRIC AND GYNECOLOGIC EMERGENCIES

DAVID STREITMAN AND W. ALLEN HOGGE

ACUTE SURGICAL CARE CONSIDERATIONS IN THE PREGNANT PATIENT

Pregnant patients who require nonobstetrical surgical intervention pose unique challenges due to altered anatomy and physiology, as well as the impact of the surgical pathophysiology and its treatment upon the fetal environment. Disease processes amenable to surgical intervention are altered in their presentation, by both objective changes in maternal physiology and alteration of symptom perception by the gravid patient. Add to this the reluctance of providers to pursue a surgical therapeutic course for fear of complicating the pregnancy, and the delay of definitive treatment may become a major determinant of outcome. Furthermore, hesitancy to utilize certain diagnostic modalities can delay needed surgical intervention. Acute care surgeons should understand physiologic changes in pregnancy and abnormal presentations of common general surgical problems, since 0.5%-1% of pregnant patients will require nonobstetrical surgical intervention during pregnancy.[1]

To address these concerns, this section will review pertinent maternal physiology and typical diseases that require surgical therapy in pregnancy, provide normal laboratory values in the gravid patient, and give guidance on diagnostic modalities in pregnancy. If a gravid patient presents with signs and symptoms of disease requiring acute surgical intervention, two rules generally apply: treatment that supports or restores normal maternal physiology will help the fetus (*to help the fetus, treat the mother first*), and consultation with an obstetrician, if readily available, is advisable.

MATERNAL PHYSIOLOGY

Acid/Base

Respiratory changes during pregnancy produce a mild alkalosis via hyperventilation while maintaining normoxia. There is a concomitant, although smaller, increase in urinary excretion of bicarbonate. The result is a mild increase in pH with a lower pCO_2 and lower serum bicarbonate. These changes are reflected in the blood gas values typical of pregnancy as seen in the table of normal lab values in pregnancy (Table 44.1).[2]

Cardiovascular

Cardiac output increases in response to an increase in basal metabolic rate along with blood volume expansion that begins at 8 weeks, reaches 15% by 12 weeks, and peaks at 40%-45% increase in blood volume.[3] Reduction in systemic vascular resistance and an increase in resting heart rate of 10 beats per minute help achieve a cardiac output of 6–7 L/min in the third trimester, to 8–9 L/min in labor and in the immediate postpartum period. Maternal position can have a profound effect on cardiac output, with an increase of 1.2 L/min, about 20%, from a supine to left lateral decubitus position.[4] Uterine blood flow at term is 600 mL/min but decreases by as much as one-third in the supine position.[5] This uterine perfusion decline from supine positioning can alter fetal oxygen saturation by 10%[6] and create persistent fetal heart rate decelerations, which may result in fetal distress.

Respiratory

An increase in minute ventilation is produced by 21% increase in tidal volume, whereas respiratory rate remains stable. The diaphragm elevates 4 cm and thoracic diameter increases by 2 cm resulting in a chest circumference increase of 6 cm. However, the sum of these changes is a decrease in total lung capacity of about 200 mL. Expiratory reserve volume and residual volume (and their sum, functional residual capacity) decrease due to diaphragmatic elevation and increase in tidal volume. Inspiratory reserve volume and vital capacity are preserved. Peak expiratory flow decreases by 0.5 L/min/wk of gestation across pregnancy, translating to a loss of 10% in a woman of average height.[7] The total of these pulmonary changes is a diminished capacity of the gravida for tolerating respiratory insult, or exacerbation of underlying pulmonary disease, such as asthma.

Renal

Changes in renal function in pregnancy result in a temporarily hyperfunctioning organ. Both renal perfusion and glomerular filtration rate (GFR) increase early and rapidly. By 2 weeks postconception, GFR increases 25% over nonpregnant status; by the second trimester (13 weeks after the last menstrual period) GFR is up 50%. Renal perfusion increases to a greater degree, until late third trimester when renal perfusion declines slightly more than GFR. The increased urine production results in urinary frequency. Due to anatomic compression of the ureters and dextrorotation of the uterus, hydronephrosis and hydroureter occur, greater on the right than the left. High levels of progesterone from the placenta act as a smooth muscle relaxant, slowing ureteral peristalsis. The result is a higher risk for lower urinary tract infection, and pyelonephritis. Enhanced urine production results in a lower average serum creatinine of 0.5 mg/dL, with levels above 0.8 mg/dL considered abnormal in pregnancy. Hyperfunction allows greater excretion of bicarbonate, with a resulting decrease of serum bicarbonate by 4–5 mEq/dL, helping to balance the hyperventilation in the pulmonary system, and compensating partially for the respiratory alkalosis of pregnancy. Serum osmolarity is reduced by 10 mOsm/L, serum sodium is reduced by about 5 mEq/L, and amino acids and water-soluble vitamins are lost at a greater rate during urine production.

Metabolism

Pregnancy requires 10%-20% more caloric intake or approximately 300 kcal/d.[8] Growth of the fetus and placenta, maternal blood volume expansion, and uterine muscle hypertrophy

605

Normal reference ranges for laboratory values in pregnancy.
[a]Range from references with and without iron supplementation.
[b]Normal reference range is specific range for females.
[c]Range is for premenopausal females and varies by menstrual cycle phase.
Reproduced with permission from: Abbassi-Ghanavati M, Greer LG. *Reference table of normal laboratory values in uncomplicated pregnancies*. In: Cunningham FG, Leveno KJ, Bloom S, et al., eds. *Williams Obstetrics*, 23rd ed. New York: McGraw-Hill; 2010.

occur via addition of 1,000 g of protein. Nitrogen balance is positive due to more efficient use of dietary protein. Urinary amino acid metabolites suggest that maternal muscle is not broken down to obtain the amino acids that the placenta concentrates in the fetus. Medication metabolism is altered with many of the CYP enzymes elevated substantially throughout pregnancy, but others are reduced.[9] Along with increased maternal plasma volume and weight, drug bioavailability and metabolism may be altered in difficult-to-predict patterns.

ANESTHESIA

General endotracheal anesthesia carries greater risk for the pregnant patient, primarily due to increased risk of aspiration and vascular congestion of the airway. Gastric emptying and pH are not altered in pregnancy, but progesterone relaxes the gastroesophageal sphincter, creating the equivalent of a full stomach. Laryngeal edema, soft tissue increases in the upper chest and neck, and the chest wall diameter increase in pregnancy may complicate airway management via face mask,

laryngeal mask, or endotracheal tube. In addition, anesthetic agents, although known not to increase malformation risks for the fetus, are capable of hampering physiologic compensation for supine positioning and aortocaval compression in the second and third trimesters.

FETUS

Gestational age plays a key role in determining the approach to operative treatment in pregnancy. At term (>37 weeks gestation), delivery concomitant with surgical therapy may be an appropriate approach, though cesarean delivery is not uniformly indicated. Preterm birth occurs in about 5% of gravidas undergoing abdominal surgery before 37 weeks. Operative treatment for disease with a prominent infectious or inflammatory component is more likely to result in labor. Due to the increased risk of preterm birth, antenatal steroids (betamethasone 12 mg parenterally, 2 doses 24 hours apart) to accelerate fetal lung maturation should be considered between 24 and 34 weeks gestation, if the surgical condition is not adversely

affected. Fetal lung surfactant production stimulated by beta-methasone commences within hours and peaks by 48 hours after the first dose. However, operative intervention should not be postponed for that goal unless it is safe to do so. If maternal status allows, transfer to a tertiary care center should be made in case preterm delivery ensues. If transfer is not possible and delivery seems likely, then transport of the neonate needs to be arranged.

SURGICAL AND OBSTETRIC EMERGENCIES

Trauma

Trauma is a leading cause of maternal mortality, with homicide, accidents, and suicide being the most likely sources of trauma. Fetal death can occur, particularly after 12 weeks' gestation when the uterus becomes an abdominal organ. Severe motor vehicle crashes can result in maternal shock or death, or placental abruption, contributing to fetal loss rate of 8%.[10] Low birth weight and delivery within 48 hours are more common for unrestrained gravidas. If possible, a pregnant woman involved in a vehicular crash should be transported to a center with obstetric and intensive neonatal care capabilities. She should be placed in left lateral tilt position if injuries allow, to optimize cardiopulmonary function. The trauma survey should proceed normally, with attention to maintenance of adequate intravascular volume. Routine laboratory studies are obtained as are any imaging studies necessary for evaluating the injuries. If the mother is Rh negative, RhoGAM should be given after obtaining a type and screen and Kleihauer-Betke test to estimate the volume of any fetomaternal hemorrhage from blunt abdominal trauma. If known or thought to be 24 weeks or greater in gestation, assessment of fetal heart rate by ultrasound, or preferably, continuous external Doppler monitoring of the type used in labor and delivery, should be routine. An obstetric provider familiar with interpretation of fetal heart rate tracings (obstetrician, family practitioner, certified nurse-midwife or labor and delivery nurse) should assess fetal stability as early in the care as possible. If between 24 and 34 weeks' gestation, administration of betamethasone to accelerate fetal lung maturity should be considered, if not contraindicated.

When the pregnant patient presents with trauma, symptoms such as vaginal bleeding and abdominal pain, and signs, such as tachycardia and hypertension, can overlap with several potential pregnancy complications. With blunt trauma, separation of the placenta from deformation of the uterine wall as a result of direct impact or sudden deceleration can result in *placental abruption*. Blood loss of 1–2 L can be sequestered in the gravid uterus, resulting in severe abdominal pain or labor, and can lead to rapid onset DIC. This places the mother and fetus at grave risk, with need for immediate delivery to prevent fetal death. A large-volume transfusion protocol should be employed early in the management of abruption of this degree. In addition, a drug screen should be obtained. Illicit drug use is a common problem in obstetrical emergencies. Nearly half of trauma in pregnancy is associated with substance abuse. Heroin and methamphetamines are the most commonly abused drugs in pregnancy.

Penetrating abdominal trauma is likely to affect the uterus in the second and especially third trimesters, with the risk for fetal injury or death increasing as gestational age increases. Diagnostic peritoneal lavage can be used in the gravid patient safely, although the location for incision may be altered. Amniocentesis may be helpful to determine whether the uterus has been penetrated or the fetus directly injured. Amniotic fluid, obtained by ultrasound-guided needle aspiration, can also be sent for fetal lung maturity studies in late preterm fetuses (>30 weeks) to aid in decisions regarding delivery. Depending upon the degree of prematurity as estimated by gestational age and neonatal care capabilities of the facility, immediate delivery of a fetus injured by penetrating trauma may be indicated.

Nontraumatic Obstetric Hemorrhage

The uterus grows in weight from 70 g nonpregnant to 1,100 g near term. Enlargement is accomplished by myocyte hypertrophy and addition of fibrous and elastic tissue. Perfusion of the uterus increases to a peak of 450–650 mL/min at term[11] through uterine arteries that double their diameter by 20 weeks' gestation, resulting in flow velocity that is eightfold greater than nonpregnant. Venous dilation to accommodate this increased blood flow is accomplished through decreased elastin and reduced adrenergic innervation in response to various placental hormones. Cessation of blood loss from placental implantation site after delivery is accomplished primarily via contraction of myocytes interlaced with the uterine vasculature. In addition, there are substantial increases in several of the coagulation proteins during pregnancy, and platelet concentration is decreased only slightly at term despite a large increase in circulating volume.

However, there are several conditions that can precipitate hemorrhage before or during labor, or after delivery. Acute obstetric hemorrhage is usually evident as vaginal bleeding, but may be sequestered within the uterus. Rarely, hemorrhage can occur intraabdominally. The mother's complaints can range from painless vaginal bleeding to uterine contractions or even tetany; she may even present with signs of peritoneal irritation. Disseminated intravascular coagulation may occur with fetal death, massive placental abruption, or amniotic fluid embolism.

Abdominal Pain

Abdominal pain is a common complaint in normal pregnancy and frequently provokes acute visits to the obstetrician. Etiologies for abdominal pain may relate directly to pregnancy; "round ligament" pain, contractions, placental abruption, adnexal mass, ovarian torsion, or degenerating uterine fibroids. Other etiologies such as urinary tract infection, constipation, bowel gas, renal calculi, and gallstones are influenced by an enlarging gravid uterus and increasing levels of placental hormones. Some sources of abdominal pain are common, but unrelated to pregnancy *per se*, such as appendicitis, abdominal adhesions, bowel obstruction or intussception, and inflammatory bowel disease.

The most common diagnoses associated with abdominal pain that require surgical intervention are adnexal mass, appendicitis, and cholelithiasis/cholecystitis. Depending upon gestational age, these may be handled laparoscopically. Several series on third trimester laparoscopic operations appear to provide similar outcomes with the advantages of minimally invasive surgery. An altered approach to laparoscopic entry to the peritoneal cavity may be necessary depending upon the size of the gravid uterus. The greatest danger for appendicitis in pregnancy is delay in diagnosis, with a 50% negative appendectomy rate acceptable, given the high maternal morbidity and mortality as well as preterm birth risk of undiagnosed, ruptured appendicitis. Cholelithiasis can be treated conservatively with some success, although recurrent or prolonged symptoms may mandate cholecystectomy during pregnancy. The greatest danger is progression to cholecystitis, with a

likely increase in preterm birth risk. Risk of untreated ovarian torsion is loss of the affected ovary and ovarian vein thrombus formation.

Surgery Outside the Abdomen

In general, surgery outside the abdomen is less likely to result in preterm birth. There is less opportunity for direct stimulation of the uterus, either by the disease or the surgical procedure. However, involvement of an obstetrician is advisable, and elective surgery should still await delivery of the pregnancy at term.

For orthopedic procedures prompted by trauma, the mechanism of trauma and any concomitant abdominal trauma are factors most likely to determine impact upon pregnancy. If prolonged immobilization is anticipated, thromboprophylaxis may be indicated, possibly for longer than is routine from the orthopedic perspective. Head and neck surgery may be impacted by anatomical alterations involving the airway secondary to vascular congestion as well as soft tissue accumulation in the upper chest and neck. Neurosurgical conditions may impact maternal cardiovascular and pulmonary physiology sufficiently to endanger maternal support of the fetus. At essentially all gestational ages, if management of neurosurgical disease mandates controlled hypotension to preserve maternal life or brain function, it should be used, knowing that the fetus is intolerant of prolonged maternal hypotension and may succumb. Thoracic surgical procedures may have the largest impact on preterm birth risk or pregnancy loss rate outside of abdominal nonobstetric surgery due to the severity of disease that mandates this approach. Cases of cardiopulmonary bypass have been reported with some fetal survival.[12]

The need for fetal monitoring may be driven by the pathophysiology requiring surgical treatment. For nonemergent surgery, recording fetal heart tones prior to and after surgery will be sufficient in most cases. If there is concern for fetal compromise from obstetric disease, fetal monitoring during surgery may be indicated. If need for fetal delivery during nonemergent, nonobstetric surgery is felt to be likely, then appropriate planning for the obstetric and pediatric teams needs to be included.

PREOPERATIVE WORKUP

Preoperative workup involving laboratory testing and imaging warrants special consideration in pregnancy. The table of normal laboratory values in pregnancy (Table 44.1) can aid in understanding expression of pathophysiology. There are some limits on imaging techniques in pregnancy due to fetal concerns. Ultrasound has been used for diagnostic imaging in pregnancy for several decades with a good safety profile and is typically the modality used first in evaluation of abdominal pathology during pregnancy. Ultrasound energy emission when the unit is set for obstetric imaging is half that of routine abdominal ultrasound. However, routine abdominal settings can still be used to image abdominal organs during pregnancy, as energy transfer to the fetus is minimal in most circumstances. Ionizing radiation from x-ray, computed tomography (CT), and fluoroscopy should be minimized or avoided if possible. If used, shielding of the uterus with a lead apron should occur if feasible. However, CT and x-ray imaging protocols that minimize the amount of radiation used in pregnant patients have been developed, and if critical, timely imaging information is required, they should not be withheld. For counseling purposes, the dose of ionizing radiation that reaches the uterus, and thus the increase in risk of childhood cancer for the fetus, can be estimated; the increase in risk is generally quite low. Magnetic resonance imaging (MRI) does not involve ionizing radiation and is thought to be safe for the fetus by most authorities. The use of MRI in pregnancy has expanded over the last 10 years, and more data are available on its diagnostic accuracy, particularly for nonobstetric abdominal pathology in pregnancy. Diagnostic accuracy for appendicitis in pregnancy approaches 95% with MRI.[13] Use of gadolinium in pregnant animals has raised a concern for fetal renal impact, and use in human pregnancy has been studied on a limited basis. Given our current understanding, gadolinium should only be used if the benefit outweighs the risk. Endoscopic and endoultrasonic techniques for gastrointestinal, pulmonary, and cardiac conditions can be done safely in pregnancy. Sedation can be used. However, involvement of an anesthesia provider familiar with anesthesia management in pregnancy may be prudent.

POSTOPERATIVE MANAGEMENT

Postoperative management for a pregnant surgical patient is altered little in most cases. The same postoperative goals of adequate pain control, early ambulation, and judicious advancement of diet should be pursued. Prolonged bladder drainage via catheter should be avoided if possible, as pyelonephritis from ascending infection is more likely in pregnancy. Wound healing is altered for laparotomy incisions, in that the growing uterus will place the incision under constant tension and it may result in a wider cicatrix.

Medications

There are several medications that should be avoided or judiciously used in pregnancy. Antibiotics that should be avoided include fluoroquinolones and tetracycline. Aminoglycosides should be used in the lowest effective dose for the shortest duration to avoid auditory nerve toxicity in the fetus. Narcotic analgesics are the drug class of choice for postoperative pain in a pregnant surgical patient. The lowest dose and shortest duration of narcotic that achieves analgesia adequate to allow ambulation should be used. Such dosing is unlikely to create fetal or maternal dependence for most surgical cases. If prolonged narcotic use is anticipated, then discussion of possible fetal dependence should involve the obstetric and pediatric teams. Nonsteroidal anti-inflammatory medications have limited fetal impact if used for <72 hours below 32 weeks' gestation, but are generally avoided in favor of oral narcotic analgesics because of their effect on the fetal ductus arteriosus. Thromboprophylaxis should be considered perioperatively, with use of compressive devices advisable in all cases where feasible. If surgical treatment is expected to result in prolonged immobilization, such as lower extremity orthopedic procedures, pharmacologic thromboprophylaxis may be warranted. A hematologist or maternal–fetal medicine specialist should be consulted for appropriate dosing and duration.

GYNECOLOGIC EMERGENCIES

Gynecological emergencies can best be classified into two categories: pregnancy related, and non–pregnancy related. For some conditions that are not directly related to pregnancy, the presence of a positive pregnancy test may make that condition more, or less, likely to be the etiology of the patient's presenting complaints. Likewise, management decisions may be altered by the presence of a concomitant pregnancy.

PREGNANCY-RELATED EMERGENCIES

Ectopic Pregnancy

An ectopic pregnancy is the implantation of a fertilized ovum outside the endometrial cavity of the uterus. Approximately 95% of these abnormal implantations are in the fallopian tubes. It is the number one cause of death in the first trimester of pregnancy, and accounts for 1 in 10 pregnancy-associated deaths.[14] It is a commonly misdiagnosed condition with emergency department (ED) physicians failing to make the diagnosis on an initial visit nearly 50% of the time.[15]

Table 44.2 lists the risk factors for ectopic pregnancy. The two main categories are conditions that result in tubal damage, and a history of infertility or infertility treatments.

In the modern era of highly sensitive home pregnancy testing kits, many ectopic pregnancies are diagnosed before the onset of symptoms. For purposes of these discussions, we will concentrate on the symptomatic patient. The classic presentation is a history of a missed menstrual period, abdominal pain, and vaginal bleeding or spotting. However, ectopic pregnancy should be considered in the differential diagnosis of any patient of reproductive age who presents with lower abdominal pain.

Unless there has been rupture of the tubal pregnancy, the physical findings may be minimal. There may be mild tenderness in the lower abdomen on deep palpation. Only 50% of patients will have adnexal tenderness, and about half will have cervical motion tenderness.[16] In contrast, the patient with a ruptured ectopic pregnancy presents with shock, severe abdominal pain, and peritoneal signs.

The key diagnostic tests in the evaluation of a possible ectopic pregnancy are a quantitative beta subunit of human chorionic gonadotrophin (β-hCG), and transvaginal ultrasound. While a single value of β-hCG alone is not useful in differentiation between a normal intrauterine pregnancy, an abnormal intrauterine pregnancy, or an ectopic pregnancy, it may be useful in association with transvaginal ultrasound. In the absence of previous gestational dating, many institutions have established a discriminatory zone for β-hCG, the level above which an intrauterine pregnancy should be visualized by transvaginal ultrasound. A commonly accepted cutoff is 1,500–2,500 IU/L. However, multiple gestations may have much higher levels of β-hCG for any given gestational age, and hCG levels should be interpreted with caution in patients undergoing infertility treatments.

The differential diagnosis for the patient presenting with abdominal pain and a positive pregnancy test includes rupture of the corpus luteum cyst of pregnancy, ovarian torsion, appendicitis, and in rare situations, acute salpingitis. It is possible to have both an ectopic pregnancy and an intrauterine pregnancy simultaneously (heterotopic pregnancy), and, thus, an ultrasound indicating a normal intrauterine pregnancy does not completely exclude an ectopic pregnancy. However, these pregnancies are quite rare, except in patients undergoing infertility treatments.

Management of the patient with a suspected ectopic pregnancy depends entirely on the patient's hemodynamic situation. In the patient with a surgical abdomen, appropriate fluid and blood resuscitation should be followed by laparotomy to remove the affected tube and establish hemostasis. The laparoscopic approach is favored in most cases except in the setting of hemodynamic instability. If possible, the ectopic pregnancy is removed through an incision in the fallopian tube (salpingostomy). The quantitative serum hCG should be followed after salpingostomy to insure complete removal of the pregnancy. If salpingostomy is not possible, the entire affected fallopian tube is removed (salpingectomy). In the hemodynamically stable patient without abdominal findings on examination; that is, the nonruptured ectopic pregnancy, gynecologic consultation is appropriate to determine whether surgical or medical management (special circumstances in the compliant patient) of the unruptured ectopic pregnancy is appropriate.

Spontaneous Abortion

Vaginal bleeding in the first trimester of pregnancy should prompt first the question of whether the pregnancy is intrauterine, or represents an ectopic pregnancy. Once the diagnosis of an intrauterine pregnancy is confirmed, an evaluation to determine the cause and implications of the bleeding can be undertaken. It is important to note, however, in the setting of potentially life-threatening hemorrhage, the priority is hemodynamic stabilization before proceeding with any evaluation.

Loss, or the potential loss, of the pregnancy prior to 20 weeks' gestation is termed an abortion, and abortion is generally subdivided into five categories (*threatened*, *inevitable*, *missed*, *incomplete*, *complete*); each is briefly discussed below. *Threatened abortion* is the most common diagnosis, and is given to any woman who presents with vaginal bleeding, a closed cervix, and an apparently normal intrauterine pregnancy by transvaginal ultrasound. Some of these patients will ultimately lose the pregnancy, but the majority will result in a normal outcome. Management of these patients is conservative, and should be done in consultation with the patient's gynecologist.

Missed abortion is the patient presenting with vaginal bleeding, a closed cervix, but an ultrasound revealing a nonviable fetus (embryonic demise) or an empty gestational sac (anembryonic demise). Rarely is vaginal bleeding excessive in this situation, and the patient can be referred to her gynecologist for either surgical or medical evacuation of the uterine contents.

The two situations most likely to present with severe vaginal hemorrhage are an *inevitable abortion*, and an *incomplete abortion*. In the circumstance of an inevitable abortion, the patient will be noted by speculum examination to have a dilated cervix, often with products of conception protruding through the open cervix. As the term implies, there is no therapy to maintain the pregnancy once the cervix has dilated, and suction curettage should be performed to remove the products of conception. Incomplete abortion is diagnosed when a portion of the products of conception have been passed, but vaginal bleeding persists and ultrasound indicates retained products of conception. Incomplete abortion is the most likely diagnosis when a patient presents with severe, or life-threatening vaginal hemorrhage in the first trimester. Once the patient has been stabilized, suction curettage should be performed to remove the remaining products of conception.

TABLE 44.2

RISK FACTORS FOR ECTOPIC PREGNANCY

- Prior ectopic pregnancy
- History of pelvic inflammatory disease (PID)
- History of tubal surgery
- Current IUD use
- History of infertility for ≥ 2 y
- Current infertility treatment
- Smoking
- Older maternal age

Complete abortion refers to the clinical circumstance where the patient has had intense bleeding and cramping that has resolved on presentation. Ultrasound will confirm that the uterus is "empty" and that pregnancy has been completely expelled. Once the patient is hemodynamically stable, she can be referred to her gynecologist for postabortion care.

NON–PREGNANCY-RELATED CONDITIONS

Ovarian Cysts

Ovarian cysts commonly cause pelvic pain, and are classified as either functional (arising as a result of the normal menstrual cycle) or neoplastic (a true cyst arising from the epithelium). The patient presents with pain from rupture, hemorrhage, or torsion. Diagnosis is made by history and physical examination; pelvic examination will confirm the diagnosis and define the type of cyst. Management is supportive, including appropriate pain therapy. Nonsteroidal agents are first-line choices, with opioids used for more severe discomfort (although more pain suggests ovarian torsion). Hemorrhagic cysts may require surgical management if there is ongoing hemorrhage.

Torsion of the Ovary

Ovarian torsion is caused by rotation of the ovary or the entire adnexa about the ovarian pedicle, resulting in arterial, venous, or lymphatic obstruction. It accounts for a small percentage of surgical emergencies in women but requires immediate surgical intervention when a presumptive diagnosis is made.

The symptoms of ovarian torsion classically are sudden onset of unilateral pelvic pain with radiation to the flank, associated with nausea and vomiting. In some cases, the patient will present with a history of dull aching pain, but with sharp exacerbations. A low-grade fever is often seen, and laboratory evaluation shows a moderate leukocytosis. Abdominal examination is characterized by rigidity, spasm, and tenderness with unilateral pain on deep palpation.

Huchon et al.[17] have recently published a scoring system to assist in the diagnosis of adnexal torsion. The five criteria most associated with torsion are the absence of vaginal bleeding or discharge, an ovarian cyst of >5 cm seen on ultrasonography, unilateral lumbar or abdominal pain, pain lasting <8 hours, and vomiting. However, the authors admit that their scoring system does not perform better than good clinical judgment. A patient with a documented ovarian mass by ultrasound, presenting with pain and vomiting, must be assumed to have adnexal torsion, and immediate surgical intervention is indicated. The early diagnosis and treatment of adnexal torsion may allow preservation of the affected adnexal structure.

Ruptured Tuboovarian Abscess

The life-threatening complication of pelvic inflammatory disease (PID), is rupture of a tuboovarian abscess. Rupture of a tuboovarian abscess is associated with septic shock, and a mortality rate that approaches 15%.[18] Key features in the history are previous diagnosis of a sexually transmitted infection, previous treatment of acute salpingitis, or the presence of an IUD. Physical findings are consistent with an acute surgical abdomen.

Immediate management involves aggressive fluid resuscitation, broad-spectrum antibiotics, and intravenous sympathomimetics, if necessary. Once the patient is stabilized, she should undergo exploratory laparotomy to remove the abscess, and irrigate the peritoneal cavity. The extent of the surgery will depend upon operative findings, and the patient's desires regarding future childbearing.

Endomyometritis is an infection of the endometrium with extension to the myometrium, commonly diagnosed following a therapeutic termination of pregnancy, with an incidence of 1 per 100 procedures. Pathogens include group B beta streptococcus, *Staphylococcus aureus*, *Bacteroides* species, *Neisseria gonorrhea*, and *Chlamydia trachomatis*. The patient commonly presents within 5 days of procedure or delivery with abdominopelvic pain, fever, and a foul-smelling discharge. Physical examination reveals uterine tenderness. Management requires admission to the hospital and broad-spectrum parenteral antibiotics. Ultrasound to detect retained products of conception is important in patients not responding to antibiotic therapy. Dilation and curettage is necessary in patients with endometritis and retained products of conception.

Endometriosis is a common condition, present in up to 15% of premenopausal women. The condition is the result of hormonally responsive implants of endometrial tissue in the abdominopelvic cavity on areas such as the peritoneum, bladder, and bowel.

The etiology of endometriosis is uncertain but may be related to retrograde menstruation through the fallopian tube. The most common complaint is cyclic abdominal pain and painful menses (dysmenorrhea). Physical examination reveals abdominal or pelvic tenderness. An ovarian or pelvic mass may be palpated and may represent an endometrioma. Rectovaginal examination may reveal nodularity in the rectovaginal septum or uterosacral ligaments. Similar to simple ovarian cysts, acute management centers on pain control. Patients with endometriosis will need outpatient gynecologic management to determine what medical or surgical treatment plan is most appropriate. Endometrial implants may also be found in incisions for obstetric or gynecologic procedures.

Pelvic Inflammatory Disease is an inflammatory condition of the upper genital tract thought to be caused by ascension of microorganisms from the lower genital tract. This disease may include infection of the endometrium (endometritis), fallopian tubes (salpingitis), or peritoneal cavity. The disease may progress to tuboovarian abscess, as mentioned above. Prompt diagnosis and treatment of PID is important to prevent both short- and long-term morbidity in women with the diagnosis. The consequences of PID include infertility, increased risk of ectopic pregnancy, and chronic pelvic pain.

The CDC estimates that there are approximately 780,000 new cases of PID being diagnosed annually in the United States. Risk factors for development of PID include young age, multiple sex partners, young age of sexual debut, and lack of use of barrier contraception. Cases caused by *N. gonorrhea* is 43%, 10% is by *C. trachomatis* alone, and 12% is caused by coinfection with both organisms; the remaining 30% of PID is caused by infection with anaerobic bacteria, *Mycoplasma,* and *Ureaplasma.*

Diagnosis is often difficult and inaccurate secondary to wide variation in severity of symptoms. The gold standard for diagnosis remains laparoscopy with directed biopsy and culture, although this is not practical or necessary for most patients. The CDC criteria for the diagnosis of PID require the presence of uterine or adnexal tenderness AND cervical motion tenderness. The patient may also have one or more of the following: temperature of >101°F, a mucopurulent cervical discharge, white blood cells on wet mount, elevated sedimentation rate, elevated C-reactive protein, or positive testing for *N. gonorrhea* or *C. trachomatis*.

The goals of management are treatment of the immediate symptoms of abdominal pain and pelvic pain, and prevention of later consequences: infertility, ectopic pregnancy, and chronic pelvic pain.

Vaginal Bleeding

Profuse vaginal blood loss to the extent to compromise hemodynamic status can either be pregnancy related or not. Regardless of the etiology, if the vital signs point to an acute and profound process, the patient should be managed as a trauma patient with fluid resuscitation and rapid transfusion. Vaginal examination should be performed to confirm the source of bleeding, search for vaginal trauma or cervical neoplasm, or ensure whether the source is intrauterine. Bimanual examination is helpful to assess for uterine size or adnexal pathology that might explain the etiology of the blood loss. The two key laboratory tests are complete blood count and a quantitative β-hCG. Once pregnancy is excluded, the first-line treatment for excessive intensive bleeding is high-dose estrogen, or combination of estrogen/progestin, therapy to control the bleeding. Once the bleeding has been controlled, the patient can be evaluated as an outpatient. In the rare circumstance where the bleeding does not respond to medical therapy, alternative therapies include endometrial ablation or uterine artery embolization.

Sexual Assault is a common problem in the United States, with increasing prevalence. Although most sexual assaults go unreported, many victims present for care following an assault. The true incidence is unknown, although in some studies, up to 24% of women report that they have been the victim of a completed rape, with another 20% reporting that they have been the victim of an attempted rape. Women between the ages of 17 and 25 are the most common victims of rape, and nearly three quarters of women know the assailant. One-third of rapes involve oral and/or anal penetration.

MANAGEMENT

Victims should be immediately taken to a private room in the ED. With the permission of the victims, and not to impede evaluation and treatment of medical conditions or injury, law enforcement personnel should be contacted early to aid with the combined medical–legal needs. If available, a sexual assault team, or an experienced clinician, is preferred to provide the best possible evaluation and care. Many EDs have a "rape kit" with guided evaluation to thoroughly obtain and protect evidence. A thorough history should be taken detailing all of the specifics of the assault that the patient can remember. Clothes should be gathered and labeled with the patient's name, date, and time of collection. Evidence should never be left unattended to maintain the chain of evidence of clinician to law enforcement. Physical examination should include a complete body examination. Any moist or dried secretions, stains, hair, or foreign material should be collected. A Wood's lamp may ease collection. A complete pelvic examination should be performed, with attention to the presence of any secretions, stains, hair, or foreign material. The pubic hair must be combed and the material collected sent with the comb to the laboratory. A speculum examination should be performed, with careful attention to trauma to the vaginal walls. Also, vaginal fluid should be collected, to be examined for the presence of sperm. Swabs should be obtained, to examine for gonorrhea, chlamydia, and Trichomonas. A bimanual examination should be performed, to assess for pelvic trauma. Rectal examination should be included as necessary, with the collection of appropriate specimens. Finally, blood should be obtained to test for HIV, hepatitis B, and syphilis. In select cases, directed toxicology screening may be needed. Emergency contraception should be offered to all victims of sexual assault. Immediate counseling should be available, along with structured follow-up for medical and psychologic assessment after the initial evaluation. Depending upon state and local regulations, other specimens may be collected such as blood, saliva, and fingernail debris.

EMERGENCY SURGERY

CHAPTER 45 ■ NONTRAUMATIC VASCULAR EMERGENCIES

BRIAN L. CHEN, JARROD D. DAY, BABATUNDE H. ALMAROOF, SADAF S. AHANCHI, AND JEAN M. PANNETON

Nontraumatic vascular emergencies span the entirety of the body as would be expected given the life-essential nature of the vascular system. The diverse presentations reflect the specifics of each affected tissue bed. However, common themes unite the management of these conditions. First, thorough physical examination is essential as many of the vascular beds can be interrogated directly by examination or its extension, Doppler ultrasound. Second, imaging modalities, including color duplex ultrasound, computed tomographic angiography, and angiography, complement the evaluation of a vascular patient, helping to determine the optimal treatment. Finally, technologic advances in transcatheter intervention now present the surgeon with attractive alternatives to traditional open surgery. Some endovascular interventions complement rather than replace surgery, so multidisciplinary vascular skill sets are becoming essential. Given the rapid evolution of vascular surgery, continuing medical education is essential in caring for these conditions.

In this chapter, the breadth of both arterial and venous conditions most commonly presenting in the emergency room is addressed. For the arterial system, rupture and ischemia in multiple anatomic territories and acute aortic dissection are discussed. For the venous system, the management of venous thrombosis in multiple organ systems is reviewed.

ARTERIAL EMERGENCIES AND ARTERIAL RUPTURE

Abdominal Aortic Rupture. Approximately, 15,000 deaths per year due to ruptured abdominal aortic aneurysms (rAAAs) occur in the United States, making it the 13th leading cause of death.[1] These deaths represent a small fraction of the estimated 1.7 million patients with abdominal aortic aneurysm (AAA) in the United States, with 190,000 new cases discovered each year.[1]

To date, the cause of AAA in the majority of patients is unknown. Although atherosclerosis, hypertension, smoking (8:1), and male gender (4:1) have been found to be associated with AAA, no specific mechanism accounts for the development of AAA.[2] In a minority of patients, AAA is known to be related to underlying connective tissue disorders, such as Marfan's syndrome or Ehlers-Danlos syndrome, aortitis due to syphilis or other aggressive microorganisms, or degeneration of wall integrity with aortic dissection and cystic medial necrosis.

The classical presentation of rAAA is hypotension, abdominal or back pain, and a pulsatile abdominal mass. However, rAAA can present insidiously even while the rupture is contained by the retroperitoneum or if only a small leak has developed. Inevitably, acute decompensation with loss of tamponade occurs within 24 hours leading to hemorrhagic shock. The rupture frequently occurs through the left posterolateral aortic wall into the retroperitoneum (Fig. 45.1). Rupture into the gastrointestinal tract or inferior vena cava (IVC) (aortocaval fistula) have been reported. Patients with aortocaval fistula

may also have an audible abdominal bruit and venous hypertension resulting in swollen cyanotic legs, lower gastrointestinal bleeding, and hematuria. Rarely, contained rAAA presents with radicular symptoms due to nerve root compression and bowel obstruction due to compression. Additionally, fever and leukocytosis in the presence of rAAA symptoms merit consideration of infected AAA, as these patients are at high risk for rupture.[3]

The classic presentation of rAAA remains an indication for proceeding directly to the operating room (OR). However, for patients who present with stable hemodynamics, the diagnostic algorithm has evolved over the last decade. With the increased availability of spiral computed tomography (CT), patients can be screened for rAAA within minutes. The anatomical information provided by a CT angiogram (CTA) helps determine suitability for an endovascular aortic repair (EVAR).

Controversy exists with regard to the optimal technique for repair of rAAA. However, multiple studies have been published demonstrating decreased mortality for EVAR compared to open repair. In a recent meta-analysis, a 38% reduction in mortality was reported in patients treated with EVAR versus open repair for rAAA.[4] However, the substantial institutional, material, and manpower commitments necessary to execute an emergent EVAR for rAAA must be emphasized.

Mehta published the Albany Vascular Group's standardized protocol for endovascular aneurysm repair of rAAA (Algorithm 45.1).[5] Hemodynamically unstable patients (systolic blood pressure <80 mm Hg) proceed directly to the OR. Permissive hypotension is utilized in these patients to limit further hemorrhage. Stable patients undergo emergent CTA to evaluate for EVAR anatomic suitability and then proceed to the OR. While in the OR, a femoral artery cutdown is completed to allow placement of a long 12–14 French arterial sheath, which is advanced over a guidewire into the juxtarenal aortic position, allowing both performance of an angiogram via the sheath and support of an aortic occlusion balloon. If a patient remains hemodynamically unstable, an aortic occlusion balloon is advanced over the wire into the supraceliac position. Inflation of the occlusion balloon replaces the traditional supraceliac aortic clamp, allowing the anesthesia team to resuscitate the patient with free rupture from the aorta thus controlled. An angiogram is performed to evaluate the neck of the aneurysm to determine if an EVAR is feasible. A detailed discussion of the technique of EVAR is beyond the scope of this chapter, but in short, the technique involves placement of a covered stent graft inside the aorta to cover the rupture and exclude the aneurysm. Current commercially available endografts require a 10–15 mm proximal neck and a 20 mm iliac landing zone to complete an EVAR successfully.

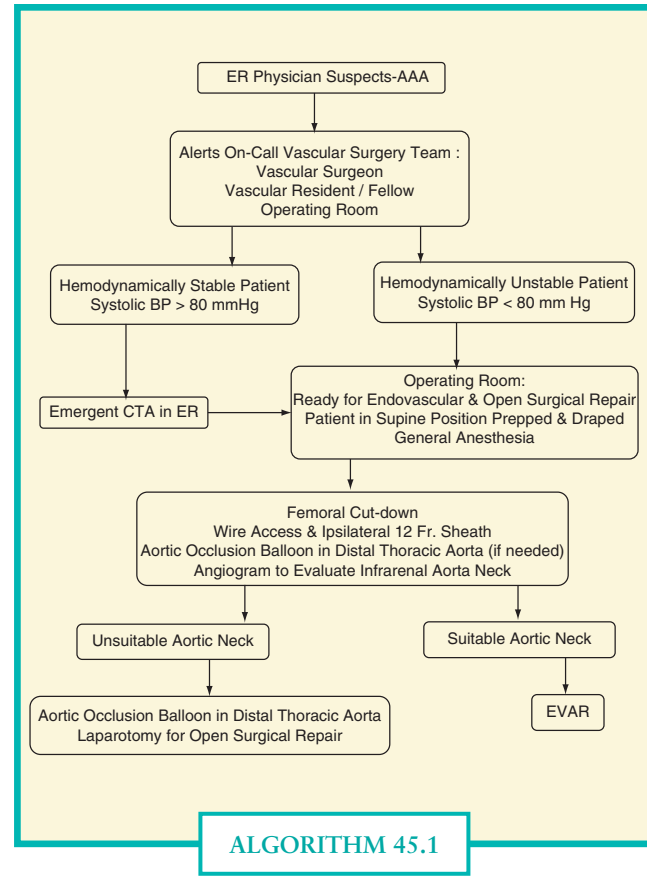
If the patient's anatomy is not compatible with EVAR, an open repair is necessary. First, an abdominal incision is made, either midline or wide transverse for a transperitoneal approach or a left flank lazy S incision for a retroperitoneal approach. If the retroperitoneal hematoma extends to the pararenal aorta or root of the mesentery, the supraceliac aorta is exposed by dividing the left triangular ligament of the liver and opening the lesser omentum. If the hematoma is
FIGURE 45.1. Abdominal aortic aneurysm ruptured with left posterolateral retroperitoneal hematoma.

ALGORITHM 45.1

ALGORITHM 45.1 Albany vascular group ruptured AAA protocol. (Reproduced from Mehta M, et al. Establishing a protocol for endovascular treatment of ruptured abdominal aortic aneurysm: outcomes of a prospective analysis. *J Vasc Surg*. 2006;44:1–8, with permission.)

more contained, then direct exposure of the infrarenal aorta can be accomplished, taking care to avoid injury to the crossing left renal vein. Also, remember that the left renal vein is posterior to the abdominal aorta in 5% of patients. Once the supraceliac aorta is exposed, the occlusion balloon can be exchanged for a supraceliac clamp, if necessary. The distal extent of the aneurysm is determined with dissection of the distal aorta. Depending upon the status of the iliac arteries and aortic bifurcation, a bifurcated or tube graft replacement of the aorta is performed. Based on the clinical status of the patient, systemic heparinization may be used. The aorta is controlled proximally and distally with clamps and the aneurysm sac is opened longitudinally. The thrombus is removed from the aneurysm sac and lumbar arteries are suture ligated from within the aorta. If heavy back bleeding is present from the inferior mesenteric artery, its orifice is also suture ligated. A synthetic Dacron graft is sewn into place with permanent synthetic monofilament sutures. The sac should be reapproximated over the graft and the retroperitoneum is closed if possible. If not, a tongue of omentum is rotated into the retroperitoneum to cover the aortic repair in order to prevent aortoenteric fistula formation. Not infrequently, abdominal compartment syndrome develops in rAAA due to the fluid shifts associated with aggressive resuscitation, bowel edema, and accumulation of large intraperitoneal or retroperitoneal hematomas.[6] Thus, consideration of delayed fascia closure or temporary mesh closure may be necessary.

Thoracic Aortic Rupture. Similar to abdominal aortic rupture, ruptured thoracic aortic aneurysms (rTAAs) comprise the majority of the nontraumatic thoracic aortic ruptures. The literature documents an annual incidence of rTAA of 5 per 100,000.[7] The majority of rTAAs are localized to the ascending aorta and arch, with only 30% in the descending aorta.[7] These patients have a mortality rate as high as 97%, with the majority of patients dying before reaching the hospital.[7] In a recent meta-analysis, a male predominance of 70% was reported with an average age of 70 ± 5.6 years old.[8]

Thoracic aortic aneurysms (TAAs) most commonly result from age-related atherosclerotic medial degenerative disease (70%-93%) or aortic dissection (4%-30%).[9] Connective tissue disorders such as Marfan's syndrome (1.6%-10.9%) or Ehlers-Danlos syndrome (1.1%-4.2%), aortitis due to syphilis or granulomatous disease, aortitis such as Takayasu's disease (0.9%-2.1%), and trauma (0.1%-1.8%) have been reported as causes for development of TAA.[9]


Ruptured TAA frequently presents with a mixture of aneurysm and rupture symptoms. Pain is commonly cited: ascending aortic involvement presenting with anterior chest pain, aortic arch involvement leading to neck pain, descending aortic involvement presenting with back pain localized between the scapulae, and diaphragmatic level aortic involvement causing midback and epigastric pain. Interestingly, TAA tend to be more symptomatic (48%) and more likely to rupture than AAA.[9] Ascending aortic aneurysms can cause superior vena cava (SVC) obstruction, aortic valvular insufficiency, and heart failure. Arch aneurysms can cause hoarseness due to recurrent laryngeal nerve compression. Descending thoracic aneurysms can compress adjacent structures, causing dyspnea or stridor with compression of the trachea or a major bronchus, or dysphagia with compression of the esophagus. Thrombus from TAA can embolize to the anterior spinal artery, causing paraparesis or paraplegia, and also to distal tissue beds, resulting in a variety of symptoms dependent on the specific organ or limb affected. Rupture of the ascending aorta may result in pericardial tamponade, dissection of the aortic valve leading to aortic insufficiency, or dissection of the coronary arteries leading to a myocardial infarction. Rupture of a TAA into an adjacent structure can result in hemoptysis, hematemesis, gastrointestinal bleeding, and progressive dyspnea from parenchymal lung compression from intrapleural hemorrhage.

To date, surgical repair in the hands of cardiothoracic surgeons (or vascular surgeons at some centers) continues to be used in the management of ascending aorta and aortic arch rupture. The details of such repairs are beyond the scope of this chapter. In general, repair of ascending aortic rupture involves replacement of the aorta with a Dacron supracoronary tube graft from the sinotubular junction to the origin of the innominate artery under cardiopulmonary bypass with possible aortic valvuloplasty or replacement. For aortic arch aneurysms, deep hypothermic circulatory arrest with cerebral perfusion is used with replacement of the arch with a Dacron graft extending to the descending thoracic aorta. The supra-aortic trunk vessels are either reimplanted or sewn as a patch to the graft. If a concomitant descending thoracic aneurysm is present, an elephant trunk procedure may be completed, in which the graft is allowed to telescope into the descending aorta beyond the arch repair's distal anastomotic suture line.

With the advent of thoracic endovascular aortic repair (TEVAR), the paradigm for repair of ruptured descending TAA has evolved, although the rarity of rTAA limits the availability of class I evidence. TEVAR technology, in short, involves intravascular deployment of a covered stent, which covers the rupture and excludes blood flow from the aneurysm sac, (Fig. 45.2). TEVAR requires proximal and distal landing zones of 20 mm and a commercially available device large enough to exclude blood flow from the aneurysm at these seal zones. Other adjunctive procedures, such as common carotid to common carotid bypass, common carotid to subclavian bypass, or visceral debranching procedures may also be necessary. A recent meta-analysis for ruptured descending TAA demonstrated a lower 30-day mortality in patients treated with TEVAR compared to open repair, 18.9% versus 33.3%.[8] Additionally, myocardial infarction was less common, 3.5% versus 11.1%, and a trend toward improved stroke and permanent paraplegia rates was demonstrated.[10] Other retrospective series support the benefits of this paradigm shift in management.[10,11]

If the patient's anatomy is unfavorable for endovascular repair, surgical repair of the ruptured descending TAA is

A

C

B

necessary. A detailed discussion of such surgical technique is beyond the scope of this chapter. Simplified, the surgical technique involves a left posterolateral thoracotomy or thoracoabdominal incision and clamping the aortic arch either distal to the left subclavian artery or between the left common carotid and left subclavian artery. At the surgeon's judgment, atrio-femoral bypass may be utilized to provide retrograde perfusion to the spinal cord, viscera, and kidneys. Finally, a segmental aortic clamp and sew technique is utilized to minimize segmental spinal ischemia, reimplanting large intercostals arteries as deemed necessary. If mesenteric and renal arteries are compromised by the aortic repair, they should be reimplanted either separately or via a Carrell patch including the compromised arteries.

Iliac Artery Rupture. Similar to rAAA, iliac artery rupture presents in the setting of preexisting iliac artery aneurysms (IAAs). Due to their location in the pelvis, IAAs frequently are not discovered until they are larger than the currently recommended repair size of 3.5 cm. The average mortality for emergent repair of ruptured arteries is 28% versus 5% for elective repair, emphasizing the importance of early detection.[12]

Isolated IAAs are rare with a prevalence of only 0.4%-1.9% of all aneurysms.[12] IAAs are more commonly found with AAAs, being prevalent in 10%-20% of cases of AAA.[12] The primary iliac artery segments involved are: common iliac artery (CIA) (70%), internal iliac artery (IIA) (20%), multiple segments (10%), and external iliac artery (rare).[12] Also, one-third of patients with an IAA will have an aneurysm in the contralateral iliac artery. Etiologies for these aneurysms are unknown, but thought to be similar to the etiologies observed for AAA, with medial degeneration from atherosclerosis being the most common cause.

Ruptured iliac arteries frequently present with sudden abdominal, groin, or thigh pain with a pulsatile mass in the affected groin. Prior to rupture, 50% of IAA will be symptomatic due to compression or erosion into surrounding structures: compression of ureters leading to pyelonephritis and sepsis, compression of the rectum leading to pain with defecation, and compression of pelvic nerves leading to paraesthesias of the lower extremities. Rarely, IAA present with thromboembolic symptoms or cardiac overload due to erosion into an iliac vein.

Open operative repair of IAA remains the gold standard. In short, CIA aneurysms are repaired with interposition graft and IIA aneurysms are repaired by ligation with or without interposition graft placement.[12,13] With the advent of endovascular interventions, multiple series now document endovascular treatment of IAA. IAA in the setting of AAA is now treated by exclusion with endograft iliac limbs as part of EVAR.[12,13] Additionally, embolization of the IIA, consisting of placement of coils in the main IIA trunk if nonaneurysmal and additional coiling of the anterior and posterior divisions of the IIA if aneurysmal, may be a necessary adjunct to prevent a type II endoleak in these cases. In the setting of isolated CIA aneurysm, an endograft iliac limb is deployed if the proximal CIA landing zone is ≥ 20 mm; otherwise, a bifurcated EVAR is completed with iliac limb coverage of the IIA.[12,13] If an isolated IIA aneurysm is present, the IIA is embolized as described above with or without coverage with an iliac endograft limb.[12,13]

Peripheral Artery Rupture. Nontraumatic rupture of peripheral arteries, consisting of arteries distal to and including the subclavian artery and distal to and including the femoral artery, is rare. This is in part due to the rarity of bland aneurysms of these arteries and their tendency to present with thromboembolic symptoms rather than rupture.

In contrast, mycotic aneurysms of peripheral arteries usually rupture. The root cause is infection with bacteria or fungi that lodge in vessels and cause transmural necrosis, leading to aneurysm formation. The clinical presentation of these aneurysms ranges from overwhelming sepsis to more insidious symptoms of fever, malaise, chills, night sweats, and pain. Often on examination, the skin demonstrates erythema, tenderness, and a palpable pulsatile mass.

The high rate of rupture of mycotic peripheral aneurysms justifies intervention in all cases, as antibiotics are inadequate to treat the compromised arterial wall. Debridement of necrotic tissue is essential in all cases. For subclavian and axillary arteries, a discussion of surgical approaches to repairing these arteries is beyond the scope of this chapter, as exposure of these arteries depends on location of involved segment, ranging from median sternotomy or left posterolateral thoracotomy to simple supraclavicular or axillary incisions. In short, if injury to the subclavian vein and brachial plexus can be avoided, treatment involves excision and reconstruction of artery with vein interposition graft.[14] If adjacent structures are likely to be injured, arterial ligation with incision and drainage of the aneurysm has been reported. Forearm and hand mycotic aneurysms usually require only excision and ligation.[15] Finally, femoral and popliteal artery mycotic aneurysms require aneurysm excision and arterial reconstruction with saphenous or femoral vein conduit.[14] Adjuncts such as a sartorius flap may be needed to help cover the arterial reconstruction, allowing then use of aggressive local wound care including negative pressure dressings.

Visceral Artery Rupture. Ruptured visceral arteries are rare yet lethal entities, with 20%-70% presenting as emergencies and 8.5%-75% of patients dying from their ruptured visceral artery.[16] In most cases, rupture is the result of unrecognized preexisting aneurysms, which themselves are rare with a 0.01%-0.2% incidence during autopsy.[17] More than 3,000 visceral artery aneurysms have been reported in the literature, with variable rupture rates depending on the tissue bed involved (Table 45.1). In decreasing order of prevalence in the general population, the most commonly involved visceral arteries include the splenic, hepatic, superior mesenteric, and celiac arteries.[18,19] In reported series, there is a male predominance for visceral artery aneurysms, except for splenic artery aneurysms where there is a 4:1 female predominance. Reported rupture rates are summarized in Table 45.1.[20,21]

In most series, atherosclerosis is cited as the most common etiology for ruptured visceral arteries.[16–19,22] Other etiologies include fibrodysplasia, mycotic aneurysms, blunt trauma, connective tissues disorders such as Marfan's syndrome and Ehlers-Danlos syndrome, vasculitides such as giant cell arteritis and

TABLE 45.1

COMPILATION OF REPORTED VISCERAL ARTERY ANEURYSM RUPTURE RATES AND ASSOCIATED MORTALITY

■ VISCERAL ARTERY INVOLVED	■ RUPTURE RATE	■ MORTALITY FROM RUPTURE

Hepatic artery	<20%	21%-35%
Superior Mesenteric Artery	38%-50%	30%
Celiac artery	13%	50%

polyarteritis nodosa, and gastrointestinal conditions such as pancreatitis and chronic peptic ulcer disease.[16–19,22] Pregnancy merits special mention as the hormonal-mediated changes in vessel wall structure and increased splanchnic and splenic arterial flow result in an increased incidence of rupture with a maternal and fetal mortality rate of 64%-75% and 72.5%-95%, respectively.[23]

Clinical presentation of visceral artery rupture is dependent on the pattern of rupture, with free peritoneal rupture acutely presenting as hemorrhagic shock and retroperitoneal rupture possibly presenting delayed symptoms due to initial tamponade. Most commonly cited presentations are hypotension, abdominal and back pain, and gastrointestinal bleeding, including hemobilia in cases of hepatic artery rupture.[16,18,19] Splenic aneurysm rupture not infrequently presents with minimal symptoms followed by acute decompensation.

Traditional treatment of visceral artery rupture has been open surgical approach consisting of ligation and bypass or possible reconstruction of the vessel as tolerated by the patient. For splenic artery aneurysm rupture, splenic artery ligation as part of splenectomy has historically been the treatment of choice. However, with the recognition of the importance of the spleen in immune function, more attempts at splenic salvage, consisting of splenic artery aneurysmectomy or exclusion, have occurred. Of special note, because of the exceedingly high maternal and fetal mortality rates from ruptured splenic artery aneurysms, elective surgical management of splenic aneurysms in females of childbearing age should be recommended when the splenic artery aneurysm is ≥2 cm.[23] In fact, some experts recommend surgical intervention on all splenic artery aneurysms during pregnancy regardless of size, ideally after the first trimester.[23] Hepatic arterial rupture can be managed with aneurysmectomy or aneurysmal exclusion as long as gastroduodenal and gastroepiploic collaterals are patent. Superior mesenteric artery (SMA) rupture frequently requires aneurysmorrhaphy and simple ligation, assuming adequate collateral blood flow through the inferior pancreaticoduodenal and middle colic arteries. Given the importance of the SMA to intestinal perfusion, attempts at repair of the SMA in the hemodynamically stable patient with aneurysmorrhaphy or interposition graft have been reported. Celiac artery rupture has been treated with aneurysmectomy and primary reanastomosis or interposition graft.

With the advent of endovascular technology, multiple case series have been published on endovascular embolization with coils and glues and exclusion of visceral artery aneurysms with covered stent grafts. However, the numbers of endovascular interventions for ruptured visceral arteries are limited in these series and no long-term follow-up on these interventions is available. Common complications from endovascular interventions include inadequate embolization, end tissue infarction from embolization, abscess formation from infarcted tissue, and embolization of glue or coils from initial delivery site.[16,19,23–26]

Arterial Ischemia

The bulk of emergency vascular interventions can be attributed to arterial ischemia. This seemingly diverse group of disease processes shares a common mechanism—compromised arterial blood flow whether due to embolism, thrombosis, dissection or poor cardiac function (Table 45.2). Symptoms and long-term outcomes are partially dependent on the ischemic tolerance of the affected tissue bed, for example, 6 hours for lower extremities and 5 minutes for the brain. Even after successful revascularization, risk of reperfusion injury and development of a compartment syndrome or systemic inflammatory response syndrome plagues these patients. This section

will review arterial ischemia according to the limb or organ affected.

Lower Limb Ischemia. The incidence of acute leg ischemia (ALI) has been reported to be 9–14 per 100,000 with a peak incidence of 180 per 100,000 in patients older than 90 years.[27,28] The most common causes of lower limb ischemia are thrombosis and embolism. Most emboli to the lower extremities originate from the heart (80%-90%), and 60%-70% of these patients have an underlying cardiac condition.[27,29] These cardiogenic emboli lodge at branch points due to changes in laminar blood flow caused by vessel divisions and sequential reduction in diameter of branch arteries with each division. In decreasing order of relative frequency: the femoral bifurcation, the aortic bifurcation, the popliteal trifurcation. Aggressive medical management of atrial fibrillation with anticoagulation and rheumatic heart disease with antibiotics has shifted the incidence toward thrombosis.

The Trans-Atlantic Inter-Society Consensus (TASC II) Working Group in 2007 redefined acute limb ischemia as "any sudden decrease in limb perfusion causing a potential threat to limb viability."[30] As no reliable biochemical or radiologic indices of limb viability exists, a high index of clinical suspicion is required for rapid diagnosis and management. The clinical severity and presentation of ALI depends not only on the etiology, but on the location, proportion of luminal obstruction, and the capability of existing collateral circulation to transport blood around the obstruction. ALI due to emboli is more likely to present with sudden, severe limb-threatening ischemia. In contrast, patients with chronic arterial occlusive disease may also develop acute thrombosis, but their chronically diseased vascular beds develop collateral circulation, partially mitigating ischemia.

Acute limb ischemia is essentially a clinical diagnosis with a range of symptoms classically described as the 6 P's: pain, paresthesia, paralysis, pallor, pulselessness, and poikilothermia. Pain in the toes and feet is usually the first presenting symptom of ALI. As ischemia continues, paraesthesia develops as large sensory nerves transmitting pain, temperature, and light touch become malperfused. Finally, in the most severe ischemic conditions, paralysis ensues with loss of toe flexion and extension. This is followed by an absence of foot dorsiflexion and plantarflexion due to ischemic myopathy of the calf muscles. As the muscles infarct, the leg swells and becomes more tender, and eventually the foot loses passive movement.

After 6–8 hours, muscles become rigid and contracted and the limb is unsalvageable. Amputation is necessary at this point to prevent renal failure from rhabdomyolysis.

The clinical findings of pallor include a white, waxy extremity with absent capillary refill. With thrombosis, as the collateral circulation dilates to restore flow, there may be gradual improvement in capillary refill. If there is still refill after blanching, the limb is still salvageable. However, with fixed mottling or cyanosis the capillaries have thrombosed or ruptured and limb recovery is unlikely. Pulselessness is the sine qua non of acute limb ischemia. Palpable pulses in the contralateral extremity suggest embolism as the cause. With thrombosis, there are usually signs of chronic limb ischemia such as thickened toe nails, loss of hair, reduced or absent contralateral pulses. Finally, poikilothermia, or perishing cold, is the finding of decreasing skin temperature from the proximal unaffected limb to the distal ischemic limb.

With the advent of endovascular therapy, the range of management options for acute limb ischemia has expanded. These options include open surgical revascularization, endovascular revascularization, or anticoagulation with observation. First, a determination of ischemia severity is completed using the clinical classification of acute limb ischemia listed in Table 45.3.[31] In this initial step, the degree of motor and sensory dysfunction is determined and the presence of arterial and venous flow verified with a handheld continuous Doppler unit. If no contraindication exists, the patient is started on systemic anticoagulation with heparin to prevent further clot propagation. Patients with level I ischemia should be treated with heparinization and close observation for symptom deterioration, especially older sedentary patients with substantial comorbidities who may become completely asymptomatic with aggressive management of associated comorbidities. In the younger, more active patient with level I ischemia, a more aggressive approach of proceeding directly to endovascular intervention, using catheter-directed thrombolysis or thrombectomy, or surgery is more prudent since the earlier the thrombus is removed, the better the outcome. This same strategy is employed for level IIA and IIB ischemia, but revascularization must be done expeditiously and four compartments calf fasciotomy much more likely to be needed to treat compartment syndrome. Most patients with level III ischemia should receive primary amputation only with treatment of comorbidities due to the potential consequences of reperfusion injury.

TABLE 45.3

RUTHERFORD'S CLASSIFICATION OF ACUTE LIMB ISCHEMIA

CATEGORY	DESCRIPTION	PROGNOSIS	SENSORY LOSS	MOTOR DEFICIT	ARTERIAL DOPPLER	VENOUS DOPPLER
I	Viable	No immediate threat	None	None	Audible	Audible
IIA	Marginally threatened	Salvageable if promptly treated	Minimal (toes) or none	None	Inaudible	Audible
IIB	Immediately threatened	Salvageable if immediately revascularized	More than toes, rest pain	Mild/Moderate	Inaudible	Audible
III	Irreversible	Major tissue loss, permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

Modified from Rutherford RB, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg*. 1997;26:517–538.

After addressing the embolus or thrombus with either endovascular or open surgical intervention, underlying atherosclerotic lesions are frequently revealed. For endovascular intervention, angioplasty and stenting may be utilized as indicated by the angiographic findings. For open surgical intervention, endarterectomy and patch angioplasty is often utilized. For more diffuse disease, surgical bypass is often preferred. However, endovascular methods have developed to provide transcatheter alternatives, which may be less morbid in a high risk patient.[32]

Popliteal Artery Aneurysm. Though popliteal artery aneurysms (PAAs) are the most common peripheral arterial aneurysm, they have only a reported prevalence of <1.0%.[33] Rupture of these aneurysms is so rare, that the exact prevalence is unknown. Rather than rupture, acute limb ischemia from thrombosis of PAA and subsequent embolization to the pedal arteries is the most common mode of presentation and has been reported in 17%-46% of cases.[33] These patients may present with a history of recent claudication consistent with compromise of the popliteal or tibial arteries. With progression of distal embolization, these patients usually develop the signs of acute limb ischemia discussed in the above section.

If Rutherford class IIB and III acute ischemia is present, immediate intervention in the OR is necessary to salvage the limb as catheter-directed thrombolysis frequently requires 24 hours. An above the knee medial exposure of the distal superficial femoral artery and below the knee exposure of the popliteal artery, trifurcation, and tibial arteries are necessary for proximal and distal ligation of the PAA to prevent further embolization and to allow direct thromboembolectomy of the tibial arteries. Intraoperative thrombolytic infusion can be used to facilitate thrombus clearance of the tibial arteries. Intraoperative angiogram is used to confirm tibial artery recanalization. Once this is verified, a bypass, preferably with saphenous vein conduit, is completed from the superficial femoral artery down to the distal popliteal artery or to the tibial artery with direct inline flow to the foot. If no tibial arteries are visualized and there is no obvious target for revascularization, prolonged catheter-directed thrombolytic infusion may be warranted to obtain limb salvage. In some situation when the runoff vessels are absent and the leg no longer deemed salvageable, the patient is placed on systemic Heparin to allow the limb to demarcate to minimize future amputation level. However, if substantial leg muscle ischemia is present, an urgent high level amputation, such as an above knee or through knee amputation may become necessary. If the patient presents with acute limb ischemia but without neurologic symptoms, a preoperative angiogram can be completed to identify any open tibial arteries and optimize the outflow with catheter-directed thrombolysis of thrombosed tibial arteries. If the patient's condition deteriorates or fails to improve, surgical revascularization as discussed above is recommended. To date, while complete endovascular treatment of thrombosed PAA has been reported, inadequate numbers and follow-up are available in the literature to recommend such therapy.[33,34]

Upper Extremity Ischemia. Acute arm ischemia is relatively uncommon and is usually not immediately limb-threatening due to the robust collateral circulation of the upper extremity. Studies report an incidence of acute arm ischemia of 1.2-3.5 per 100,000 population with a female predominance (2:1).[28] Unlike lower limb ischemia, embolus, due to atrial fibrillation most commonly, is the cause of 90% of acute arm ischemia. Other sources of emboli include recent myocardial infarction, ventricular aneurysms, atrial myxomas, and paradoxical emboli. Thrombosis comprises 5% of acute arm ischemia with atherosclerotic narrowing as the most common

predisposing condition. Thoracic outlet syndrome, aneurysm, and arteritis are other thrombotic causes that deserve mention. Less common sources are hypercoagulable states, malignancy (Trousseau's syndrome), and radiation injury. Trauma and iatrogenic injuries make up the remainder of acute arm ischemia cases.

Patients with upper extremity ischemia present with acute pain and coolness of the extremity, the exact location depending on the level of obstruction. In most instances, emboli lodge in the brachial artery (60%) or axillary artery (26%). A slightly increased occurrence of embolic ischemia occurs in the right arm due to the brachiocephalic artery's proximity to the heart and larger ostium. The extremity appears pale with poor capillary refill compared to the contralateral unaffected arm. The hand may be weaker and numb, but muscle function is normally preserved. Examination often reveals the level of obstruction by the level of loss of pulse. With heparinization, some capillary refill may return to the distal extremity with improvement in neurologic function. Hand mottling is rarely observed in embolic disease, rather more often in the setting of shock where inotropes are used to support systemic blood pressure. The impact of underlying arterial stenosis is accentuated in this setting, as the blood pressure is inadequate to exceed the resistance caused by the stenosis. Also, inotropes used to augment cardiac function may cause peripheral vasoconstriction, further aggravating a difficult situation.

Nonoperative management consists of anticoagulation with heparin and treatment of contributing comorbidities such as cardiac failure or dysrhythmia. Most natural history studies demonstrate some degree of compromised arm function with nonoperative management and thus justify a more aggressive approach.[35,36] Thromboembolectomy is the most frequently performed procedure in this setting. Optimization of the patient's comorbidities is also essential to long-term success, as untreated comorbidities can cause recurrence. Thromboembolectomy of the brachial, radial, and ulnar arteries can be performed under local anesthesia through an antecubital fossa incision. Exposure of the brachial artery at its bifurcation allows proximal and distal embolectomy through a single incision. Long-term anticoagulation, unless contraindicated, should be routinely prescribed to reduce recurrence risk and postoperative mortality.[37] When the source of emboli is a proximal artery lesion, definitive surgery or angioplasty may be required after thromboembolectomy. After thromboembolectomy, atherosclerotic lesions of the subclavian or axillary arteries are increasingly managed with percutaneous angioplasty with selective stenting, falling back to surgical bypass if endovascular therapy fails.

Cerebrovascular Ischemia

Great Vessels. Conditions involving the great vessels for example, the subclavian, common carotid, and brachiocephalic arteries may cause low-flow states or embolization leading to stroke, transient ischemic attacks (TIAs) or arm ischemia. Atherosclerotic occlusive disease is the most common etiology, reported in 69%-100% of cases.[38] Takayasu's arteritis is the second most common cause, followed by radiation arteritis. Peak occurrence has been reported in the age range of 50–61 years old with slight female predominance of disease (53%). Also, cigarette smoking is an important risk factor for the development of atherosclerotic disease in this distribution, often with multiple vessel involvement.

Most patients are symptomatic (80%) with the mean interval between symptoms and revascularization of 15 years. Generally, atherosclerotic lesions cause thromboembolic events, in contrast to the smooth tapering lesions of Takayasu's aortitis that normally cause low-flow symptoms.[39] The Mayo Clinic

series demonstrated that 63% of patients with an atherosclerotic lesion in the great vessels presented with embolic events: cerebrovascular (53%), upper extremity (10%) and mixed (5%).[38]

The presence of symptomatic disease is an indication for intervention. Direct surgical reconstruction via a transsternal approach has been the gold standard for patients with multiple branch involvement. Alternatively, ministernotomy to the third intercostal space can be performed with transection of the sternum. Cervical reconstruction through a transverse supraclavicular incision is the preferred option for isolated disease of the common carotid and proximal subclavian arteries. With subclavian lesions proximal to the vertebral origin, subclavian–carotid transposition is preferable to bypass due to the superior patency rates.[40] Synthetic conduits are preferred over vein grafts for surgical reconstruction of the great vessels. Endovascular management has been successfully performed for a variety of supra-aortic trunk diseases. Percutaneous angioplasty of lesions of varying lengths has been reported with high technical success. However, total occlusion has higher failure rates (65% vs. 100%) and worse patency rates when compared to stenoses.[41] Due to the inferior patency of endovascular management of subclavian occlusions, some advocate endovascular management for subclavian stenoses only, and surgery (subclavian–carotid transposition) for subclavian artery occlusions.[42]

Carotid Artery. Stroke is the third leading cause of death in the United States, and the most common cause of death as a result of a neurologic disease. The overall incidence of new stroke is approximately 160 per 100,000 population per year. Based on more recent data in a population-based study, the cerebral infarction rate approaches 632 per 100,000 population in the 65–74-year age group, and the older than 75-year age group had a stroke rate of 1,786 per 100,000 population per year.[43] The rates in men are approximately 1.5 times that of women of the same age. The primary pathologic process is atherosclerosis, responsible for 90% of lesions of the extracranial system. The remaining 10% of cases is due to fibromuscular dysplasia, kinking from arterial elongation and tortuosity, migraine vasospasm, spontaneous nontraumatic intimal dissection, inflammatory angiopathies, or radiation injury. Atherosclerotic plaques typically occur at branches or bifurcations. The most commonly affected sites include the bifurcation of the common carotid artery, the carotid siphon, and the origins of the middle and anterior cerebral arteries. The ratio of extracranial to intracranial lesions is over 2:1 in the Western world.

Many clinical syndromes are associated with carotid artery disease. These are classified as either a TIA or stroke. TIA is defined as a sudden focal neurologic deficit that completely resolves within 24 hours. Stroke is due to cerebral infarction as a result of hypoperfusion, embolization, or hemorrhage. Any of these mechanisms can result in speech deficits consisting of dysarthria, dysphasia, or aphasia. Motor deficits range from loss of fine motor skills to hemiplegia contralateral to the affected carotid disease. There may also be numbness or paresthesia. Transient visual disturbances consisting of monocular blindness or visual field defects, termed amaurosis fugax, can also arise. Occasionally, there may be global cerebral hypoperfusion causing decreased mentation, presyncope, or even vertebrobasilar symptoms.

The goal of therapy for carotid artery disease is prevention of cerebral infarction. Patients with symptomatic 70%-99% internal carotid artery (ICA) stenosis derive the greatest benefit from carotid endarterectomy (CEA) compared to best medical therapy (BMT). The North American Symptomatic Carotid Endarterectomy Trial (NASCET) demonstrated a reduction of ipsilateral stroke from 26% over 2 years with BMT alone to

9% with the addition of CEA.[44] In patients with symptomatic moderate grade (50%-69%) ICA stenosis, there is some benefit of CEA compared to BMT with a stroke risk reduction from 22% to 15%.[45] In this particular group of patients, subgroup analysis identified cohorts that benefitted the most from CEA: males, patients with stroke rather than TIAs, and patients with hemispheric stroke symptoms rather than retinal symptoms.

With the increased acceptance of carotid artery stenting (CAS), controversy remains regarding the optimal management of symptomatic patients with ICA stenosis. The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial showed noninferiority of CAS with distal embolic protection (DEP) compared to CEA in high-risk patients. Some surgeons use this data as a reason to offer CAS with DEP to patients who are considered at high-risk due to anatomic (prior neck irradiation, recurrent stenosis after CEA) or medical (severe cardiac or pulmonary disease) conditions.[46]

Regardless of the method selected to treat a symptomatic carotid stenosis (CEA vs. CAS), it is essential to rapidly start antiplatelet therapy with acetylsalicylic acid (ASA) or clopidogrel when a patient becomes symptomatic. Prior to initiating anticoagulation therapy, a hemorrhagic stroke needs to be ruled out by a head CT.

Visceral Ischemia

Mesenteric Ischemia. Acute mesenteric ischemia (AMI) is a vascular emergency with a mortality of 70%-90% that has not improved over the past 70 years.[47] Most patients with AMI present in the sixth to seventh decade with multiple comorbidities. In a Swedish autopsy study, the overall incidence rate was 12.9 per 100,000 person-years.[48] After normalizing for the increased longevity of females, the distribution is roughly equal between men and women.

The four well recognized clinical patterns of AMI include arterial embolism, arterial thrombosis, mesenteric vein thrombosis (MVT), and nonocclusive mesenteric ischemia (NOMI). MVT will be addressed in the venous emergency section. The two primary arterial causes of AMI are embolism and thrombosis. Arterial emboli are responsible for 40%-50% of cases and usually originate from a cardiogenic source such as a recent myocardial infarction, tachyarrhythmia, cardiomyopathy, or valvular disease. Emboli primarily lodge in the SMA and branches due to the oblique takeoff from the aorta. Most emboli (50%) lodge distal to the middle colic artery branch rather than at the origin (15%). Mesenteric arterial thrombosis occurs in 25%-30% of AMI cases and usually in the setting of chronic atherosclerotic SMA stenosis. The insidious nature of atherosclerosis allows collaterals to form; however, this capacity eventually is exceeded. Due to the pervasive nature of mesenteric arterial thrombosis, 70%-100% mortality rates have been reported. It remains unclear which particular patients with considerable mesenteric artery stenosis will ultimately develop thrombosis. Finally, NOMI is primarily a cardiogenic disease. Frequently, the mesenteric vessels are patent yet the heart fails to adequately perfuse the intestines. NOMI is frequently seen in the setting of critically ill patients in which the mesenteric blood flow is further constricted by inotropic drugs utilized to augment cardiac function.

Due to the rich collateral blood flow between the celiac, superior mesenteric, and inferior mesenteric arteries, compromise of at least two of these arteries is necessary to cause ischemic symptoms. Many of the signs and symptoms of AMI are similar to other acute abdominal pathologies (i.e. pancreatitis, small bowel obstruction) and depend on the underlying cause. With SMA embolism, there is an acute onset of unrelenting

abdominal pain associated with immediate bowel evacuation. Classically, the pain is described as out of proportion to the physical examination. There is also nausea and vomiting, along with excessive third spacing, leading to dehydration and tachycardia, mental confusion, and sometimes respiratory collapse. Laboratory findings include hemoconcentration, leukocytosis, elevated lactate level, and metabolic acidosis with an increased anion gap. This should be contrasted against patients with chronic mesenteric ischemia who not infrequently have a prior history of postprandial abdominal pain with unintentional weight loss. As expected, chronic mesenteric ischemia patients can also present emergently with acute occlusion in the setting of chronically diseased mesenteric arteries. Regardless of the etiology, once bowel infarction occurs, the patient develops peritonitis and hemodynamic instability with multiorgan system failure if bowel resection is not performed expeditiously and the remaining viable bowel reperfused promptly.

In any patient older than 60 years with a history of atrial fibrillation, recent myocardial infarction, or any history of prior postprandial pain and weight loss, a high index of suspicion for AMI should be maintained. If the diagnosis is made in the first 24 hours, the survival rate is 50%, dropping to 30% with delay.[49] Older planar abdominal CT has poor sensitivity and specificity for the diagnosis of AMI; however, newer dynamic contrast-enhanced, multislice CT demonstrates greater sensitivity in detecting bowel ischemia. The gold standard for diagnosis continues to be angiography; however, this modality does not evaluate bowel viability. If an acute abdomen is present on exam, exploratory laparotomy is indicated regardless of availability of a mesenteric angiogram. Also with a high index of suspicion and contrast-enhanced CT findings suggestive of AMI, most vascular surgeons would proceed directly to exploratory laparotomy.

Once the diagnosis is made, treatment should begin immediately with aggressive fluid resuscitation, correction of metabolic abnormalities and optimization of any medical conditions. Broad-spectrum antibiotics should be started as early as possible. Efforts to reduce thrombus propagation should be initiated with systemic anticoagulation unless there is a contraindication. With peritoneal signs, bowel infarction is likely and emergency laparotomy is indicated. Even without peritonitis, surgical revascularization is indicated once the diagnosis is made. After laparotomy, visceral revascularization should proceed prior to bowel resection. For embolism, a standard embolectomy is performed through a transverse arteriotomy in the proximal SMA. If the etiology is unknown, a proximal SMA longitudinal arteriotomy can be completed instead to facilitate an aortomesenteric bypass. If embolectomy returns pulsatile back-bleeding, then the arteriotomy is closed with a patch angioplasty, preferably with vein. If an aortomesenteric bypass is needed, often the case with arterial thrombosis, inflow is obtained from either the infrarenal or supraceliac aorta. Vein is preferably used as the conduit in this setting, due to the presence of ischemic or necrotic bowel. After revascularization, the bowel is evaluated and frankly necrotic bowel is resected. Intraoperative assessment of bowel viability is often inaccurate and second-look laparotomy is the rule.

Another revascularization option in the setting of AMI is retrograde open mesenteric stenting (ROMS).[50] After the initial bowel exploration, the intestines are packed away to limit contamination. An infracolic exposure is obtained, which facilitates dissection of the SMA or a large SMA branch. The artery is cannulated with a micropuncture needle and a microwire is placed into the SMA in a retrograde fashion. A sheath is placed in the usual fashion and using a Glidewire and catheter, re-entry into the aorta is obtained. A limited aortogram is performed from this catheter, allowing identification of the length of the stenosis or obstruction. The catheter is exchanged for an appropriately sized angioplasty balloon

that is inflated to profile to predilate the SMA, then a balloon expandable stent is placed to limit luminal recoil in the SMA. A completion angiogram is performed to document successful revascularization of the SMA. The puncture hole in the SMA or branch is repaired with a 6–0 nylon. The advantages of ROMS is greater speed, less physiologic stress as aortic clamping is avoided, and avoidance of any synthetic material in a potentially contaminated field.[50]

Due to the rarity of NOMI, with an incidence of only 2 per 100,000 person-years, guidelines for treatment of NOMI derive from reported case series.[48] Currently, authors recommend intra-arterial administration of vasodilators, including papaverin, nitroglycerin, or glucagon.[51] Antibiotics are also frequently administrated to treat bacterial translocation caused by the compromised mucosal integrity observed in NOMI.[51] Optimization of underlying cardiac function accompanies these interventions.

Renovascular Ischemia. Acute ischemic events involving the renal vasculature include embolism, thrombosis, renal artery dissection, trauma, and renal vein thrombosis (RVT). The first two will be discussed in this section and further discussion on RVT deferred to the venous emergency section. Embolic or thrombotic renal occlusion is a rare occurrence, reported as 1.4% of a series of 14,411 autopsies.[52] Emboli typically originate from the heart from conditions such as atrial fibrillation, mitral valvular disease, and acute myocardial infarction. Up to 30% of renal emboli from cardiogenic sequelae are bilateral. Proximal aortic aneurysms and aortic plaques can also be a source, especially after manipulation with percutaneous catheters. Concomitant embolism to other aortic branches is also common. Renal artery thrombosis occurs with advanced atherosclerotic disease of the aorta and can progress into the proximal renal artery. This condition is generally clinically silent due to the collateralization with ureteral, lumbar, adrenal or capsular arteries. As expected, this subset of patients is at highest risk of iatrogenic thromboembolism with catheter-based interventions.

The clinical presentation of acute renal ischemia is variable and vague, thus this diagnosis is rarely considered. Common symptoms are flank, back or abdominal pain, hematuria, or hypertensive crisis. Bilateral renal artery occlusion may present with pyrexia, acute renal failure, and anuria. On urinalysis, leukocytosis, erythrocytosis, and proteinuria are frequently found. Any patient with these symptoms and history of dysrhythmia, recent myocardial infarction, or malignancy should have renal artery occlusion in their differential diagnosis.

Due to its vague symptoms, renal artery compromise often is diagnosed only by radiographic studies. Contrast-enhanced CT scan demonstrates filling defects indicating abnormal perfusion. Angiography not only confirms the diagnosis but also the degree of atherosclerotic disease and the pattern of collateral blood flow to the distal renal artery, which helps in differentiating renal artery embolism from thrombosis.

Previous studies suggest that open surgical treatment is less effective than anticoagulation alone, especially when the duration of symptoms is >12 hours.[53] However, percutaneous thrombolysis is a viable option even for individuals with chronic symptoms.[53] For embolism, early open surgical embolectomy, percutaneous thrombolysis, or pharmacomechanical thrombectomy should be offered. Surgical intervention should especially be considered in otherwise healthy patients with partial renal occlusion, bilateral renal emboli, or an embolus to a solitary kidney. Mortality is considerably reduced if preoperative correction of metabolic abnormalities is initiated prior to embolectomy. Thrombolysis typically reveals the underlying atherosclerotic process which can then be treated with balloon angioplasty with or without stent placement.

Unlike renal artery embolism, arterial thrombosis less often requires urgent operative intervention. Surgical revascularization proceeds after resuscitation and correction of metabolic disturbances. Surgical options include aortorenal bypass with saphenous vein or synthetic grafts. With severe aortic atherosclerotic disease, extra-anatomic bypass including hepatorenal, splenorenal, or iliorenal bypasses may be necessary. Percutaneous thrombolysis has been performed in this group of patients with primary stenting and offers an alternative approach with good outcomes.[53]

ACUTE AORTIC DISSECTION

Aortic dissection is well recognized as a lethal aortic pathology, with most deaths resulting from malperfusion or rupture of the aorta. It involves an intimal tear that allows pressured systemic blood flow to hydrostatically dissect the aortic media. Eventually the pressure dissects back into the true lumen, in this process creating a false lumen. Early recognition of this entity is essential as acute ascending aortic dissection and descending aortic dissection with malperfusion require immediate intervention. In recent years, development of thoracic endograft technology has reshaped the management of aortic dissection.

Aortic dissection affects 3–4 per 100,000 people annually.[54] An early mortality rate as high as 1% per hour if untreated has been reported, and 21% of aortic dissection patients die before receiving treatment in the hospital.[55] The classic clinical profile for an aortic dissection patient is an elderly male with hypertension. Peak incidence has been reported for the 40- to 70-year old age groups, and males have two to five times increased incidence of aortic dissection.[56]

Chronic hypertension is the most commonly cited risk factor for aortic dissection, followed by increased age and male gender. Connective tissue disorders, such as Ehlers-Danlos syndrome, Loeys-Dietz syndrome, or Turner's syndrome, and aortic vasculitidies which destroy aortic medial layers, predispose patients to dissection. Bicuspid aortic valve has been linked to dissection, though the exact mechanism is unknown. Finally, pregnancy is a major risk factor, as one-half of aortic dissections in women younger than 40 years old occur during pregnancy.

According to the International Registry of Acute Aortic Dissection, most patients with aortic dissection present with an abrupt onset of pain, described as a sharp or tearing pain.[57] Interestingly, most patients present between 6 AM and noon with the highest rate of dissection occurring during winter. Stanford type A dissections (involving the ascending aorta) more frequently present with anterior chest pain, while Stanford type B dissections (originating distal to the origin of the left subclavian artery) frequently present with back pain radiating to the interscapular region. Other symptoms in type A are dependent on retrograde dissection into the aortic root leading to development of pericardial tamponade, aortic valvular regurgitation, or myocardial infarction. For type B, depending on visceral or lower extremity malperfusion, abdominal or leg pain with possible neurologic compromise may be present. Also, dissection in the aortic arch can lead to compromised blood flow in the great vessels, causing upper extremity and cerebrovascular ischemia.

Rapid diagnosis allows identification of appropriate therapy for these patients. CTA is considered the gold standard for identification of aortic dissection due to its speed and general availability. The limited availability and speed of magnetic resonance angiography make it a second tier imaging study, better suited for evaluation of chronic aortic dissection. Transesophageal echocardiogram can detect ascending aortic dissection and the presence of aortic root compromise and pericardial effusion.

The data for type A dissection continues to support open surgical interventions. 91% percent of patients with type A dissection die within 1 week without surgery. Even with ascending aortic replacement with aortic root valvuloplasty or replacement, a mortality rate of 13%-33% has been cited.[58]

In contrast, uncomplicated type B dissection is preferentially treated with maximal medical management consisting of antihypertensive and antiimpulse medications. The first line agents are beta blockers, followed by calcium channel blockers, angiotensin-converting enzyme inhibitors, and vasodilators such as nipride.[59] Even without medical therapy, 40% of these patients will survive to 1 year. However, with optimal medical management, a mortality rate of 7%-11% can be achieved, compared to 17%-19% with surgical intervention.[59] Complicated type B dissection, however, requires intervention for pain or hypertension recalcitrant to maximal medical therapy, rapidly increasing aortic diameter, imminent or verified aortic rupture, or evidence of visceral or limb malperfusion.[59,60]

Open surgical intervention on type B dissection consists of either a segmental aortic graft replacement or an open fenestration technique in which the dissection flap is excised to restore visceral flow.[61] An endovascular fenestration technique consists of endovascular perforation of the dissection septum and widening the perforation with an angioplasty balloon, usually at the level of the compromised visceral vessels. Similarly, aortic branch compromise from the aortic dissection can be managed through endovascular techniques with direct stenting of visceral, renal, or iliac arteries to restore flow.[60]

Since the advent of thoracic endografting, multiple thoracic centers are adopting TEVAR as their intervention of choice for complicated type B dissection. The operative goal of TEVAR for acute aortic dissection is to cover the proximal entry tear and reexpand the true lumen to help restore distal aortic perfusion (Fig. 45.2). Understand that most thoracic centers treating type B dissection are extrapolating TEVAR for aneurysmal disease into TEVAR for aortic dissection. However, no commercially available thoracic endograft has a Federal Drug Administration approved indication for aortic dissection. Additionally, the one randomized clinical trial for TEVAR use in aortic dissection (INSTEAD) focused on simple chronic dissection, not acute or complicated dissection.[62] Thus, the intervention offered to a complicated type B dissection patient will vary with the expertise of the local treatment center.

VENOUS EMERGENCIES

While arterial emergencies are often more dramatic clinically, venous disease is more pervasive than arterial disease, with an estimated two-thirds of the general population having varying degrees of venous disease. Venous emergencies can be as dramatic as phlegmasia cerulea dolens, with impending gangrene of the affected lower extremity, or as subtle as the insidious onset of renal vein thrombosis. These conditions are frequently discovered in the setting of other systemic diseases.

Lower Extremity

Superficial Vein Thrombosis. The majority of lower extremity superficial vein thrombosis (SVT) affects branches of the greater saphenous vein in patients with varicose veins. This is treated with rest and nonsteroidal anti-inflammatory drugs. Complications such as recurrent SVT, thrombus propagation, and pulmonary embolism (PE) occur in 5%-10% of patients. Patients with greater saphenous vein thrombus are at particular risk for thrombus propagation, mandating a follow-up duplex scan. If thrombus propagates to within 5 cm of the saphenofemoral junction, ligation should be performed

EMERGENCY SURGERY

as the thrombus often extends 5–10 cm beyond the imaged location.[63] If the junction itself is involved, the patient should receive anticoagulation therapy for at least 3 months.[63] Recent evidence suggests that patients with acute initial idiopathic greater saphenous vein thrombosis may benefit from a short course of fondaparinux.[64]

Lower Extremity Deep Vein Thrombosis. The incidence of lower extremity deep venous thrombosis (DVT) ranges from 56 to 160 per 100,000 annually. Stasis is the predominant factor causing DVT, especially in postoperative or trauma patients. DVT symptoms are nonspecific and include leg swelling, pain, fever, erythema or cyanosis. Venous duplex ultrasound is the initial diagnostic study of choice, demonstrating vein incompressibility, absence of phasic flow, and possibly hypoechoic appearance, which differentiates between acute and chronic thrombus. While D-dimer assay has an excellent negative predictive value for DVT, it is not specific during the postoperative period.

Treatment should be started promptly to prevent clot propagation and reduce the risk of PE and postthrombotic syndrome. Low molecular weight heparin or unfractionated heparin is used for initial treatment before conversion to Warfarin. Patients should be monitored for Heparin-induced thrombocytopenia while on heparin drip. If there are no contraindications, thrombolysis and thrombectomy may be beneficial in patients with venous gangrene or extensive iliofemoral thrombus. Prevention is the key to avoid DVT and its complications. Hallmarks of prevention are ambulation, application of graduated compression stockings or intermittent pneumatic compression, and pharmacologic prophylaxis with subcutaneous heparin, whether fractionated or unfractionated.

Phlegmasia Alba/Cerulea Dolens. The two clinical syndromes associated with extensive iliofemoral venous thrombosis are phlegmasia alba dolens and the more severe phlegmasia cerulea dolens. In phlegmasia alba dolens, the common iliac vein or external iliac vein is occluded but the internal iliac and collateral veins remain patent. The patient has moderate to severe swelling, leg tenderness, pallor but no ischemia. Management is either anticoagulation, catheter-directed lysis, or pharmacomechanical thrombectomy in good-risk patients.

Phlegmasia cerulea dolens occurs in patients with extensive thrombosis of the iliofemoral venous system with loss of collateral circulation. Half of these patients will progress to venous gangrene, with more than 90% of patients having an underlying malignancy. Patients typically present with pain, poikilothermia, and severe swelling of the affected limb but often have palpable pulses initially, then progress to loss of arterial inflow due to elevated compartment pressures caused by occlusion of the iliofemoral venous system. Management is systemic anticoagulation, intravenous fluid, and leg elevation. Also, both catheter-directed thrombolysis and pharmacomechanical thrombectomy have emerged as effective acute interventions. Surgical thrombectomy has been relegated to recalcitrant cases not responsive to other interventions. Palliative care is appropriate for those patients with disseminated malignancy.

Upper Extremity

Septic Phlebitis. Septic thrombophlebitis is characterized by venous thrombosis, inflammation, and bactermia.[65] The clinical course and severity of septic thrombophlebitis is variable. Placement of an intravascular catheter is the main causative factor in the development of phlebitis and superficial septic thrombophlebitis. Many cases present as benign localized venous cords that resolve completely with removal of peripheral catheters. Some cases present as severe systemic infections culminating in profound shock that is refractory to management. These cases should be managed aggressively with surgical resection of the vein, broad-spectrum antibiotics, and intensive care. Any associated abscesses should be incised and drained.

Upper Extremity Deep Vein Thrombosis. Central venous catheters are the most common cause of upper extremity deep vein thrombosis. In young patients with spontaneous subclavian and axillary vein thromboses, Paget-Schroetter syndrome must be considered. Treated with anticoagulation alone, these patients are often left with chronic pain and swelling of the arm. Aggressive management with catheter-directed thrombolysis followed by delayed thoracic-outlet decompression and first-rib resection provides excellent functional results. Patients without evidence of Paget-Schroetter syndrome can be treated with heparin and warfarin, although consideration should be given to thrombolysis in good-risk patients.

Infected Internal Jugular Vein Thrombosis. Thrombus in the internal jugular veins is usually due to catheter insertion. Intravenous drug abuse is also a risk factor. A feared complication is secondary infection of the thrombus by a local oropharyngeal infection (Lemierre's syndrome), usually by anaerobes or methicillin-resistant *Staphylococcus aureus*. Other reported sources of secondary infection of internal jugular thrombus include pneumonia and liver abscess. Management of internal jugular vein thrombosis caused by catheters is catheter removal followed by anticoagulation. Septic complications are managed by intravenous antibiotics. Rarely, surgical excision of all the infected tissue may be necessary.[66]

Visceral Venous Thrombosis

Portal Vein Thrombosis. The exact frequency of portal vein thrombosis (PVT) is unknown, but segmental or complete PVT occurs in as many as 30% of patients with hepatocellular carcinoma. The incidence of PVT in patients with cirrhosis and portal hypertension is approximately 5%. Reduced portal blood flow caused by hepatic parenchymal disease, abdominal sepsis, and hypercoagulable syndromes are potential causes. PVT is often not discovered until gastrointestinal hemorrhage develops, unless the thrombosis is discovered during routine surveillance for a known underlying pathologic condition. In most patients, PVT occurs slowly and silently. The signs and symptoms of PVT can be subtle or nonspecific, and often are overshadowed by underlying diseases. The exceptions are patients with thrombophilia and portal and mesenteric venous thromboses who present with moderate or severe abdominal pain after acute or subacute development of PVT. The development of PVT can precipitate the need for emergency endoscopy for sclerotherapy of gastroesophageal varices, transjugular intrahepatic portosystemic shunt placement, surgical portocaval shunt creation, transjugular or transhepatic portomesenteric thrombolysis and thrombectomy, or even resection of ischemic bowel or liver transplantation.[67]

Mesenteric Vein Thrombosis. MVT accounts for 5%-10% of cases of AMI. As the venous end-branches of the SMV and inferior mesenteric vein are frequently also thrombosed, thromboembolectomy of the mesenteric veins is often inadequate. Treatment of the end-branches requires catheter-directed SMA delivery of a thrombolytic agent, assuming adequate exchange of the thrombolytic agent to the venous drainage of the intestines. As a survival advantage to aggressive therapy has not been demonstrated, the treatment of MVT is generally systemic anticoagulation therapy.[68]

Similar to patients with mesenteric ischemia secondary to nonocclusive mesenteric ischemia, close observation for signs of worsening bowel ischemia, peritonitis, and systemic inflammation are essential; up to one-third of patients with MVT require exploration for necrotic bowel. These patients should undergo second-look laparotomy to assess viability of marginally perfused bowel. In addition, patients with MVT should undergo a hypercoagulable workup to identify any underlying etiology that would necessitate lifelong anticoagulation therapy.[67]

Renal Vein Thrombosis. Occlusion due to thrombus in the major renal veins or tributaries is rare, as often these patients are asymptomatic or their symptoms are ascribed to other diseases. The renal veins, particularly on the left side, have a generous collateral network both inside and outside the kidney, reducing symptoms. Cases of spontaneous recanalization or resolution of RVT have been documented. RVT in both adults and children is associated with renal diseases and nephrotic syndrome.[69] The kidney's response to venous occlusion is determined by the acuteness of the disease, extent and timely development of collateral circulation, involvement of one or both kidneys, and origin of the underlying disease.[69] In renal vein occlusion, anticoagulation is the primary option, and catheter-directed pharmacomechanical thrombectomy with or without thrombolysis can be applied in selected cases.[70] The role of surgery in the treatment of RVT is limited because of high risk of rethrombosis. Nephrectomy may be indicated in rare cases of hemorrhagic infarction of the kidney with rupture and bleeding.

Central venous obstruction

Superior Vena Cava Obstruction. Superior vena cava syndrome (SVCS) is caused by obstruction of flow in the SVC because of either extraluminal compression or intraluminal obstruction of the SVC. The majority of cases of SVCS are caused by neoplastic progression into the venous wall with resultant compression of the tumor mass against the relatively fixed thin-walled SVC. Alternatively, SVC obstruction can also occur as a result of intravascular thrombosis caused by neoplastic involvement.

SVCS usually has an indolent course related to progression of the underlying malignancy. Clinical progression of SVCS usually takes place over the course of several weeks often with facial and upper extremity edema, distended neck veins, and visible chest wall venous collaterals. With an acute onset of SVCS, venous collaterals may not have sufficient time to develop and patients may exhibit more rapid worsening of clinical symptoms. Other symptoms include dyspnea, facial plethora, cough, headaches, dizziness, and stridor. In severe conditions, SVC obstruction can give rise to venous congestion resulting in cerebral edema, leading to altered mental status and even coma.[71]

The traditional treatment of SVCS associated with thoracic malignancy has been radiotherapy, chemotherapy, or both. Patients with nonmalignant SVCS traditionally underwent surgical reconstruction of the SVC, enabling future dialysis access or placement of a pacemaker.[72] Currently, the first line treatment of SVCS is catheter-based percutaneous interventions such as balloon angioplasty, stenting, and directed thrombolysis.[72] These interventions expedite the establishment of luminal patency and provide rapid symptom relief. In patients whose SVC obstruction is caused by intraluminal thrombosis, thrombolytic therapy is an effective means of dissolving the SVC thrombus. The only contraindication to endovascular therapy is a contraindication to thrombolytic therapy or anticoagulation. Patients who fail to respond or who are not candidates for endovascular therapy should be evaluated for surgical reconstruction or palliative care.

Inferior Vena Cava Obstruction. IVC occlusion is a rare condition associated with iliofemoral thrombus extension, congenital IVC anomalies, malignancy, hypercoagulable disorders, trauma, radiation, inflammation, pregnancy, or external compression by adjacent pathologies, IVC filter placement, or liver transplant. Clinical findings in these patients range from moderate bilateral lower extremity swelling to limb pain, discoloration, and venous stasis ulcerations. The symptoms are exacerbated by the presence of associated venous reflux. The patients may be asymptomatic if the occlusion is chronic and adequate venous collateralization has developed. When compared with patients with lower extremity DVT alone, these patients have a higher incidence of PE.[73] Diagnosis can be made with venous duplex ultrasound or with venography. Venous phase CT is another noninvasive means of making a rapid diagnosis. Severely symptomatic patients will usually require intervention in addition to anticoagulation. Front line of management is endovascular intervention with pharmacomechanical thrombectomy, catheter-directed thrombolysis, and balloon angioplasty and stenting of any stenotic lesions. Failure of endovascular treatment is an indication for surgical management in the form of an ilio-caval or cavo-atrial bypass.[74]

Pulmonary Embolism. In the United States, PE resulting from lower extremity DVT in 90% of patients, remains a significant cause of mortality, resulting in 300,000 deaths annually.[75] Symptomatic manifestation of PE depends not only on the burden of thrombosis within the pulmonary circulation, but also on the patient's underlying cardiopulmonary reserve. Clinical features of PE include chest pain, dyspnea, hypoxia, cough, and hemoptysis. Massive PE can present with hypotension or even full cardiac arrest. A CT pulmonary angiography is the diagnostic test of choice but a ventilation–perfusion scan may be a viable alternative in patients with renal failure or contrast allergy. Pulmonary angiography is reserved for cases where therapeutic interventions are considered. In severe cases, right heart dysfunction will be seen on echocardiogram or electrocardiogram.

Prompt anticoagulation with heparin is started once there is a high clinical suspicion for PE, even before confirmatory tests have been completed. Catheter-directed or systemic thrombolysis has been used in patients with severe cardiopulmonary collapse as it decreases clot burden and pulmonary hypertension. Pulmonary artery embolectomy is reserved for patients with massive PE who have contraindications to thrombolysis or respond poorly to them. This can be performed surgically or percutaneously with catheter-directed embolectomy devices but the mortality rate can be up to 50%.

Oral anticoagulation can be started once diagnosis is confirmed and the patient is fully heparinized. The duration of treatment is at least 3–6 months but also depends on the etiology of the PE. Inhaled nitric oxide can help improve cardiac output and oxygenation in patients with massive PE. IVC filters are recommended for patients who have recurrent PE despite adequate anticoagulation or have contraindications to anticoagulation. IVC filters can also be placed prophylactically in patients with documented proximal lower extremity DVT and contraindication to anticoagulation.

EMERGENCY SURGERY

CHAPTER 46 ■ **INTENSIVE CARE UNIT: THE ESSENTIALS—INCLUDING ASSESSMENT OF SEVERITY OF CRITICAL ILLNESS**

MAYUR B. PATEL AND ADDISON K. MAY

Patients managed by acute care surgeons frequently present with organ system dysfunction or are at high risk to develop organ system dysfunction, increasing their risk of adverse outcome and death. The presence of infection, tissue injury, large volume transfusions, or ischemia/reperfusion in this patient population may contribute to the development of a systemic inflammatory response or subsequent immunosuppression contributing to altered tissue healing, infectious complications, organ injury, and organ failure.[1-6] Thus, critically ill or injured acute care surgery patients frequently require critical care management to provide timely and appropriate therapeutic interventions, achieve adequate endpoints of resuscitation, appropriately assess the risk and presence of complications, mitigate the risk of organ dysfunction, and treat organ dysfunction and failure. In this chapter, the contribution of intensive care unit (ICU) and critical care management for the acute care surgical patient is reviewed as (1) timely, targeted, and appropriate application of therapeutic interventions; (2) assessment and recognition of risk; and (3) prevention of complications and minimization of the propagation of organ injury.

THE CRITICAL CARE TEAM AND SYSTEM OF CARE

The concept of critical care has evolved dramatically since the first three-bed ICU was established by Walter Dandy at the Johns Hopkins Hospital in 1926.[7] ICUs were originally developed to provide increased nurse staffing ratios, increased monitoring, and ventilator management. As our understanding of the pathophysiology of critical illness and its treatment has progressed and as patient acuity has increased over time, the concept of critical care has evolved into one of a multidisciplinary team providing a system of care to deliver timely and targeted interventions to address the underlying pathologic condition and the global and organ-specific dysfunction. This is achieved while limiting the risk of complications and iatrogenic organ injury. Critical care may be defined as the process of high-intensity physiologic monitoring coupled with short response pharmacologic, hemodynamic, ventilatory, and procedural interventions. These efforts are designed to reestablish normal homeostasis and minimize primary, secondary, and iatrogenic injury. Importantly, the mitigation of risk of complications and further exacerbation of organ

injury may be the most significant contribution of critical care systems. Critical care is generally the most expensive, technologically advanced, and resource intensive component of medical care. Despite the high incremental cost of providing intensivist-directed critical care management, numerous studies have demonstrated considerable incremental benefits of intensivist-directed critical care on mortality, morbidity, and overall cost.[8-15]

Considerable heterogeneity exists across ICUs relative to physician responsibility, physician staffing and availability, provision of ancillary services, and organization of teams and processes. This heterogeneity complicates the ability to assess the contribution of individual components of critical care to the outcome. In Table 46.1, various descriptions of physician staffing models are provided.[16] In general, closed unit staffing models provide reductions in mortality when compared to open unit models[9-13] and the inclusion of multidisciplinary teams appears to provide incrementally greater reductions in mortality when combined with closed unit models.[17]

TIMELY, TARGETED, AND APPROPRIATE APPLICATION OF THERAPEUTIC INTERVENTIONS

Regardless of the structural organization of individual ICUs, the provision of timely, targeted, and appropriate therapeutic interventions improves the outcome of critically ill and injured patients. These concepts are discussed in detail in Chapters 4, 7, 12, and 13 and in chapters in Section IV. Mainstays of therapy for the critically ill acute care surgery population include (1) goal-directed resuscitation and appropriate inotropic support, (2) appropriate and timely antibiotic therapy, and (3) timely and effective source control of infectious, hemorrhagic, or ischemic insults.

While early resuscitation has long been accepted to improve outcomes in the critically ill acute care surgery population, debate continues regarding strategies and appropriate endpoints.[4,18-23] Measures of tissue hypoxia such as base deficit, elevated lactate, and decreased mixed venous saturation correlate with the development of organ system dysfunction and mortality following the onset of

TABLE 46.1

TERMINOLOGIES TO DESCRIBE ICU PHYSICIAN STAFFING MODELS

Closed	Intensivist responsible for day-to-day management of patients, including all admissions and discharges, orders, and clinical management
Open	Primary physician responsible for day-to-day management decisions. ICU admission and discharge policies exist, but the primary physician is the ultimate decision maker. There may be no full-time intensivist or may be involved at the discretion of the primary physicians
High intensity and closed	Intensivist responsible for all patient care in a closed ICU
High intensity and open	The ICU is open but it is mandatory to consult the intensivist
Low intensity and open	The ICU is open and consulting the intensivist is optional
Low intensity	No intensivist available
High intensity	>80% of patients managed by intensivist
Intermediate intensity	>0 but <80% of patients managed by intensivist
No intensivist	No intensivist available
Choice	The ICU is open and consulting the intensivist is optional
No choice and closed	Closed ICU or mandatory ICU consultation
No choice and no intensivist	No intensivist available

Gajic O, Afessa B. Physician staffing models and patient safety in the ICU. *Chest*. 2009;135:1038–1044.

hemorrhage and sepsis and early correction (likely within 6 hours in at-risk groups) of these abnormalities is associated with improved outcomes.[4,18-21,23-29] Resuscitation strategies that target adequate tissue oxygenation as endpoints, and that both respond to the alteration in physiology and limit excessive fluids, appear to have better outcomes than those that do not employ these measures. However, no perfect set of markers has been identified to guide resuscitation in all settings.

For patients with both community and hospital-acquired infections, the time to appropriate antibiotic therapy has been shown to significantly alter outcomes. Thus, establishment of the likelihood of the presence of infection, the source of infection if present, likely pathogens, and potential resistance of pathogens involved, all factor into timing and selection of antibiotic therapy. Inadequate empiric antimicrobial therapy is associated with twice the mortality in studies of mixed hospital-acquired infections,[30] ventilator-associated pneumonia,[31-33] hospital-acquired bloodstream infections,[34,35] and peritonitis.[36,37] Prior antibiotic exposure was associated with inadequate empiric therapy in many of these studies with selection of more resistant pathogens.[30,34,36] As the severity of illness increases, the timing of antibiotic initiation appears to assume increasing importance in septic patients. In a study of 335 surgical ICU patients with infections, using logistic regression analysis, Barie et al.[38] demonstrated that each 30-minute delay in initiation of antibiotic therapy from the onset of fever was associated with a 2% increase in mortality. For patients with septic shock, the influence of antibiotic timing appears to be even greater. In a study of 2,731 patients with septic shock from 14 ICUs in the United States and Canada, Kumar et al.[39] demonstrated that each 1-hour delay in antibiotic therapy from the onset of hypotension was associated with a 12% increase in mortality. The increased risk of death was consistent across subcategories including intra-abdominal, skin and soft tissue, respiratory, blood stream, community, and nosocomial infections; only 50% of patients received

therapy within 6 hours of the onset of hypotension. These studies highlight the importance of systems that enable the early identification of infectious processes and the administration of early empiric antibiotic therapy appropriate for the clinical setting.

A significant portion of critically ill patients managed by acute care surgeons require source control as part of therapeutic interventions, most commonly patients with intra-abdominal processes or skin and soft tissue infections. Severely septic patients may require rapid resuscitation and stabilization in an ICU setting prior to operative intervention for source control. For patients with necrotizing skin and soft tissue infections, the time to effective source control is associated with outcome and these patients may require multiple operative interventions before source control is achieved.[40,41] Critical care support may be required during this period for the treatment of sepsis and septic shock, to support and minimize organ system dysfunction, and to assist with wound management. Critically ill patients with peritonitis present the acute care surgeon with unique challenges. In general, critically ill patients with peritonitis are at higher risk for failure of primary source control and the development of secondary complications such as abdominal compartment syndrome, recurrent intra-abdominal infection (abscess and tertiary peritonitis), and fistula formation than patients with peritonitis who are not critically ill.

One clear demonstration of compliance with timely, targeted, appropriate interventions in critically ill patients is provided through the efforts of the Surviving Sepsis Campaign (SSC).[43] The SSC established evidence-based management guidelines and implemented a broad educational program to facilitate integration of these guidelines in clinical practice in North America, South America, and Europe. Elements of the guidelines were grouped or bundled into two sets of targets to be completed within either 6 hours or within 24 hours of admission. Numerous studies have demonstrated an associated benefit of compliance with the SSC.[45] A before and after analysis of participating sites was

conducted on data submitted from January 2005 through March 2008. Compliance with elements in the bundle increased linearly throughout the period and resulted in a 5.4% adjusted absolute decline in mortality over the 2-year period.[46]

ASSESSMENT AND RECOGNITION OF RISK: ASSESSMENT OF PATIENTS WITH PERITONITIS

Patients with severe sepsis (organ dysfunction and criteria of systemic inflammatory response syndrome) secondary to peritonitis, while representing a small portion of all patients with peritonitis, are at higher risk of mortality.[47] Patients more likely to develop severe sepsis from peritonitis include those with more advanced age, those with diffuse peritonitis, and those with preexisting organ dysfunction.[47] Not surprisingly, factors that predict development of severe sepsis are similar to those that predict failure of treatment and mortality from peritonitis as well. Multivariate analysis in numerous studies has identified advanced age, low serum albumin, poor nutrition, preexisting organ dysfunction, and high Acute Physiology and Chronic Health Evaluation (APACHE) II scores as associated with failure of source control and death.[48-54] In an analysis of 217 patients entered into a randomized trial of complicated intra-abdominal infections, 14% of patients had APACHE II scores of 15 or greater with failure rates in these patients >40%. If APACHE II scores were >20, failure rate exceeded 50%.[55] Each of these risk factors is a measure of the degree of variance from the host's normal physiologic state. In addition to these physiologic risk factors, the degree of inflammation and bacterial burden within the peritoneum also predicts the risk of failure of source control. Diffuse peritonitis, moderate or extensive residual contamination at the completion of the source control procedure, or inability to achieve adequate source control also predicts failure.[54,56-58] Risk factors for failure of source control from intra-abdominal infections are summarized in Table 46.2. Knowledge of these risk factors should be utilized to estimate the postoperative clinical course, to help determine the level of support and monitoring, and predict the likelihood of postoperative intra-abdominal infectious complications. The assessment of

TABLE 46.2

CLINICAL FACTORS THAT PREDICT FAILURE OF SOURCE CONTROL FOR INTRA-ABDOMINAL INFECTIONS[55,59-61]

Delay in the initial intervention (>24 h)
High severity of illness (APACHE II ≥ 15)
Advanced age
Comorbidity and degree of organ dysfunction
Low albumin
Poor nutritional status
Degree of peritoneal involvement/diffuse peritonitis (Peritonitis severity score, Mannheim Peritonitis index)
Inability to achieve adequate debridement or control of drainage
Presence of malignancy

risk of failure is important as delays to definitive therapy in patients who fail source control are associated with increased mortality.[62]

ASSESSMENT AND RECOGNITION OF RISK: MODELING SEVERITY OF ILLNESS IN THE ICU

Scoring systems for severity of illness can broadly be divided into those that are targeted for a specific disease process or organ system (e.g., the Model for End-Stage Liver Disease (MELD) score in liver disease, the Mannheim Peritonitis Index for intra-abdominal infection, and the Glasgow Coma Score for brain injury) and those that are generic for all ICU patients. This section focuses on these generic scores that can be divided into those that assess disease severity on admission and those that assess the degree of organ system derangement or injury at variable time points in any given patient. Scoring systems for severity of illness utilize a variety of demographic, clinical, physiological, and laboratory variables. The most common scoring systems that assess disease severity upon admission include the APACHE, the Simplified Acute Physiology Score (SAPS), and the Mortality Probability Model (MPM), all of which were developed to predict likelihood of survival.[63] Common scoring systems used to assess the presence and severity of organ dysfunction on admission and during the ICU stay include the Multiple Organ Dysfunction Score and the Sequential Organ Failure Assessment.[63]

Each of the three scoring systems used to assess disease severity upon admission and predict outcome (i.e., APACHE, SAPS, MPM) uses variables obtained within a 24-hour period of admission, typically the worst value recorded. Each has had multiple generations, with the most recent version undergoing adjustment of the prediction model based upon new datasets, equations for which are proprietary. Prediction equations for older, nonproprietary versions are no longer being adjusted. Versions of these scores are frequently used to stratify patient severity within studies or to control for variation in severity within a defined population when assessing performance.[63] They may also be used to determine eligibility for inclusion in clinical trials, for therapeutic interventions,[42,43] or to assess the likelihood of therapeutic failure.[55] Generally, these systems perform well when comparing outcome within specific critically ill patient populations, but not across varying populations of critically ill patients.

Measures of organ injury and dysfunction may be used to assess organ dysfunction at admission but may also be used as outcome variables. Thus, they are dynamic, varying among individuals and within a given individual over time and thus can be used to assess and quantitate change in organ function over time. However, outcome prediction and organ dysfunction scores are not mutually exclusive and provide different types of information, which together can complement the clinician's subjective evaluation of a patient's status. These scores may be employed to provide a quantitative response to therapy and direct subsequent therapeutic interventions.[64,65]

More recently, a new system for analysis of sepsis has been developed, the predisposition, insult, response, organ dysfunction (PIRO) system. The PIRO system was created so that a clinically useful staging system, similar to cancer staging, could stratify patients based on their baseline risk for an adverse outcome and their potential to respond to therapy across the very heterogenous patient population defined as septic.[66] While further studies are needed, performance for the prediction of outcome in sepsis is very promising.[67]

PREVENTION OF COMPLICATIONS AND MINIMIZATION OF THE PROPAGATION OF ORGAN INJURY

While relatively few interventions have been shown in randomized, controlled trials to consistently impact outcome in the ICU, outcome of critically ill patients is improving.[38] The improvement in outcome is likely related to both the introduction of specific therapeutic strategies that limit the development and progression of organ dysfunction as well as the complex systems of delivery required to provide highly specific and targeted therapies. Several therapeutic strategies that impact the outcome of patients include those involving respiratory management, sedation and delirium management, cardiovascular risk management, renal management, transfusion practices, endocrine support, infection control, nutritional provision, prevention of airway loss, skin breakdown, deep vein thrombosis, and stress ulcers, as well as the safe performance of invasive, bedside procedures. Each of these areas has a large body of literature that continues to support the advancement of care for the critically ill and injured patient. A full discussion of these topics is beyond the scope of a single chapter, although they will be discussed briefly below. Evidence-based guidelines may assist with the appropriate application of many of these areas listed. However, maintaining high level compliance with both simple and complex components of care within each is difficult and is aided by multidisciplinary teams and informatics support.

Respiratory Management

Appropriate respiratory management of mechanically ventilated, critically ill patients impacts the outcome considerably. Strategies directed toward liberation from ventilatory management, prevention of lung and remote organ injury through low volume ventilatory strategies (i.e., ARDS Net), and strategies to limit the development of ventilator-associated pneumonia have important implications for patient outcome.[43] Clear support for systems and teams that continuously evaluate the appropriateness and ability to wean patients from ventilator support have been shown to reduce the number of ventilator days and improve outcome.[43] Application of weaning protocols, avoidance of weaning of intermittent mandatory ventilation rate, daily spontaneous breathing trials, targeted sedation and daily cessation of sedation, and appropriate use of tracheostomies reduce ventilator days and improve outcomes in certain patient populations. Use of a low-volume ventilation strategy also limits the progression and severity of acute lung injury and acute respiratory distress syndrome, as well as measures of systemic inflammation. However, despite clear data from randomized studies, application of this strategy has been slow to be widely adopted in practice.[68] The need for mechanical ventilation and the presence of an endotracheal tube greatly increases the risk of the development of pneumonia. However, the application of several interventions has been shown to limit the risk of pneumonia in randomized studies.[69,70] These include spontaneous breathing trials, targeted sedation, head of bed elevation, dental and oral care, and hypopharyngeal suctioning. However, high level compliance with each of these may be difficult to achieve and systems to monitor and enhance compliance may improve their application.[71]

Sedation and Delirium Management

The complex interrelationships between sedation, pain management, sleep, delirium, cognitive dysfunction, and outcome are increasingly recognized but are incompletely understood.

While the prevention of pain and anxiety remains an important goal in the management of critically ill patients, oversedation has been recognized to contribute to prolonged mechanical ventilation, altered sleep patterns, and increased delirium.[72-75] Targeted sedation and pain control and daily cessation of sedation have been shown to substantially decrease the time of mechanical ventilation, ICU and hospital length of stay, and outcome.[73,74] Delirium occurs in up to 80% of ICU patients but is frequently underrecognized.[76] The presence and severity of delirium correlates with both cognitive deficits post discharge and overall outcome.[76-78] Both the depth of sedation and agents used to provide sedation contribute to the severity of delirium. At present, inadequate data regarding pharmacologic therapy to limit the development of delirium exists to make recommendations.[73] For the treatment of agitated delirium, few randomized trials exist and the use of antipsychotics, either conventional (Haldol) or less common agents, may be considered. A summation of recommendations for nonpharmacologic efforts to limit delirium and approach to ICU sedation is provided in Table 46.3.

Cardiovascular Risk Management

Surgery is a physiologically stressful event and may precipitate myocardial infarction (MI) in high risk patients any time during the perioperative period. While several studies have shown a significant reduction in perioperative MI and death from cardiac causes with the institution of perioperative beta blockade in high risk patients, all cause mortality with beta blockade may be higher in lower risk patients.[73,79-81] Patients with

---

TABLE 46.3

RECOMMENDATIONS FOR DELIRIUM AND SEDATION MANAGEMENT IN THE ICU

Nonpharmacologic to limit delirium:
Systematic programs to enhance orientation and cognition sleep quality, and mobilization
- Noise reduction
- Light management to facilitate day/night cycles
- Minimization of sleep interruptions
- Introduction of therapeutic activities
- Early mobilization and physical and occupational therapy

Approach to ICU sedation:
1. Provide adequate analgesia first and monitor adequacy with validated assessment tool
2. Employ targeted sedation protocols with validated assessment tools
3. Consider daily cessation of sedation in conjunction with spontaneous breathing trials in ventilated patients.
4. Avoid the adverse effects commonly associated with standard sedative regimens
   - Propofol and dexmedetomidine may be beneficial when compared with benzodiazepines, particularly with short-term needs
   - Avoid midazolam accumulation with targeted sedation to the lightest appropriate target and daily cessation
   - Avoid continuous infusion lorazepam if possible to limit propylene glycol toxicity and monitor serum anion gap if dose exceeds 1 mg/kg.
   - Avoid prolonged or high dose (70 mg/kg/h) of propofol to limit the risk of propofol infusion syndrome.

preoperative history of beta blockade and those at high risk of cardiovascular events should undergo institution therapy with appropriate targets. However, appropriate limitation of hypotension and bradycardia should be achieved to minimize complications.

Renal Management

Acute kidney injury (AKI) is common in the critically ill population, occurring in one-third to two-thirds of patients, and is associated with a substantial increase in morbidity and mortality.[82] The mortality associated with AKI increases proportionally with the severity of injury and is >50% in those requiring renal replacement therapy. Serum creatinine, the most commonly used parameter to assess renal function, lacks both sensitivity and specificity. In addition, increases in serum creatinine lag considerably behind the decline in glomerular filtration rate. Thus, early decline in renal function may go unnoticed. The etiology of AKI in critically ill patients is commonly multifactorial and often difficult to assign to single insults. However, recognition of risk with avoidance of repeated insults is the mainstay of prevention. The most common cause of renal failure in the general ICU population is sepsis. Other causes/ risk factors include hypovolemia, hypoperfusion, rhabdomyolysis, obstruction, abdominal syndrome, and nephrotoxic agents. Common nephrotoxic agents include nonsteroidal anti-inflammatory drugs, aminoglycosides, amphotericin, penicillins, acyclovir, and radio-contrast agents. Maintenance of adequate renal perfusion and renal perfusion pressure in the setting of sepsis and ischemia/reperfusion syndrome requires assurance of adequate volume resuscitation and inotropic and vasopressor therapy. Adequate data supports the use of prevention strategies for contrast-induced nephropathy including; hydration with either sodium chloride or sodium bicarbonate, the use of *N*-acetyl cysteine (NAC), and the use of low-volume nonionic, low-osmolar or iso-osmolar contrast. The choice of sodium chloride versus sodium bicarbonate remains controversial but the weight of the current evidence suggests that bicarbonate may be superior. Meta-analysis of the use of NAC provides conflicting results, although none have demonstrated harm.

Transfusion Practice

While transfusions are common in critically ill patients and may be lifesaving in severely anemic patients (Hgb < 5 g/dL) and actively hemorrhaging patients, transfusion of blood carries a significant risk of transfusion reactions, transmission of infectious agents, transfusion-related acute lung injury, and immunomodulation.[83-85] Hebert's landmark study published in 1999 compared a restrictive versus liberal transfusion strategy in critically ill patients. The authors demonstrated that patients restricted to a transfusion trigger of 7.0 g/dL Hgb with a target of 7.0–9.0 g/dL Hgb fared better than patients transfused at 10.0 g/dL Hgb and maintained at 10.0–12.0 g/dL.[86] The deleterious effect of severe postoperative anemia on mortality was shown in a study of 300 patients with a postoperative hemoglobin concentration <8.0 g/dL who refused blood transfusion for religious reasons with significant increases in mortality occurring when hemoglobin concentrations fell to <5 g/dL.[83] Patients with a recent history of acute MI or unstable angina may benefit from a higher transfusion threshold (trigger of 10 g/dL Hgb).[84,87] The benefit of transfusion in sepsis and in those with inadequate oxygen consumption remains to be established.[84] No single criterion should be used as an indication for red cell component therapy. Multiple factors related to the patient's clinical status and oxygen delivery needs should be

considered. Accordingly, the decision to transfuse erythrocytes must be based upon an assessment of the risks of anemia versus the risks of transfusion.

Endocrine Support

Endocrine dysfunction has gained attention in critical care in the last decade. The most prominent areas of endocrine dysfunction include the development of stress-induced insulin resistance and resulting hyperglycemia, acute adrenal insufficiency in sepsis, and thyroid dysfunction in critical illness. Stress-related hyperglycemia occurs commonly following surgery, trauma, and sepsis. The magnitude of hyperglycemia is strongly associated with poor outcome in both the noncritically ill and the critically ill population, particularly in the nondiabetic patients.[88-90] The development of hyperglycemia, while multifactorial, is significantly related to stress-induced insulin resistance. Following the landmark Leuven study published in 2001,[91] glycemic control in the form of intensive insulin therapy (IIT) in the ICU has received much attention in a variety of critically ill populations. While the interpretation of data on this topic is confounded by variation in patient populations, incidence of hypoglycemia, variation of IIT protocols, and variation in nutritional provision, several conclusions can be drawn from the existing literature and are summarized:

- Hyperglycemia should be controlled in the critically ill surgical population[92]
- Intravenous insulin should be used to achieve this, but efforts to measure and limit hypoglycemia are essential[92-94]
- Periods of glycemic analysis longer than 2 hours result in poorer control and increased hypoglycemia[94,95]

Important areas of uncertainty exist regarding glycemic control that include

- The optimal target for glycemic control
- The optimal early nutritional provision and its influence on glycemic control

Adrenal insufficiency and relative adrenal insufficiency in critical illness and sepsis has also received considerable attention in the past decade. Following the publication by Annane et al.[96] with treatment of patients with refractory septic shock with low dose hydrocortisone, considerable debate has occurred over the appropriate indications. Current recommendations supported by meta-analysis of studies in sepsis include[43,97]:

- Consideration of intravenous hydrocortisone in doses of ≤300 mg/d for patients in septic shock when hypotension responds poorly to fluid resuscitation and vasopressors.
- Steroid therapy may be discontinued once vasopressors are no longer required.

Nutritional Provision

Critical illness is associated with a strongly catabolic state, the severity of which coincides with the severity of the systemic inflammatory response. The provision of nutritional support to critically ill patients is paramount and may preserve lean body mass, immune function, and reduce metabolic complications. Specific, targeted nutritional therapy may modulate the stress response in various settings and have a favorable impact on outcome.[98] Despite significant advances in our understanding of optimal nutritional provision, much remains unknown and this area has been inadequately studied. Enteral nutrition is strongly preferred over parenteral and can safely be delivered in the majority of patients within 48 hours of surgery or completion of resuscitation and achievement of hemodynamic

stability. The role of early nutritional provision (<48 hours) via the parenteral route has been inadequately studied at this point and American and European organizations differ in their recommendations. Recommendations of the Society of Critical Care Medicine and the American Society for Parenteral and Enteral Nutrition have recently been published.[98,99]

Antibiotic Stewardship Programs

Critically ill patients are at high risk of health care-acquired infections that prolong ICU and hospital stay and increase morbidity and mortality. While antibiotics are paramount for prophylaxis and treatment, antibiotic exposure is associated with an increased risk of subsequent infection in critically ill patients and strongly associated with the acquisition of resistant pathogens.[30,100-104] Antibiotic stewardship programs have been shown to reduce antibiotic use, hospital-acquired infections, and antibiotic resistance in hospital-acquired pathogens.[105,106] Stewardship should assure appropriate empiric coverage with antibiotics, an organized diagnostic approach to identification of therapy, deescalation of antibiotics to known or highly suspected pathogens, limitation of antibiotic therapy to evidence-based treatment courses, and appropriate dosing regimens.

SURGICAL CRITICAL CARE

GIANA HYSTAD DAVIDSON AND EILEEN BULGER

The primary functions of the respiratory system are to adequately deliver oxygen from the external environment to meet the metabolic demands of tissues and eliminate the buildup of carbon dioxide. The acute care surgeon is faced with a number of injuries and acute illnesses that impair pulmonary function. This chapter focuses on acute respiratory dysfunction and the common conditions and treatment strategies important for the acute care surgeon.

PHYSIOLOGY OF RESPIRATION

The two main functions of the respiratory system are ventilation to eliminate carbon dioxide and oxygenation to deliver oxygen to the tissues. Efficiency of ventilation is achieved by matching ventilation to perfusion in the gas-exchange regions of the lung. Minute ventilation is calculated by multiplying the tidal volume by the respiratory rate and can be directly measured by collecting exhaled gas over a measured time. Higher minute ventilation represents greater carbon dioxide release. Normal minute ventilation volume is 5–8 L/minute for a 70 kg man. Increased cellular metabolism in response to injury results in increased CO_2 production, which must be matched by increased release from the lungs. Normally, a resting adult must eliminate 200 mL/kg/minute of CO_2. In the hypermetabolic state, CO_2 production increases to the range of 425 mL/kg/minute.[1] The minute ventilation required to maintain eucapnia rises concurrently from approximately 5 L/minute (resting rate) to 10 L/minute. This represents a 100% increase in the work of breathing required to meet metabolic demands under these circumstances.

Oxygenation is primarily dependent on binding to hemoglobin (Hb). Hb is composed of four polypeptide chains including two alpha and two beta chains totaling 146 amino acids. Each polypeptide contains an iron atom on the heme group that is capable of binding oxygen. For each gram of Hb, 1.39 mL of O_2 can be stored. Arterial O_2 content (CaO_2) is related to Hb concentration and Hb saturation (SaO_2) by the following equation[2]:

$$CaO_2 = [Hb] \times 1.36 \left(mL\ O_2/gO_2 \right) \times SaO_2 + 0.003\ mL \times PaO_2$$

The oxygen dissociation curve seen (Fig. 47.1) shows the percent saturation of Hb at various partial pressures of oxygen. As erythrocytes travel to areas with low oxygen saturation, the partial pressure of oxygen decreases leading to delivery of oxygen to tissue. Temperature, organic phosphates such as DPG and pH directly affect Hb affinity for oxygen and oxygen delivery.

Obstructive airway disease such as chronic obstructive pulmonary disease (COPD), asthma, chronic bronchitis, and emphysema decrease gas flow and therefore gas exchange. As a consequence, arterial partial pressure of O_2 drops (hypoxemia) and arterial partial pressure of CO_2 increases (hypercapnia). Interventions to improve the match between ventilation and pulmonary perfusion may be required. In the setting of acute respiratory failure secondary to acute respiratory distress syndrome (ARDS), pulmonary contusion, or severe pneumonia, hypoxia is the primary factor due to consolidation of the pulmonary parenchyma. In the setting of acute pulmonary embolism (PE), ventilation/perfusion (V/Q) mismatch is also enhanced secondary to disruption of perfusion to segments of lung tissue.

Basic features of respiratory dysfunction include dyspnea, hypoxia, and hypercarbia. There are a variety of medicine conditions leading to respiratory dysfunction, which is defined as a drop in PO_2 <60 mm Hg or a rise in PCO_2 >50 mm Hg. Table 47.1 is an overview of the four main mechanisms of respiratory dysfunction.

Hypoxemia

The rate and severity of hypoxia and hypercarbia affect the clinical and neurologic presentation of the patient. Patients may experience mild confusion and headache to loss of consciousness. Hypoxemia should always be considered a cause of altered mental status. Prolonged central nervous system hypoxia has the potential to lead to hypoxic–ischemic encephalopathy through neuronal death. Hypoxia may be secondary to airflow obstruction in conditions such as asthma or airspace flooding as seen in pneumonia, aspiration, or hemorrhage. Acute airflow obstruction can cause hypoxemia that is typically treatable with supplemental oxygen. However, conditions that result in airspace flooding typically require adjuvant therapies and are not reversible by additional oxygen alone. Pulmonary shunting occurs when the alveoli of the lung is perfused normally; however, there is ventilation failure to the perfused regions leading a change in the ventilation/perfusion ratio. In a healthy individual, the physiologic shunt is rarely over 4%.[3] Shunting is minimized by the reflexive constriction of pulmonary vasculature to hypoxia. In conditions such as pulmonary contusion, the shunt increases considerably and mechanical ventilation may be required. Therapy should always focus on treatment for the underlying cause of hypoxemia.

Ventilatory Failure

The etiology of hypocapnia and hypoxia are frequently different. With neurologic depression, the decrease in the drive to breathe reduces minute ventilation leading to increase $PaCO_2$. In patients who require a high minute ventilation to maintain a normal $PaCO_2$, there is often elevated CO_2, increased dead space, or a high degree of ventilated but poorly perfused alveoli.[4] This is a common etiology in our trauma and perioperative patients in combination with neurologic impairment.

Perioperative and Neurologic Impairment

The perioperative period is high risk for progression of respiratory dysfunction. Patients have a significant risk for atelectasis, which is the primary mechanism of perioperative respiratory
FIGURE 47.1. Oxygen dissociation curve.

dysfunction. Abnormal abdominal mechanics reduce the end-expired lung volume leading to progressive lung collapse in the dependent portions of the lung. The addition of narcotics or benzodiazepines can lead to a combination of ventilatory dysfunction leading to respiratory failure. Treatment of patients in the perioperative patients should focus on excellent bronchopulmonary hygiene to minimize atelectasis and clear secretions. This includes incentive spirometry, early ambulation, maintenance of euvolemia, and patient positioning. Attention to abdominal/thoracic pain and incisional pain is necessary and epidural anesthesia or transcutaneous electrical nerve stimulation should be considered for those individuals at high risk for pulmonary dysfunction including the obese, elderly, and patients with thoracic trauma. Lung collapse can

be detected radiographically and on routine exam and should be treated aggressively with techniques for lung recruitment.

Shock

Patients with hypotension secondary to cardiogenic, hypovolemic, or septic shock often present with respiratory dysfunction. While there is no primary pulmonary mechanism, mechanical ventilation is often necessary. This allows for stabilization of gas exchange and minimizes cardiac steal until the underlying cause is identified and treated.

The mainstay of treating acute respiratory dysfunction is mechanical ventilatory support. Identification and treatment of the underlying cause is paramount. Prompt initiation of supportive ventilation during this time is key to preserving neurologic function and preventing permanent sequelae.

SPECIAL POPULATIONS

Children

The unique anatomy of children is important for both diagnosis and treatment of acute respiratory dysfunction. Children have a large head and tongue in proportion to the size of the oral cavity as well as prominent tonsils and adenoid tissue. Increased neck flexion from the prominent occipital bulge can lead to airway obstruction. Focus on proper head positioning including chin-lift and jaw-thrust is especially important in this population.[5] Equipment sizing is also imperative. Broselow tape and equipment of various sizes should be immediately available.

Neonates and infants are obligate nose breathers. Nasal obstruction can cause both increased work of breathing and

TABLE 47.1

MECHANISM OF RESPIRATORY DYSFUNCTION

	■ HYPOXEMIA	■ VENTILATORY FAILURE	■ PERIOPERATIVE	■ SHOCK
Mechanism	Intrapulmonary shunting	Alveolar hypoventilation	Atelectasis	Hypoperfusion
Etiology	Airspace obstruction	CNS depression, loss of neuromuscular coupling, Increased work of breathing/dead-space	Collapse of dependent portions of the lung	Cardiogenic shock Hypovolemic shock Sepsis
Clinical presentation	Hypoxemia often refractory to O_2 therapy	Hypercapnia with hypoxemia. Often corrects with O_2 therapy.	Hypoxemia, frequently tachypnea, May respond to O_2 therapy, maneuvers to improve lung collapse	Hypoxemia, hypotension, frequently tachypnea
Common manifestation	ARDS, cardiopulmonary edema, pneumonia, alveolar hemorrhage	Narcotic/benzodiazepine overdose, asthma, COPD, pulmonary fibrosis	Obesity, ascites, pain, anesthesia, fluid overload, smoking history, Secretions	MI, pulmonary hypertension, hemorrhage, tamponade, bacteremia
Treatment: mechanical ventilation if indicated.	Treat pneumonia, drain pleural effusions, minimize dead-space	Oxygen therapy, reverse sedation, bronchodilation, positioning and suctioning to clear secretions, chest tube, Pain control,	Positioning, suctioning secretions, 45 degree upright, pain control, drain ascites, re-expand atelectasis, stop smoking 6 wks preoperatively, maintain euvolemia	Correct underlying cause, treat sepsis, maintain euvolemia, appropriate management of electrolytes

respiratory distress. Nasal suctioning can help to improve respiratory status in these patients.[6] The larynx is well protected behind the mandibular arch and due to the relatively short neck; only a small portion of the trachea is unprotected above the manubrium. There is increased elasticity of the tracheobronchial tree. Laryngeal injuries are rare but often present with vague symptoms including hoarseness and subcutaneous emphysema, whereas tracheobronchial injuries often present with pneumothorax with or without a persistent airleak.[7]

Due to the increased plasticity of the chest wall in children, blunt injury to the chest is transmitted to deeper structures. Thirty-four percent of pediatric patients with pulmonary contusions do not show radiographic evidence of rib fractures.[8] Injuries such as pulmonary contusion, pneumothorax, hemothorax, blunt cardiac injury, and great vessel trauma can be found without rib fractures and a high index of suspicion is required for quick diagnosis.[6]

Elderly

A broad range of physiologic changes compromise the anatomic and functional integrity of the respiratory system in the elderly. This includes impared elastic recoil of the lung and decreased dynamic compliance, both which increase airflow resistance leading to progressive airflow trapping. Decreased size and number of muscle fibers impairs the strength of intercostal and diaphram contraction. Individual response to hypoxemia and hypercapnia also wanes with age.[9-11] Reduced plasticity of the chest wall also increases the risk of the elderly for rib fractures and the associated complications.

Obesity

Excess adipose tissue in obese individuals reduces chest wall compliance, increases airway and pulmonary resistence, and increases work of breathing.[12] Obesity-hypoventilation syndrome (pickwickian syndrome) is found in one-third of individuals with a BMI of >35 (morbidly obese).[13] Nearly all have obstructive sleep apnea and >50% develop pulmonary hypertension.[14] Care must be taken to maintain adequate oxygen saturation (of >88%), especially in the setting of narcotics and/ or benzodiazepines in trauma or postoperative patients. Continuous airway monitoring should be considered as diminished neuromuscular response to hypercapnia may quickly lead to hypoventilation, hypercapnia, acidemia, and respiratory distress.[14,15] The risk and rate of deterioration will be accelerated by intoxication, rib fractures, spine immobilization, and limited mobility in all patients, but perhaps to a greater degree in the obese and elderly population.

While the management of respiratory distress of obese patients is similar to normal weight individuals, bilevel positive airway pressure (BIPAP) should be considered in stable patients. However, BIPAP should never delay or be used instead of endotracheal intubation.[14]

Pregnancy

One of the principal causes of morbidity and mortality among pregnant women is acute respiratory dysfunction. Studies suggest that up to 30% of maternal deaths results from acute respiratory failure. Predominent causes include adult respiratory distress syndrome, thromboembolism, venous air embolism, beta-adrenergic tocolytic therapy, and amniotic fluid embolism.[16] The etiology of respiratory failure is similar in nonpregnant patients but the physiologic changes of pregnancy complicate standard management. In pregnancy,

minute ventilation increases by 50% due to increased respiratory rate and tidal volume required to compensate for changes in maternal, fetal, and placental oxygen requirements and CO_2 production. There is a mild respiratory alkalosis in pregnancy with a reduction in $PaCO_2$ to 27–34 mm Hg (normal 35–45 mm Hg) and a compensatory reduction in bicarbonate to 18–21 mL/Eq/L (normal 22–30 mL/Eq/L) to maintain arterial blood pH of 7.4–7.45.[17,18] Oxygen consumption increases by up to 20%–30% in the third trimester and maternal cardiac output increases by 50% during the first two trimesters due to both an increased stroke volume and heart rate and a decrease in systemic vascular resistance. Fetal oxygenation depends on maternal cardiac output. Therefore, diuresis, positive end-expiratory pressure (PEEP), and vasopressor treatments, which may change the maternal blood flow and shunt blood away from the uterus, may put the fetus at risk.[19] As long as the maternal PaO_2 is maintained above 60 mm Hg and both cardiac output and fetal blood flow remains stable, the fetus will not be affected adversely.[17]

Standard treatment for respiratory dysfunction includes ventilatory, hemodynamic, and nutritional support. However, in pregnancy, maternal–fetal physiology and drug safety require additional consideration. Respiratory dysfunction in pregnancy results from hypoxic and hypercapnic–hypoxic physiologic causes. Hypoxic respiratory dysfunction is the predominant cause of pregnancy-related respiratory failure that includes ARDS, PE, venous air embolism and amniotic fluid embolism pneumonia, cardiogenic pulmonary edema, and pneumothorax. Hypercapnic–hypoxic respiratory dysfunction results from narcotics or sedatives, asthma, myasthenia gravis, and Guillain Barre.[17]

ARDS is a common final pathway of pulmonary injury and has a similar presentation and mortality rate for both gravid and nongravid patients. Outcomes are related to comorbidities, age, injury, and etiology and range in the literature from 30% to 70%.[16,20] Causes of ARDS unique to pregnancy include tocolytic-induced pulmonary edema, eclampsia, aspiration chorioamnionitis, amniotic fluid embolism, trophoblastic embolism, placental abruption, obstetric hemorrhage, endometritis, retained placental products, and septic abortion.[17] Pregnancy brings the additional challenge of evaluating for the presence and etiology of pulmonary edema and fetal monitoring. The use of a pulmonary artery catheter may aid in diagnosis and tailoring therapeutic decisions.[16] Fetal assessment is best with continuous fetal heart monitoring and sonographic biophysical profile done in consultation with obstetrics colleagues.[21] Hypovolemia of pregnancy, particularly during the 30th to 32nd week gestation, may also contribute to progression and poor outcomes of ARDS in this population.[16]

The mainstay of therapy in respiratory failure in the pregnant patient is maternal stabilization, fetal monitoring, treatment of underlying cause, prevention of aspiration, and low-tidal lung protective mechanical ventilation with the application of PEEP when indicated. As PEEP exceeds 10 cm H_2O, there is decreased venous return, decreased cardiac output, which worsens fetal oxygen delivery. The effect of hypercapnia on fetal blood flow is unknown.[17] Fluid restriction in pregnancy is controversial. While it improves oxygenation, fluid restriction worsens cardiac output and organ perfusion.[17]

COMMON CAUSES OF ACUTE RESPIRATORY DYSFUNCTION

Acute Respiratory Distress Syndrome

ARDS is characterized by dysfunction in respiratory mechanics and gas exchange. The mortality rate ranges from 40% to 50%.[22] The incidence in the United States is approximately

190,000 cases per year affecting a wide distribution of both medical and surgical patients and is associated with >74,000 deaths per year.[23] In 1994, the American-European Consensus Committee recommended seperating patients with lung disease into two groups, those with acute lung injury (ALI) and those with more severe hypoxia, ARDS. Criteria include: acute onset, bilateral infiltrates on chest radiograph, pulmonary artery wedge pressure <18 mm Hg or the absence of left atrial hypertension. ALI is considered to be present if the PaO_2:FiO_2 ratio is <300, whereas ARDS requires a PaO_2:FiO_2 ratio to be <200.[24]

Several studies have sought to improve outcome following ARDS. The only study that has demonstrated a major improvement in outcome utilized a lung-protective ventilation strategy with lower than usual tidal volumes.[20] The pathogenesis of ALI and ARDS in surgical patients is variable. These most commonly include sepsis, trauma, aspiration, near drowning, blood transfusion, pulmonary contusion, and inhalation injury.[25] Typically, an initial inflammatory stage with neutrophil infiltration and massive capillary leak is then followed by a fibroproliferative phase, drastically changing the elasticity of the lung.[24,25]

The clinical course of ARDS is variable with patients recovering within weeks to months of prolonged ventilation. Rather than respiratory failure itself, it is prolonged ventilation with superimposed infection and multisystem organ failure that ultimately leads to death. Treatment strategies include ventilatory support to minimize iatrogenic injury with a goal to avoid progression of pulmonary damage and modulation of inflammatory response through pharmacologic options.[25] Studies of treatment options have only shown a mortality benefit for patients with ARDS with low-tidal ventilation.[26] The Acute Respiratory Distress Syndrome network (ARDSnet) trial randomized patients to receive ventilatory support with 6 mL/kg versus 12 mL/kg based on predicted body weight. Allowing for hypercapnia, there is a goal plateau pressure of <30 cm H_2O. The low tidal volume group (6 mL/kg) had a significantly lower mortality rate (31% vs. 40%), and increased number of ventilator-free days.[20]

Pneumothoraces

A breach in the parietal or visceral pleural can result in air in the pleural space (pneumothorax). Diagnosis of small pneumothoraces is most commonly made by chest radiograph; however, the presence of a tension pneumothorax should be evident on physical exam. A small separation of space may translate into a large pneumothorax, particularly depending on the position of the patient during chest radiograph. A tension pneumothorax is created when a large amount of intrapleural air causes a shift in the mediastinum toward the contralateral lung. Stab or gunshot wounds may create a sucking chest wound. Ventilation and venous return of blood to the heart may be compromised resulting in hypotension that can lead to cardiovascular collapse. Open and tension pneumothoraces should be diagnosed clinically based on physical exam including decreased breath sounds and hypotension and treated as a surgical emergency.

Pneumothoraces are classically classified as spontaneous or acquired. Typically, spontaneous pneumothoraces are secondary to rupture of small blebs due to increased transpulmonary pressure. In addition to connective tissue disorders, common causes of spontaneous pneumothorax are rupture of subpleural blebs after coughing, blunt chest trauma, rapid fall in atmospheric pressure, rapid decompression (seen in scuba diving), and high altitude with flying. Presentation ranges from asymptomatic to pleuritic chest pain, decreased breath sounds, and dyspnea, and may progress to hypotension, tachycardia,

diaphoresis, and cyanosis, and deviation of trachea if a pneumothorax progresses to a tension pneumothorax.[27]

Pneumothoraces are the most common intrathoracic blunt chest injury.[28] Delay in diagnosis or missed pneumothorax is a significant cause of preventable death.[29] The emergency department use of CT scanning and ultrasound along with supine chest radiographs may contribute to the delay in diagnosis of occult pneumothoraces. The incidence of the occult pneumothorax varies in the literature. In children with blunt trauma, the incidence of undiagnosed pneumothorax is 3.7% on abdominal CT.[30] Intubated trauma patients with an average injury severity score (ISS) of 30 had an incidence of missed initial pneumothorax as high as 64%.[31] Ball et al.[32] demonstrated that at one trauma center, 15% of patients with an ISS of >11 had an occult pneumothorax on abdominal CT with 55% not detected by initial chest radiograph. There is no general consensus for treatment of the occult pneumothorax as progression is not well understood. Generally, in asymptomatic patients without mechanical ventilation, observation and monitoring for increasing size is safe and effective. Patients with positive-pressure ventilation have a higher likelihood for development of a tension pneumothorax and chest tube placement should be considered as these patients often have a low cardiopulmonary reserve.[33]

Hemothorax

Blood in the pleural space is typically secondary to trauma, iatrogenic injury, neoplasms, pulmonary infarction, or infections.[27] One-third of all thoracic traumas requires tube thoracostomy for hemothorax.[28] Effective drainage can frequently be done with a large (36 French) chest tube. Early evacuation of retained hemothorax has been shown to improve clinical outcomes.[34] A small number of patients will require thoracotomy for complete evacuation. The pleura is able to resorb a significant amount of fluid, however, it is unclear what quantity may be assumed to resolve spontaneously in adults. Retained clot is the primary predisposing risk factor in the development of posttraumatic empyema. Furthermore, in trauma patients there is significant upregulation of inflammatory cytokines causing recruitment of neutrophils to the site of injury and thickening of the pleura. This pleura thickening reduces the likelihood of resolution of the hemothorax.[35] The parietal peel may lead to chronic lung entrapment and recurrent pneumonia. If significant thrombus has formed following trauma, the patient is at risk for retained hemothorax and development of secondary infection may lead to empyema. Additionally, host immune system may be impaired by hypotension and blood transfusions. The reported prevalence of posttraumatic empyema is 5%–10%.[36] Penetrating chest injuries are often clean wounds. However, secondary contamination of the pleura from injuries to the gastrointestinal tract, devitalized tissue from chest wall trauma, unsterile chest tube placement or other foreign body, trapped lung or underlying pneumonia may lead to empyema. *Staphylococcus aureus* is the primary causative organism in posttraumatic empyema.[37,38]

Chest Wall Trauma

Blunt chest trauma at a regional trauma center has a reported incidence of 10% among all trauma patients.[39] Pulmonary contusion is reported in 25% of patients with blunt chest trauma.[40] Pathophysiology of blunt chest trauma includes increased alveolocapillary permeability, increased intrapulmonary shunting, pulmonary edema, ventilation–perfusion mismatching, and loss of compliance.[41] Clinically, presentation depends on degree of involvement, additional injuries, and

comorbid conditions. Symptoms range from increased work of breathing to acute respiratory decompensation.[41] Complications following injury, including respiratory failure, ARDS, and pneumonia, are common and lead to a reported mortality rate between 9% and 50%, depending on associated injuries.[42,43] Flail chest and pulmonary contusion are associated with a mortality rate of nearly double either alone.[42]

Imaging modalities to evaluate blunt chest trauma include chest radiography and thoracic CT. In evaluating pediatric patients with a pulmonary contusion, Wylie et al. found that 15% of patients had an initial chest x-ray (CXR) that did not identify the lung contusion.[44] These results were similar to adult studies that show progression of radiographic findings over time. Thoracic CT has been found to be more sensitive for pulmonary contusion than CXR alone.[45] Typically, chest CT has been the gold standard for detection of pulmonary contusion with 100% sensitivity. Chest radiography sensitivity for pulmonary contusion on initial exam is typically reported at approximately 40%.[46] Despite decreased sensitivity, CXR is still the primary modality for initial evaluation in the unstable patient.

There is an inconsistent correlation between contused lung volume and severity of clinical disease. In 2009, Hamrick et al. attempted to quantify lung volume involved in pulmonary contusions using computerized topography. They found that patients with >20% of total contused lung volume frequently required mechanical ventilation within 48 hours of injury.[47] Rib fractures, patient age, inflammation, aspiration, sepsis, and possibly surfactant dysfunction all affect progression and severity of pulmonary dysfuntion with lung contusion.[48]

There is controversy surrounding fluid management in the treatment of patients with pulmonary contusions. Excessive crystalloid resuscitation has been associated with worsening hypoxia. However, prospective studies have failed prove causation.[49,50] Euvolemia is recommended with crystalloids and blood products as indicated for other injuries. The use of steroids has been shown to be of no benefit and may impair bacterial clearance within the pulmonary tissue.[49,51]

Associated injuries are largely predictive of morbidity and mortality in patients with blunt chest trauma. Rib fractures are clinically important as a marker for serious intrathoracic and abdominal injury. They are a source of significant pain and an independent predictor for respiratory failure, particularly in the elderly. The presence of three or more rib fractures is associated with increased intensive care and hospital stay and increased mortality.[52] In a retrospective study of patients over 65 years old with rib fractures, 31% of patients with rib fractures develop nosocomal pneumonia and 22% died.[53,54] Adequate analgesia and pulmonary hygiene are the mainstays of therapy for patients with multiple rib fractures. The pain associated with rib fractures impairs ventilatory function leading to poor outcomes. Bulger et al. demonstarted that when epidural anesthesia was used in adult patients with greater than three rib fractues, there was a sixfold decrease in the risk of pneumonia and twofold decrease in time on a ventilator. There was no difference demonstrated in mortality in this study.[54]

Blunt chest trauma affects a substantial portion of trauma patients and can result in considerable morbidity. Elderly patients are at hightened risk for decompensation and may require close monitoring. Mainstays of therapy include mechanical ventilation when indicated, pain control, and aggressive pulmonary toilet.

Laryngotracheal Trauma

Laryngotracheal trauma occurs in <1% of all trauma patients but has a mortality rate of 20%–40%.[55–57] The most commonly reported mechanism is blunt force trauma to the cervical region. This mechanism may also lead to damage to the esophogus, cervical spine, closed head and vascular injuries. The most immediate and fundamental treatment is securing the airway. Schaefer recommended tracheostomy with local anesthesia to avoid endotracheal intubation.[58] However, others argue that endotracheal intubation can be done safely with experienced personnel under direct visualization with a small endotracheal tube.[54,59] After securing the airway, a high index of suspicion should be maintained to rule out additional injuries. Larrngoscopy may be helpful in identifying edema, hematoma, laceration to thyroid cartilage, or laynx.[57] CT scan may be helpful in identifying additional injuries including fractures. After initial exam and radiography, consideration should be given to contrast swallow studies and esophagogastroduodenoscopy to rule out esophageal injury.[58]

Pulmonary Embolism

An estimated 250,000 deaths from PE occur in the United States per year.[60] Mortality is typically secondary to right ventricular failure.[61] The risk for thrombosis in surgical patients is greatest at the time of injury and during the perioperative phase.[62–64] In patients without prophylaxis against venous thromboembolic disease (VTE), deep vein thrombosis is reported in as many as 30% with a fatality rate of 1%.[59] Due to the significant mortality rate as well as the risk of respiratory compromise from PE, prevention of VTE is the mainstay of therapy.[65] We will focus on clinical presentation of respiratory dysfunction associated with PE as Chapter 57 provides more details on thromboembolic disease.

Diagnosis of PE requires suspicion based on risk factors, nonspecific signs and symptoms. The lack of specificity of clinical presentation leads to additional testing for confirmatory diagnosis. PE should be considered for any unexplained dyspnea or hypoxia. Common symptoms of PE include anxiety and pleuritic chest pain. Tachypnea and tachycardia are the most common clinical signs of PE.[60] Electrocardiographic (ECG) abnormalities include T-wave changes, ST segment abnormalities, and/or axis deviation, and have been demonstrated in 87% of patients with a diagnosed PE without underlying cardiac disease.[66] The low specificity of ECG change was confirmed in the prospective investigation of pulmonary embolism diagnosis (PIOPED) study.[67] Young patients with good functional pulmonary reserve may have a normal PaO_2. However, especially in the elderly, hypoxemia is commonly present. In patients over age 40, the PaO_2 has been found to be >80 mm Hg in 3% of patients while in those younger than age 40, 29% of patients with proven PE had a PaO_2 over 80 mm Hg.[68] The alveolar–arterial oxygen tension difference was >20 mm Hg in 86% of patients with diagnosed PE in the PIOPED study.[66] While helpful in developing the clinical picture, PaO_2 remains nonspecific and can be normal in a patient with normal cardiopulmonary reserve.

Chest radiography is often the appropriate first step in the work up for acute respiratory dysfunction. In the setting of acute respiratory dysfunction, a normal chest radiograph is strongly suggestive of PE. The most common radiograph findings for PE are both nonspecific and common in postoperative and trauma patients including atelectasis, pleural effusion, elevated hemidiaphragm, and pulmonary infiltrates.[69] Spiral CT remains the most common method for diagnosis of PE. Limitations include poor peripheral visualization and false positive results due to pulmonary lymph nodes.[60] Reliability of CT for diagnosis varies in the literature. Using pulmonary angiography as the gold standard gave a positive predictive value range of 60%–89% and negative predictive value of approximately 80% for spiral CT.[70] This indicates that interpretation by the radiologist plays a large role in diagnostic accuracy. Other

studies have shown a 95% sensitivity and specificity of spiral CT scan for diagnosis of PE.[71,72] In patients with documented PE, >80% have right ventricular size or function abnormalities on echocardiography suggesting PE.[73,74] These are nonspecific findings and can be found in other causes of right heart dysfunction including COPD exacerbations.

If the patient has a low bleeding risk and suspicion is high, it is reasonable to start anticoagulation therapy during diagnostic testing. Patients presenting with hemodynamic compromise secondary to PE may be candidates for thrombolytic therapy. Indications include arterial hypotension (systolic blood pressure (SBP) <90 mm Hg or a decrease of >40 mm Hg), cardiogenic shock, circulatory collapse, right ventricular dilation or pulmonary hypertension, arterial–alveolar O_2 gradient of >50 mm Hg.[60] Systemic thrombolytic therapy is frequently contraindicated in postsurgical and trauma patients.

It is important to consider prevention of subsequent PE in the patient who has a history of PE. Inferior vena cava (IVC) filters are a therapeutic option in patients with VTE. Indications IVC filter placement include patients who have deep venous thrombosis (DVT) and contraindications to anticoagulation or in patients who have the risk of hemorrhage while anticoagulated.[75] In addition, the use of prophylactic IVC filters in high-risk patients has been evaluated in small studies. Thirty-nine patients at two institutions undergoing major spinal reconstruction had permanent IVC filters placed preoperatively. There were no PEs diagnosed in patients who had IVC filter placed compared to 12% of patients who developed PE in a matched cohort control group at the same institutions.[76] Trauma patients with injuries or comorbidities indicating high risk for DVT and PE may be candidates for prophylactic IVC filter placement. Those at highest risk include: severe head injury, spinal cord injuries with neurologic deficit, pelvic, and long bone fractures.[77] Prophylactic IVC filters have been increasingly placed in the trauma population over the past decade with minimal complications.[74] In evaluating placement of permanent filters placed for blunt trauma injuries, Wojcik et al. reported a series ($N = 105$) of patients who were treated with permanent IVC filters for DVT diagnosis and prophylaxis with a mean follow up of 29 months. They found no PEs in the patients with filters placed and no clinically identifiable complications related to insertion of the vena cava filters. In follow-up, they reported minimal migration one filter, one vena cava occlusion, 11 patients experienced lower extremity edema following discharge, and 28 of the 64 patients with prophylactic IVC filters developed a DVT following placement.[78] In an additional study using Greenfield filters placed within 48 hours of trauma, PE-related mortality decreased from 17% to 2.5%, with only 2 of 40 patients developing substantial venous stasis of the lower extremities.[79] Additional studies support prophylactic IVC filter placement in trauma patients at high risk for DVT and PE. However, above-mentioned studies are small and additional studies are needed to further elucidate clear populations that will benefit from prophylactic filter placement, long-term complications, and adequacy of filter removal. Modern IVC filters are frequently removable once the period of high thrombotic risk has passed; however, a recent study reported that poor follow-up of injured patients can lead to low retrieval rates.[80]

Fat Embolism

Fat embolism is associated most commonly with trauma and orthopedic fractures, particularity long bone fractures. Fat embolism is defined as the presence of fat droplets within the peripheral and lung microcirculation.[81] Fat embolism syndrome (FES) is a manifestation of fat embolism that occurs in the presence of fat in the pulmonary vasculature. FES presents with clinical signs typically 12–72 hours following trauma with symptoms of progressive respiratory failure with hypoxemia, petechial rash, and altered mental status variably present.[82] Additional clinical features include tachycardia, fever, retinal changes, jaundice, renal involvement (anuria or oliguria), fat in the urine or sputum, unexplained drop in Hb or platelets, and fat macroglobulinemia.[80] FES has a heterogeneous pattern of presentation. There is no confirmatory test and there is ongoing debate on the precise diagnostic criteria making diagnosis and accurate incidence rates difficult. FES is a diagnosis of exclusion based on clinical characteristics and risk factors. A 10-year review at a level-one trauma center identified 27 patients with clinically apparent FES from 1985 to 1995. This was 0.9% of all long-bone fractures treated during this time. These patients had a mean ISS of 9.5 and 44% required mechanical ventilation.[83] Treatment is primarily supportive and alternative causes for respiratory dysfunction should be excluded. Chest radiograph in patients with FES often have abnormalities. Classically, these include diffuse, bilateral interstitial and alveolar densities. However, findings are nonspecific and there is a lag time related to the clinical symptoms.[81] Intraoperative pulmonary fat embolism can be identified using transesophogeal echocardiography with a sensitivity of 80% and a specificity of 100% in patients with pulmonary fat embolism large enough to produce hemodynamic instability.[84] Treatment for FES is supportive.[83] Prophylactic strategies including early stabilization of fractures involving the pelvis or long bones have been shown to result in a decrease in the incidence of FES.[85] Early rigid fixation of fractures decreases the recurrent bouts of fat embolism.[81]

Inhalation Injuries

Inhalation injuries from smoke affect between 5% and 35% of hospitalized burn patients and lead to increased morbidity and mortality.[86] The incidence of respiratory dysfunction is high following inhalation injury. Furthermore, complications including pneumonia, hypoxemia, and prolonged ventilation are common.[84,87] Mortality increases by 20% in burn patients with inhalation injury compared to those without an inhalation component and complications such as pneumonia increase mortality by 60%.[88] There are various unreliable clinical signs of inhalation injury.[89,90] Bronchoscopy may diagnose mucosal erythema, airway edema, erosions, necrosis, and soot. Elevated carboxyhemoglobin (COHb) concentration is a poor marker of inhalation injury because the half-life of COHb with 100% oxygen therapy is 30–40 minutes. Smokers and urban residents exposed to significant pollution will have a COHb concentration elevated to 10% and COHb concentrations are not an accurate predictor of mortality.[91–93] A PaO_2/FIO_2 ratio of <300 after resuscitation in children with inhalation injury is considered predictive of mortality in children.[89] The PaO_2/FIO_2 ratio was lower in patients who received more fluids.[91] The goal of fluid resuscitation should be to achieve euvolemia.

THORACOSTOMY TUBE PLACEMENT

Potential complications of chest tube placement can be avoided by vigilant monitoring and strict adherence to sterility. Morbidity from chest tube placement includes vascular injury, improper positioning of the tube leading to both injury and poor function, inadvertent tube removal, increased length of hospital stay, undrained pneumothorax and/or hemothorax, empyema, and pneumonia. Complications are reported

in up to 21% of cases. The risk of complication varies greatly by training of provider placing the thoracostomy tube. These complication rates from one level-one trauma center included 6% by surgeon, 13% by emergency physician, and 38% prior to transfer to the trauma center.[94]

Most patients with significant pneumothoraces (>30%) require placement of a closed-chest catheter for acceptable pulmonary re-expansion. This catheter then can be placed either to underwater suction drainage or to a Heimlich (one-way) valve. If a Heimlich valve fails to re-expand the lung fully or if the patient has additional injuries, admission to hospital and chest tube suction drainage is recommended. Unless contraindication exists, chest tubes should be placed in the midaxillary line at the level of the fifth intercostal space (nipple line). In women, the breast tissue should be retracted medially and avoided in the dissection to the chest wall. Placement of the thoracostomy tube with the use of blunt clamp dissection avoids the dangers of trocar insertion. Following resolution of any air leak and pneumothorax on upright chest radiograph, the tube may be taken off suction (water seal) and removed if the lung remains fully inflated.

The routine administration of systemic antibiotics for chest tube placement has remained controversial in the trauma literature. The risk of infectious complications, most commonly pneumonia and empyema, is reported between 2% and 25%.[95,96] When antibiotics are given prophylactically, they should be directed toward the most common organisms including gram-positive cocci and *Haemophilus*. There are a number of studies that show favorable effects of prophylactic antibiotics on empyema and pneumonia prevention and several that show no benefit. The Eastern Association for the Surgery of Trauma (EAST) Practice Management Guidelines Work Group concluded that there was insufficient data available to recommend routine use of presumptive antibiotics in the management of tube thoracostomy for traumatic hemopneumothorax.[97]

SUMMARY

Acute respiratory dysfunction has a broad etiology and clinical manifestations. However, treatment is straightforward with initial management always including airway management and consideration of mechanical ventilation. The etiology should then be elucidated and treated appropriately. Prevention of progression of respiratory dysfunction to respiratory failure is paramount in the care of the surgical patient.

- Trauma patients are at significant risk for infectious complications and development of ARDS.
- Goal of fluid management is euvolemia.
- Evidence shows that incomplete drainage of hemothorax is an important risk factor in empyema development. Prophylactic antibiotic therapy remains controversial.
- Low tidal ventilation with permissive hypercapnia is recommended for patients with ALI/ARDS.
- All staff should have training on pulmonary hygiene including suctioning, elevation of the head of bed, incentive spirometry, and early ambulation.
- DVT prophylaxis, IVC filters, and early fracture fixations are important for decreasing the incidence of PE.

CHAPTER 48 ■ MULTIPLE ORGAN DYSFUNCTION SYNDROME

PHILIP S. BARIE AND FREDRIC M. PIERACCI

Multiple organ dysfunction syndrome (MODS) is a potentially progressive syndrome of reversible dysfunction of two or more organ systems as a consequence of acute, life-threatening, pathologic interactions among host defenses, the inflammasome, and the coagulation system that, once deranged, disrupt systemic homeostasis. Nearly 40 years since the initial description,[1] MODS is unquestionably the leading cause of death among critically ill surgical patients, and the leading cause of late deaths (not related to exsanguination or overwhelming central nervous system [CNS] injury) following trauma.[2] Moreover, the financial burden to both individual hospitals and the health care system as a result of the acute care of patients with MODS is astronomical, and the long-term needs of survivors are substantial.[3]

Currently, the MODS is believed to represent a severe manifestation of dysregulated or uncontrolled systemic inflammation.[4,5] Despite a sophisticated understanding of the pathogenesis of MODS, effective therapies have remained elusive; therefore prevention or early mitigation becomes crucial if lives are to be saved. This is likely because of the heterogeneous manifestations of MODS; organ dysfunction may follow a vast array of physiologic or metabolic insults, and may affect variable numbers of organ systems to varying degrees at different times. The development of targeted therapeutics has been hampered by the redundancy and interrelationships of the dysregulated immune response, or because such therapies have been targeted too narrowly, if not mistargeted altogether.[6] Better understanding of these interrelationships is crucial if patient care is to improve or new therapies are to be found.

HISTORICAL PERSPECTIVES

Multiple organ failure (MOF) following a severe physiologic insult was recognized first during the late 1960s as the unwanted consequence of advancements in the management of shock. Successful resuscitation of shock was followed by death from hitherto unidentified disease manifestations characterized by progressive, irreversible failure of several organs. In 1975, Baue coalesced early case reports of organ failure following severe injury[7,8] into the concept of MOF as a distinct entity, which he described as "the progressive failure of many or all systems after an overwhelming injury or operation."[9] In doing so, Baue gleaned two concepts fundamental to mortality during critical illness: First, that mortality in the intensive care unit (ICU) was the consequence of the interaction of multiple failing organs; and second, that individual organ systems were interrelated; injury to one organ system could cause dysfunction of another. For example, pulmonary failure was found more often than not to occur along with dysfunction of at least one other organ system.[10] Moreover, mortality from acute respiratory failure is usually determined by the magnitude of nonpulmonary organ dysfunction; the combination of respiratory and hepatic dysfunction is especially deleterious.[10,11] Furthermore, improvements in the treatment of the acute respiratory distress syndrome (ARDS), such as ventilation at low tidal volumes, also decreased the likelihood

of additional, subsequent organ failure.[12,13] Soon after Baue's initial description of MOF, Fry et al.[14] reported a linear relationship between the number of failed organs and mortality during critical illness; whereas mortality following failure of a single organ was 30%, mortality following failure of four or more organs was 100%.

The etiology of MOF was believed initially to be always infection.[15] However, clinical, pathologic, and experimental findings have discredited this theory. Autopsies of patients with MOF did not always demonstrate a focus of infection; either infection was never present, or organ dysfunction progressed despite successful anti-infective therapy.[16,17] Trauma patients with organ failure were sometimes never infected.[18] When infection did occur during critical illness, it sometimes followed organ failure, rather than preceding it.[19] Under experimental conditions, characteristic hemodynamic and inflammatory derangements could be replicated absent any infection.[20,21]

This discrepancy was reconciled by observations that an occult reservoir of pathogens (e.g., the gastrointestinal [GI] tract) could initiate or perpetuate sepsis and organ dysfunction without any overt infection.[22,23] According to this "gut-motor" hypothesis, bacterial overgrowth during critical illness (secondary to gastric acid suppressive therapy, impaired intestinal immunity, or both) caused organ dysfunction. However, selective gut decontamination (topical oral antibiotics and enteral antibiotics by gavage, with or without systemic antibiotic prophylaxis) although effective in reducing the incidence of nosocomial infection, neither attenuated MODS nor improved mortality, calling the gut-motor hypothesis into question.[21,24] Even if ultimately correct, it may be that mediators (elaborated in intestinal lymph as a result of intestinal ischemia-reperfusion (I-R) injury, thence becoming systemic) are more important than the intestinal flora.

That infection was sufficient, but unnecessary to cause organ damage stimulated the reevaluation of the pathophysiology of MOF. Goris et al.[18] suggested "massive activation of inflammatory mediators by severe tissue trauma or intra-abdominal sepsis" as the etiology of MOF. Marshall and Sweeney[25] reinforced this theory by observing that the degree of the inflammatory response to infection predicted ICU mortality, rather than the type or extent of infection itself. Eventually, the hypothesis developed that a hypodynamic, excessive, or otherwise dysfunctional immune response was the principal cause of organ damage, rather than the cytotoxic effects of invading microorganisms *per se*.[4] This theory synthesized myriad, seemingly unrelated causes of organ failure into a unifying hypothesis, and was consistent with extant clinical and experimental observations. In recognition, and in an attempt at standardization, an American College of Chest Physicians/Society of Critical Care Medicine consensus statement defined diagnostic criteria for what was termed the *systemic inflammatory response syndrome* (SIRS) in 1992.[26] The diagnosis of SIRS was fulfilled by the presence of at least two of the host-response criteria: (1) Core body temperature >38°C or <36°C, (2) heart rate >90 beats/min, (3) respiratory rate >20 breaths/min (not ventilated) or $PaCO_2$ < 32 mm Hg (ventilated), and

TABLE 48.1

HISTORIC SYNONYMS FOR WHAT IS REFERRED TO CURRENTLY AS THE MODS

Sequential organ failure
Progressive systems failure
Remote organ failure
Multiple organ failure
Multiple organ failure syndrome
Multiple systems organ failure
Postinjury multiple organ failure
MODS, multiple organ dysfunction syndrome.

(4) WBC > 12,000, <4,000 or >10% immature forms (bands) absent any other cause, such as antineoplastic chemotherapy. *Sepsis* is the characterization of the host response to the insult and thus has a specific definition: SIRS caused by infection. *Severe sepsis* is sepsis complicated by dysfunction of at least one organ, whereas *septic shock* is severe sepsis with hypotension (cardiac dysfunction) that is refractory to fluid administration (see Chapter 14). Organ dysfunction is also recognized as a common consequence of SIRS, and the term MODS signifies the presence of altered organ function in critically ill patients such that homeostasis cannot not be achieved without intervention. But which intervention (see below)? Specifically, SIRS correlates with both the incidence and magnitude of MODS, and ultimately mortality.[27]

Currently, MODS remains the acronym used most commonly to describe organ dysfunction during critical illness. However, several other terms have been used, and may remain in use (Table 48.1).[28–31] No scoring system is "right or "wrong"; indeed, scores such as the MOD score[28] (Table 48.2) and the Sequential Organ Failure Assessment (SOFA) score[30] quantify largely the same pathophysiology and behave similarly.[32–35] However, the absence of a validated score that is recognized universally leads to conflicting reports of the incidence, time course, and mortality of MODS, hampering both research and clinical understanding.[36] Consensus is needed urgently.

EPIDEMIOLOGY

The MODS is the leading cause of death among nontrauma ICU patients.[37–40]. As many as 19% of ICU patients will develop MODS,[35,37–40] and MODS is responsible for approximately 50%[41,42] to 80%-94%[38,43,44] of ICU mortality. Patients who develop MODS experience a 25-fold increase in mortality[43] and a doubled length of stay compared to critically ill patients who do not develop organ dysfunction.[45] MODS is the most common ICU diagnosis in patients associated with prolonged stay (>21 days) in the ICU;[46] even modest degrees of MODS[47] prolong hospitalization.

Any biologic stress that activates systemic inflammation may precipitate SIRS, thus placing the patient at risk of MODS. Known precipitants of MODS are listed in Table 48.3; hypoperfusion/I-R injury without shock was the most common etiologic insult responsible for MODS in one study, followed by sepsis without shock, and shock regardless of etiology.[45] In another prospective study of elderly patients with ARDS, I-R injury was the leading cause.[48] Moreover, Sauaia et al.[49] found that an Injury Severity Score (ISS) of ≥25 points combined with a transfusion requirement of ≥ 6 units of red blood cell concentrates was associated with a 46% likelihood of developing MODS. Cryer et al.[50] further defined these risk factors, reporting a 66% incidence of MODS in patients with an ISS ≥ 25, regardless of transfusion requirement. For any given mechanism, both increased age[39] and number of comorbidities[39,51] increase the likelihood of MODS. Population data indicate that black persons may have higher case rates of infection, severe sepsis, acute organ dysfunction, and mortality.[52] Critically ill children may also develop MODS.[53,54] The pathophysiology appears to be similar[53] (see below), and neonates and younger children appear to be at higher risk than older children.[54]

Furthermore, certain individuals may harbor a genetic predisposition to MODS in the form of an exaggerated innate

TABLE 48.2

THE MULTIPLE ORGAN DYSFUNCTION SCORE

■ ORGAN SYSTEM	■ SCORE				
	■ 0	■ 1	■ 2	■ 3	■ 4
Respiratory (PaO$_2$:FiO$_2$)^a	>300	226–300	151–225	76–150	≤75
Renal (serum [creatinine])^b	≤100	101–200	201–350	351–500	>500
Hepatic (serum [bilirubin])^c	≤20	21–60	61–120	121–240	>240
Cardiovascular (PAR)^d	≤10	10.1–15.0	15.1–20.0	20.1–30.0	>30.0
Hematologic (platelet count)^d	>120	81–120	51–80	21–50	≤20
Neurologic (GCS)	15	13–14	10–12	7–9	≤6

^{a}PaO$_2$:FiO$_2$ is calculated without reference to the use or mode of mechanical ventilation, and without reference to the use or level of positive end-expiratory pressure.
^{b}The serum creatinine concentration is measured in mmol/L, without reference to the use of dialysis.
^{c}The serum bilirubin concentration is measured in mmol/L.
^{d}The platelet count is measured in platelets/mL × 10^{-3}; PAR, pressure adjusted heart rate; GCS, Glasgow Coma Scale score. To convert the serum creatinine concentration from mmol/L to mg/dL, divide by 88.4. To convert the serum bilirubin concentration from mmol/L to mg/dL, divide by 17.1.
Reproduced from Marshall JC, Cook DJ, Christou NV, et al. Multiple Organ Dysfunction Score: a reliable descriptor of a complex clinical outcome. *Crit Care Med*. 1995;23:1638–1652.

Thrombin-activatable fibrinolysis inhibitor

MODS, multiple organ dysfunction syndrome.

immunity/inflammatory response to illness.[55–58] Single nucleotide polymorphisms (SNPs) have now been identified for a number of genes and peptides related to pattern recognition receptors (PRRs), signal transduction molecules, effector cytokines, and coagulation proteins (Table 48.4), but owing to their multiplicity (with more likely to be identified), it is unlikely that causality will be established for a single SNP or combination. However, their assay does hold promise as a biomarker of risk, predisposition, or the development of MODS.

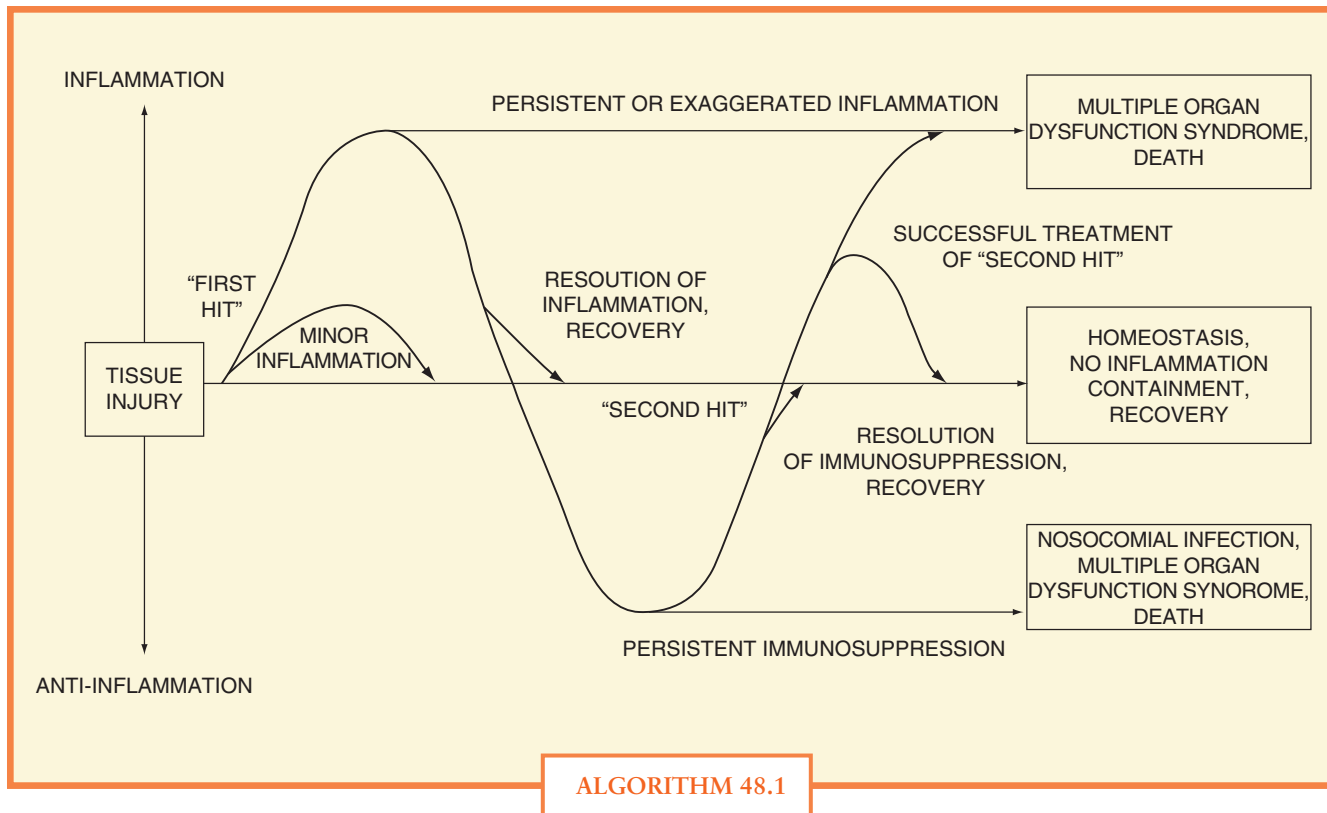
PATHOPHYSIOLOGY

Several phenotypes have been proposed to describe the onset of MODS[59] (Algorithm 48.1). According to the *one-hit model*, organ dysfunction develops as the direct result of a massive initial insult (e.g., burn or multiple injuries, severe pancreatitis), which itself is sufficient to cause MODS. By contrast, the *two-hit model* describes sequential insults, usually isolated temporally. According to the two-hit model, a "priming" insult (e.g., burn) is followed by a subsequent insult (e.g., central line–associated blood stream infection). The inflammatory response, "primed" by the first insult to react in an exaggerated manner to the second, induces further immune dysfunction and MODS. According to the *sustained-hit model*, a continuous, smoldering insult, such as ventilator-associated pneumonia caused by a difficult-to-treat, multi-drug-resistant bacterium, at once causes and sustains organ dysfunction. In reality, any of these mechanisms, alone or in combination, may result in MODS.

Organ failure may manifest in several organ systems (Table 48.5), and is no longer believed to follow a particular temporal sequence. Cardiovascular instability is often the first manifestation of dysfunctional homeostasis, resulting in I-R injury after resuscitation. The splanchnic and renal circulations are particularly susceptible to I-R injury. Pulmonary failure is equally common and is usually an early manifestation, whereas hepatic, hematologic, and GI dysfunctions and acute kidney injury usually are later manifestations, if they occur at all.[9,14,43,60] In particular, hepatic dysfunction may not be recognized promptly because the liver has redundant metabolic capacity; substantial hepatic dysfunction may precede elevation of the serum bilirubin concentration. Furthermore, certain combinations of organ failure have been shown to be especially deleterious (e.g., hepatic and pulmonary, or renal and pulmonary).[10,11]

Two distinct periods of altered immune function characterize MODS. The first is dominated by upregulated innate immunity (Table 48.6), uncontrolled inflammation, increased endothelial permeability, microvascular thrombosis, apoptosis (programmed cell death), and disruption of parenchymal cellular integrity.[61–63] The second involves a predominance of anti-inflammatory cytokines, downregulated adaptive immunity (Table 48.6), immunosuppression,[64] and an increased risk of infection. This general disruption of the normal regulation of the immune system during MODS has been termed *immunologic dissonance*.[65]

Inflammation and Tissue Injury

Organ damage following severe injury is believed to occur secondary to uncontrolled activation of the inflammatory response caused by tissue hypoxia. Following tissue injury,


ALGORITHM 48.1 Ebb and flow of pro- and anti-inflammatory responses to tissue injury, resulting in recovery, organ dysfunction, nosocomial infection, or death.

the early stage of the inflammatory response is characterized by macrophage activation as well as secretion of inflammatory cytotoxins and cytokines. Cytotoxins are released primarily by cluster of differentiation 8 (CD8)+ cells (e.g., cytotoxic T cells, dendritic cells), a cell surface co-receptor for major histocompatibility Class II (MHC Class II); these cells act locally by causing damage to cell walls and tight junctions.[66] By contrast, cytokines mediate primarily the CD4+ (a cell surface co-receptor for MHC Class I) response, and may be secreted by a variety of cell types (e.g., platelets, endothelial cells) in addition to those of the immune system (e.g., T helper [Th] cells, regulatory T cells, monocytes, macrophages, and dendritic cells). Cytokines may act both locally and systemically. Although they may be classified broadly into groups by function (Table 48.7), the cytokine-mediated inflammatory response is redundant; each cytokine has multiple activities on different cell types, some of which are salutary. The balance of pro and anti-inflammatory responses is not always self-regulatory and balanced; predominance of either influence may be deleterious. As such, the inflammatory response has been challenging to manipulate for therapeutic effect.

Recruitment of polymorphonuclear (PMN) leukocytes into tissue represents a second prominent feature of MODS. Postmortem examination of patients with ARDS has demonstrated massive PMN leukocyte infiltration into lung parenchyma.[67] Neutrophil activation (respiratory burst) generates large amounts of reactive oxygen species and lipid mediators (e.g., prostaglandins, leukotrienes) that are autodestructive. Furthermore, depletion[68] or inhibition[69–71] of PMN leukocytes decreases the severity of lung injury in animal models of ARDS. Infiltration of PMN leukocytes is accompanied by

upregulation of hepatic inflammatory proteins (e.g., C-reactive protein) and the complement system,[72] increased capillary permeability, and the formation of reactive oxygen and nitrogen species (Table 48.8). The clinical manifestation of increased capillary permeability is tissue edema, whether of connective tissue, lung, or brain.

Innate immune cells have evolved to sense microbial pathogens through PRRs, which interact with conserved pathogen-associated molecular patterns (PAMPs) to convey microbial information into immune cell signaling and activation events.[73] PRRs also recognize endogenous damage-associated molecular patterns (DAMPs) (also called alarmins or endokines) released during microbial invasion, mediated in part by Toll-like receptors (TLRs). The DAMP molecules, including high mobility group box-1 protein (HMGB1), heat-shock proteins (HSPs), uric acid, altered matrix proteins, and S100 proteins, represent important danger signals that mediate inflammatory responses through the receptor for advanced glycation end-products (RAGE) and TLRs, after release from activated or necrotic cells. The HMGB1 protein is released actively after stimulation of the innate immune system by PAMPs and is released passively by sterile ischemia or cell injury.[74–77] The RAGE is a multiligand MHC Class III receptor of the immunoglobulin gene superfamily. Infection is associated with the release of HMGB1 and S100A12. Engagement of RAGE by its diverse ligands, which include HMGB1, results in receptor-dependent signaling and activation of nuclear factor-kappa beta (NF-kB). Furthermore, RAGE acts as an endothelial adhesion receptor for leukocyte integrins and promotes leukocyte recruitment. Inhibition of RAGE signaling reduces inflammatory responses in several noninfectious and infection models of inflammation.

EFFECTS OF SHOCK AND SEPSIS ON ORGAN
FUNCTION: CLINICAL MANIFESTATIONS

Heart:
Myocardial depression

Lungs:
Acute respiratory distress syndrome

Kidneys:
Acute tubular necrosis (acute kidney injury)

Gut:
Cholestasis
Erosive gastritis
Failure of the hepatosplenic RE system
Ileus
Bacterial translocation (?)
Acalculous cholecystitis (?)

CNS:
Encephalopathy
Polyneuropathy
Neuromuscular dysfunction

Coagulation:
Thrombocytopenia
Coagulopathy

BASIC FUNCTIONS OF THE INNATE AND ADAPTIVE
IMMUNE SYSTEMS

Innate immune system:
- Recruitment of immune cells to sites of infection, via production of specialized chemical mediators (e.g., chemokines, cytokines).
- Activation of the complement cascade to identify bacteria, activate phagocytes, and to promote clearance of dead cells (efferocytosis) or antibody complexes.
- Identification and removal of foreign substances present in organs, tissues, and the blood and lymph, by specialized phagocytes.
- Activation of the adaptive immune system through antigen presentation.

Adaptive immune system:
- Recognition of specific "nonself" antigens in the presence of "self", during the process of antigen presentation.
- Generation of responses that are tailored to maximally eliminate specific pathogens or pathogen-infected cells.
- Development of immunologic memory, to be called upon quickly to eliminate a pathogen should a subsequent infection occur.

A key question concerns how sterile injury activates innate immunity to mediate damaging inflammation in the absence of invasion by pathogens. That HMGB1, a ubiquitous nuclear protein, mediates the activation of innate immune responses, led to the understanding that HMGB1 plays a crucial role at the intersection of the host inflammatory response to sterile and infectious threat through TLR4 signaling pathways that mediate cytokine release and tissue damage. The RAGE-HMGB1 complex also regulates *autophagy* (programmed cell survival) and *apoptosis* (programmed cell death), sustaining the former and inhibiting the latter.

Apoptosis is deranged in MODS. Markers of apoptosis such as the Fas receptor (also known as tumor necrosis factor [TNF] receptor superfamily member 6 and CD 95)[78] (a cell-surface protein receptor expressed on essentially all cells of the body that when bound to its ligand [FasL] is internalized and signals an initiator caspase cascade [caspase-8, -10], ultimately resulting in apoptosis), and nuclear matrix proteins[79] have been identified in patients with MODS. Interestingly, whereas some cell types (e.g., splenocytes and hepatocytes) demonstrate accelerated apoptosis, other cell types, such as circulating neutrophils, exhibit inhibited apoptosis. Still other tissues, such as the kidney and lung, show only minimal changes in rates of cellular death.[80–82]

There are two major pathways of apoptosis: The *death-receptor pathway*, which is mediated by activation of death receptors and the B-cell leukemia/lymphoma 2 (Bcl2)-regulated *mitochondrial pathway,* which is mediated by stimuli that ultimately lead to mitochondrial injury.[83] Ligation of death receptors recruits the adaptor protein, Fas-associated death domain, which in turn recruits caspase-8. This latter ultimately activates caspase-3, the key "executioner" caspase. In the mitochondrial pathway, proapoptotic Bcl homology (BH)-3 proteins are activated by noxious stimuli, which interact with and inhibit antiapoptotic Bcl2 or Bcl-extra large (BCL-XL) proteins. Thus, Bcl2-associated X protein (BAX, a proapoptotic antagonist of Bcl2) and BAK (Bcl-2 homologous antagonist/killer) act unopposed to alter transmembrane potential and induce mitochondrial permeability with release of cytochrome c, which ultimately results in the activation of caspase-9 through the apoptosome. Caspase-9 then activates caspase-3.

The uncontrolled inflammation characteristic of MODS is accompanied by microvascular thrombosis.[84,85] Indeed, the inflammatory and coagulation systems are related intimately,[85] manifesting as failure of the microcirculation. Several proinflammatory cytokines (e.g., TNF-α) may activate tissue factor and initiate the coagulation cascade.[86] In turn, the thrombin receptor activates nuclear factor kappa beta (NF-κB), which causes increased transcription of proinflammatory gene products.[87] Microvascular thrombosis results in tissue hypoxia, thus perpetuating the inflammatory response. Early coagulopathy increases the risk of developing MODS.[87]

Anti-inflammatory Response

Whereas the initial phase of MODS is characterized by a disruption of homeostatic mechanisms to favor inflammation, a second, distinct later period is characterized by impaired adaptive immunity and increased susceptibility to infection.[88] This phenomenon has been called the compensatory anti-inflammatory response system, and the result referred to as *immunoparalysis*.[65] During this later period, increased elaboration of anti-inflammatory cytokines such as IL-10 and -13 and transforming growth factor (TGF)-β, impaired antibody synthesis, and anergy of T lymphocytes are characteristic.[89–91]

In many cases of sepsis, failure of the immune system to eradicate pathogens presages a prolonged phase of immune suppression, characterized not only by failure to eradicate the primary infection but also by development of secondary nosocomial infections.[88] The immune suppression is mediated by multiple mechanisms, including massive apoptosis-induced depletion of lymphocytes and dendritic cells, decreased

TABLE 48.7

MAJOR CLASSES OF INFLAMMATORY CYTOKINES, REPRESENTATIVE MEMBERS, AND THEIR MAIN ACTION(S)

■ CYTOKINE	■ PRODUCER CELL	■ MAIN ACTIONS
Hematopoietins		
IL-1	Macrophages, epithelial cells	Fever, T-cell activation, macrophage activation
IL-2		T-cell proliferation
IL-6	T cells	T- and B-cell growth and differentiation, acute phase
	T cells, macrophages, astrocytes	protein production
IL-7	Bone marrow stroma	Growth and differentiation of immature T cells and B cells, prevents apoptosis
IL-15	Mononuclear phagocytes	Increases production of natural killer cells, prevents apoptosis
Chemokines		
IL-8[a]	Macrophages, others	Chemotactic for neutrophils, T cells
MCP-1 (now CCL2)[b]	Macrophages, others	Chemotactic for monocytes
Modulators of immune response		
TNF-α	Macrophage, NK cells	Local inflammation, endothelial activation
TNF-β	T cells, B cells	Killing, endothelial activation
IL-4	Th2 cells, mast cells, macrophages	B- and T-cell proliferation, IgE and IgG synthesis
IL-6	T cells, macrophages, astrocytes	General upregulator of inflammation
IL-12	B cells, macrophages	NK cell activation, T-cell differentiation
IL-16	Lymphocytes, epithelial cells, CD8+	CD4+ chemoattractant
IL-17	T cells	Upregulates production of chemokines and antibacterial peptides. Antagonizes anti-inflammatory effects of T regulatory cells
IL-18	T helper 17 (Th17) cells	Induces IFN-γ production, natural killer cell activity
IFN-γ	Macrophages, T cells, natural killer cells	Macrophage activation, increased MHC production
Anti-inflammatory		
IL-10	T cells, macrophages	Inhibition macrophage function
IL-13	T cells	Inhibition of macrophage cytokine production
TGF-β	Monocytes, T cells	Inhibition of cell growth, anti-inflammatory

IL, interleukin; MCP, macrophage chemoattractant protein; TNF, tumor necrosis factor; NK, natural killer; IFN, interferon; MHC, major histocompatibility complex; TGF, transforming growth factor.

[a]Seventeen CXC chemokines (so named because one amino acid separates two cysteine molecules) have been identified in this subgroup of the chemokine family, of which IL-8 is one, along with seven G protein–coupled receptors.

[b]Twenty-seven CC chemokines (so named because of the adjacency of two cysteine molecules) have been identified in this subgroup of the chemokine family. CCL2: CC ligand 2.

expression of the HLA-DR cell-surface antigen-presenting complex, and increased expression of the negative costimulatory molecules programmed death 1, cytotoxic T-lymphocyte–associated antigen 4, and B- and T-lymphocyte attenuator and their corresponding ligands. Numbers of regulatory T cells and myeloid-derived suppressor cells are increased, and there is a phenotypic shift from inflammatory type 1 helper T (Th1) cells to an anti-inflammatory phenotype of type 2 helper T (Th2) cells that is associated with the production of IL-10. The innate and adaptive immune systems are both compromised severely with poorly functional "exhausted" CD8+ and anergic CD4+ T cells.

An alternative, systems biology-derived theory describes the pathogenesis of MODS as a disruption of interorgan or intercellular communication.[92] Accordingly, each organ system is viewed as a stochastic (random) biologic oscillator, whose activity varies periodically with time. The dynamic behavior of any one organ necessarily reflects the state of the organism as a whole. During normal homeostasis, variability within each oscillator is preserved through mechanical, neural, hormonal, and immune (e.g., cytokine and prostaglandin) inputs. As a result of massive physiologic insult, interoscillator communication becomes uncoupled, resulting in a regularization of normally variable organ outputs.

The majority of research in the area of biologic oscillators has been conducted using loss of normal heart rate variability as a marker of uncoupling. Clinical investigations have reported increased cardiac regularity after administration of endotoxin to healthy volunteers,[93] as well as in emergency department patients with sepsis.[94] Furthermore, low heart rate variability correlates with both ICU mortality[95,96] and mortality from MODS.[97,98] As a result, measurement of heart rate variability has emerged as a noninvasive, accurate, and validated tool to predict outcomes during critical illness.[99]

The uncoupling of stochastic biologic oscillators offers an intriguing alternative theory for the pathogenesis of MODS, and has been used to explain the failure of antimediator trials aimed at attenuating the inflammatory response in these patients (discussed below).[100] However, substantial additional research, as well as a fundamental shift in the current conceptualization of MODS, will be required to provide tangible options for the treatment of patient with MODS. One such

TABLE 48.8

OXIDANTS AND TISSUE INJURY

■ OXIDANT	■ DESCRIPTION
$\bullet O_2^-$, superoxide anion	Formed in many auto-oxidation reactions and by the electron transport chain. Relatively unreactive but can release Fe^{2+} from iron–sulfur proteins and ferritin. Undergoes dismutation to form H_2O_2 spontaneously or by enzymatic catalysis, and is a precursor for metal-catalyzed $\bullet OH$ formation
	H_2O_2, hydrogen peroxide formed by dismutation of $\bullet O_2^-$ or by direct reduction of O_2. Lipid-soluble, and thus able to diffuse across membranes
$\bullet OH$, hydroxyl radical	Formed by Fenton reaction and decomposition of peroxynitrite. Extremely reactive
$RO\bullet$ and $ROO\bullet$, peroxy	Oxygen-centered organic radicals that participate in lipid peroxidation reactions
$HOCl$, hypochlorous acid	Formed from H_2O_2 by myeloperoxidase. Lipid-soluble and highly reactive. Oxidizes protein constituents, including thiol groups and amino groups
$ONOO-$, peroxynitrite	Formed in a reaction between $\bullet O_2^-$ and $\bullet NO$. Lipid soluble and similar in reactivity to $HOCl$. Protonation forms peroxynitrous acid, which undergoes cleavage to form $\bullet OH$ and nitrogen dioxide (NO_2)

Production of oxidizing species plays a central role in killing of pathogens, with activated phagocytes producing both reactive oxygen and nitrogen species. These include superoxide ($\bullet O2^-$), nitric oxide ($\bullet NO$) and their particularly reactive product, peroxynitrite ($ONOO^-$). This effect is non-specific; almost every part of the target cell is damaged, preventing a pathogen from escaping destruction by mutation of a single molecular target, but damage to host tissues is problematic.

example suggested by Buchman involves a shift from traditional random or scheduled sampling of physiologic parameters to continuous sampling strategies in order to better capture loss of organ variability.[97] The feasibility of "physiologically dense data capture" has been demonstrated,[101] but outcomes have not been improved demonstrably.

ORGAN SYSTEM MANIFESTATIONS

Although uncontrolled inflammation exerts distinct, predictable effects on each organ system, organ dysfunction rarely occurs in isolation. Moreover, it is important to note that organ dysfunction in critical illness is usually multifactorial. For example, acute kidney injury is often iatrogenic, resulting from hypovolemia or nephrotoxic drugs such as radiocontrast media. Listed below are the known consequences of systemic inflammation on individual organ systems (Table 48.5).

Although cardiovascular failure manifested as shock is often the cause of SIRS and ultimately MODS, inflammation also results in impaired cardiac function.[102] TNF and reactive oxygen and nitrogen species inhibit cardiac contractility.[103] Inflammation also causes increased endothelial permeability and vasodilation, decreasing blood volume and systemic vascular resistance, respectively. Thus, each component of blood pressure is affected (preload, contractility, and afterload), resulting in hypotension that may be refractory to volume replacement, thus necessitating vasopressor therapy.

Lung inflammation results in impaired gas exchange that is manifested primarily as hypoxia rather than hypercarbia. The most severe pulmonary manifestation of MODS is ARDS, characterized by $PaO_2:FiO_2 < 200$ and diffuse, bilateral pulmonary infiltrates on chest radiography in the presence of a pulmonary wedge pressure <18 mm Hg. The ARDS is a relatively common complication of SIRS, its pathophysiology and management have been described in detail,[104,105] and it is discussed elsewhere in this volume (see Chapter 47). The interplay of coagulation and inflammation is a crucial determinant of acute lung inflammation in ARDS.[106]

In addition to alterations in leukocyte function, both thrombopoiesis and erythropoiesis are inhibited during MODS. Thrombocytopenia is a well-recognized sequela of both SIRS and sepsis and results not only from bone marrow suppression, but also from increased consumption and sequestration within the reticuloendothelial (RE) system.[85] Furthermore, IL-1, TNF-α, and TGF-β inhibit erythropoietin synthesis and action.[107–110] Recombinant TNF-α induces anemia and hypoferremia associated with decreased iron release from the RE system and incorporation into red blood cells.[111,112] Interleukin-1 and TNF-α also induce ferritin production as part of the *acute-phase reaction*, sequestering iron that would otherwise be available for erythropoiesis.[113] Both generalized inflammation and microvascular thrombosis lead to consumption of clotting factors, which may cause disseminated intravascular coagulation.

Manifestations of GI injury are protean in MODS. Patients may have gastric, small bowel, or colonic ileus (e.g., acute colonic pseudo-obstruction, or Ogilvie's syndrome) after GI surgery; an estimated 50% of patients have delayed gastric emptying during mechanical ventilation, and up to 80% with increased intracranial pressure after traumatic brain injury.[114] Furthermore, ileus, malabsorption, and diarrhea are common sequelae of mucosal inflammation. Potential causes of GI dysmotility during critical illness are numerous and common, including impaired innervation, inflammation, I-R injury, medications, electrolyte disturbances, and sepsis; it is likely that many cases are multifactorial, as interplay among inflammation, immunity, and neuronal pathways has been demonstrated.[115] The gut is innervated by intrinsic enteric nerves and extrinsic autonomic pathways (predominantly parasympathetic, via the vagus nerve). Vagal pathways mediate both a cholinergic anti-inflammatory pathway and act indirectly to modulate inflammatory processes via postganglionic neuromodulation of immune cells in organs such as the spleen. Manifestations of I-R injury range from stress-related gastric mucosal hemorrhage ("stress gastritis") to acute acalculous

cholecystitis.[116] Disruption of intestinal mucosal integrity as a result of splanchnic I-R injury or due to the actions of inflammatory cytokines may facilitate the translocation of invading microorganisms and cause both bacteremia and infection (i.e., "gut-motor" hypothesis, see above).[22,117] Increased intestinal permeability has been associated with the subsequent development of both SIRS and MODS.[118] Unfortunately, most conventional tests for gut dysmotility are cumbersome in the ICU; measurement of the non-protein amino acid citrulline (which is derived almost entirely from enterocytes) as a marker of decreased enterocyte mass has been suggested as a way to quantify small bowel function in critical illness.[119]

Hepatic dysfunction in patients with MODS is characterized by cholestatic jaundice.[120] Leakage of bilirubin from the hepatic canalicula into the intracellular and eventually intravascular space results from disruption of tight junctions by cytotoxic inflammation.[66] Hepatic synthetic function during inflammation is characterized by early upregulation of positive acute-phase proteins (e.g., C-reactive protein and ferritin), and downregulation of negative acute-phase proteins (e.g., albumin and transferrin). This initial period is followed by generalized impairment, including decreased synthesis of coagulation factors manifest as hypoprothrombinemia that is not correctable by vitamin K administration. However, the liver has substantial redundant metabolic capacity, and up to 80% of hepatic synthetic function may be lost before the serum bilirubin concentration increases. Measurement of metabolites of drugs metabolized by the liver may provide an earlier and more sensitive quantitative assessment of hepatic dysfunction.[121]

The traditional assessment of neurologic dysfunction in MODS has been the calculation of the Glasgow Coma Scale (GCS) score, for which purpose it was not designed. Application of the GCS is complicated in critical illness due to the fact that many patients are intubated endotracheally (such that the verbal component cannot be assessed), and sedated, if not anesthetized recently. Nonetheless, and despite having to give patients substantial benefit of the doubt in calculation of the GCS, it remains a powerful predictor of outcome in MODS. Nonetheless, alternatives are sought. Hypoperfusion, microvascular thrombosis, and cerebral edema combine to cause encephalopathy in MODS, but neurologic manifestations may include neuropathies and myopathies.[122] Furthermore, the *critical illness polyneuropathy syndrome*, characterized by debility, muscle weakness, and eventual atrophy, has been associated with the development of MODS.[123] Risk factors for development of ICU-acquired weakness include bed rest, sepsis, and corticosteroid therapy. A strong association exists between weakness and long-term ventilator dependence, and may be present for months after recovery, if not indefinitely. Alterations of autonomic tone manifested as loss of normal heart rate variability, baroreflex sensitivity, and chemoreflex sensitivity are common in patients with MODS, and the degree of autonomic dysfunction correlates with mortality.[95,96] Critical illness polyneuropathy may prove to be a better indicator of neurologic dysfunction than encephalopathy, in that it may be quantified by electrophysiologic testing and is not affected by sedatives, analgesics, or anesthetics.

Hypoxic/ischemic insults to the kidney are the most common cause of acute kidney injury, characterized by oliguria, azotemia, fluid overload, and accumulation of nitrogenous waste (see Chapter 52). Other common causes of acute kidney injury include rhabdomyolysis and drug toxicity (e.g., iodinated radiocontrast media, antibiotics). Electrolyte abnormalities are not prominent unless caused by rhabdomyolysis (hyperkalemia and hyperphosphatemia), likely because they are monitored and corrected readily by the clinician. Although renal dysfunction usually becomes apparent (i.e., elevated serum creatinine concentration) later in the course of MODS,

hypoxic injury likely occurs at the time of the initial insult. Even mild degrees of renal impairment (well short of the need for renal replacement therapy) translate into substantial morbidity and mortality. Proinflammatory cytokines such as TNF-α may also activate the renin–angiotensin–aldosterone axis.[45] Interleukin-1, TNF-α, and TGF-β inhibit erythropoietin synthesis and function,[111–113] which essentially cease below a glomerular filtration rate < 25 mL/min.

Diagnosis

Early characterizations depicted organ failure as an "all-or-nothing" response. Organ failure was described as a dichotomous event for each organ. Moreover, failure of each organ was accorded the same weight, regardless of severity. Organ failure was considered present if an iatrogenic intervention to support organ function was necessary (e.g., renal replacement therapy). Prognosis was related solely to the number of failed organs, rather than the severity and the timing of failure. The former observation remains true, but more subtle gradations of organ dysfunction are now recognized.

The current conceptualization of MODS is more nuanced: MODS is not an "all-or-nothing" phenomenon, not every organ "fails" even when dysfunction develops, and not every organ becomes dysfunctional to the same extent.[124] Rather, organ dysfunction is recognized to occur in a continuum of altered physiology. In response to this conceptualization, several scoring systems have been developed to quantify the extent of organ dysfunction associated with MODS.[28–32]

Organ systems typically considered in the scoring of MODS are: (1) Respiratory, (2) cardiovascular, (3) renal, (4) hepatic, (5) hematologic, and (6) CNS. Notably absent from this list are both the GI and endocrine systems, owing to a lack of objective descriptors of organ failure. Five scoring systems are currently employed with frequency.[28–32] Central to each is a gradation of organ dysfunction based on mostly objective measurements of altered physiologic function.

One such scoring system, the multiple organ dysfunction (MOD) score, is shown in Table 48.2.[28] The MOD score was developed from a MEDLINE review of clinical studies involving patients with MODS between 1969 and 1993. Five organ systems were evaluated using available physiologic markers: (1) Respiratory (PaO_2:FiO_2), (2) renal (serum creatinine concentration), (3) hepatic (serum bilirubin concentration), (4) hematologic (platelet count), and (5) CNS (GCS score—the most subjective of the measurements). Cardiovascular dysfunction is quantified by the pressure-adjusted heart rate, which is defined as the product of the heart rate and the ratio of central venous pressure to mean arterial pressure. Each organ system is graded on a scale from 0 to 4 points for a maximum total score of 24. A MOD score of 0 for any organ system corresponds to a mortality of <5%, whereas a score of 4 correlates with a mortality of >50%. The aggregate MOD score for survivors is calculated using the worst value for each organ system for each day, or can be scored on a cumulative basis for the episode of care.

Other scoring systems follow similar patterns and include the now-obsolete Brussels score,[29] the sepsis-related organ failure assessment (SOFA),[30] the logistic organ dysfunction system,[31] and the Denver MOF score.[32] These scoring systems have been validated similarly using cohorts of critically ill patients.

Data obtained using scoring systems is useful for prognostication. Initial, aggregate, and mean scores have all been correlated with mortality. For example, the total MOD score correlates in a linear fashion with ICU mortality both when calculated on ICU day one and when the maximum score is compared to the score on day 1.[28,44] Similarly, calculations of

the initial, highest, and mean SOFA score all correlate with mortality.[124] Because daily scores may fluctuate, cumulative or aggregate scores possess the greatest prognostic utility.[44]

Because patients may demonstrate altered physiology in the immediate postoperative period related to anesthesia and recovery or transient, stereotypical surgical stress, some authors have criticized both SIRS and MODS scoring systems as being oversensitive during this time period. Furthermore, some scoring systems have traditionally omitted data obtained during the first 48 hours. However, evidence suggests that both SIRS and MODS scores calculated as early as 24 hours after injury can predict mortality from MODS.[27] These results have called into question the traditional pathophysiologic framework that depicts MODS as an occurrence relatively late in the ICU course (i.e., the two-hit model), and suggest that substantial organ dysfunction occurs much earlier. For these reasons, early resuscitation to avoid or minimize the consequences of I-R injury is of paramount importance.[125] Indeed, markers of organ dysfunction observed as early as post-injury day 1 are perhaps better viewed as outcome measures rather than risk factors.

Much interest has been afforded the use of biomarkers for the diagnosis of inflammatory states and infection and to guide therapy, but results have been modest. Disease processes are inherently heterogeneous, the appearance of biomarkers may be transitory, relevant biomarkers may not circulate in blood, or assay may be timed for an irrelevant period. Using pancreatitis as an example, nearly 40 putative biomarkers have been evaluated in at least three clinical reports,[126] but methodologic quality is poor and uneven, and little useful information has translated into clinical practice. Early clearance of lactate as a surrogate for resuscitation-related resolution of global tissue hypoxia after injury and during severe sepsis is validated as a marker of favorable outcome, and has been correlated with decreased concentrations of several biomarkers and decreased risk of MODS.[127] Among trauma and burns patients, increased plasma concentrations of IL-6 have been correlated with increased risk of organ dysfunction, but not invariably nosocomial infection or death.[128] Multiplexed cytokine assays of multiple candidate biomarkers have established associations between elevated concentrations of circulating cytokines in trauma patients[129,130] and patients with sepsis,[131] but other than for IL-6, the studies have little in common, and assay of IL-6 is not available routinely from clinical laboratories in the United States.

Procalcitonin has been studied extensively as a biomarker for infectious and inflammatory conditions, and as a guide to therapy. Some evidence suggests that procalcitonin has diagnostic and prognostic utility for diagnosis of MODS and outcomes thereof and from injury.[132–134] However, data are few, studies are heterogeneous, and correlations are modest. Further study is needed.

MANAGEMENT

Management of MODS may be classified broadly as either prophylaxis or treatment, which in turn is either supportive care or attenuation of the proinflammatory response. Supportive care involves early recognition, resuscitation, and artificial maintenance of organ function. Evidence-based strategies include ventilation with lower tidal volumes for ARDS,[12] renal replacement therapy for acute kidney injury,[135] and intensive insulin therapy (serum glucose concentration < 140 mg/dL).[136–138]

Of note, although tissue and cellular hypoxia play an important role in the initial pathophysiology of MODS, resuscitation to supranormal levels of tissue oxygenation to prevent or attenuate MODS using high FiO_2, inotropes

(e.g., dobutamine), or blood transfusion has not improved outcomes, and may in fact worsen the severity of organ dysfunction during MODS.[139–142] Exacerbation of tissue damage following the introduction of supranormal levels of oxygen may be explained by increased substrate for the generation of cytotoxic reactive oxygen species.

Transfusion of blood and blood products must be parsimonious. Oxygen transport is not improved acutely by blood transfusion because the "storage lesion" characteristic of banked blood depletes erythrocyte high-energy phosphates, leading to two deleterious consequences. First, 2,3-diphosphoglycerate is depleted within 48 hours of storage, leading to a "left shift" of the oxyhemoglobin dissociation curve, inhibiting oxygen offloading. Second, loss of cell membrane adenosine triphosphate after about 2 weeks of storage leads to membrane fragility and deformation such that the erythrocyte cannot deform to transit the microcirculation, preventing oxygen offloading. Large-volume transfusion, transfusion of increasing quantities of blood stored more than 14 days, and administration of fresh frozen plasma have all to be associated with the development of ARDS and MODS,[143–146] but the observation regarding fresh frozen plasma remains controversial.[147]

Early, appropriate antibiotic therapy remains a cornerstone of successful therapy for severe sepsis and septic shock. Although dosing recommendations for renal insufficiency are plentiful (see Chapter 13), few data exist to guide antibiotic dosing in MODS.[148] The two pharmacokinetic factors likely to vary most in patients with MODS are volume of distribution and clearance (see Chapter 13). Disease- and resuscitation-driven increases in volume of distribution may lead to lower-than-expected plasma drug concentrations, at least for the first day of therapy. Thereafter, organ dysfunction may decrease drug clearance, leading to potential toxicity. Maintenance dosing must be guided by drug clearance and adjusted to the degree of MODS.

Anti-mediator Therapy

Efforts to manipulate the dysregulated immune response characteristic of MODS have constituted a substantial portion of experimental research in the field of critical care for two decades. Early attempts sought to achieve generalized immune suppression. However, treatment with nonspecific inhibitors of inflammation such as non-steroidal anti-inflammatory drugs, corticosteroids, and dietary fish oil did not improve outcomes. Indeed, non-steroidal anti-inflammatory agents may worsen organ dysfunction, particularly by decreasing renal perfusion and disrupting gastric mucosal integrity.

As understanding grew of the role of individual cytokines in the inflammatory response, attention turned towards targeted, mediator-directed therapy for MODS. Nearly 100 such clinical trials have been conducted to date, including anti-mediator monoclonal antibodies (e.g., anti-TNF, anti-endotoxin) and receptor antagonists or inhibitors (e.g., IL-1 receptor antagonist, tissue factor pathway inhibitor, TLR-4 antagonist). However, targeted interventions aimed at cytokine neutralization have been largely disappointing.[149,150] A recent, combined analysis of clinical trials of mediator-directed therapy in patients with SIRS reported only a modest (3%) overall reduction in 28-day mortality,[151] and no mediator-directed treatment has been licensed specifically for use in patients with established MODS in the United States.

The failure of mediator-directed therapy is likely multifactorial. Measurement of elevated serum concentrations of inflammatory cytokines during MODS does not confirm causality. Expression of mediators may vary over time, and is regulated by a variety of complementary mediators, each

of which has several targets. Furthermore, measurement of serum concentrations may not reflect tissue activity. Finally, regional variations in ICU practice may explain partially the discrepancy between efficacy and effectiveness observed when comparing clinical trials.

Drotrecogin alfa (activated) (drotAA, or recombinant human activated protein C [rhAPC], an endogenous coagulation factor with anti-inflammatory, anticoagulant, and fibrinolytic properties), was approved from 2001–2011 for the treatment of severe sepsis associated with a high risk of death,[152] but has now been withdrawn from the market.[153] The development of drotAA galvanized appreciation of the interrelationship between inflammation and coagulation in the pathophysiology of both SIRS and MODS. Although the primary outcome variable reported following therapy with drotrecogin alfa (activated) was a reduction in 28-day mortality (19.4% relative risk reduction in death compared with placebo [$p = 0.005$]),[152] a subsequent analysis also revealed a substantial improvement in mean SOFA scores at 28 days in patients treated with drotrecogin alfa (activated) versus placebo[154] Additional therapies for the management of sepsis, distinct from mediator-based efforts, have been organized into "bundles" (see Chapter 12), with favorable effects upon mortality.[155,156]

OUTCOMES OF MULTIPLE ORGAN DYSFUNCTION SYNDROME

Both the heterogeneous patient population and lack of standardized scoring systems limit the tracking of progress in the management of MODS. Furthermore, both temporal and spatial comparisons are hindered by variations in severity of illness and thus likelihood of developing MODS. An earlier report of mortality following MODS reported no difference in either the incidence of (14%) or mortality from (60%) MODS when comparing patients admitted from 1979 to 1982 to those admitted from 1988 to 1990.[39] However, a substantial decrease in mortality was noted in those patients with what was considered severe organ failure (≥3 organs failed on day 4 or later). A later study (March-December 1997) found that mortality from MODS, defined as a MOD score of ≥2 for two organ systems and the necessity of an active ICU intervention, was 53%.[46] A still more recent prospective study (2005), reported a 17% incidence of MODS and 45% mortality in over 7,000 patients from 79 ICUs.[35] Barie et al.[44] showed that the severity-adjusted risk of mortality from MODS decreased steadily over a 17-year period of observation. Thus, mortality from MODS is decreasing over time. However, future studies using both standardized, incremental scoring systems and similar subject populations to compare outcomes in patients with organ failure are warranted.

Survival and Long-term Outcomes

Fewer than one-half of survivors of severe sepsis are alive 1 year later[157]; even less is known about survivors of MODS. Mortality is increased compared with life-table norms for several years thereafter. Risk factors for decreased long-term survival that are identifiable before hospital discharge have not been reported.

In one study, 56% of end-stage renal disease patients who required critical care for an episode of MODS survived their ICU stay.[158] Fifty-six percent of the survivors (31% of the total) were alive 2 years later; the mortality rate was higher for medical ICU patients as compared with surgical ICU patients. Survivors died at a faster rate than end-stage renal disease (ESRD) patients who

did not require critical care, but this difference was abolished when deaths within 30 days of ICU discharge were discounted.

Ulvik et al.[159] examined long-term outcomes after trauma in a cohort of patients who developed MODS. Among 322 patients, 47% had MODS as assessed by the SOFA score, and 28% had single organ failure. The patients were contacted by telephone 2–7 years after discharge. At follow-up, 75% were still alive, and 52% had enjoyed a complete recovery. Long-term survival and functional status did not differ between survivors with no or single organ failure, whereas survivors of MODS had a six-fold increased risk of death, and a 3.9-fold increased risk of requiring assistance with activities of daily living.

THE FUTURE?

Understanding that sepsis and MODS are complex, chaotic systems and that taking a systems biology approach to their characterization is in its infancy, the future holds promise.[6] Genomic profiling may allow more useful characterizations of risk and outcomes.[160,161] Mathematical modeling (*translational systems biology*) aims to harness the power of computational simulation to streamline design of devices or drugs, identify therapeutic targets, simulate clinical trials, and predict the effects of drugs on individuals.[162–164]

The emerging field of metabolomics, a science of systems biology, is the global assessment of endogenous metabolites within a biologic system.[165] Detection of metabolites, whether in cells, tissues, or fluids, is conducted either by nuclear magnetic resonance spectroscopy or mass spectroscopy, with the data input into sophisticated multivariable analyses. Metobolomics could advance understanding of complex biologic systems such as ARDS and MODS, or aid in biomarker of drug target identification, it being reasonable to assume that a profile or pattern of indices is more likely to elucidate disease severity and progression than any one parameter (i.e., biomarker).

With new knowledge will come new approaches to therapy, likely in the realm of immunotherapy.[166] As sepsis-induced immunosuppression has come to be recognized as the overriding immune dysfunction in MODS, therapies may be directed in the future at enhancing immune responsiveness, as the opposite tactic (i.e., suppressing inflammation) clearly has not been successful. The prevention of sepsis-induced immune suppression, or its treatment if it occurs, is a research priority.[166] Although immunostimulatory therapy with agents such as IFN-γ and granulocyte-colony stimulating factor (G-CSF) has not been successful so far, IL- and IL-15 may be useful in the future. IL-7 (already in clinical trials to treat cancer and hepatitis C virus and human immunodeficiency virus infections) and IL-15 are anti-apoptotic, immunostimulatory cytokines that diminish the immunosuppressive effects on phagocytes by relieving them of the burden of clearing large numbers of apoptotic cells. IL-7 also improves the effector function of lymphocytes and their migration. Personalized medicine, for example, to use flow cytometry to identify patients with high levels of expression of negative co-stimulatory molecules on leukocytes, could be used to support the decision to use immunostimulatory therapy. Candidates for such therapy could be those patients with infections caused by opportunistic pathogens (e.g., *Stenotrophomonas*, *Acinetobacter*).

Ultimately, Cobb[167] has speculated that therapy of sepsis and MODS may evolve through several phases. Macrosystems engineering is possible now, in that performance improvement is a fixture of every ICU. Henceforth, advances in tissue engineering will allow the deployment of bioartificial organs for replacement. Ultimately, a new science of molecular engineering may permit the reprogramming of dysfunctional somatic cells by the manipulated overexpression of a

few DNA transcription factors known to be central to the fate of embryonic stem cells. The reprogramming of the dysfunctional somatic cells to a more robust phenotype, referred to as *induced pluripotent stem cells*, has already been hailed as a scientific breakthrough.[168] These stem cells could be administered as cellular therapy to reprogram aged or dysfunctional organs to a state of renewed health, although many questions remain to be answered before these techniques are ready for the clinic.

MECHANICAL VENTILATOR SUPPORT

MARC J. SHAPIRO AND BRIAN M. HALL

The respiratory system is responsible for both oxygenation and ventilation. Oxygenation is the ability to provide oxygen to the tissues. Ventilation is the removal of carbon dioxide via the lungs to maintain a neutral pH. When the ability to breathe is compromised, whether it is secondary to hypoxia, acidosis, injury, oversedation, somnolence, muscle fatigue, or other issues, supplemental and artificial modes must be employed in order to provide adequate oxygenation and ventilation; these methods will be discussed.

NONINVASIVE VENTILATION

As part of the evaluation and treatment of patients, there are a number of adjuncts that can be utilized in an attempt to preclude the need for intubation with an artificial airway and mechanical ventilation.[1] To address hypoxemia, supplemental oxygen should be initiated.

The basic form of oxygen supplementation is via a nasal cannula. Oxygen is delivered through prongs that are inserted into the nares and can be regulated between a low flow (1–2 L/minute) and a high flow concentration (10 L/minute), although the higher flow rates can be uncomfortable for a patient. Flows up to 20 L/min with humidification have also been used to create a continuous positive airway pressure (CPAP) effect as well. This oxygen supply is either from a wall source via a regulator or from an oxygen tank. Caution must be exercised in patients with end-stage or chronic pulmonary disease as many of these patients rely on hypoxia to provide their respiratory drive. Providing too high an arterial oxygen saturation can abolish this drive.

If a nasal cannula is inefficient in oxygen delivery, that is, delivery of oxygen to a mouth breather, other modalities may be employed. Oxygen delivery via a face mask is a simple means to improve oxygenation in a patient. Oxygen flow from a wall circuit or a specialized tank can increase the concentration of oxygen in inspired air to approximately 55%. Openings on the side of the mask allow removal of CO_2 without effort. However, if an individual's tidal volume (TV) is high, room air may be entrained into the mask, thus diminishing the enriched oxygen concentration. To diminish this latter effect, the patient may be switched to a venturi mask. This apparatus is similar in appearance to a face mask, but has one way valves replacing the openings on the side of the mask. This allows an increase in enriched oxygen concentrations up to 80% at the tertiary bronchioles, as well as CO_2 removal. Another less frequently used noninvasive oxygen delivery system is a face tent. This fits below the chin and oxygen flow is directed into the oral and nasal passages without the mask actually touching the face. This is particularly useful in patients with burns, macerated facial skin, etc. and can provide up to 50% oxygen concentration levels.

Higher concentrated levels of oxygen can be provided by CPAP or bilevel positive airway pressure mask. This is a mask that is firmly secured over the nose and/or mouth, and delivers concentrated oxygen under positive pressure. Prior to initiation of this treatment, the patient should be awake, able to cough and may require gastric decompression via a nasogastric tube. This is done to avoid gastric distension and aspiration resulting from the aerophagia generated from the provided pressure.

MECHANICAL VENTILATION

Ventilation using mechanical means has seen changes from a century ago when the use of negative pressure ventilation and the so called "iron lung" was utilized during the polio epidemic. This has progressed to the current usage of positive pressure ventilation with digital rather than analogue technology. Advanced computer technology incorporating patient data and operator data, coupled with pharmacomanipulation and ancillary assistance described below has also led to the improvement of mechanical ventilation.[2–6]

Ventilation–perfusion ratio (V/Q) looks at oxygen consumption and CO_2 production. It assumes that there is a near linear relationship between CO_2 and PCO_2. Alveolar–capillary gas transport can be expressed as $DO_2I = (SaO_2 \times Hb \times 1.34) + (0.0031 \times PaO_2) \times CI \times 10$ where DO_2I is oxygen delivery index and normal values are 500–600 mL O_2/min/m². Oxygen consumption is generally 25% of oxygen delivery and together give rise to the extraction ratio or A-VO_2 difference, with normal being 5 mL O_2/dL of blood. In times of high O_2 demands, the normal tissues can extract 50% or more O_2 from the blood. In various conditions however, such as SIRS, the extraction is less.

Ventilation

The ventilator circuit is approximately 60 inches of corrugated plastic tubing connecting the ventilator to the artificial patient airway, for example, an endotracheal (ET) or tracheostomy tube. The circuit may contain filters, humidifiers, water traps, heated wires, artificial noses, closed suction catheters, and devices for aerosol administration or capnography and is directly connected to the ventilator.

To determine acceptable placement of the ET tube, a colorimetric CO_2 detector may be used. This device has a pH-sensitive chemical bonded to a specialized paper element that changes color with ventilation in the presence of CO_2. During CPR this detector is of limited value. The cardiac output, and thus the pulmonary blood flow, may both be diminished and CO_2 may not be exchanged, let alone exhaled. Another device available to verify ET tube placement into the trachea is the esophageal detection device. Negative pressure applied at the end of the artificial airway allows the bulb to inflate if the ET tube is in the trachea on inspiration. This relies on the fact that with inspiration the lungs are distended and the esophagus is collapsed and thus the bulb will not fill if the ET tube is in the esophagus, unless the patient has had a large amount of gas insufflated into the esophagus such as from manual ventilation.

Aside from the traditional ET tube, tubes impregnated with silver and tubes with a supraglottic suction port to prevent

SURGICAL CRITICAL CARE

secretions from contaminating the respiratory tree, have been used. Both adjuncts add considerable cost to the tubes with little proven benefit.

The cycle of respiration using mechanical ventilation consists of the following steps:

1. A trigger either by the patient or the machine to initiate a breath may be in the form of a set time, pressure, or volume.
2. The volume or pressure goal, if set, is reached and may also be influenced by flow sensitivity.
3. Then based on whether volume cycled, time cycled, flow cycled, or pressure cycled, the inspiratory phase is completed and there may be a pause.
4. The exhalation phase then begins, which in most cases is passive and dependent in part on pulmonary compliance and airway and equipment resistance, the product of which is called the time constant (Tc).

Terms Utilized for Mechanical Ventilation

1. TV is the amount of air the patient inspires or is delivered by the ventilator during an inspiration (mL).
2. Respiratory rate or frequency is the number of breaths per minute and may include the patient's breaths, the ventilator breaths or both.
3. Minute volume ventilation (MVV) is the product of the TV and the frequency (L/minute).
4. Peak airway pressure (Paw) is the pressure required to deliver the set TV to the patient (cm H_2O).
5. Plateau pressure (Pplat) is the pressure necessary to distend the lung at end inspiration (cm H_2O).
6. Mean airway pressure (Maw) is the average pressure delivered (cm H_2O).
7. Inspiratory time (IT) is the number of seconds required to deliver a set TV.
8. Peak inspiratory flow is the highest flow during the inspiratory phase used to deliver the set TV (L/min).
9. FiO$_2$ is the fraction of inspired oxygen or the concentration of inspired oxygen gas with 0.21 (21%) being room air and 1.0 (100%) being the maximum short of using a hyperbaric chamber.
10. Compliance is the change in volume divided by the change in transthoracic pressure.
11. Elastance is the change in transthoracic pressure divided by the change in volume.
12. Resistance is the ratio of change in pressure to change in volume.
13. Static compliance is the ability of the alveoli to expand with increasing volume or pressure and is measured in a no-flow condition. It is expressed as the ratio of the change in volume over the change in alveolar pressure. Dynamic compliance is the same ratio while flow is occurring. The opposite of compliance is elastance.

Modes of Mechanical Ventilation

Mechanical ventilators operate via one of two modes: pressure control or volume control (Table 49.1). Pressure control is a mode of ventilation where the pressure delivered with each breath is constant.[7] Volume control ventilation is a mode where the volume of each breath delivered remains constant. Dual control implies that breaths are a combination of volume and pressure control. There are wide ranges of other modes of mechanical ventilation, which are detailed below (Table 49.2):

CMV is continuous mandatory ventilation in which all breaths are delivered by the ventilator at a minimum preset frequency to a preset volume (Table 49.1). It is rarely used today as it is considered an unnatural form of ventilation, and thus should only be considered in patients who are chemically paralyzed.

ACV is assist–control ventilation in which a set volume is delivered at a set minimum frequency. In addition, the patient can trigger the ventilator to deliver an additional breath at the preset volume or pressure above the preset frequency.

IMV is intermittent mandatory ventilation in which the machine breaths are delivered at a set frequency, volume, and pressure.[8] Any additional breaths are spontaneous with patient generated volumes or pressure. This form of ventilation is primarily utilized in the NICU.

SIMV is synchronized intermittent mandatory ventilation where the ventilator delivered breath is presented within a preset time, preferably in concert with the patient's inspiratory effort. If there is little or no spontaneous breathing, a time triggered breath is delivered in the absence of a patient generated breath. Patients can be weaned from this mode of ventilation.

PSV is pressure support ventilation in which the patient's inspiratory effort is assisted by the ventilator to a preset pressure. This mode of ventilation is patient triggered, pressure limited, and flow cycled, allowing patients to set their own frequency, IT, and volume. Patients can be weaned from this mode of ventilation (Algorithm 49.1).

CPAP is continuous positive airway pressure where a constant level of positive pressure is set while the patient is breathing spontaneously. This mode can be used prior to extubation or decannulation of a mechanically ventilated patient.

APRV is airway pressure release ventilation that allows spontaneous breathing. The patient ventilates with a high pressure (P*hi*) level, which is essentially CPAP, and during the inspiratory phase the *Phi* is released at a set low pressure level (P*lo*). The time spent at each level of ventilation is the T*hi* or the IT and T*lo*, which is the expiratory time. The spontaneous breaths are pressure controlled, pressure triggered, pressure limited, and pressure cycled. APRV allows spontaneous breaths during the inflation period. This mode is attractive in that it may limit acute lung injury (ALI) by decreasing maximal pressures and increasing mean pressures, thus improving oxygenation.[9–11]

PCIRV is pressure controlled inverse ratio ventilation and is a time triggered, pressure limited, and time cycled mode of ventilation in which all breaths are mandatory.[7] This mode generally has inspiration times longer than exhalation. When spontaneous breathing is absent this is similar to APRV.

PRVC is pressure-regulated volume control where the TV is set and the inspiratory pressure is adjusted by the ventilator to assure the preset volume delivery.

TABLE 49.1

CONTROLLED MANDATORY VENTILATION VS. PRESSURE CONTROLLED VENTILATION

	■ CMV	■ PCV
Tidal volume	Constant	Variable
Peak inspiratory pressure	Variable	Constant
Inspiratory time	Set directly or indirectly	Constant
Inspiratory flow	Set directly or indirectly	Variable
Inspiratory flow waveform	Constant	Variable

TABLE 49.2

BASIC MODES OF MECHANICAL VENTILATION

	■ TIDAL VOLUME (TV)	■ ADVANTAGE	■ DISADVANTAGE
Volume Assist Control (VAC)	Volume triggered	MVV set	Plateau pressure varies
Pressure Assist Control (PAC)	Pressure triggered	Comfortable for patient Pressure limited	Variable V_T
Pressure Support (PS)	Patient triggered Pressure target	Comfortable for patient Good synchrony	Requires patient respiratory drive
Synchronous Intermittent Mechanical Ventilation (SIMV)	Preset, synchronized TV	More natural form of ventilation	Increases work of breathing

HFOV is high-frequency oscillatory ventilation with low TVs and small airway fluctuations. The goal of this mode is to decrease mean airway pressures, while avoiding stacking of breaths. The frequencies may vary between 100 and 900 breaths per minute with gas transport via nonconvective mechanisms.[12] The most successful use for HFOV has been in the treatment of respiratory failure in premature infants.

PAV is proportional assist ventilation, which is an interactive ventilatory mode to improve synchrony between patient ventilatory demand and ventilator support.[13] The ventilator provides dynamic inspiratory pressure assistance in linear proportion to patient inspiratory effort. For PAV to work the patient must be spontaneously breathing. If the patient tires, PAV will not provide the ventilatory support for a targeted pressure or volume.

Permissive hypercapnia is a modality of ventilation utilized to remove carbon dioxide from the blood when more conventional methods, that is, increasing the rate and decreasing TV, are unsuccessful. The manipulation of the ventilator to allow the PCO_2 to rise upwards to 50–80 mm Hg or higher, while not jeopardizing arterial pH, is the goal of this therapy. This form of ventilation is another mode of lung-protective ventilation, and may be required in patients with a $PaO_2:FiO_2$ ratio below 300.

PEEP is positive end-expiratory pressure and occurs at the end of exhalation and prevents the deflation and collapse of an alveolus opened during inspiration. The primary role of PEEP is alveoli recruitment. Under normal circumstances, the alveolar and airway pressures are equal with complete lung emptying. Intrinsic PEEP occurs when lung emptying is not complete and the airway pressure rises to equal that of the elevated alveolar pressure. In this circumstance, if PEEP continues to rise, barotrauma to the lungs can lead to a pneumothorax.

Independent lung ventilation is a form of ventilation that commonly uses a dual lumen ET tube to allow individual lung ventilation. This may also be accomplished using two small ET tubes, one ending in each mainstem bronchus. This form of therapy is used during a thoracotomy or thoracoscopy, so the surgical side can be preferentially deflated and TV lowered to facilitate exposure for operation. Other indications for use in the operating room or the intensive care unit (ICU) include massive hemoptysis, pulmonary alveolar proteinosis, unilateral lung injury, single-lung transplantation, or bronchopleural fistula. A single or dual ventilator can be used and even set to different modes of ventilation for use with independent lung ventilation.

ACUTE LUNG INJURY

Mechanical ventilation is used to treat hypoxemia, acidosis, and other life-threatening conditions. Although lifesaving, it may incite ventilator-induced lung injury. This may occur by barotrauma manifesting as extra-alveolar air, volutrauma from mechanical stretch, atelectrauma from alveolar mechanical stress, and biotrauma from systemic inflammatory mediators.

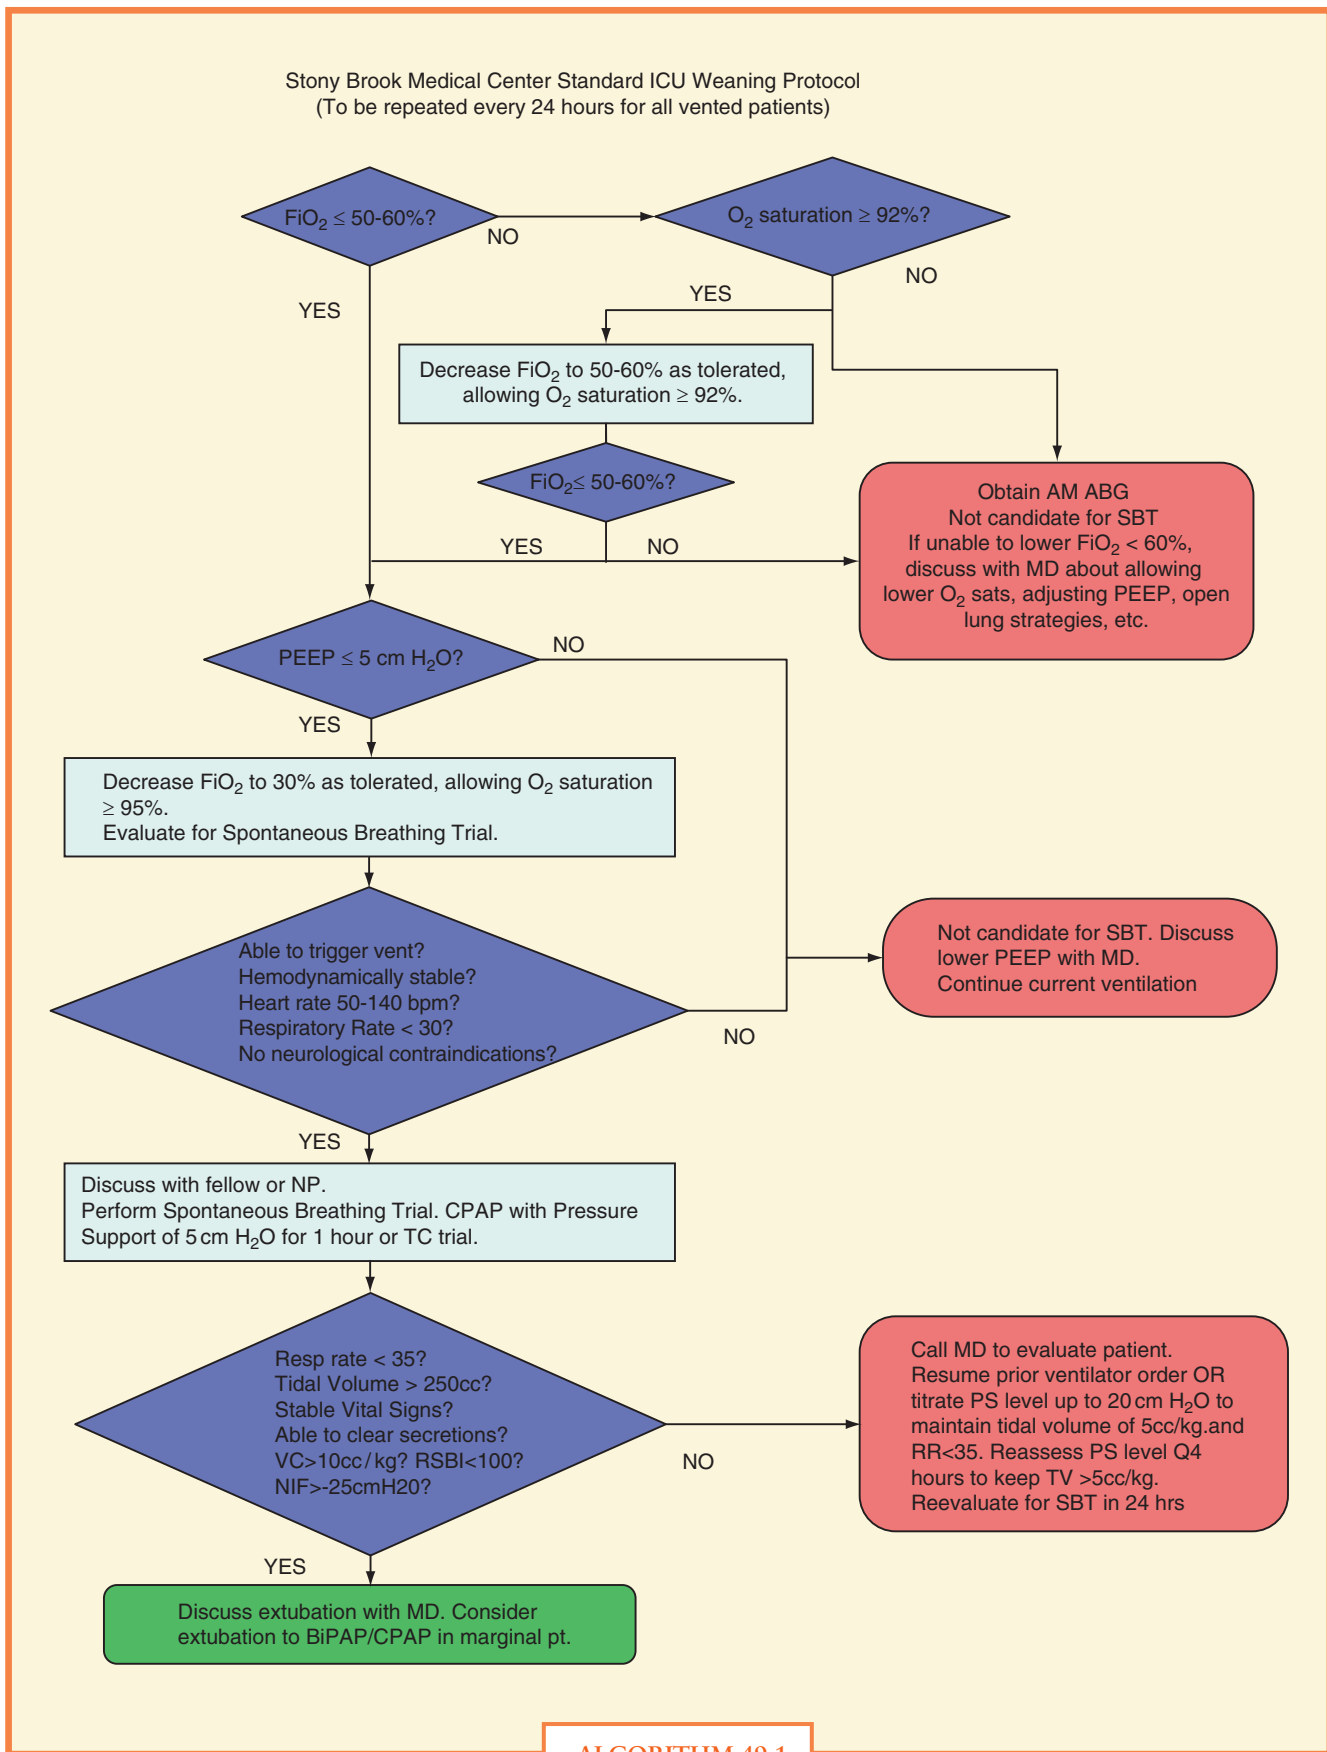
A pneumothorax is extra-alveolar, intraplueral air and occurs in 4%–15% of patients mechanically ventilated over 24 hours. Patients most prone are those with asthma, chronic obstructive pulmonary disease (COPD), ALI, and the adult respiratory distress syndrome (ARDS). Due to the observation that this may be precipitated by right mainstem intubation, alveolar overdistension may play a major role in its pathogenesis.[14]

In 2000, the NIH-sponsored ARDS Network phase III study looked at two groups of patients with respiratory failure and divided them based on TV calculated from the predicted body weight.[15–17] These variables were 6 and 12 mL/kg, respectively. In the 6 mL/kg group, the plateau pressure goal of <30 cm H_2O was achieved by decreasing the TV to a minimum of 4 mL/kg predicted body weight. The study was terminated early due to the statistical superiority of diminished mortality in the low TV group and substantial decrease in ventilator free days. Parsons also found that these low TV patients had a substantial decrease in inflammatory mediators such as IL-6, 8, and 10.

PHARMACOLOGIC APPROACH TO MECHANICAL VENTILATION

Up to 71% of SICU and seriously ill patients experience considerable pain. If untreated pain can lead to increases in sympathomimetics, catecholamines, and cytokines.

Elevated cytokines such as TNF-alpha, IL-1, IL-6, IL-8, as well as a decrease in IL-2, can adversely affect the T cell mediated immune response. The hyperglycemia that pain and stress induce may decrease chemotaxis and phagocytosis by neutrophils, leading to an increase in the infection rate, specifically ventilator-associated pneumonias (VAPs). Increased fibrinogen concentrations, increased plasminogen activator inhibitor, and increased platelet reactivity from stress can lead to a hypercoagulable state and thrombosis. In addition, stress increases

Stony Brook Medical Center Standard ICU Weaning Protocol
(To be repeated every 24 hours for all vented patients)


ALGORITHM 49.1

ALGORITHM 49.1 Stony Brook Medical Center Standard ICU Weaning Protocol. To be repeated every 24 hours for all vented patients.

myocardial oxygen consumption, placing more stress on the heart. Thus, control of pain is important in controlling and weaning patients from mechanical ventilation. Attenuation or removal of painful and noxious stimuli is a crucial goal in oxygenation, ventilation, and weaning of these patients. Simple maneuvers such as proper positioning, using an appropriate type of bed, stabilization of fractures, and removing any physical irritants can also help decrease pain medication requirements.

Pharmacologic adjuncts are helpful, and include opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and neural blockade. Opioids are the most common medications used for analgesia in the SICU (Table 49.3). They act centrally and peripherally via both mu and kappa receptors. Administration occurs by many avenues and includes oral, patch-transdermal, sublingual, epidural, intramuscular, or intravenous such as with a patient controlled analgesia device. There are a number of potential side effects of opioid use, the most important of which include respiratory depression, hypotension, altered mental status, constipation, and urinary retention. Naloxone is a narcotic antagonist that assists in reversal of unwanted opioid side effects.

IV ketamine, a nonopioid analgesic, may cause tachycardia, hypertension, hallucinations, and elevation in intracranial pressure, even at subanesthetic doses. Therefore, ketamine is generally avoided in the traumatic brain injured patient. Acetaminophen is used primarily for treatment of pyrexia, mild analgesic relief, and as an adjunct with narcotics. Hepatotoxicity may occur, especially in patients with depleted glutathione stores. NSAIDS can be used for analgesia; however their role is limited in ICU patients due to their side effects of gastric irritability and bleeding.

Epidural catheters are effective in control of more diffuse pain that may occur with multiple rib fractures or a laparotomy incision. Side effects include hypotension and respiratory depression. With the placement and removal of these catheters, be aware of recent anticoagulant or platelet inhibitor administration, due to the concern of developing an epidural hematoma.

Delirium

Delirium is an acute, potentially reversible impairment of consciousness and cognitive function that may occur in up to 80% of elderly ICU patients. There are a number of tools that can be used to identify and grade the degree of delirium in the ICU. The CAM-ICU confusion assessment method is based on the acute onset of mental status changes, inattention, disorganized thinking, and an altered level of consciousness. This tool has a high sensitivity and specificity.

Delirium is generally treated with neuroleptic drugs that antagonize basal ganglia dopamine. Intermittent IV boluses of haloperidol in dosages of 2–5 mg repeated every 15–20 minutes until agitation abates, up to a daily dose of 300 mg, may be used. However, with higher dosages the incidence of Torsades de pointes increases due to dose-dependent QT-interval prolongation. Cardiac monitoring, repletion of electrolytes, and extra caution in patients with a cardiac history are warranted. Neuroleptic agents can also lead to extrapyramidal side effects such as tremors and neuroleptic malignant syndrome. When possible, modification of behavior and environment should also be undertaken, such as limiting interruptions and noise. Other agents such as seroquel, which is only available via the oral route, can be beneficial.

Sedation and Anxiety

Anxiety or a state of apprehension in response to new or perceived threats is not uncommon in the ICU. It is an unfamiliar environment with bells and whistles leading to multiple types and forms of distractions. As with delirium, there are a number of scales available to assess the level of sedation, such as the Richmond Agitation-Sedation Scale, the Ramsay Scale, and the Motor Activity Assessment Scale.

There are many different classes of medications that are used for sedation. The use of benzodiazepines may actually assist in lowering the dosages of opioids required. If necessary, benzodiazepines can be reversed with flumazenil. These commonly used agents differ in their duration of action and rapidity of onset, as shown in Table 49.4. Propofol causes antegrade amnesia and sedation, and is only available in an intravenous formulation. It has also been used as an anticonvulsant. Propofol is a favored benzodiazepine in the ICU setting because of its rapid onset of action and quick metabolic elimination. Drawbacks of propofol are its increased cost as compared to other benzodiazepines, and the increased risk of hypertriglyceridemia and pancreatitis. Dexmedetomidine, another frequently used sedative, has the advantage of analgesic and sympatholytic properties with little respiratory suppression.

NEUROMUSCULAR BLOCKADE

With the increase in the variability of the different modes of mechanical ventilation, manipulations with flow rate and I:E ratio, and the availability of different sedative/analgesic agents, paralytics have seen a marked decrease in utilization in the ICU. Intensivists place patients on sedation vacations to assess ability to wean/extubate, to decrease the incidence of VAPs, and to decrease other conditions such as neuromuscular

SURGICAL CRITICAL CARE

TABLE 49.3

COMMONLY USED OPIOIDS IN THE ICU

■ DRUG	■ BOLUS DOSE	■ INFUSION RATE	■ HALF-LIFE	■ ELIMINATION	■ COMMENTS
Morphine sulfate	2.5–5.0 mg	5–35 mg/h or 0.07–0.5 mg/kg/h	2–4 h	Hepatic/renal	Histamine release Accumulates in renal insufficiency
Fentanyl citrate	25–100 μg	0.7–10 μg/kg/h	2–4 h	Hepatic	May accumulate with large doses
Hydromorphone	0.2–0.6 mg	0.5–1 mg/h or 7–15 μg/kg/h	2–3 h	Hepatic	

COMMONLY USED SEDATIVES IN THE ICU

DRUG	BOLUS DOSE	ONSET OF ACTION	INFUSION RATE	HALF-LIFE	ELIMINATION	COMMENTS
Diazepam	0.03–0.1 mg/kg	2–5 min	N/A	20–50 h	Hepatic/renal	Metabolic acidosis Active metabolites
Lorazepam	0.02–0.06 mg/kg	5–20 min	0.01–0.1 mg/kg/h	10–16 h	Hepatic/renal	Metabolic acidosis Prolonged sedation
Midazolam	2–5 mg	1–5 min	0.04–0.2 mg/kg/h	1–4 h	Hepatic/renal	Increased levels with obesity Shorter half-life
Propofol	5 µg/kg	1–2 min	5–80 µg/kg/min	3–12 h	Hepatic	Increased triglycerides, accumulates in tissues
Dexmedetomidine	1.0 µg/kg over 10 min	5–10 min	0.2–0.7 µg/kg/h	1 h	Hepatic	Alpha2 agonist Minimal respiratory depression
Haloperidol	2–10 mg	30–60 min	3–25 mg/h	18 h	Hepatic	QT prolongation Torsades de pointes Extrapyramidal side effects

illness of critical care, which would be precluded with the routine use of neuromuscular blockade. Paralytics are divided into two classes, depolarizing and nondepolarizing agents (Table 49.5). Succinylcholine, the only depolarizing paralytic agent used today, is similar to acetylcholine and binds to and activates (depolarizes) nicotinic acetylcholine receptors as manifested by muscle fasciculation. It is often used for intubation due to its rapid onset and offset. However, when hyperkalemia is present, such as in burn patients and in patients with neuromuscular disease, another agent should be considered. The

nondepolarizing agents bind but do not activate acetylcholine receptors; they include the aminosteroids and benzylisoquinolinium agents. The benzylisoquinolinium drugs atracurium and cisatracurium are inactivated by ester hydrolysis and Hoffman's elimination and thus not directly dependent on renal or hepatic function.

The neuromuscular blocking agents (NMBAs) should be monitored both subjectively for skeletal and respiratory movement, and objectively with a peripheral nerve stimulator using train of four electrical impulses. Acute myopathy of critical

COMMONLY USED PARALYTICS IN THE ICU

DRUG	BOLUS DOSE	ONSET OF ACTION	DURATION	ELIMINATION	COMMENTS
Depolarizing agent Succinylcholine	0.3–1.1 mg/kg	<1 min	4–6 min	Plasma Pseudocholinesterase	
Nondepolarizing agent (A) Aminosteroids (B) Benzylisoquinolinium					
Pancuronium (A)	0.04–0.1 mg /kg	2–3 min	60–100 min	Hepatic	Tachycardia
Vecuronium (A)	0.08–0.1 mg/kg	3–5 min	45–65 min	Biliary/renal	Prolonged effects with hepatic failure
Rocuronium (A)	0.6–1.0 mg/kg	2–4 min	30 min	Hepatic	Rapid onset
Atracurium (B)	0.4–0.5 mg/kg	2–3 min	60–70 min	Hoffman degradation	Histamine release leads to hypotension
Cisatracurium (B)	0.15–0.2 mg/kg	2–3 min	30–60 min	Hoffman degradation	
Mivacurium (B)	0.2 mg/kg	1.5–2.5 min	15–20 min	Cholinesterase	Short half-life

illness is seen with prolonged use of NMBAs and may be manifested by inability to wean from the ventilator or with symmetrical and distal muscle group weakness after discontinuing the NMBA.

ADDITIONAL THERAPY TO IMPROVE OXYGENATION

Prone Ventilation

ARDS is a life-threatening pulmonary condition that produces severe hypoxemia. ARDS leads to an accumulation of fluid in the alveoli, which hinders oxygen transport across the alveoli membrane into the bloodstream, thus creating a state of hypoxemia. First described in 1976, prone ventilation is a modality used to improve oxygenation in severe hypoxemia.[18–22] Primarily used as a rescue maneuver, prone ventilation is employed in those patients who have required a sustained elevation of the FiO_2 and/or elevation of plateau pressures despite multiple changes to conventional ventilation. It is a known fact that elevation of these specific indices can be deleterious to a patient's respiratory recovery.

While patients lie in a supine position on a flat surface, ventilation generally occurs preferentially in the anterior and nondependent areas of the lung. Hence, the posterior and dependent portion of the lung, although theoretically better perfused, experiences somewhat ineffective ventilation, leading to a shunt. By placing a patient in the prone position using a specialized bed, the pulmonary mechanics of the patient can potentially be reversed resulting in a decrease in both the shunt and dead space. This results in an increase in recruitment of the posterior alveoli, and an increase in the end-expiratory lung volume. Prone positioning has also been shown to assist with the drainage of secretions from the tracheobronchial tree. With improvement in arterial oxygenation leading to lower inspired oxygen concentrations and PEEP levels, weaning the patient from the ventilator can be facilitated.

Using computerized tomography to evaluate and measure regional lung inflation, Gattinoni and Pelosi suggested that positional changes in FRC are related to regional lung inflation gradients. This reemphasizes work published in the 1960s by West and colleagues in describing the three zone model of pulmonary perfusion. In the apical zone, Zone 1, alveolar pressure exceeds arterial pressure, which exceeds venous pressure. In zone 2 or the middle lung fields, arterial pressure exceeds alveolar pressure, which exceeds venous pressure and in zone 3 arterial pressure exceeds venous pressure, which exceeds alveolar pressure.

In 2001, Gattinoni et al. [23] published a randomized control trial detailing the use of prone ventilation in the ICU setting. In this study, prone ventilation was applied for an average of 6 hours/day for approximately 10 days. The primary endpoint was mortality at 10 days, at time of discharge from the ICU, and at 6 months. At the conclusion of the study, there was no difference observed between both the supine and prone groups at 10 days (21% vs. 25%), and at the time of discharge from the ICU (51% vs. 48%). However a secondary endpoint, improvement in respiratory failure, was seen in nearly 70% of the prone group. Although no survival benefit was proven, this study became an outline for future studies. Mancebo et al. investigated prone ventilation applied over a longer duration. Patients were placed in the prone position for an average of 17 hours/day within 48 hours of oral–tracheal intubation. Although the results were not statistically significant, there was a 15% absolute and 25% relative reduction in ICU mortality compared with those who were ventilated supine. Upon further analysis, supine position was found to be an independent risk factor for mortality. In 2009, Taccone published a study designed to correct the issues that were viewed as possible reasons for the negative findings of previous trials. The results were similar to previous trials as there was no statistically significant survival benefit in patients with ARDS regardless of severity of hypoxemia.

Prone positioning should be employed in those whose oxygenation is severely impaired. Even though previous clinical experience has been derived from its use with ventilator dependent patients with ARDS, improvement in oxygenation has been seen in other respiratory disease processes.[24–30] Prone ventilation can be used in chronic obstructive lung disease and acute cardiogenic pulmonary edema. In 2004, studies by Guerin et al.[31] found a reduction of the prevalence of nosocomial pneumonia and incidence of VAP, respectively. This may be related to improved mobilization of secretions. Once the patient's condition improves and is able to tolerate more conventional methods, prone ventilation should be discontinued.[32]

The number, and in general, types of complications associated with prone ventilation are similar to that of supine positioning. Patients requiring prone ventilation are critically ill and commonly have arterial and venous access catheters and an endotracheal or tracheostomy tube. Care should be taken to ensure there are no displacements of these tubes and catheters to prevent an adverse event from occurring since prone positioning presents a definite challenge for cardiopulmonary resuscitation. Other complication that may occur with prone ventilation includes arrhythmias, facial and periorbital edema, and pressure ulcers.

Heliox

Heliox is an 80% helium and 20% oxygen mixture with a density much lower than pure oxygen and thus able to diffuse at a rate 1.8 times greater than oxygen alone. It assists in reducing resistance seen with partial upper airway obstruction such as with post extubation stridor. Evidence based studies for its use in the surgical critical care setting are lacking at this time.

Nitric Oxide

Inhaled nitric oxide is a highly reactive gaseous radical that is a potent vasodilator, especially for the pulmonary vasculature.[33] There have been mixed results with its use in ARDS refractive to traditional forms of ventilation. Treatment is initiated at 10 parts per million (ppm), and increased to a maximum of 20 ppm if no clinical response is detected. This is an expensive mode of therapy and Box 49.1 is the policy currently used at Stony Brook University Medical Center.

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation (ECMO) or extracorporeal life support is available in certain centers to provide cardiocirculatory assist in patients with severe reversible cardiac and/or pulmonary failure.[34–36] As a salvage therapy, it is used when other more conventional modalities have failed. By providing gas exchange extracorporeally the lungs

BOX 49.1

POLICY
Inhaled nitric oxide (iNO) is a selective pulmonary vasodilator approved by the FDA for use in term or near term (>34 weeks) neonates with hypoxic respiratory failure associated with clinical or echocardiographic evidence of pulmonary hypertension where it improves oxygenation and reduces the need for ECMO. Nonneonatal use of nitric oxide will be governed by this policy to ensure appropriate *and safe administration of iNO.*

SCOPE
All pediatric and adult patients treated with iNO. Administration of iNO in the Cardiac Catheterization lab for vasoreactivity determination has been addressed in a separate policy.

KEYWORDS
Inhaled nitric oxide, critical care, mechanical ventilation

DEFINITIONS
Inhaled nitric oxide (iNO): a medical gas with selective pulmonary vasodilator properties.
Vasoreactivity: evidence of acute vasodilation to a pharmacologic agent.

PROCEDURES
A. iNO delivery and safety
   1. Nitric oxide administration will be performed in the intensive care unit (ICU) or Cardiac Cath lab only.
   2. Nitric oxide will be administered via a device (Inovent) that precisely regulates iNO delivery and monitors concentrations of nitric oxide, nitrogen dioxide, and oxygen.
   3. Nitrogen dioxide (NO_2) is a toxic byproduct of nitric oxide and oxygen. If NO_2 levels exceed five (5) ppm, lower concentrations of nitric oxide should be administered.
   4. If methemoglobin levels (MetHb) increase above 5%, iNO should be weaned to a lower dose. Assure that the patient is not receiving other medications that can cause methemoglobinemia, such as dapsone, metoclopramide, sulfonamides, lidocaine, or nitroglycerin. If MetHb levels remain elevated despite iNO reduction, iNO should be discontinued and treatment with methylene blue should be considered.

B. Approved Indications
   1. Vasoreactivity testing in the Cardiac Cath lab is outlined in a separate policy.
   2. Refractory hypoxemia in acute respiratory distress syndrome (ARDS). Early in the course of ARDS atelectatic portions of the lungs are often recruitable. Adjunct therapies including optimum positive end expiratory pressure (PEEP), prone positioning and an open-lung ventilatory strategy may allow reduction of the inspired oxygen concentration to a nontoxic level (≤60%). If the patient remains hypoxemic (PaO_2/FiO_2) <150 despite optimizing ventilatory parameters, iNO administration may be considered.
   3. Pulmonary artery hypertension (PAH).

C. Procedure
   1. An open-lung ventilatory strategy should be utilized, including optimizing PEEP, airway pressure release ventilation (APRV), or high frequency oscillatory ventilation (HFOV), if appropriate.
   2. ABG should be obtained prior to the initiation of iNO. Baseline calculation of PaO_2/FiO_2 will be made and may include hemodynamic measurements, pulmonary artery pressure (PAP) and pulmonary vascular resistance (PVR).
   3. iNO will be started at 10 ppm.
   4. ABG and MetHb analysis will be performed 1 hour after initiation of iNO to determine oxygenation response.
   5. If an ICU patient is being ruled out for pulmonary hypertension and is unable to have a pulmonary artery catheter inserted, response can be assessed by improvement in PaO_2/FiO_2 ratio and/or echocardiography. Echocardiographic or hemodynamic assessment can be made within 10–20 minutes of iNO administration.
   6. iNO response is considered positive if the PaO_2/FiO_2 ratio increases by 20% or if the mean PAP or PVR decreases by 20%.
   7. If there is no response at 10 ppm, a trial of 20 ppm may be conducted. There has been no efficacy demonstrated in this patient population at doses > 20 ppm. Nonresponders will not be continued on iNO.
   8. Responders will be continued on iNO with the goal of reducing the FiO_2 ≤ 60% with an oxygen saturation ≥90%.
   9. Once the FiO2 is lowered to a nontoxic range, iNO should be weaned aggressively as patients responsive to iNO become tolerant over a 96-hour period.
   10. All patients managed with iNO will be evaluated on a daily basis to determine weaning readiness.

D. Weaning
   1. iNO dose should be reduced by half, every 4 hours, keeping the FiO_2 ≤ 60% and SpO_2 ≥ 90% until the dose is 5 ppm. If the MetHb level remains low, SpO_2 monitoring may be used to guide the weaning process.
   2. At 5 ppm wean by 1 ppm, every 2 hours.
   3. If SpO_2 < 90% during weaning process, return to previous nitric oxide level, consider alternative lung recruitment measures, and attempt to wean again in 4 hours
   4. ABG will be obtained 1 hour post wean.

TABLE 49.6

BROCHODILATORS—BETA ADERNERGIC

■ DRUG	■ METHOD	■ STRENGTH	■ DOSAGE
Albuterol	Nebulizer/MDI (metered dose inhaler)	0.5% (5 mg/mL)/90 µg/puff	2.5 mg q4–8 h/2 puffs q4–6 h
Epinephrine	Nebulizer	0.5 mL	1–3 inhalations q3 h
Isoproterenol	Nebulizer	0.5% solution	5–15 inhalations up to 5 times daily
Metaproterenol	Nebulizer/MDI	5.0% (0.3 mL/2.5 mL)/0.65 mg/puff	0.3 mL q4–6 h 2–3 puffs q4 h
Pirbuterol	MDI	200 µg/puff	2 puffs q4–6 h
Racemic epinephrine	Nebulizer	2.25% inhalation solution	**Handheld**-add 0.5 mL to nebulizer, 1–3 inhalations; not more q3 h **Jet**-add 0.5 mL to nebulizer and dilute with 3 mL of NS; administer over 15 min q3–4 h prn
Salmeterol	MDI	50 µg/puff	1 puff q12 h
Terbutaline	MDI	500 µg/puff	1 puff prn, may repeat after 5 min; avoid more than 6 inhalations in a 24 h period.

can be bypassed or its reliance on mechanical ventilation diminished, allowing the heart and the lungs to recover. These circuits usually involve an external roller pump, and either a venous–venous circuit such as femoral–jugular or arterial–venous circuit such as between the femoral artery and either femoral or internal jugular vein. Either circuit is used to retrieve the blood, oxygenate it in an extracorporeal fashion and return the blood back into the systemic circulation. Since this process requires systemic anticoagulation to prevent clot formation, bleeding is a major concern. Its use in adult patients remains controversial, especially with ALI and ARDS.

SURFACTANT THERAPY AND LIQUID VENTILATION

Surfactant therapy uses a recombinant agent to supplement the surfactant, which normally is at the air–liquid interface of the alveoli serving to reduce surface tension.[37–41] It is 90% lipid and 10% protein. Liquid ventilation uses perfluorocarbons rather than gas for respiratory support.[42–48] The use of either of these modalities remains controversial as study results have been mixed when used in patients with ARDS and ALI.

INHALATIONAL THERAPY

Inhaled aerosols delivered directly into the respiratory tract, whether through the ventilator circuit or as a metered dose inhalant by a spontaneously breathing patient, can be effective to deliver medication. The beta-adrenergic bronchodilators are used to treat reversible airflow obstruction conditions such as asthma, bronchitis, or bronchospasm. They relax bronchial smooth muscle, stimulate mucociliary activity, and provide some inhibition on inflammatory mediator release (Table 49.6). Side effects include tachycardia, palpitations, dizziness, nausea, tachyphylaxis, and bronchospasm related to the propellant.

Anticholinergic bronchodilators block cholinergic-induced bronchoconstriction and are used to maintain treatment for bronchoconstriction in such conditions as COPD (Table 49.7). They act as an antimuscarinic agent and a competitive antagonist for acetylcholine. Side effects include dry mouth, pupillary dilation, increased intraocular pressure, tachycardia, urinary retention, and altered mental status.

Aerosolized glucocorticosteroids exert an anti-inflammatory effect and are used in mild to moderate persistent asthma. As the systemic effects are less than those of systemic steroid administration, adrenal suppression is usually not seen. Local side effects include oral candidiasis (Table 49.8).

VENTILATOR-ASSOCIATED PNEUMONIA

Pneumonia has been reported in 10%–48% of patients on mechanical ventilation. VAP is the most common nosocomial infection in the ICU with an incidence of 1–20/1,000 ventilator days, with neurosurgical, surgical, and burn ICUs having the highest rates according to NNIS. VAPs increase ICU length of stay from 4 to 26 days, hospital stay from 13 to 38 days and hospital costs from $21,620 to $70,568. In

Flunisolide	MDI	250 μg/actuation	500 μg bid

general, early onset VAP has a better prognosis and the etiology is less likely due to multidrug resistant pathogens than a VAP that develops many days after intubation. There are a number of factors that may contribute to VAP (Table 49.9). In addition, colonization of ventilator tubing, heat and moisture exchangers, in line medication nebulizers, and suction catheters are possible sources of VAP.

INITIATING MECHANICAL VENTILATION

Once the patient has been intubated and assessed, the mode of ventilation should be selected. Many will begin with an SIMV mode in the acute setting with the FiO_2 set at 100%, a volume set at 6–8 mL/kg of ideal body weight, a rate of 12–16 breaths per minute, and a PEEP of 5 cm H_2O. For ARDS patients, 6 mL/kg is initially chosen. If the patient is not exhaling the volume delivered, the circuit, ET cuff, and ET position all need to be reassessed as does the chest itself with auscultation. If a chest tube is in place and there is evidence of a pleural leak, the mechanical ventilator volume may need to be decreased with the rate increased to maintain the same MVV to decrease the peak, mean, and plateau airway pressures and thus decrease the air-leak. The rate may have to be increased for hypoxemia and hypercarbia and a slower rate given to provide for permissive

hypercapnia, increased IT, or to lower the MVV. A setting of PEEP of 5 cm H_2O is considered physiologic, due the fact that we all breathe against a certain amount of water vapor and this helps avoid absorptive atelectasis. With volume modes of ventilation the inspiratory flow rate is usually set at 40–90 L/minute with rates up to 120 L/minute to improve comfort and decrease inspiratory work.

For pressure ventilator modes where the pressure is set, peak and plateau airway pressures must be followed and if the ventilator pressures for a nonneuromuscular blocked patient reach over 40 cm H_2O, an investigation should be initiated to look for the reason, such as pneumothorax, increased resistance with decreased compliance, air trapping, or another reason that would dictate a decrease in pressure without greatly compromising TV.

WEANING FROM MECHANICAL VENTILATION

There are multiple methods to wean patients from mechanical ventilation. Table 49.10 lists a number of criteria that can be used. If a patient can comprehend instructions and lift his/her head off the bed, it is a crude sign of muscular tone. In addition to clinical exam, a chest radiograph when applicable, acceptable ventilator settings with an acceptable FiO_2, acceptable

TABLE 49.9

INCREASED MORTALITY FACTORS RELATED TO VAP

Antacid or H_2 receptor antagonist use	Duration of mechanical ventilation	Multiple central lines
APACHE II > 18	Higher organ system failure	Nasogastric tube use or enteral feeding
ARDS	Inappropriate antibiotic therapy	Nonsurgical diagnosis
Blood transfusion	Infection with high risk Pathogens	Premorbid lifestyle
Bronchoscopy	*Acinetobacter*	Reintubation
Cardiothoracic surgery	*Methicillin-resistant S. aureus*	Supine head position
Chronic pulmonary disorders	*Stenotrophomonas maltophilia*	Trauma
CNS disorder	*Pseudomonas aeruginosa*	Tracheostomy
Corticosteroid use	Male > 59 years old	

TABLE 49.10

EXTUBATION PARAMETERS

Minute ventilation volume (MVV)	<10 L/min
Negative inspiratory force (NIF)	<–25 cm H_2O
Tidal volume	>5 mL/kg
Rapid shallow breath index (RSBI)	<105
Oxygen saturation (SaO_2)	≥ 92%
Arterial blood gas	If applicable
Chest x-ray	If applicable
Lack of dyspnea	
Lack of accessory muscle use	
Control of agitation	
Control of anxiety	
Control of tachycardia	

arterial blood gases (ABGs) when applicable, pulse oximetry, capnography when present, frequency, TV, and rapid shallow breathing index can all help discern if the patient is ready to be weaned and extubated. Algorithm 49.1 is the protocol currently used at Stony Brook University Medical Center.

CHAPTER 50 ■ CARDIOVASCULAR FAILURE AND CIRCULATORY SUPPORT—MONITORING AND ESSENTIAL ADJUNCTS

JOHN A. MORRIS, MICKEY OTT, FITZGERALD J. CASIMIR, WALTER K. CLAIR, AND MARK GLAZER

The acute care surgery patient is at increased risk of cardiovascular compromise. Whether the trauma patient with severe hemorrhage, or the emergency general surgery patient with peritonitis, these patients encounter fluid "shifts" and a systemic inflammatory response unseen in other areas of surgery or medicine. To optimize patient care, the acute care surgeon must have a firm grasp of the physiology, diagnosis, and management of cardiovascular failure.

Cardiovascular compromise leads to shock, the inadequate delivery of oxygen to supply cellular metabolic needs. In the acute care setting, the patient in cardiovascular failure will present with unique, but identifiable causes of shock that follow a predictable pattern of illness.

- *Hypovolemic shock* related to direct intravascular volume loss from hemorrhage or intravascular volume depletion from sequestration of fluid into the "third space".
- *Septic shock* related to organ dysfunction or hypoperfusion as a result of infection (Discussed in Chapter 12).
- *Cardiogenic shock related to intrinsic cardiac disease* or as a component of multiple organ dysfunction syndrome (MDS), resulting in decreased myocardial contractility that impairs oxygen delivery.
- *Cardiogenic shock related to extrinsic causes* that inhibit the heart from delivering oxygen by affecting preload, afterload, contractility, or a combination of the three.

Treatment of cardiovascular failure is focused on identification of the etiology of shock, and restoration of adequate oxygen delivery. This chapter discusses the determinants of cardiac output and oxygen delivery, techniques to diagnose and monitor the patient in shock, the clinical situations most frequently observed in the acute care setting, and the treatment and support of the patient in cardiovascular failure.

CARDIOVASCULAR PHYSIOLOGY

Oxygen must be uploaded to the blood at the pulmonary capillary level, adequately transported by the heart, and offloaded at the tissue level. Whereas factors such as pH, temperature, and alveolar and capillary membrane permeability will influence these processes, this chapter focuses specifically on the heart's ability to transport oxygen to the tissue (see Box 50.1).

Evaluation of Cardiovascular Performance

Hypotension is the harbinger of cardiovascular collapse. Although vasopressors may be appropriate in certain circumstances, the shock state should be diagnosed and categorized as a problem of preload, afterload, or contractility. Basic monitoring of oxygen saturation, continuous electrocardiography (ECG), and blood pressure measurements are vital, but other adjuncts help address this clinical scenario.

Determination of Preload

Controversy exists over the best method to determine preload.[1-8] In general, each of the devices measures a pressure in an attempt to estimate or correlate with intravascular volume.

Central Venous Pressure. Central venous catheters have the dual benefit of access to large veins for (IV) fluid resuscitation and drug delivery, but also allow the surgeon to estimate intravascular volume. The central venous pressure (CVP) is a measure of the right atrial pressure that is proportional to the right ventricular end-diastolic volume (EDV). This measurement, however, is influenced by a multitude of variables in the critically ill patient. Patients on mechanical ventilation with positive end-expiratory pressure (PEEP) demonstrate decreased venous return from increased intrathoracic pressure. These patients require higher filling pressures to maintain preload. Changes in venous capacitance, intra-abdominal pressure, or heart failure can also affect the accuracy of the CVP. Although CVP is not an exact measurement of intravascular volume, it provides a trend of the intravascular filling pressures, which is a useful guide to resuscitation[6,7,9,10]

Pulmonary Artery Catheter. Despite controversy, the use of the pulmonary artery catheter (PAC) remains widespread in intensive care units[2-6,11-17] One area where the use of the PAC has been demonstrated to improve outcomes is in the trauma population.[18] In a retrospective database analysis examining over 50,000 patients, the use of PAC was shown to improve mortality in three specific groups: (1) patients with Injury Severity Score > 25, (2) patients with initial base deficit >11, and (3) patients older than 61 years of age.[18] Given the similarities between the trauma population and the emergency general surgery population (huge volume shifts over a short period of time, the presence of a systemic inflammatory response, frequent comorbidities, and large number of elderly patients), the use of a PAC to determine adequate perfusion warrants consideration. Moreover, the PAC also provides other hemodynamic data that can potentially assist patient care, and are discussed below.

PULMONARY ARTERY OCCLUSION PRESSURE

Also known as the pulmonary artery "wedge" pressure, the pulmonary artery occlusion pressure (PAOP) approximates the left ventricular EDV. However, in the setting of increased intrathoracic pressure from positive-pressure ventilation,

BOX 50.1

The determinants of oxygen delivery are the amount of oxygen in the blood and how much blood is being pumped to the tissue:

$$DO_2 = CO\ [(Hb \times 1.34)\ SaO_2 + 0.003\ PaO_2]$$

where…

CO = Cardiac output, Hb = Hemoglobin, SaO_2 = Arterial oxygen saturation,

PaO_2 = Partial pressure of oxygen in arterial blood, and DO_2 = oxygen delivery

and…

Cardiac output = Amount of blood pumped by the heart in 1 minute

= Stroke volume × heart rate

Stroke volume is determined by:
- Preload
  - The initial length of myocardial muscle fibers is proportional to the left ventricular end-diastolic volume.
  - As these fibers stretch, the energy of contraction increases proportionally until an optimal tension develops (i.e., ideal preload = ideal cardiac contraction)
- Afterload
  - Resistance to ventricular ejection
  - Measured clinically by blood pressure or SVR.
- Contractility
  - Ability of the heart to alter its contractile strength independent of fiber length (preload)
  - Decreased in intrinsic cardiac disease, contractility initially increased in sepsis but decreases in the later stages of sepsis, myocardial ischemia

structural heart defects, or certain tachyarrhythmias the PAOP becomes less reliable.[19-22]

END-DIASTOLIC VOLUME INDEX

End-diastolic volume index (EDVI) can be calculated based on the right ventricular ejection fraction and cardiac output, and provides an accurate assessment of preload.[23] Cheatham et al.[24] showed in a series of 64 critically ill patients that EDVI correlates more closely to cardiac index than PAOP, when variable levels of PEEP were applied to patients on mechanical ventilation.[24]

TRANSTHORACIC AND TRANSESOPHAGEAL ECHOCARDIOGRAPHY

The use of echocardiography has been investigated as a tool to guide resuscitation in the critically ill patient.[22,25-29] Doppler data on blood velocity and measurements of the vessel diameter of the vena cava can be used to estimate preload. Echocardiography has the added benefit of examination of the heart chambers and cardiac wall motion to estimate cardiac index. It has also becomes a useful tool for the initial evaluation of the trauma patient as part of the Focused Assessment by Sonography in Trauma (FAST) exam to demonstrate cardiac tamponade.[30-35] Handheld ultrasound devices allow measurements of vessel diameter and may help guide resuscitation in critical illness.[28,36,37] Transesophageal echocardiogram has shown promise in initial studies and may replace transthoracic echo as a guide for adequate resuscitation. However, widespread use of echocardiography has been limited by availability, cost, and the skill required for interpretation.

DETERMINATION OF AFTERLOAD

Afterload can be approximated by calculating the systemic vascular resistance (SVR). $SVR = (80)\ (MAP - CVP)/CO$ (where MAP is mean arterial pressure and CO is cardiac output). This can be directly calculated with the use of a PAC. High afterload leads to increased work on the heart and decreased cardiac output. In contrast, cardiovascular failure secondary to a profound decrease in afterload is the classic clinical scenario of distributive shock (e.g., septic shock).

DETERMINING CONTRACTILITY

Exact measurements of contractility are difficult to ascertain. However, the acute care surgeon can use the other above-described tools such as echocardiography or a PAC to estimate contractility. In the hypotensive patient, if values determined for preload and afterload are within normal range, it is assumed that contractility is impaired.

Oxygen Delivery. Perhaps the most important question to answer is, "is enough oxygen being provided to the tissues?" Oxygen delivery can be determined indirectly by measuring products of metabolism and monitoring acid base status, or directly by measuring the oxygen content in the blood returning to the heart. Thus, oxygen delivery is the product of cardiac output and arterial oxygen content.

MIXED VENOUS OXYGEN SATURATION

In the nonstressed setting, only 25%–30% of oxygen delivered to the tissues is actually extracted from the blood. Therefore, the blood returning to the heart from both the upper and lower parts of the body, or the mixed venous oxygen saturation (SVO_2), is normally 70%.[38] In the setting of shock, a low SVO_2 reflects inadequate delivery or increased extraction of oxygen by the tissue. The SVO_2 is most accurately measured at the coronary sinus where there is mixing of blood from the IVC and SVC, but for practical purposes it can be measured from an upper extremity central line or a PAC. SVO_2 can now be monitored in a continuous fashion with the help of continuous cardiac output PACs. Measuring SVO_2 and normalizing SVO_2 during resuscitation has been shown to improve survival.[10]

Lactate and Base Deficit

In the setting of insufficient oxygen delivery, lactate is generated as a result of altered metabolism in the pyruvate kinase

pathway. Serum lactate concentration is an indirect measurement of oxygen debt. The admission lactate, highest lactate concentration, and time required to normalize lactate have all been shown to predict survival.[10,39-43] Base deficit is a measurement calculated, usually from an arterial blood gas, of the amount of alkali required to correct a pH to 7.4 with a $PaCO_2$ of 40. Base deficit has also been shown to correlate with survival in the trauma patient, and both lactate and base deficit can be used as guides to resuscitation.[10,39-43]

Several modalities have also shown promise as alternative measurements to assess cardiac performance:

- *Oxygen extraction index*—A potential variable to measure oxygen delivery[44]
- *Heart rate variability*—A biomarker that potentially can be followed to predict and monitor physiologic reserve in the critically ill patient[45-49]

In summary, the first step in treatment of the acute care surgery patient in cardiovascular failure is to determine why the patient is in failure. Elucidation of the etiology of heart failure as a problem of preload, afterload, or contractility, using the tools above, provides the necessary information to support the patient.

SUPPORT FOR CARDIOVASCULAR DYSFUNCTION

The key to treatment of the patient in cardiovascular failure is restoration of adequate oxygen delivery; think of this as "source control" first. In the case of hypovolemic shock in the trauma patient, the source is bleeding. In the case of infection, the source may be an abscess. In the case of intrinsic cardiogenic shock, the source may be the heart itself. In extrinsic cardiogenic shock, the source may be due to failure of another organ system; an adverse side effect of a medication; or a disease process that negatively affects preload, afterload, or contractility. The earlier the treatment to restore cardiovascular function is begun, the better the patient outcome.

Fluid Resuscitation

After 30 years of active investigation, controversy still exists over the use of crystalloid versus colloid for fluid replacement. Not only does the acute care surgeon need to choose what type of fluid to give, but how much. The danger of too much fluid compartment syndrome, acute respiratory distress syndrome [ARDS], versus the danger of too little fluid, (acute kidney injury tissue ischemia) must be balanced. In general, in the face of hypovolemia and shock, fluid resuscitation should be performed aggressively in the acute setting. On the other hand, resuscitation should be to specific endpoints, rather than undirected fluid infusion. Some data exist that permissive hypotension and minimal fluid resuscitation in the prehospital setting may improve outcomes in trauma patients,[50,51] the theory being that if bleeding has not been controlled, fluid resuscitation and relative hypertension will lead to more bleeding, hemodilution, and coagulopathy. Permissive hypotension assumes rapid transfer from the scene to definitive treatment, and is most applicable to the penetrating trauma population. Further study is necessary before this method can be applied outside of this every specific penetrating trauma population.

In some instances, the choice of fluid must also include the use of blood products. Blood product transfusion is potentially deleterious[52-61] As a simplified rule, when bleeding is the cause of hypotension, blood should be used as the resuscitative fluid. When bleeding is not the cause, it should not be used. Recently, the Eastern Association for the Surgery of Trauma and the Society of Critical Care Medicine published practice management guidelines for red blood cell transfusion in the critically ill[62] (Box 50.2). Another topic, which has

---

BOX 50.2

CLINICAL PRACTICE GUIDELINES: RED BLOOD CELL (RBC) TRANSFUSION IN ADULT TRAUMA AND CRITICAL CARE

■ LEVEL 1	■ LEVEL 2
1. RBC transfusion is indicated for patients with evidence of hemorrhagic shock	4. The use of only Hb concentration as a "trigger" for transfusion should be avoided. Decision for RBC transfusion should be based on individual patient's intravascular volume status, evidence of shock, duration and extent of anemia, and cardiopulmonary physiologic parameters.
2. RBC transfusion may be indicated for patients with evidence of acute hemorrhage and hemodynamic instability or inadequate oxygen delivery.	5. In the absence of acute hemorrhage, RBC transfusion should be given as single units, one at a time.
3. A "restrictive" strategy of RBC transfusion (transfuse when Hb <7 g/dL) is as effective as a "liberal" transfusion strategy (transfusion when Hb <10 g/dL) in critically ill patients with hemodynamically stable anemia, except possibly in patients with acute myocardial ischemia.	6. Consider transfusion if Hb <7 g/dL in critically ill patients requiring mechanical ventilation. There is no benefit of a "liberal" transfusion strategy (transfusion when Hb <10 g/dL) in critically ill patients requiring mechanical ventilation.
	7. Consider transfusion if Hb <7 g/dL in resuscitated critically ill trauma patients. There is no benefit of a "liberal" transfusion strategy (transfusion when Hb <10 g/dL) in resuscitated critically ill trauma patients.
	8. Consider transfusion if Hb <7 g/dL in critically ill patients with stable cardiac disease. There is no benefit of a "liberal" transfusion strategy (transfusion when Hb <10 g/dL) in critically ill patients with stable cardiac disease.
	9. RBC transfusion should not be considered as an absolute method to improve tissue oxygen consumption in critically ill patients.

SURGICAL CRITICAL CARE

received attention, is the ratio of blood products being transfused. Experience from the military suggests that red blood cell concentrates (packed red blood cells, PRBCs) FFP, and platelets should be given in a 1:1:1 ratio in the traumatically injured, exsanguinating patient.[63-68] This research has been confirmed in the civilian population as well by the improved survival demonstrated by the initiation of institutional massive transfusion protocols.[69,70] The ideal ratio among packed red blood cells, fresh frozen plasma, and platelets is still to be determined, but it seems clear that the transfusion of PRBCs alone in the face of bleeding is not as effective as adding the additional clotting factor products; that is, replace what the patient has lost.

Pharmacologic Support

Multiple medications are available to assist the patient in cardiovascular failure, depending on the specific cause (Table 50.1). It is important to remember that these medications have multiple effects on the cardiovascular system. Catecholamine agents (dopamine, dobutamine, epinephrine, norepinephrine) exert their effects through binding to alpha and beta receptors. Activation of alpha-1 receptors increases SVR. Activation of beta-1 receptors leads to inotropy. Activation of beta-2 receptors leads to peripheral vasodilation. Phosphodiesterase inhibitors such as milrinone cause an increase in intracellular cyclic adenosine monophosphate (cAMP), and subsequent inotropy. In general, when the cause of failure is reduced afterload, a vasopressor should be chosen. When the etiology is related to contractility, an inotrope should be used. An algorithm for the management of the patient in cardiovascular failure is presented in Algorithm 50.1. Make sure "the tank is full" (the patient is volumerepleted), and that mean arterial blood pressure, oxygen delivery, and cardiac output are adequate.

In summary:

- A thorough understanding of cardiovascular physiology is a necessity for the acute care surgeon.
- When treating the patient in cardiovascular failure, first determine whether the problem is one of preload, afterload, or contractility, and their effect on oxygen delivery.

- By using adjuncts such as a PAC, measuring pressures such as CVP or PAOP and measuring markers of oxygen delivery such as SVO_2, lactate, and base deficit, the acute care surgeon can guide the resuscitation of the patient in cardiovascular failure.
- Once the cause of the cardiovascular failure is recognized, "source control" is the key to treatment. Through the use of fluid resuscitation, vasopressor, and inotropic support, the acute care surgeon may return the critically ill patient to his/her normal physiologic state.

CLASSIFICATION OF CARDIOVASCULAR FAILURE

The acutely ill surgical patient may develop cardiovascular failure from a variety of pathologic causes. These disease processes can be simply classified into either *intrinsic* or *extrinsic* causes of heart failure. Intrinsic causes of cardiovascular failure stem from a disease of the myocardium, the heart valves, or the conducting system of the heart. Extrinsic causes of cardiovascular failure occur in the presence of a structurally normal heart; however, an external source impedes contractility or negatively affects afterload or preload. Although their etiologies differ, both extrinsic and intrinsic causes prevent adequate oxygen delivery in light of increased metabolic demand.

Intrinsic Cause of Cardiovascular Failure

There are four basic causes of intrinsic cardiovascular failure in the postoperative patient. These include myocardial ischemia, congestive heart failure (CHF), valvular heart defects, and cardiac arrhythmias. Patients with intrinsic cardiovascular failure suffer from a substantial increase in perioperative morbidity and mortality in the setting of acute surgical illness (see Table 50.2).

Myocardial Ischemia and Infarction. Myocardial infarction (MI) occurs in 5%–7% of postoperative elective general surgery patients, but is associated with a mortality

TABLE 50.2

RISK STRATIFICATION OF NONCARDIAC SURGICAL PROCEDURES

High cardiac risk > 5%	Aortic repair and major vascular repair, esophagectomy
Intermediate cardiac risk 1%–5%	Intraabdominal Intraperitoneal, thoracic, carotid endarterectomy, head and neck surgery, orthopedic surgery, prostate surgery
Low cardiac risk <1%	Endoscopic procedures, subcutaneous procedures, ophthalmologic surgery

as high as 40–70% in the symptomatic patient.[71] The acute care general surgery patient is two to five times more likely to suffer from cardiovascular complications when compared to age-matched controls undergoing similar procedures on an elective basis.[71] The risk of postoperative MI is highest from the time of surgery through the first 3 postoperative days. This may correlate with increased perioperative fluid shifts accompanied by an increase in circulating catecholamines, leading to a supply/demand mismatch of the myocardium. In addition, the hypercoagulable state induced by recent surgery increases the risk of coronary artery thrombosis.[71-73]

DIAGNOSIS OF POSTOPERATIVE MI

Insidious in the postoperative period, MI can be misdiagnosed without a heightened level of suspicion. There are four risk factors for perioperative MI: (1) the presence of preoperative cardiac risk factors, (2) perioperative hypotension, (3) new onset ST or T wave changes, and (4) large intraoperative blood loss necessitating transfusion.[71,72,74] Unlike the elective general surgery patient, diagnostic testing and risk stratification in the acutely ill surgical patient often occurs *after* the operation. It is imperative that patients with a history of MI, diabetes mellitus, hypertension, or stroke be monitored with postoperative 12-lead ECG's and cardiac enzyme determination. Only 50% of postoperative MI patients present with classic anginal symptoms. ECG and cardiac enzymes are useful screening tests. The 99th percentile of the normal value range for both troponin and CK-MB is the cut off value for the diagnosis of acute MI. Transthoracic echocardiography (TTE) provides additional information such as preservation of left ventricular function, the presence of a ventricular aneurysm, or wall motion abnormalities, all of which affect postoperative management. Other signs of acute MI include a fixed defect on echocardiogram or radionuclide perfusion scan, new pathologic Q waves, or perioperative arrhythmia or hypotension.

CLASSIFICATION OF ST SEGMENT ELEVATION VERSUS NON–ST SEGMENT ELEVATION MI

In addition to the patient's hemodynamic status, treatment of an acute MI is directed by the presence or absence of ST segment elevation on ECG.[72,74-76] A non–ST segment elevation MI (NSTEMI) is initially managed with medical therapy. If there is not an adequate response to medical therapy, coronary angiography may be necessary. In addition to medical therapy, an ST segment elevation MI (STEMI) will require emergent coronary angiography to determine need for coronary revascularization. The absence of ST elevation (NSTEMI) indicates reversible subendocardial ischemia from partial occlusion

of the coronary artery. The presence of acute ST elevation (STEMI) indicates complete occlusion of the coronary artery with transmural infarction of the myocardium. The patient with acute ST elevation is at risk to develop irreversible myocardial damage if reperfusion does not occur quickly. These patients suffer from ventricular aneurysm, papillary muscle rupture, or ventricular arrhythmias and are at increased risk for sudden cardiac death.

THE DILEMMA OF POSTOPERATIVE BLEEDING IN ACUTE TREATMENT OF MI

Due to concern of postoperative bleeding, there is a paucity of class 1 data on the treatment of postoperative MI in the acute care surgery patient population. We advocate postoperative antiplatelet therapy with or without anticoagulation in the treatment of acute MI for the following reasons. The mortality of postoperative MI in the acute care surgery population is 40%–70%.[72-76] With the exclusion of neurosurgical procedures, the mortality of postoperative anticoagulation in the noncardiac surgical population is low. However, the morbidity is not inconsequential, leading to major increase in postoperative hemorrhage and reoperation rates.

MEDICAL MANAGEMENT OF ACUTE MYOCARDIAL INFARCTION

Multiple medical treatments should be initiated once the diagnosis of postoperative MI has been made. These include antiplatelet therapy, systemic anticoagulation, beta-adrenergic blockade, adequate analgesia, statin therapy, and mechanical adjuncts for treatment of cardiogenic shock.[72-74,76]

Antiplatelet therapy is the gold standard for the treatment of acute coronary syndrome and has been shown in randomized clinical trials to decrease mortality when administered early in the course of MI in the general population.[74,77,78] *Aspirin and clopidogrel* are currently the most commonly used antiplatelet agents. Aspirin directly inhibits cyclooxygenase and is an inhibitor of thromboxane synthesis. Clopidogrel inhibits platelet aggregation via the adenosine diphosphate (ADP) pathway and offers greater survival benefit than the use of aspirin alone. The risk of postoperative bleeding with the use of both drugs is substantial. There are no randomized trials that clearly delineate the risk:benefit ratio of postoperative antiplatelet therapy in the acute care surgery patient. There are, however, class II data that support the therapeutic benefit of aspirin therapy in the treatment of acute MI in the noncardiac surgery patient.[72-74] Aspirin therapy may increase the risk of re-operation for postoperative bleeding but there has been no demonstrated increase in mortality from this. Antiplatelet therapy must also be considered postendovascular intervention. Recommendations for antiplatelet therapy after percutaneous coronary intervention are described elsewhere in this chapter (Table 50.3).

Anticoagulation with unfractionated or low molecular weight heparin is considered an adjunct to antiplatelet therapy. These agents inhibit fibrinolysis, leading to thrombin generation in acute coronary syndrome. For this reason, the low molecular weight heparins may afford an advantage of being direct thrombin inhibitors. Their disadvantages may be their long half-life and accumulation in renal insufficiency, which may be problematic in the case of postoperative bleeding.

BETA-BLOCKER THERAPY

The benefits of beta-blockade, when appropriately used in the treatment of acute MI, have been detailed in the literature.[71] Beta-blockers decrease tachycardia, ventricular arrhythmias, increase preload and have been proved to decrease the perioperative mortality by 28% in the first week, with the

TABLE 50.3

AMERICAN HEART ASSOCIATION/AMERICAN COLLEGE OF CARDIOLOGY RECOMMENDATIONS FOR ANTIPLATELET THERAPY AFTER PERCUTANEOUS CORONARY INTERVENTION (STENT PLACEMENT) IN THE PERIOPERATIVE PERIOD

■ PERCUTANEOUS INTERVENTION	■ ANTI-PLATELET THERAPY	■ TIME OF DELAY OF OPERATION
Angioplasty	Monotherapy[b]	2–4 wk elective surgery, immediately for urgent or emergent surgery
Bare metal stent	Dual therapy for 4 wk followed by monotherapy Monotherapy in surgical emergency	4–6 wk ideally, 2 wk for urgent surgery, immediate or emergent surgery however increases risk of stent occlusion 0.1% in retrospective data
DES (sirolimus)	Dual therapy[a] for 3 mo if no bleeding risk	3 mo elective surgery 3 mo nonelective surgery rethrombosis rates of 0.35%–2.60% (retrospective data)
DES (paclitaxel)	Dual therapy[a] for 6 and 12 mo if no risk of rebleeding	6 mo

Recommendations for antiplatelet therapy poststent placement.
[a]Dual therapy, aspirin plus thienopyridine (ticlopidine or clopidogrel).
[b]Monotherapy, aspirin.

most benefit achieved in the first 48 hours. All patients previously placed on a beta blocker should continue beta blockade in the peri-operative period. Premature discontinuation of beta blockade in the perioperative period is associated with an increased risk of MI.

Morphine provides analgesia and has a cardioprotective effect in patients with NSTEMI.[72,74] It decreases sympathetic tone, reduces heart rate, and lowers blood pressure. Morphine may also offer some benefit in treatment of acute pulmonary edema. Its vasodilator effects decrease afterload and left end-diastolic pressure, thus increasing cardiac output. Its vasodilatory effects, however, may induce hypotension. In addition, excessive use of narcotics in the postoperative setting has been associated with prolonged mechanical ventilation and increased length of ICU stay.[72,73]

Prophylactic use of nitroglycerin may provide symptomatic relief of anginal symptoms but does not provide a meaningful increase in survival benefit.[72-74] Indiscriminate use of nitroglycerin in the postoperative period has been associated with increased risk of hypotension.

HMG-CoA reductase inhibitors or statins have been shown to decrease mortality at 6 months to a year in patients who are considered to be at high coronary risk.[72-74] In addition, they have been shown to decrease the incidence of sudden cardiac death. Patients who have been on statin therapy previously should continue with it in the perioperative period. For patients undergoing vascular surgery with at least one coronary risk factor, the addition of statin therapy may afford meaningful survival benefit.[72-74]

Angiotensin concerting enzyme (ACE) inhibitors have also been shown to reduce morbidity in acute MI.[72-74] The greatest therapeutic benefit is in patients with a decreased left ventricular ejection fraction (<45%) and symptoms of heart failure. In addition patients who have suffered an acute MI with preexisting hypertension or documented mitral regurgitation have an elevated risk of developing ischemic cardiomyopathy, and should be started on an ACE inhibitor within 48 hours of the acute ischemic event.

There are currently no randomized clinical trials that clearly define the therapeutic benefit of cardiac catheterization in the postoperative acute general surgery patient. Indications for catheterization are listed in Table 50.4 and a decision tree regarding catheterization of the postoperative patient is presented in Algorithm 50.2.[72,74,76-78]

MECHANICAL ADJUNCTS IN THE TREATMENT OF ACUTE MYOCARDIAL INFARCTION

Intraaortic balloon pump (IABP) therapy may be necessary in the event of refractory cardiogenic shock. It decreases afterload and increases coronary perfusion. It can be used as an adjunct to reperfusion therapy because it preserves left ventricular function. IABP is contraindicated in patients with previous documented aortoiliac occlusive disease or previous

TABLE 50.4

lower extremity bypass. Upon placement of an IABP, frequent peripheral vascular monitoring is mandatory.[79-81]

As a last resort, emergent venoarterial extracorporeal membrane oxygenation (ECMO) may be used as rescue therapy in the treatment of cardiogenic shock or cardiac arrest secondary to myocardial ischemia.[40,81-83] This may be required in the rare patient population with refractory cardiogenic shock despite maximal inotropic and intraaortic balloon pump support. ECMO may function as a bridge to revascularization therapy or as treatment for myocardial stunning secondary to reperfusion injury. This therapy requires anticoagulation and cannulation of the femoral artery, and may comprise lower extremity circulation. In addition, ECMO does not offload the left ventricle and is contraindicated in aortic regurgitation.

Finally, of growing interest in the acute care surgery patient is the phenomenon of "troponin leak" in the physiologically stressed and injured patient.[84-86] A poor choice of terminology once believed to be related to actual cardiac trauma, it is now being recognized that elevated troponin I concentrations can be found in patients with no previous history of ischemic heart disease and no evidence of mechanical trauma to the heart. The phenomenon likely correlates with the physiologic burden of

the disease state, but scientific evidence is lacking in regards to effect on outcome. A thorough work up for acute MI is warranted in the patient with elevated troponin until the phenomenon is more clearly defined.

In summary:

- Acute myocardial ischemia is a major cause of morbidity and mortality in the acute care surgery patient.
- Acute surgical illness leads to an inflammatory cascade causing a oxygen/perfusion supply/demand mismatch of the myocardium.
- Rapid surgical correction of underlying disease and prompt treatment of myocardial ischemia according to American Heart Association (AHA)/American College of Cardiology (ACC)/AC guidelines is imperative.
- Initial medical management should include beta blockade, antiplatelet therapy with or without anticoagulation, adequate analgesia, and a high-dose statin.
- The presence of acute ST elevation, worsening anginal symptoms, or hemodynamic compromise with increasing cardiac enzymes concentrations warrants coronary angiography to determine the need for angioplasty/stent placement.
- With the exception of the neurosurgical population, postoperative anticoagulation for acute MI is problematic but

seldom fatal, whereas the mortality of untreated postoperative MI is high, generally favoring anticoagulation in the risk:benegit analysis.

- In refractory cases of cardiogenic shock, mechanical adjuncts such as placement of a IABP or ECMO may be necessary.

CONGESTIVE HEART FAILURE

Nearly 5 million people have been diagnosed with CHF and it is estimated that 500,000 new cases of CHF will be diagnosed in the United States annually. It is a common diagnosis in elderly patients, and as the population continues to age, these patients will comprise a major portion of the acute care surgery practice.

CHF is defined as a clinical syndrome that impedes the filling or emptying of the left or right ventricle and can be categorized as either right- or left-sided CHF.[72,73,87] Abnormalities of ventricular emptying are termed as systolic dysfunction whereas abnormalities of ventricular filling are referred to as diastolic dysfunction. Left-sided systolic dysfunction is the most common cause of heart failure, and is caused by impaired contractility or increased afterload. Example of systolic dysfunction from increased afterload, include hypertension and aortic stenosis. Inability of the ventricles to fill at normal pressures represents diastolic dysfunction. An example of diastolic dysfunction include left ventricular hypertrophy cardiomyopathy. Both systolic and diastolic dysfunction lead to a clinical syndrome of dyspnea, exercise intolerance, fluid retention, and pulmonary edema. Right-sided heart failure is uncommon, but it carries substantive mortality, particularly in the postoperative patient. Acute right-sided heart failure is caused by a sudden increase in afterload due to a decrease in compliance of the pulmonary artery, or intrinsic lung disease. However, the most common cause of right-sided heart failure is chronic pulmonary venous congestion from left-sided heart failure.

Uncontrolled hypertension is the most common cause of left sided CHF. Aortic stenosis is the second most common cause of left-sided heart failure. Diastolic dysfunction, impairment of left ventricular filling in diastole, is characterized by a decrease in left ventricular stroke volume, thus leading to decreased cardiac output. These patients are extremely preload dependent. Because they cannot increase stroke volume, their only compensatory mechanism to increase oxygen delivery tachycardia. This maladaptive mechanism leads to increased myocardial ischemia. Hypertrophic obstructive cardiomyopathy, left ventricular hypertrophy, ischemic cardiomyopathy of the left ventricle, mitral stenosis, or pericardial tamponade cause diastolic dysfunction.

Right-sided heart failure is less common than left-sided heart failure because the right ventricle is thinwalled and highly compliant. It is able to accept a wide range of filling volumes without an increase in the end-diastolic pressure. The right ventricle is susceptible to failure when there is a sudden increase in afterload. The three major causes of right-sided heart failure are: parenchymal pulmonary disease, primary pulmonary hypertension and pulmonary embolism. Treatment of right-sided heart failure entails successfully treating the underlying cause. Acute onset of pulmonary edema secondary to right ventricular overload should be cautiously treated with diuretic therapy. Hypoxia worsens pulmonary vasoconstriction and can worsen the effects of pulmonary hypertension. Close attention should be given to maintenance of arterial oxygen saturation. In patients with chronic obstructive pulmonary disease and pulmonary hypertension, it is important not to suppress the respiratory drive with too much oxygen therapy. In addition, this patient population will benefit from treatment of bronchospasm with beta agonist therapy, and occasionally parenteral steroids. Several medications may afford some benefit in primary pulmonary hypertension; these include calcium channel blockers and pulmonary vasodilators.

The medical treatments of heart failure includes diuretics, vasodilators, beta blockers, and drugs that inhibit the renin–angiotensin–aldosterone pathway. Fluid status and adequate perfusion should be optimized prior to administration of drugs, as the majority of heart failure regimens may exacerbate the hypotension of cardiogenic shock. If the patient is symptomatic from hypertensive heart failure with pulmonary venous congestion from volume overload, diuretics are the initial treatment. In the euvolemic hypertensive heart failure patient, peripheral vasodilators are useful. In the patient with ischemic cardiomyopathy, a beta blocker may be beneficial. Once the patient is stabilized on a beta blocker or loop diuretic, long-term therapy with an ACE inhibitor or angiotensin receptor blocker (ARB) should be initiated. Aldosterone inhibitors can be used in conjunction with the standard regimen of a beta blocker, ACE/ARB inhibitor, and loop diuretic in patients with refractory hypertensive heart failure. Digoxin was the mainstay of treatment of CHF historically and may be considered in the treatment of chronic CHF with associated atrial fibrillation. This provides a general treatment algorithm, but in the case of refractory CHF, early cardiology consultation is warranted.

Takotsubo cardiomyopathy, also known as stress-induced cardiomyopathy or "broken heart" syndrome, is a non-ischemic cardiomyopathy that causes transient weakening of the myocardium.[88,89] The usual presentation of chest pain, ST-segment changes, and cardiac enzyme abnormalities can be observed in this type of cardiomyopathy. The characteristic "apical ballooning" can often be observed by echocardiography. The etiology is unclear, but is likely multifactorial and related to the myocardial response to circulating catecholamines. It is most common in women, especially those who have undergone extreme emotional distress, or an accumulation of multiple physiologic stresses. We make special note of this rare disease process that is being diagnosed with increasing frequency in our acute care surgery patient population. Treatment is supportive and includes the diagnostic and therapeutic modalities discussed above.

In summary:

- CHF is a major cause of morbidity and mortality in the acute care surgery patient.
- There are four categories of CHF based on the location and function of the ventricles. It is either left-sided or right-sided, or an abnormality of filling (diastolic dysfunction) or emptying (systolic dysfunction).
- Cardiovascular medications used in the treatment of heart failure decrease preload (diuretics); decrease afterload (vasodilators, ACE/ARB inhibitors), or increase contractility ACE/ARB inhibitors, digoxin.

VALVULAR HEART DISEASE

Valvular heart disease is common and responsible for nearly 10% of heart failure in the United States.[90] Its prevalence continues to increase as average life expectancy increases. The severity of a patient's valvular disease may determine the patient's ability to survive an operation. When the severity of the patient's valvular disease outweighs the benefits of a high-risk operation, the acute care surgeon should reconsider the risk:benefit of surgical options. For example, placement of a cholecystomy tube, percutaneous drainage of an intra-abdominal abscess, or fecal diversion with a transverse loop colostomy are temporizing procedures, but may provide adequate source control in a moribund patient. If

SURGICAL CRITICAL CARE

the operative procedure cannot be delayed, hemodynamic assessment tools such as transesophageal echocardiography (TEE) or the PAC may be essential in perioperative management (Refer to previous section on "Evaluation of Cardiac Performance"). Staffing the operative case with an anesthesiologist comfortable with TEE or emergent consultation of the interventional cardiologist may be necessary to optimize patient outcome.

Aortic stenosis is the most common valvular lesion and is most often caused by degenerative calcific disease.[90,91] The diagnostic criteria for critical aortic stenosis include an aortic valve area <0.8 cm^2 or trans-valvular gradient >50 mm Hg. Risk factors include male gender, age >65 years, hypertension, and cigarette smoking. In the asymptomatic patient, the acute care surgeon should proceed if the procedure is considered to be of low or moderate risk (Table 50.1) without further testing. If the surgery is considered highrisk, or if the patient is symptomatic, intraoperative TEE and placement of a PAC may be advisable. Particular attention should be given to the gradient across the aortic valve and evidence of left ventricular hypertrophy. Untreated severe aortic stenosis carries an intraoperative mortality of 10% and a relative risk for 1.55 of perioperative MI for an elective noncardiac surgical procedure.[90,91] An interventional cardiologist should be consulted to discuss percutaneous valvuloplasty as a therapeutic option if the patient's left ventricular failure worsens despite maximal medical therapy. Data on percutaneous valvuloplasty in the adult population shows only temporary improvement of symptoms.[90,91] It also carries a complication rate of 10% with no increase in long-term survival. Its primary function is to serve as a bridge to aortic valve replacement.

Aortic regurgitation can be caused by various etiologies such as a bicuspid aortic valve, rheumatic fever, or infective endocarditis.[90,91] An asymptomatic patient with preserved left ventricular function is considered to be lowrisk. These patients most likely have chronic aortic regurgitation, where left ventricular dilation adequately compensates for increased LVEDV. If a patient is symptomatic or has decreapressed left ventricular function, they are at elevated risk of perioperative complications such as acute onset of CHF.

Mitral stenosis is most commonly caused by rheumatic heart disease. Symptoms include orthopnea, paroxysmal nocturnal dyspnea, and hoarseness caused by compression of the recurrent laryngeal nerve by the left atrium. Mitral valve fusion leads to an increase in the left atrial pressure and increase in the pulmonary vascular pressure. A mitral valve area of <1 cm^2 is considered critical.[72,73,90,91] This leads to an inability of the left atrium to effectively empty, causing pulmonary venous congestion. Impedance of pulmonary venous flow leads to elevated pulmonary artery pressures. This mechanical cause of pulmonary hypertension may lead to right-sided heart failure. These patients are very sensitive to preload and benefit from perioperative beta blockade with adequate but not excessive volume resuscitation. Measurement of pulmonary wedge pressure, EDVI, and CVP are essential for perioperative management of mitral stenosis. Bedside TTE to determine left atrial dilation, LVEF, or respiratory variation of inferior vena cava diameter on echocardiogram also provides clinically useful information. Patients with a mitral valve area <1.5 cm^2 and a gradient of >5 mm Hg without evidence of a mural thrombus may be considered for balloon valvuloplasty.

Mitral regurgitation is the second most common valvular heart defect and is primarily caused by myxomatous degeneration.[90,91] Myocardial ischemia causing left ventricular remodeling or papillary muscle rupture is the second most common cause of mitral regurgitation. This is a high-risk population. Without surgical valve repair these patients have a 5-year survival of 19%–36%. Patients present with dyspnea on exertion with a holosystolic murmur that radiates to the axilla. Increased left atrial pressure leads to left atrial distension causing atrial fibrillation. These patients should be anticoagulated owing to increased risk of thromboembolic disease. It is important to differentiate chronic mitral regurgitation from acute-onset mitral regurgitation. In chronic mitral regurgitation, the left ventricle is distended and unable to accommodate the increased volume of the enlarged left atrium. In acute mitral regurgitation, there is discordance between the left ventricle and left atrium leading to left-sided heart failure and acute pulmonary edema. These patients are sensitive to fluid overload and may benefit from diuretics and afterload reduction.

Pathologic tricuspid regurgitation secondary to right ventricular failure is more common than primary valvular disease. Right ventricular overload, atrial septal defects, idiopathic pulmonary hypertension, or massive pulmonary embolism are causes of tricuspid regurgitation.[90,91] Treatment of tricuspid regurgitation often involves treatment of the underlying pathology leading to right-sided heart failure.

In summary:

- The elderly patient with pre-existing valvular heart disease is becoming more common in the acute care surgery practice.
- To limit perioperative morbidity and mortality the acute care surgeon must choose the operation based on the patient's physiologic reserve.
- In addition, success in this often-moribund population depends not only on the skill of the surgeon, but also on the foresight necessary to generate a treatment plan which includes capable operative staff, comprehensive critical care, and timely consultation.

Arrhythmias in the Postoperative Patient. Postoperative arrhythmias may be the continuance of preoperative (known or unknown) electrical abnormalities of the patient's cardiac electrical system. Alternatively, they may be related to or a consequence of the patient's surgery. Preoperative symptomatic arrhythmias are considered major predictors of perioperative risk; arrhythmias after cardiothoracic surgery are particularly common. The causes of postoperative arrhythmias are often multifactorial, but may be related to increased sympathetic tone, ischemia, postoperative fluid shifts, and electrolyte abnormalities that destabilize the myocardium membrane. Acute care surgeons must recognize that arrhythmias in the immediate postoperative period may indicate an undiagnosed intraoperative complication. If so, these patients may continue to deteriorate in spite of medical management without prompt surgical re-intervention.

One approach to managing postoperative arrhythmias in the acute care surgery patient is to classify them into one of three categories: benign; potentially troublesome; or dangerous. Using this classification we will discuss specific arrhythmias with their treatments.

BENIGN

Sinus tachycardia, atrial premature beats, and premature ventricular beats are typically benign. Increased sympathetic tone, missed doses of preoperative antiarrhythmic medications, postoperative fluid shifts, electrolyte abnormalities, sepsis, anemia, and postoperative pain are possible causes of these arrhythmias in surgical patients. The treatment is to identify the underlying cause and rectify it. Although listed as benign, sinus tachycardia is the most consistent sign of an enteric leak in the early postoperative period and may

be an indicat or of a need for reexploration. Asymptomatic bradycardia, first-degree (AV) block or type 1 second-degree atrioventricular (AV) block (Wenckebach block) may also be observed in the postoperative patient, especially in the setting of preexisting sinus node disease, enhanced vagal tone related to nausea, pain, or narcotic medication. These arrhythmias are only specifically treated (see Dangerous below) when they result in hemodynamic compromise.

POTENTIALLY TROUBLESOME

Supraventricular arrhythmias (atrial fibrillation, atrial flutter, paroxysmal supraventricular tachycardia [PSVT] or multifocal atrial tachycardia [MAT]) and nonsustained ventricular tachycardia may have as their cause many of the same factors as the usually "benign" arrhythmias. Nonetheless, they require a more urgent assessment and imply that the patient's cardiac status may be more compromised than expected. Additionally, these arrhythmias are more likely to stress the patient's heart or lead to hemodynamic problems.

Atrial fibrillation is the most common postoperative supraventricular arrhythmia and is an insidious cause of postoperative morbidity. Tachycardia from atrial fibrillation leads to increased myocardial demand and stagnant blood flow in the fibrillating atria promotes mural thrombus formation with the potential for thromboembolic complications. In a hemodynamically unstable patient (chest pain, hypotension, altered mental status, shock) with atrial fibrillation the treatment of choice is direct-current synchronous cardioversion. In the more stable patient, the initial management is rate control with a calcium channel blocker (e.g., verapamil) or beta blocker (e.g., metoprolol), followed by pharmacologic conversion to sinus rhythm (e.g., amiodarone); digoxin is used rarely but may control both rate and rhythm. Consideration of anticoagulation while precipitating causes are sought and addressed if sinus rhythm cannot be restored within 24-48 hours. Immediate cardioversion is also the appropriate approach to poorly tolerated PSVT or atrial flutter. However, MAT must be distinguished from atrial fibrillation, as MAT is likely to recur immediately if the underlying cause is not corrected. At times, an unmonitored patient is found to be in atrial fibrillation of unknown duration. This may happen when an ECG is done because of an irregular pulse or a change in the patient's clinical status. If the atrial fibrillation is not definitively confirmed to have been present for <48 hours and the patient has not been fully anticoagulated, it is safest to cardiovert with drugs or direct electrical current only after a transesophageal echocardiogram excludes a thrombus. If a thrombus is present, cardioversion should be deferred and the patient should be anticoagulated and simply rate-controlled with a beta blocker or calcium channel blocker. The cumulative risk of thromboembolism from atrial fibrillation is 1% per year or more depending on other risk factors such as CHF, hypertension, age >75 years, diabetes, or prior stroke. The acute care surgeon must weigh this against the risk of bleeding with anticoagulation.

Atrial flutter is treated in the same manner as atrial fibrillation, except that there may be a greater role for digoxin. On the other hand PSVT, which is a narrow-complex QRS tachycardia, may be initially diagnosed medically with the administration of adenosine; AV nodal reentry the tachycardia will break. In the case of an atrial tachycardia or atrial fibrillation or flutter, the transitory blockade of the AV node induced by adenosine will allow atrial activity to be parsed more clearly. Then with metabolism of adenosine, AV conduction and the tachycardia will resume within seconds. At this point, oral or intravenous calcium channel blockers or beta blockers can be used to slow the tachycardia.

Nonsustained ventricular tachycardia (VT lasting <30 seconds) in the early postoperative period must be treated as stress on the heart that may be related to a surgical complication until proven otherwise. While a surgical complication is being sought, the acute care surgeon should initiate a prompt work up for ischemia, hypoxia, and electrolyte abnormalities. In addition, central venous catheters that are advanced too far can irritate the ventricle and precipitate ventricular arrhythmias.

DANGEROUS

Sustained wide-complex QRS tachycardias are likely to compromise the postoperative patient and need to be managed emergently because of the difficulty of distinguishing between sustained VT and PSVT with aberrant conduction. If the patient is stable, a 12-lead ECG should be obtained while consultation is being requested from a cardiologist or cardiac electrophysiologist. Amiodarone-IV may be initiated and is unlikely to compromise the patient's evaluation and management. If the patient becomes hypotensive or pulseless with a wide-QRS tachycardia, immediate initiation of advanced cardiac life support protocols is mandatory.

Bradycardia with evidence of poor perfusion such as hypotension, shock, chest pain, or altered mental status is another situation in which one must be able to immediately initiate the advanced cardiac life support protocol. This would include the use of atropine, epinephrine, or dopamine. It may also require the use of transcutaneous or temporary transvenous pacing.

Ventricular fibrillation and pulseless electrical activity are the most catastrophic postoperative arrhythmias and clearly call for initiation of the appropriate resuscitation protocols. If the precipitant is in doubt and the patient continues to decline despite medical intervention, surgical exploration should be considered.

In summary:

- Acute surgical illness incites an inflammatory cascade that leads to multiple physiologic derangements, which destabilize the myocardium, leading to postoperative arrhythmias.
- A useful approach is to classify these arrhythmias as benign (sinus tachycardia, sinus bradycardia, premature atrial or ventricular beats); potentially dangerous (atrial fibrillation, atrial flutter, PSVT, and MAT), or dangerous (ventricular tachycardia and ventricular fibrillation)
- In addition to initiation of resuscitation protocols, the acute care surgeon must rectify the initiating pathologic condition.

Extrinsic Causes of Cardiovascular Failure. Pulmonary embolism is diagnosed in 650,000 new cases every year and is a major cause of morbidity and mortality in the postoperative patient.[72,73] Patients with a previous history of pulmonary embolism, recent surgery, or diagnosed hypercoagulable state are at increased risk. Physical examination is often unreliable but patients may present with tachycardia, tachypnea, or acuteonset of lower extremity swelling. The most common ECG abnormality is sinus tachycardia. In the case of a massive pulmonary embolism, the classic pattern of S1-Q3-T3 pattern of right heart strain may be present. Spiral computed tomography (CT) is the gold standard for diagnosis. In the unstable patient, an echocardiogram may be useful to exclude the presence of a massive pulmonary embolus. Treatment of acute pulmonary embolism requires prompt administration of anticoagulation with unfractionated or low-molecular-weight heparin. Massive pulmonary embolism with associated right heart failure may require operative or endovascular embolectomy. Thrombolytic therapy, although

described, is not practical in the early postoperative patient because of a very high risk of bleeding.

FAT OR AIR EMBOLISM

Patients with long bone fractures are at increased risk of fat embolization to the pulmonary arterial system. Moreover, those patients undergoing orthopedic surgery are at an increased risk of fat embolism in the postoperative period. This disease process presents with the triad of hypoxemia, neurologic abnormalities, and a characteristic petechial rash. Chest CT scan may show focal areas of ground glass opacification and lobar thickening. On fundoscopic exam patients may have "cotton wool" spots as a result of fat deposition in the retinal vessels; treatment is supportive.

Air embolism is a rare, but life-threatening emergency in the perioperative period. Increasingly, the acute care surgery patient is being treated with laparoscopy for their disease process. Other potential causes include major hepatic surgery or major head and neck surgery. With insufflation and the establishment of pneumoperitoneum, air may enter the venous system and embolize to the heart. Clinically the patient will present with hypotension and tachycardia. On physical examination, the patient may demonstrate the classic "mill wheel" murmur embolus. Treatment is placement of the patient in Trendelenburg position with the right side up to avoid further embolization and to avoid obstruction of the pulmonary outflow tract. Evacuation of the air by aspiration from a PAC or central venous catheter can then be attempted.

TENSION PNEUMO-OR HEMOTHORAX

Trauma patients frequently present with hemo- or pneumothoraces; as the amount of blood or air increases in the pleural space, the patient is at an increased risk to develop tension pneumothorax. This results from a decrease in venous return to the heart. Iatrogenic pneumothorax is associated with central venous catheter placement; sudden decompensation in this patient population should trigger an immediate needle decompression followed by tube thoracostomy. Because of the clinical urgency, remember that tension pneumothorax should be a clinical diagnosis, not one made by imaging.

THYROID DYSFUNCTION

Patients with abnormalities of thyroid function often have myocardial dysfunction and are at risk for development of a dilated cardiomyopathy.[73] Hyperthyroidism has been associated with new-onset atrial fibrillation and ventricular arrhythmias. Hypothyroidism can lead to decreased contractility and left-sided heart failure if left untreated. Treatment is aimed at restoration of the patient to the euthyroid state.

ADRENAL INSUFFICIENCY

Elevated circulating concentrations of corticosteroids are part of the normal response to critical illness. However, those patients unable to mount this physiologic response can develop profound cardiovascular failure. Relative adrenal insufficiency is an important cause of cardiovascular failure in the acute care surgery population.[73,92-94] These patients fail to increase their cardiac output due to inappropriately low concentrations of cortisol in the face of acute surgical illness. They may exhibit profound hypotension due to vasodilatory shock despite maximal vasopressor therapy. The diagnosis of adrenal insufficiency can be made by measurement of serum cortisol, or by performing a cosyntropin (corticotropin [ACTH] analogue) stimulation test. Treatment of relative adrenal insufficiency with intravenous corticosteroids, (hydrocortisone 50 mg IV q6-8h) with or without mineralocorticoids, (fludrocortisone 50 mcg qd), has been shown to decrease mortality and vasopressors requirements when compared to placebo in randomized clinical trials.[95-100] However, several other studies have failed to confirm this effect. In addition, prolonged steroid use in the postoperative patient may lead to impaired wound healing and immunosuppression. At our institution we recommend treatment with a short course of intravenous steroids in patients who meet the following criteria: (1) Patients who have profound vasodilatory shock despite adequate fluid resuscitation and a maximal dose of vasopressor therapy; and (2) patients who are hypotensive and have relatively low random serum cortisol levels, or fail to stimulate appropriately on the ACTH stimulation test.

DRUG REACTIONS

Propofol infusion syndrome is rare but fatal if left untreated in the acute care surgery patient.[101] It occurs with prolonged use of propofol in the setting of a systemic immune inflammatory response. Critical illness, sepsis, and use of corticosteroids often precipitate this syndrome. The exact mechanism is unknown. It is believed that there is an interaction between the metabolites of propofol and endogenous catecholamines that leads to a massive cytokine release. These patients present with profound bradycardia, rhabdomyolysis, metabolic acidosis, hyperkalemia, and renal and hepatic failure. Treatment involves symptomatic support. However the presence of organ dysfunction with this syndrome is generally fatal.

Etomidate is a frequently used induction medication for endotracheal intubation. However, evidence exists that even one-time dosing of this medication causes adrenal suppression that can lead to adrenal insufficiency in the critically ill patient.[88,89,102,103] Many recreational drugs have been associated with cardiovascular failure. Stimulants such as cocaine or methamphetamines can lead to acute decompensated heart failure. The cardiotoxic effects of cocaine are not completely understood. However, cocaine may increase myocardial ischemia by causing coronary artery vasospasm, tachyarrhythmias, and coronary artery thrombosis. Acute treatment of cocaine toxicity with a beta-blocker is ill-advised, as it may lead to unopposed alpha adrenergic activity that may precipitate severe hypertension or may exacerbate preexisting heart failure.[73] Chronic stimulant use is associated with dilated cardiomyopathy. Chronic ethanol intoxication has been associated with a dilated cardiomyopathy.

In summary:

- Causes of intrinsic cardiovascular failure in the acute care surgery patient include myocardial ischemia, CHF, arrhythmias, and valvular heart disease, and present a unique challenge in the perioperative period (Algorithm 50.3).
- Extrinsic causes of cardiovascular failure occur in the face of a structurally normal heart, but external impedance results in decreased cardiac output. Treatment is aimed at removal of the external cause and support of the patient (Algorithm 50.4).

CHAPTER 51 ■ ACUTE LIVER FAILURE AND PORTAL HYPERTENSION

DEANNA BLISARD AND MICHAEL E. DE VERA

ACUTE LIVER FAILURE

Fulminant hepatic failure is synonymous with acute liver failure (ALF), a rare disorder that often leads to devastating consequences. ALF is rapid deterioration of liver function resulting in altered mutation and coagulopathy in previously normal individuals. The loss of hepatic function quickly leads to multiorgan failure and frequently death. Approximately 2,000 cases of ALF occur in the United States per year.[1] The clinical syndrome was originally described as "sudden severe impairment of hepatic function resulting in jaundice and followed by hepatic encephalopathy (HE) within 8 weeks of the onset, in the absence of prior liver disease."[2] The most widely accepted definition of ALF is the presence of coagulation abnormality and any degree of encephalopathy in a patient without preexisting cirrhosis and with an illness of <26 weeks duration.[3] ALF can be classified according to the length of illness such as hyperacute (<7 days), acute (7–21 days), or subacute (>21 days and <26 weeks), but these terms are not helpful since there is no prognostic significance distinct from the cause of the illness.

The etiology of ALF provides one of the best indicators of prognosis[4] and also dictates specific management options. ALF can be induced by viral (hepatitis A, hepatitis B, herpes, cytomegalovirus, Epstein-Barr virus), vascular (Budd-Chiari syndrome, right heart failure, shock liver), metabolic (Wilson's disease, hemolysis–elevated liver enzymes–low platelet count syndrome, acute fatty liver of pregnancy, tyrosinemia), drugs and toxins (acetaminophen, *Amanita phalloides*, *Bacillus cereus* toxin, herbal remedies), or miscellaneous/indeterminate (malignant infiltration, autoimmune hepatitis, sepsis) causes. Acetaminophen toxicity is the leading cause of ALF in the United States, accounting for 40% of cases.[1] Acetaminophen-induced ALF is suspected with evidence of excessive ingestion, usually because of a suicide attempt or supratherapeutic quantities of pain medication. Acetaminophen is a dose-related toxin with most ingestions which lead to ALF exceeding 10 g/day. Acetaminophen levels should be drawn on all patients presenting with ALF, and the agent *N*-acetylcysteine (NAC) started. Acetaminophen overdose leads to the accumulation of *N*-acetyl-*p*-benzoquinone imine, a metabolite normally conjugated by glutathione that is toxic to hepatocytes.[5] Excessive ingestion of acetaminophen leads to depletion of glutathione stores, and NAC augments glutathione levels. NAC should be started as early as possible but may still be useful even 48 hours or more after ingestion. The oral dose of NAC is 140 mg/kg diluted to 5% solution, followed by 70 mg/kg by mouth q4h × 17 doses. NAC can also be administered intravenously in patients with worsening mental status or gastrointestinal (GI) bleeding. The loading dose is 150 mg/kg in 5% dextrose over 15 minutes; maintenance dose is 50 mg/kg given over 4 hours followed by 100 mg/kg administered over 16 hours.[3] Numerous clinical trials have established the efficacy of NAC for the treatment of acetaminophen-induced ALF. ALF patients are heterogeneous but share the common disease process of acute hepatocyte necrosis and its sequelae. Presenting symptoms are often nonspecific, including fatigue, malaise, anorexia, nausea, abdominal pain, fever, and jaundice.[1] Often these symptoms progress to severe coagulopathy and encephalopathy and/or coma. The patient's clinical condition should be monitored regularly including frequent vital signs, blood glucose, and neurologic status. Initial laboratory testing should include a complete blood count, biochemical, hematologic, immunologic, hepatitis panel, and toxic drug screens. An arterial blood gas and lactate levels should be checked to assess metabolic disturbances. Radiographic tests include an abdominal ultrasound to evaluate hepatic and portal venous flow patterns, and triphasic CT to evaluate the hepatic parenchyma (unless renal insufficiency or failure is present in which case intravenous contrast use is precluded). Clinical deterioration is *often rapid and any worsening in the patient's condition should warrant urgent referral* to a transplant center. Patients who present in full-blown ALF often have severe metabolic acidosis, hypoglycemia, coagulopathy, and encephalopathy or coma.[6] Stabilization of these patients includes volume resuscitation, mechanical ventilation, and hemodynamic support. Appropriate candidates should be urgently listed for liver transplantation as quickly as possible. Next, we will discuss the systemic effects of ALF by going through each organ system in detail.

Encephalopathy and Intracranial Hypertension (IH)

The neurologic effects of ALF range from minimal to striking. Encephalopathy, the hallmark feature of ALF, may vary from subtle changes in affect, insomnia, and difficulties with concentration (stage I), to deep coma (stage IV).[1] The prognosis of ALF is inversely correlated with the degree of encephalopathy. Table 51.1 illustrates the grades of encephalopathy. The most serious complication of ALF is cerebral edema and intracranial hypertension (ICH) which affects approximately 50%-80% of patients with severe ALF (grade III or IV coma).[7] Uncal herniation can result and is uniformly fatal. Patients with grade I-II encephalopathy seldom show signs of cerebral edema. The risk of edema increases to 25%-35% with progression to grade III, and 65%-75% or more in patients reaching grade IV coma.[3] Patients with grade I-II encephalopathy should be managed in a quiet environment to minimize agitation, and sedation should be avoided. Frequent mental status checks should be performed and head imaging with CT obtained to exclude other causes of encephalopathy. Lactulose can reduce elevated ammonia levels which may play a pathogenic role in the development of cerebral edema/ICH. As patients progress to grade III or IV encephalopathy, intubation for airway protection must be undertaken. The patients should be positioned with the head elevated at 30 degrees and efforts made to avoid patient stimulation. Propofol is often used as the choice of sedation because it may reduce cerebral blood flow (CBF)[3]; however, its effectiveness has not been shown in controlled studies.

Two theories have been proposed to account for intracranial hypertension in ALF: (1) brain edema due to osmotic astrocyte

685

TABLE 51.1

STAGES OF ENCEPHALOPATHY IN ALF

■ STAGE	■ MENTAL STATUS	■ TREMOR	■ EEG
I	Euphoria, occasional depression, fluctuant mild confusion, slowness of mentation and affect, untidy, slurred speech	Slight	Usually normal
II	Accentuation of stage I, drowsiness, inappropriate behavior, able to maintain sphincter control	Present (easily elicited)	Abnormal, generalized slowing
III	Sleeps most of the time but is arousable, incoherent speech, marked confusion	Usually present if patient cooperative	Always abnormal
IV	Not arousable, may or may not respond to painful stimuli	Usually absent	Always abnormal

swelling secondary to ammonia-induced accumulation of glutamine, and (2) alteration of CBF regulation with increased intracranial blood volume.[8] The typical course of grade III or IV HE includes a reduction in CBF coupled with a reduction in cerebral metabolic rate early on, followed by gradual cerebral vasodilatation due to the loss of cerebral autoregulation. This results in increased cerebral blood volume and edema. The preterminal phase shows a marked reduction in CBF resulting from cerebral edema, with cerebral herniation as the end result.[7]

Clinical signs of IH include systemic hypertension, bradycardia, abnormal pupillary signs, aggravation of HE, epileptiform activity, and decerebrate posturing. However, most of these clinical signs are nonspecific. The most accurate method to diagnose IH is intracranial pressure (ICP) monitoring. Although the advantages of ICP monitoring in ALF patients have not been demonstrated by a randomized study, ICP monitoring may be helpful to establish the presence of IH and guide specific therapy.[8] ICP transducers can be placed in the brain parenchyma, epidural, or subdural spaces. Epidural devices have lower complication rates (3.8%) than subdural bolts (20%) or parenchymal monitors (22%).[9,10] In ALF, epidural transducers may be the safest choice to monitor ICP even though they are less precise than the other devices.[10] Although placement of these invasive monitors is associated with the risk of hemorrhage, the use of recombinant factor VIIa (rFVIIa) before the procedure appears to minimize this risk[11]; a single dose of 40 μg/kg of rFVIIa is recommended prior to placement.

Transcranial Doppler is a noninvasive measurement of the systolic flow velocity of the middle cerebral artery. Attenuation of the diastolic flow signal may be a sign of IH and decreased cerebral perfusion. A pulsatility index (systolic velocity–diastolic velocity/systolic velocity) >1.6 is a poor prognostic sign.[7] Jugular venous oximetry measures venous oxygenation in the superior jugular bulb of the internal jugular vein, which is representative of cerebral oxygen consumption and delivery. If one assumes that the cerebral metabolic rate remains constant, the arteriojugular venous oxygen difference (AVjDO2) will change in response to changes in CBF; this will essentially be a reflection of the ratio of the flow to metabolism. A normal AVjDO2 is 5–6 mL/100 mL; a narrow AVjDO2 difference is suggestive of cerebral hyperemia and a widened AVjDO2 difference is suggestive of cerebral ischemia. AVjDO2 measurements can be obtained at two different levels of pCO_2 to see the variability in CBF in response

to CO_2 reactivity. If the AVjDO2 difference normalizes from a low value, hyperventilation may be effective to decrease cerebral hyperemia. Alternatively, an AVjDO2 difference >6 when the pCO_2 is low suggests cerebral ischemia, and elevating the pCO_2 is needed to maintain adequate CBF.

The treatment of elevated ICP involves decreasing the brain volume or decreasing the CBF and intracranial blood volume (or both). Mannitol and hypertonic saline increase blood osmolarity, thereby inducing fluid movement from the brain to the vascular space. Mannitol (0.5–1 g/kg IV) repeated once or twice as needed, provided serum osmolality does not exceed 320 mOsm/L, is recommended to treat ICH.[3] The efficacy of mannitol is affected by acute renal failure, and hemodialysis may also be needed to remove fluid. A recent controlled trial of 30% hypertonic saline to maintain serum sodium levels of 145–155 mEq/L suggests that induction and maintenance of hypernatremia may be used to prevent the rise in ICP.[12] Survival benefits could not be demonstrated in this trial however, and the role of hypertonic saline as a prophylactic measure requires larger studies.

Hyperventilation, indomethacin, thiopental, and induced hypothermia reduce ICP through vasoconstriction of cerebral blood vessels, thereby decreasing CBF. The American Association for the Study of Liver Diseases (AASLD) position paper on the management of ALF does not support prophylactic hyperventilation in patients with ALF.[3] If ICH cannot be controlled with mannitol and other general management guidelines; hyperventilation may be instituted temporarily in an attempt to acutely lower ICP and prevent impending herniation. Indomethacin induces cerebral vasoconstriction through inhibition of the endothelial cyclooxygenase pathway, alterations in extracellular pH, and reduction in cerebral temperature.[13] Studies using indomethacin are of small scale, and its use should be evaluated in a randomized, controlled study before wider use. Thiopental induces cerebral vasoconstriction possibly by inhibition of nitric oxide synthase, which is thought to be important in the pathogenesis of increased ICP in ALF. A continuous infusion is started and titrated based upon the EEG (5–10 second EEG burst suppression), ICP, and hemodynamics. Most systemic hypotension limits its use and may necessitate additional pressors or inotropes to maintain adequate mean arterial pressures. Patients who develop worsening encephalopathy and those with signs of IH must be urgently listed for liver transplantation if they are appropriate candidates; needless to say, the workup should be expeditious.

Cardiovascular

Nausea, vomiting, and loss of appetite are part of the prodrome of ALF, and patients may present with profound dehydration. Most patients will require fluid resuscitation initially with colloids primarily and complemented with crystalloid solutions.[6] Systemic vasodilation, low systemic vascular resistance, hypotension, and a compensatory increase in cardiac output are the notable clinical cardiovascular sequelae of ALF. Abnormal oxygen transport and utilization is also present; delivery of oxygen to the tissues is adequate but there is a decrease in tissue oxygen uptake,[1] resulting in tissue hypoxia and lactic acidosis.[14] Low systemic vascular resistance results in hypotension even in the volume-resuscitated patient, and a pulmonary artery catheter is often useful to assess volume status and guide further management. Inotropic or pressor support may be required to maintain an adequate mean arterial pressure. Norepinephrine and dopamine are generally used if needed to maintain vital organ perfusion.[1,3,6] Vasoconstrictive agents such as vasopressin (VP) are generally avoided unless major systemic hypotension is present.[3]

Respiratory

Patients often hyperventilate and develop a respiratory alkalosis before a metabolic acidosis as liver failure progresses.[2] Mortality in ALF escalates with the presence of pulmonary edema and acute respiratory distress syndrome (ARDS).[1,2] ARDS is present in as many as one-third of patients.[15] Ventilation–perfusion mismatch may develop acutely and worsen as the liver function deteriorates, and resulting hypoxia can contribute to neurologic injury. Positive end-expiratory pressure may compromise cardiac output and oxygen delivery, and result in increased ICP and hepatic congestion.[1,2] Treatment with increased FiO_2 is the most appropriate intervention. Patients who develop ARDS in the setting of ALF can successfully undergo liver transplantation, but the risk of death is high.[16]

Gastrointestinal/Metabolic

Upper GI bleeding is a recognized complication and often stress related. Histamine-2 receptors blocking agents and proton pump inhibitors have been shown to be efficacious in several trials. Numerous metabolic derangements are common in ALF including alkalosis, acidosis, hypoglycemia, hypophosphatemia, and hypokalemia. Hypoglycemia, seen in up to 45% of ALF patients,[1] is an indicator of major hepatic necrosis which leads to defective glycogenolysis, gluconeogenesis, and insulin metabolism. Treatment is with continuous glucose infusion. Electrolytes should be supplemented and followed closely. Enteral nutrition should be started early when feasible.

Renal Failure

Renal failure is common, with the reported incidence varying from 40% to 85%.[6] It is often multifactorial, with prerenal azotemia, renal ischemia, acute tubular necrosis, and hepatorenal syndrome (HRS) as common causes. Although few patients die of renal failure alone, it often contributes to mortality and suggests a poorer prognosis.[3] Avoidance of nephrotoxins and maintenance of adequate intravascular volume are important to maintain renal function. When hemodialysis is needed, continuous venovenous hemodialysis (CVVHD) is the preferred mode.[2,3,6,17] CVVHD tends to be better tolerated and may have more beneficial effects on ICP.[17,18] Intermittent hemodialysis has been associated with increases in ICP and decreases in CPP, whereas the opposite has been shown in patients receiving CVVHD.[18,19]

Hematologic

The normal liver is responsible for the synthesis of several clotting factors involved in the clotting cascade. The primary hematologic derangements seen in ALF include platelet dysfunction and thrombocytopenia, reduced fibrinogen, and a prolonged prothrombin time (PT).[1,3,6,18] However, spontaneous, clinically meaningful bleeding is uncommon in ALF patients (<10%).[18] The PT is used as a prognostic indicator as well as a tool to follow the progress of the liver injury; thus, correction of the PT is not necessary unless there is clinical bleeding or an invasive procedure is planned. Complete correction of the coagulopathy and thrombocytopenia is generally not achievable and can lead to volume overload and oxygenation issues, as well as exacerbation of ICH. The use of rFVIIa has been examined in treatment of the coagulopathy in ALF and may be useful in facilitating performance of invasive procedures (such as intracranial monitoring devices) in these patients, especially in the setting of renal failure and volume overload.[20] Further studies and analysis of cost–benefit ratio are needed prior to becoming standard therapy.

Infection

The liver is the site of complement synthesis, with low levels of complement reported in ALF.[6] Reduced complement has been associated with impaired opsonization[1,6] leading to sepsis. The most common pathogens are Staphylococcal species, streptococcal species, and gram-negative rods.[1,6,18] Fungal infections (particularly Candida albicans) occur in up to one-third of ALF patients with risk factors including renal failure and prolonged antibiotic therapy for existing bacterial infections. Common sites of infection include pneumonia (50%), bacteremia (20%), and urinary tract infection (25%).[17] Prophylactic antimicrobial therapy reduces the incidence of infection in certain groups of patients with ALF, but no actual survival benefit has been shown. If prophylactic antibiotics are not given, surveillance for infection including chest x-rays and periodic cultures of sputum, blood, and urine should be done.

Transplantation and Prognosis

Orthotopic liver transplantation (OLT) remains the only definitive therapy for patients who have sustained massive hepatic necrosis without regeneration of enough hepatocytes to sustain life. Overall survival rates in ALF have improved from 15% in the pretransplant era to >60% with transplantation.[3] Advances in critical care and trends toward etiologies such as acetaminophen have helped improve survival. A delay in a patient getting on the transplant list can lead to the probability of a complication precluding transplant. Contraindications to transplant include an extrahepatic malignancy, uncontrolled sepsis, irreversible brain damage, or unresponsive cerebral edema with a sustained elevation of ICP (>50 mm Hg) and a decrease in CPP (<40 mm Hg).[17]

Accurate prognosis for survival in ALF is important, given the limited organ supply and lack of good alternative therapies. The most commonly utilized and most frequently tested of the many prognostic criteria for ALF are from the King's College (Table 51.2).[21] More published data exist to support the use of acetaminophen than the nonacetaminophen criteria.

TABLE 51.2

KING'S COLLEGE CRITERIA

■ KING'S COLLEGE CRITERIA

- Tylenol
  - pH <7.3 irrespective of grade of encephalopathy or
  - Lactate >3.5 mmol/L following early fluid resuscitation or
  - Lactate >3.0 mmol/L following 12 h fluid resuscitation or
  - Phosphate >1.2 mmol/L at 48–96 h after ingestion or
  - Encephalopathy III/IV and
  - INR >6.5 and
  - Creatinine >3.4 mg/dL within 24 h
- Other etiologies
  - INR >6.5 or at least three of the following:
  - Age <10 or >40 y
  - Hepatitis non A-E, halothane hepatitis, idiosyncratic drug reaction
  - Jaundice to encephalopathy time >7 d
  - INR >3.5
  - Serum bilirubin >17.4 mg/dL

From O'Grady J, Alexander G, Hayllar K, Williams R. Early indicators of prognosis in fulminant hepatic failure. *Gastroenterology*, (1989);97(2):439–455 with permission

Other criteria including the patient's MELD score on admission and APACHE II scores have been looked at in several studies. Currently, available prognostic scoring systems do not adequately predict outcome and determine candidacy for liver transplantation, therefore, decisions on whether to transplant a patient or not should look at the whole picture and not rely on these guidelines entirely.

PORTAL HYPERTENSION

In this section, we will discuss the critical care management of patients with complications of portal hypertension (PH), decompensated cirrhosis, and end-stage liver disease (ESLD). PH is most commonly an accompanying consequence of cirrhosis and is defined as a portal pressure gradient between the portal vein and hepatic veins (hepatic venous pressure gradient [HVPG]) of >5 mm Hg.[22] PH can be classified as prehepatic (e.g., portal or splenic vein thrombosis), intrahepatic (e.g., cirrhosis, parenchymal disease), or posthepatic (e.g., hepatic vein stenosis, Budd-Chiari syndrome, cardiac disease). The common clinical manifestations of cirrhosis and PH include GI bleeding, ascites, and encephalopathy. The ICU management of these patients can be challenging, as these patients also often have thrombocytopenia, leukopenia, or pancytopenia because of accompanying splenomegaly. Furthermore, other complications of ESLD such as HRS, coagulopathy, or malnourishment/deconditioning may also be present. Sepsis and infections are also common in these patients, further increasing the complexity of care.

The emergence of OLT as a successful and definitive therapy for ESLD has changed the approach to the care of these patients. Over 6,000 liver transplants are performed in the United States annually with excellent outcomes, with average 1-, 5-, and 10-year patient and graft survival rates of 88.4%/73.8%/60% and 84.3%/68.4%/54.1%, respectively.[23] The most common disease indications in adults for OLT in the United States are alcoholic liver disease and hepatitis C,

accounting for 30%-40% of all cases. Other disease states include hepatocellular carcinoma, cholestatic liver diseases (Primary Biliary Cirrhosis, Primary Sclerosing Cholangitis), and metabolic diseases (hemochromatosis, alpha-1-antitrypsin deficiency). Nonalcoholic fatty liver disease (NAFLD) is being diagnosed with increasing frequency, and nonalcoholic steatohepatitis which is the advanced and pathologic form of NAFLD, may surpass hepatitis C in the next several years as the leading indication for OLT in the United States.[24] In patients with hepatic decompensation who are active on the liver transplant list, management is directed toward stabilizing, supporting, and ensuring that these patients continue to be viable candidates for transplantation. For patients who have not yet been evaluated for transplantation, early referral for OLT is important. The care of these patients must be multidisciplinary in nature, with the critical care team, transplant surgeons, hepatologists, nephrologists, infectious disease specialists, and ancillary support services such as social workers, involved and interacting with one another.

Upper GI (UGI) Bleeding in the Portal Hypertensive Patient

The portal-mesenteric venous system drains the entire GI tract, from the esophagus to the rectum. Because these are low-pressure venous beds that are separate from, and in normal states have no connection to the systemic venous system, PH results in the formation of either varices or shunts (collaterals). Varices occur most commonly in the distal esophagus, the umbilicus ("caput medusae"), around the spleen, and in the rectum. The GI mucosal tract can also be congested leading to portal hypertensive gastropathy (PHG) or colopathy. Natural shunts occur most frequently between the splenic and left renal veins, forming spontaneous splenorenal shunts. The presence of these shunts does not necessarily alleviate GI bleeding secondary to PH.

The prevalence of esophageal varices in patients with chronic liver disease has been reported to range from 24% to 81%,[25] and upper GI bleeding from varices account for 60%-90% of bleeding in patients with cirrhosis.[26,27] The pathophysiology of variceal hemorrhage is not completely understood. Bleeding is not wholly dependent on elevated portal pressures; on the one hand, varices are usually not encountered in patients who have a portal pressure gradient of <11–12 mm Hg.[28] However, many patients with pressures above this threshold also do not bleed from their varices. There is a correlation between the size of the varices and the risk of bleeding; the larger the varices, the greater the risk of hemorrhage. Other factors that most likely play an important role on whether varices will bleed include the patient's fluid status, respiratory cycle, meal ingestion, presence of esophagitis, and Valsalva's maneuvers.[28] The presence of red color signs (red streaks of longitudinal dilated veins) in the distal esophagus seen in endoscopy has also been shown to be an independent risk factor for variceal bleeding.[29] The mortality rate associated with esophageal variceal hemorrhage in most series ranges from 30% to 50%; mortality is greatest within the first 6 weeks of the bleed and in subjects with more advanced liver disease.[29] The Child's status is a good indicator of the severity of the liver disease (Table 51.3). In a recent study, the mortality associated with an UGI bleed in Child's B and C cirrhosis was 15% and 36%, respectively, with no deaths occurring in Child's A patients.[30]

Gastric varices (GV) are estimated to be present in 20% of patients with cirrhosis[29] and are frequently found in conjunction with esophageal varices. GV can be found in the fundus of the stomach or along the lesser curvature, with the former accounting for the majority of bleeding.[31] GV tend to bleed

TABLE 51.3

CHILD'S CLASSIFICATION

	1 POINT	2 POINTS	3 POINTS
Serum albumin (g/dL)	>3.5	2.8–3.5	<2.8
Total bilirubin (mg/dL)	<2	2–3	>3
INR	<1.7	1.7–2.2	>2.2
Ascites	None	Medically managed	Poorly controlled
Encephalopathy	None	Medically managed	Poorly controlled

Child's A: <7 points, B: 7–9 points, C: ≥10 points

less frequently but more severely than esophageal varices. PHG is a condition characterized endoscopically by gastric mucosal changes (typically a mosaic pattern) found in the setting of PH. Histologically, there is dilation of capillaries and venules in the gastric mucosa.[32] Bleeding from PHG is usually less severe compared to esophageal varices.

Management. The initial management of the portal hypertensive patient with UGI bleeding is the same as that for a trauma victim, focusing primarily on the "ABC's." Patients with acute UGI bleeding may present with hematemesis or hematochezia. The subject's airway and breathing must be protected and maintained, and circulation must be preserved. There must be a low threshold to intubate the patient, especially one with hematemesis. Along with securing the airway, mechanical ventilation reduces the risk of aspiration pneumonia and facilitates the performance of upper endoscopy. The placement of multiple large bore intravenous lines is critical, and hemodynamic monitoring with an arterial line and central venous catheterization as well as bladder catheterization to monitor urine output are recommended. Patients must be typed and crossed with blood and fresh frozen plasma, and resuscitation with blood and correction of coagulopathy and thrombocytopenia is of prime importance. Serum lactate levels are good indicators of the effectiveness of resuscitation, as well as the degree of blood loss. Placement of a nasogastric tube is important to confirm that the upper GI tract is the source of bleeding and also to decompress the stomach. The first level of treatment consists of pharmacologic therapy with vasoactive drugs. The most commonly used agent in the United States is Octreotide, a somatostatin analog. Somatostatin is a naturally occurring 14 amino acid peptide that has been shown to decrease portal pressure.[33] Its half-life in the circulation is only 1–3 minutes, thus longer acting analogs with greater potency such as octreotide have been synthesized. Octreotide (Sandostatin) is administered intravenously as a 50-µg bolus, followed by 50 µg/hour IV for 5 days. VP is a potent vasoconstricting agent with an added effect of causing splanchnic vasoconstriction. VP use, however, may be associated with a reduction in cardiac output as well as systemic vasoconstriction, so proper monitoring is essential. Concomitant nitroglycerin use has been advocated by some to decrease the systemic effects of VP but we do not routinely utilize this agent at our unit. Terlipressin, a semisynthetic VP analog, is widely used in Europe but has not yet obtained approval by the Food and Drug Administration for use in the United States. Patients are also routinely placed on proton pump inhibitors (intravenous

drip) and prophylactic broad spectrum antibiotics for 5 days. A Doppler ultrasound of the liver is performed at the bedside to assess vessel patency, particularly to assess portal vein flow.

Once the patient has been stabilized, identification of the source of bleeding is the next goal of management. Esophagogastroduodenoscopy (EGD) complements vasoactive therapy and must be performed as soon as possible to determine the source of the bleed. Other causes of bleeding such as gastritis, ulcer disease, or Mallory-Weiss tears can also occur in patients with cirrhosis and PH. EGD serves as both the most important diagnostic tool and the primary therapeutic modality for variceal hemorrhage. Endoscopic strategies to stop variceal bleeding include sclerotherapy injection or rubber band ligation of bleeding varices. Sclerotherapy involves the injection of agents (e.g., ethanolamine oleate, sodium tetradecyl sulfate, absolute alcohol) either around or into a varix. This technique has largely been supplanted by band ligation which involves endoscopic placement of a rubber band around a varix, eventually causing its thrombosis. Endoscopic or pharmacologic treatments control variceal bleeding in over 90% of cases. GV are best treated with gastric variceal obliteration using endoscopic injection with cyanoacrylate rather than band ligation.[29]

In patients who continue to hemorrhage profusely despite the management and endoscopic therapies outlined above, the next option is to control bleeding with balloon tamponade using a Sengstaken-Blakemore (SB) or a Minnesota tube. These are multiluminal nasogastric tubes that have esophageal and gastric balloons that when inflated serve to tamponade varices (Fig. 51.1A). There are also esophageal and gastric ports that can be utilized for aspiration of contents or administration of medications. Once an SB tube is passed into the esophagus and stomach, its placement must be confirmed radiographically with plain films prior to inflation of the balloons (Fig. 51.1B,C). We rarely inflate the esophageal balloon; our experience has been that inflation of the gastric balloon and placement of the SB tube in traction with 1–2 lb of weight provides excellent control of bleeding esophageal varices. Balloon tamponade can typically be used for 24 hours and has been shown to be effective in controlling variceal bleeding in 80%-100% of cases, allowing the patient to be stabilized for more definitive therapy, as rebleeding occurs in up to 50% of patients once the balloon is deflated.[33]

Persistent bleeding refractory to medical management or massive GI bleeding necessitating SB tube placement requires further treatment involving either interventional radiology or surgical intervention. It is critical to involve the liver transplant team in the treatment strategy for these patients, especially for those on the transplant list. The management and treatment of these subjects depends on the severity of their liver disease (Child's Class status), whether they are transplant candidates, and their portomesenteric venous anatomy. It is also important to determine by angiography whether there is portomesenteric venous thrombosis and if so, define the location and extent. Although portal vein thrombosis is no longer a contraindication to OLT, subjects with extensive thrombosis in their portal and mesenteric venous systems may require liver/intestine or multivisceral transplantation (liver, stomach, duodenum, pancreas, and intestine). The development of the transjugular intrahepatic portosystemic shunt (TIPS) has revolutionized the care of patients with variceal bleeding and is preferred over surgical intervention as the next line of treatment, particularly in patients who are critically ill, unstable, or have massive bleeding. A TIPS is placed by interventional radiology under local anesthesia and involves a transjugular approach in which one of the hepatic veins (usually the right) is cannulated followed by the accession of a branch of the portal vein using a Rosch's needle[34] (Fig. 51.2). The tract between the veins is then widened after which a covered metal stent is placed, providing immediate reduction in portal pressures and relief of bleeding
FIGURE 51.1. A: Minnesota tube. **B:** Confirmatory radiograph showing good placement. **C:** The gastric balloon is inflated.

in over 90% of cases.[33] Complications associated with TIPS placement include procedural-related bleeding (e.g., perforation of the portal vein), worsening of encephalopathy, renal failure, congestive heart failure, infection, and liver failure. Relative contraindications to placing a TIPS include portal vein thrombosis and a history of severe encephalopathy. Coil embolization of varices is another option available to interventional radiologists and can be effective in appropriate patients.

Surgical options for the treatment of portal hypertensive bleeding include shunt surgery and procedures such as gastric devascularization or esophageal transection. Although esophageal transection is effective in control of bleeding, it is rarely used currently. Emergency surgery for acute variceal bleeding has markedly declined due to the success of TIPS. Surgical shunts are effective, however, and still play a role in the treatment of variceal hemorrhage, most commonly in an elective setting and targeted toward prophylaxis from recurrent bleeding. Selective shunts, that is, the distal splenorenal shunt (DSRS), are preferred over nonselective shunts (e.g., portacaval or mesocaval shunts) because hepatic flow is preserved and no dissection is carried out at the hepatic hilum, an advantage for patients who may eventually undergo OLT. Visceral angiography is critical and helps dictate the type of shunt utilized by detailing the portomesenteric venous system and diagnosing portomesenteric venous thrombosis. Gastric devascularization is indicated for patients with portomesenteric thrombosis.[35] A TIPS functions

similarly to a side-to-side portosystemic shunt but without the risk, morbidity, and mortality involved with shunt surgery. In addition, abdominal adhesions and possible dissection at the hepatic hilum are obviated, making TIPS an excellent bridge to OLT. A randomized, multicenter trial showed that TIPS was just as effective as DSRS in prevention of variceal bleeding.[36] The risk of variceal rebleeding may be up to 70% within 1 year and is greatest during the first several weeks after the index bleed.[28,33] Prophylaxis against bleeding using nonselective β-blockers or endoscopic banding is effective.[29] A recent study from Barcelona demonstrated that in a select group of patients, early placement of TIPS (within 3–4 days of acute variceal bleeding) results in substantial reduction in rebleeding rates and mortality compared to a control group treated without early TIPS.[37] Measurement of hepatic vein free and wedge pressures to calculate the HVPG has been advocated by some to help guide the management of portal hypertensive patients. In particular, reduction of HVPG by ≥20% or to <12 mm Hg in response to clinical intervention decreases the risk of rebleeding.[38]

Ascites

Another common complication of PH and cirrhosis is ascites. There are numerous physiologic alterations that eventually account for the accumulation of ascitic fluid in the cirrhotic
FIGURE 51.2. Placement of TIPS. **A:** Cannulation of the right hepatic vein. **B:** The portal vein has been accessed. **C:** Deployment of the stent.

patient. PH, the development of systemic vasodilation, and activation of the renin–angiotensin–aldosterone pathway are contributing factors.[39] Patients who develop refractory ascites have 1-year survival <50%.[39] Hyponatremia often accompanies ascites and is a poor prognostic indicator in patients awaiting OLT.[40] Medical management is primarily with diuretics (furosemide and aldactone). Therapeutic large volume paracentesis is indicated mainly for symptomatic relief; patients who may have respiratory compromise from tense ascites should be drained. We typically send ascites fluid for cell count and cultures. Our preference is to insert pig-tail catheters and "gently" drain ascites over several days, thereby minimizing rapid shifts in volume and avoiding hypotension and dehydration/renal insufficiency. We routinely replace ascitic drainage with intravenous albumin, although some have questioned this practice. TIPS may be considered in patients who are refractory to diuretics and requiring frequent drainage. Spontaneous bacterial peritonitis (SBP) is diagnosed with either positive ascitic cultures or with ascitic neutrophil count >250/mm^3 or total WBC >500/mm^3. Broad spectrum antibiotics should be administered. Gram-positive infections are the most common followed by gram-negative infections; anaerobic infections are rare. The development of SBP does not appear to lead to increased mortality in OLT patients but is associated with higher rates of sepsis posttransplantation.[41]

Encephalopathy

HE is a common indication for admission to the ICU. The pathogenesis of HE has not been precisely elucidated but is thought to be secondary to accumulation of ammonia or excessive gamma amino butyric acid neurotransmission,[42] with the

former hypothesis currently being the most popular. Standard medical therapy is with oral lactulose with or without Neomycin (500 mg po tid). Xifaxan (550 mg) is an alternative to Neomycin and has been shown to effectively reduce the occurrence of HE and the risk of hospitalization from HE.[43] The main concern with severe encephalopathy is the inability of a patient to protect the airway, in which case intubation should be performed. We administer lactulose every hour via a nasogastric tube until patient starts to have bowel movements; we also sometimes utilize lactulose enemas. HE often has a precipitating factor such as a GI bleed, new onset or worsening portal vein thrombosis, or an infection. These patients must, therefore, have blood work including a complete blood count, serum chemistries, and ammonia levels. An infectious workup is important and patients are pancultured. Ultrasound of the liver should be performed to check the patency of the portal vein.

Hepatorenal Syndrome

HRS is characterized by the development of renal insufficiency or renal failure in cirrhotic patients with advanced liver disease in the absence of intrinsic kidney disease. Clinical criteria for the diagnosis of HRS include the absence of pre- and postrenal azotemia and other causes of renal impairment (e.g., acute tubular necrosis, nephrotoxicity), the lack of improvement in renal function after withdrawal of diuretics and administration of volume, oliguria, urine sodium <10 mEq/L, urine osmolality greater than plasma osmolality, and hyponatremia (<130 mEq/L).[44] Type I HRS is a rapid and progressive form, with doubling of the serum creatinine to >2.5 mg/dL in <2 weeks, while type II HRS is slower in progression.[42] HRS is associated with high mortality; type I has a survival of <50% after 1 month while type II has a median survival of 6 months. The management of these patients involves adequate hydration, withdrawal of diuretics, and avoidance of nephrotoxic substances (e.g., drugs, IV dye). The administration of midodrine, octreotide, and albumin has been shown to improve survival and renal function in HRS patients.[45] Renal replacement therapy (RRT) should be instituted when clinically indicated. Liver transplantation is the definitive treatment for HRS. Because renal failure substantially increases the mortality risk after transplantation,[46] an increasing number of patients are undergoing combined liver and kidney transplantation. At our center, we do not consider a kidney transplant for HRS patients who have been on RRT for <8 weeks.

SURGICAL CRITICAL CARE

CHAPTER 52 ■ ACUTE KIDNEY INJURY

SOUMITRA R. EACHEMPATI, FRANK LIU, AND PHILIP S. BARIE

The functions of the kidney can be divided into secretion of hormones and maintaining the extracellular homeostasis of pH, water, and electrolytes. The kidneys weigh approximately 300 g each but receive blood flow disproportionately, approximately 20%–25% of cardiac output. The kidneys consume more oxygen per gram of mass than any other visceral organ. The kidneys secrete renin, erythropoietin, the active form of vitamin D, and certain prostaglandins. Most importantly, the kidneys regulate fluid balance, acid–base status, and solute homeostasis.

After passing through the interlobar, arcuate, and intralobar arteries, more than 85% of renal blood flow perfuses the outer cortical glomeruli, leaving the remainder to supply the juxtamedullary glomeruli.[1]

The kidney's ability to perform many of its functions depends on three fundamental functions: filtration, reabsorption, and secretion at the level of the nephron. The nephron, the smallest functional unit of the kidney, includes a renal corpuscle, which is composed of a glomerular capillary tuft enclosed in Bowman's capsule. The glomerulus is distinct from other capillary beds in that it is situated between two muscular arterioles instead of between an arteriole and a venule. The afferent arteriole feeds into the glomerular tuft; its tone is modulated principally by a myogenic reflex, which adjusts arteriolar tone in response to perfusion pressure, and by certain prostaglandins. The efferent arteriole drains the tuft; its tone is largely determined by activity of the renin–angiotensin system. By dynamic adjustment of the tone of these two arterioles, renal blood flow and glomerular filtration pressure are autoregulated over a wide range of systemic blood pressures. Cells, proteins, and other large molecules entering the glomerulus are excluded from filtration subsequently by a fenestrated endothelium and a size- and charge-specific glomerular basement membrane. However, smaller molecules, electrolytes, and plasma fluid can pass into the Bowman space by ultrafiltration, which is driven by the capillary hydrostatic forces described above. This remaining effluent, or ultrafiltrate, then passes through the proximal tubule, the loop of Henle, the distal convoluted tubule, and finally the collecting ducts.[2] During this process, fluid is modified for water and solute regulation; the resultant fluid is urine.

The proximal tubule can be divided into an initial convoluted portion and a more distal descending portion, and functions primarily to reabsorb filtered plasma components. Fluid in the filtrate entering the proximal convoluted tubule is reabsorbed into the peritubular capillaries with approximately two-thirds of the total filtered salt and water and all the filtered organic solutes, which include primarily glucose and amino acids.[3] A substantial portion of bicarbonate reclamation also occurs here, largely due to the function of carbonic anhydrase.

The loop of Henle is a U-shaped conduit that extends from the proximal tubule and consists of descending and ascending limbs. It begins in the cortex, receiving filtrate from the straight portion of the proximal tubule, and extends into the medulla as the descending limb, before it returns to the cortex as the ascending limb to empty into the distal convoluted tubule. Its primary roles are to reabsorb 25%–35% of the filtered NaCl load via the Na$^+$K$^+$2Cl$^-$ loop diuretic–sensitive transporter, and to create gradients that allow for elaboration of either dilute or concentrated urine, depending on the immediate physiologic need.[4] The descending limb is permeable to water but impermeable to salt, whereas the ascending limb is impermeable to water. In the descending limb, the hypertonic interstitium of the renal medulla (established via active transport of sodium into the interstitium in the ascending limb) causes water to flow freely out of the descending limb by osmosis until the tonicity of the filtrate and interstitium equilibrate. The ascending limb pumps sodium continuously out of the filtrate, perpetuating a hypertonic interstitium and hypotonic tubular fluid. This process is called *countercurrent multiplication*, and results in an increasingly concentrated tubular fluid and interstitium at the bottom of the loop of Henle and a progressively more dilute filtrate by the start of the distal convoluted tubule.[4] The hypertonic interstitium eventually provides the osmotic gradients to allow water reabsorption later in the nephron, whereas the newly hypotonic filtrate (~70 mOsm/L) can be diluted further in the distal convoluted tubule if free water excretion is desired.

The distal convoluted tubule reabsorbs more salt via the NaCl thiazide-sensitive channel and, in the absence of vasopressin (antidiuretic hormone, ADH), can dilute the urine to approximately 40 mOsm/L in normal kidneys. The distal convoluted tubule is also involved in calcium reabsorption and phosphate excretion under the influence of parathyroid hormone. The filtrate then passes to the collecting tubules, where final fine-tuning of acid–base, sodium, and potassium balance occur, largely under the influence of aldosterone. The cortical and medullary collecting tubules are also the main site of ADH-directed water reabsorption. Here, the highly concentrated interstitium derived from active salt transport in the loop of Henle is used to drive passive water reabsorption. Thus, from normal kidneys, urine as dilute as 40 mOsm/L and as concentrated as 1,200 mOsm/L can be elaborated based on bodily needs.[4]

OVERVIEW OF ACUTE KIDNEY INJURY

Acute kidney injury (AKI), or acute renal failure as the entity was called previously, remains a common and lethal complication of critical illness. The literature is replete with definitions of AKI, but the occurrence of AKI in a patient is most often defined as an elevation of serum creatinine concentration (s[Cr]) of 0.5 mg/dL from baseline, or as an acute need for renal replacement therapy (RRT), for example, hemodialysis.[5] The lack of consensus on the definition of AKI has affected the ability of clinicians to compare published protocols regarding diagnosis and treatment of this prevalent disorder. As such, a workgroup called the Acute Dialysis Quality Initiative developed a consensus definition of AKI (Table 52.1) incorporating risk, injury, failure, loss, and end-stage renal failure criteria ("RIFLE") for the individual patient.[6] These criteria account for either elevation of s[Cr] or decrements of glomerular filtration rate (GFR) or urine output in the determination of the different stages of AKI. These criteria also yield prognostic information regarding the status of the critically ill patient. However, although these criteria are well accepted in the

TABLE 52.1

RIFLE CRITERIA

■ CATEGORY	■ DEFINITION	■ MANIFESTATION
Risk	s[Cr] > 1.5 × baseline Urine <0.5 mL/kg for 6 h	GFR decrease 25%
Injury	s[Cr] > 2.0 × baseline Urine <0.5 mL/kg for 12 h	GFR decrease 50%
Failure	s[Cr] > 3.0 × baseline *or* s[Cr] > 4.0 mg/dL Urine <0.3 mL/kg for 24 h *or* Anuria for 12 h	GFR decrease 75%
Loss	Failure > 4 wk (either GFR or urine output criterion)	
ESRD	*Failure > 3 mo (either GFR or* *urine output criterion)*	

s[Cr], serum creatinine concentration; ESRD, end-stage renal disease; GFR, Glomerular filtration rate; RIFLE, risk, injury, failure, loss, and end-stage renal disease criteria

research community with virtually all AKI publications using the RIFLE criteria by 2006,[7] adoption in routine clinical use remains uncommon.

The occurrence of AKI may influence profoundly the outcome of critically ill patients.[8] In a study of postoperative cardiac patients, patients with even the slightest augmentations of s[Cr] that qualified them for RIFLE R criteria of AKI had a 2.2-fold greater mortality, a 1.6-fold increase in ICU length of stay, and 1.6-fold increase in total postoperative costs compared to controls.[9] Similarly, a meta-analysis encompassing 78,855 patients found that even just a 10%–24% increase in s[Cr] was associated with an 80% increase in mortality compared with matched patients and that a s[Cr] increase >50% was associated with an eightfold increase in mortality.[10] Therefore, even small changes in s[Cr] should be of concern, and should prompt careful evaluation of potential causes and treatments.

Clinical Syndromes of AKI

The etiology of AKI is multifactorial in most patients and may represent only a portion of a patient's organ dysfunction. Whereas several etiologies may lead to AKI, each individual contributor to AKI is generally classified as being prerenal, "intrinsic" renal, or postrenal (Table 52.2).

Prerenal Azotemia. "Prerenal" AKI is believed not to be due to an actual change in the kidneys' ability to clear Cr and other solutes, but rather to a perfusion-limited decrease in solute presentation to the kidneys. Most commonly, this is due to intravascular volume depletion, such as might occur during hemorrhage, desiccation, or third spacing of intravascular fluid. However, it should be noted that "prerenal" does not necessarily mean a given patient is whole body, or even volume depleted intravascularly. Congestive heart failure, for instance, is often associated with "prerenal" increments in s[Cr], and is due to inability of the heart to generate cardiac output to perfuse the kidneys adequately. As such, prerenal azotemia is best characterized by ineffective arterial blood flow to the kidneys for any reason. AKI from prerenal causes is usually reversible, and will generally respond to correction of the underlying abnormality (i.e., fluid resuscitation for intravascular volume depletion).

Intrinsic Acute Kidney Injury. Structural injury of the kidney is the hallmark of intrinsic AKI (Table 52.2). The most common form is acute tubular necrosis (ATN), whether ischemic due to progression of prerenal azotemia or interruption of renal blood flow (e.g., trauma, thromboembolism) or cytotoxic (e.g., due to toxicity from medications or ingestion syndromes).[11] ATN may occur even absent an overt, prolonged decrease in renal blood flow or a massive exposure to nephrotoxins, usually due to a confluence of events in the acute setting. For example, doses of gentamicin insufficient to cause AKI in a normal kidney may result in substantial nephrotoxicity in the setting of hypoperfusion or concurrent exposure to other nephrotoxins.[12] However, ATN occurs most commonly when the nephrons' capacity to autoregulate blood flow is overwhelmed. As noted above, this autoregulation is dependent on modulation of the relative tones of the glomerular afferent and efferent arterioles. Moreover, oxygen tension in the renal medulla tends to be low, due to both the anatomic characteristics and energy demands of the loop of Henle. The medullary microcirculation is dependent on endothelial elaboration of vasodilators such as nitric oxide and prostaglandins, which may be impaired in acute illness, existing microvascular disease, or by medications such as radiocontrast medium or nonsteroidal anti-inflammatory drugs (NSAIDs).[13] Thus, the stressed renal microvasculature loses its autoregulatory capacity and becomes more sensitive to vasoconstrictor drugs and periods of systemic hypotension, which thus may provoke additional damage that can delay recovery from ATN.[14] Although the cellular injury is observed in proximal tubules predominantly (by contrast to apoptotic cell death, which occurs primarily in the distal nephron), necrosis of the distal nephron may also occur. The distal nephron may also become obstructed by desquamated cells and cellular debris due to sloughing of more proximal tubular cells. Endogenous growth factors regulate tissue repair and recovery; administration of growth factors exogenously has been shown experimentally to ameliorate and hasten recovery from AKI, although there have been no studies suggesting benefit in clinical trials. Depletion of neutrophils and blockade of neutrophil adhesion reduce AKI following experimental ischemia, indicating that inflammation is at least partly responsible for some features of ATN, especially in postischemic injury after transplantation.[14]

TABLE 52.2

ETIOLOGIES OF AKI

Prerenal causes (decreased renal blood flow)
Hypovolemia
Renal losses (diuretics, osmotic agents, polyuria)
Gastrointestinal losses (vomiting, diarrhea)
Cutaneous losses (burns, exfoliative syndromes)
Hemorrhage
Pancreatitis
Capillary-leak syndrome with "third spacing" of intravascular volume
Decreased cardiac output
Congestive heart failure
Pulmonary embolism
Acute myocardial infarction
Severe valvular heart disease
ACS
Renal artery obstruction (stenosis, embolism, thrombosis, dissection)
Systemic vasodilation
Sepsis
Anaphylaxis
Anesthetics
Drug overdose
Afferent arteriolar vasoconstriction
Hypercalcemia
Drugs (NSAIDs, amphotericin B, calcineurin inhibitors, norepinephrine, iodinated radiocontrast agents, aminoglycosides,
    vancomycin [high doses])
Hepatorenal syndrome
Efferent arteriolar vasodilation (ACE-I, aldosterone receptor blockers)

Intrinsic renal causes
Vascular (large and small vessel)
Trauma
Renal vein obstruction (thrombosis, ventilation with high-level positive end-expiratory pressure [PEEP], ACS)
Microangiopathy (thrombotic thrombocytopenic purpura [TTP], hemolytic uremic syndrome [HUS], disseminated intravascular
    coagulation [DIC], preeclampsia)
Malignant hypertension
Scleroderma renal crisis
Transplant rejection
Atheroembolic disease
Sickle cell disease (microinfarcts)
Glomerular
    Antiglomerular basement membrane (GBM) disease (Goodpasture's syndrome)
    Antineutrophil cytoplasmic antibody–associated glomerulonephritis (e.g., Wegener granulomatosis)
    Immune complex glomerulonephritis (GN) (systemic lupus erythematosus [SLE], postinfectious, cryoglobulinemia, primary
    membranoproliferative GN, bacterial endocarditis)
Tubular
Ischemic
Cytotoxic
Heme pigment (rhabdomyolysis, intravascular hemolysis)
Crystals (tumor lysis syndrome, seizures, ethylene glycol poisoning, megadose vitamin C, acyclovir, indinavir, methotrexate)
Drugs (aminoglycosides, lithium, amphotericin B, pentamidine, cisplatin, ifosfamide, iodinated radiocontrast agents)
Interstitial
    Drugs (penicillins, cephalosporins, NSAIDs, proton pump inhibitors, allopurinol, rifampin, indinavir, mesalamine, sulfonamides)
Infection (pyelonephritis, viral infection)
Systemic disease
    Sjögren's syndrome, sarcoidosis, SLE, lymphoma, leukemia, tubulonephritis, uveitis

Postrenal
Ureteral obstruction (calculus, tumor [intrinsic or extrinsic], fibrosis, ligation during pelvic surgery)
Bladder neck obstruction (benign prostatic hypertrophy, prostate cancer, neurogenic bladder, tricyclic antidepressants, ganglionic
    blockers, bladder tumor, calculus, hemorrhage/clot)
Urethral obstruction (stricture, tumor, phimosis)
Renal calcinosis
Obstructed or malpositioned urinary catheter, ureteral stent, or ileal conduit
Trauma-pelvic retroperitoneal hematoma

Hypoperfusion-related decreases in glomerular blood flow and intrarenal vasoconstriction appear to be the dominant mechanisms for reduced GFR in ATN. The mechanisms of this vasoconstriction are not entirely clear, but tubuloglomerular (TG) feedback mechanisms appear to play a role. In the normal setting, TG feedback can modulate glomerular blood flow by causing arteriolar vasoconstriction when large amounts of chloride are presented to the macula densa, a group of cells at the end of the loop of Henle that physically abut its associated glomerulus.[4] This response is favorable from an evolutionary perspective; when there is tubular dysfunction, defects in salt and chloride reabsorption lead to activation of TG feedback and a resultant decrease in blood flow to the affected glomerulus. Salt and water losses are thereby mitigated, at the cost of some degree of GFR. Tubular obstruction from sloughed cells and interstitial edema also result in loss of the hydrostatic gradients favoring glomerular filtration.

Whereas ATN comprises the large majority of "intrinsic" causes of AKI, two other less common causes are due to host immune responses: postinfectious glomerulonephritis (PIGN) and acute interstitial nephritis (AIN). The incidence of PIGN in the acute surgical setting has not been studied but is believed to be rare, although that impression may be due to a paucity of biopsy data in this population. Although the pathophysiology of PIGN has not been elucidated, it is conceptualized as an immune complex–associated glomerulonephritis, in which antigen–antibody complexes containing bacterial (usually streptococcal) antigen deposit in the glomerulus and cause immune activation and inflammation.[15] This can result in varying degrees of renal dysfunction, from mild loss of GFR to a permanent need for RRT. Common features of PIGN include signs of acute kidney inflammation, including salt retention and edema, hypertension, hematuria, hemolysis, and proteinuria.

Interstitial nephritis is also an important contributor to intrinsic AKI. Predominantly due to allergic responses to medications, AIN was implicated as the cause in 7% of cases of AKI in a recent biopsy review.[16] Although any medication can theoretically cause AIN, the most common culprits include penicillins (especially nafcillin or methicillin [the latter now used rarely]), cephalosporins, NSAIDs, sulfa-containing medications, rifampin, fluoroquinolones, and proton pump inhibitors.[17] Time of onset of AKI is unpredictable, and can occur from 1 day to months after the second exposure to the agent. As such, awareness of and suspicion of AIN is important, especially in the setting of known potential medications, peripheral or urine eosinophilia, and rash.

Postrenal Acute Kidney Injury. "Postrenal" AKI is due to mechanical obstruction of urine flow, which results not only in failure to excrete urine, but also the eventual loss of the hydrostatic gradient favoring filtration across Bowman's capsule if the obstruction is not relieved (Table 52.2). Obstruction can occur anywhere along the urinary tract, including the ureters, bladder, and urethra. Bladder outlet obstruction due to prostate hyperplasia is the most common cause of postrenal AKI. Unilateral causes of hydronephrosis, such as a ureteral calculus or extrinsic compression of one ureter, generally do not lead to oliguria, as the contralateral kidney will continue to produce urine. As such, whereas placement of a Foley catheter does essentially rule out bladder outlet obstruction (or overcome it if present), bladder catheterization does not rule out obstructive nephropathy more proximally. In addition, although not truly "obstructive" in nature, postoperative urine leaks can also present as "postrenal" AKI. Urine leaks occur most commonly after surgical manipulation of the bladder or ureters (e.g., cystectomy, kidney transplant surgery), and can present as decreased urine output and persistently elevated or increasing s[Cr] without obvious cause. The diagnosis

is usually confirmed by radionuclide imaging that detects renal excretion of tracer into a perinephric or intraperitoneal fluid collection. Alternatively, [Cr] can be measured in a sample of the fluid; if it is higher than s[Cr], the fluid collection is at least partially urine.

DETECTION OF ACUTE KIDNEY INJURY

As noted above, the RIFLE criteria have become the standard for definition of AKI, and have provided consistency to AKI diagnoses (Table 52.1). However, complicating further the evaluation and treatment of AKI is the lack of ideal biomarkers thereof. Currently, the blood urea nitrogen concentration [BUN] and s[Cr] are the tests used most commonly to monitor renal function, and as such, s[Cr] is the main laboratory parameter used in the RIFLE classification. Nevertheless, these measures are clearly imperfect. Urea nitrogen, for example, is an end product of protein metabolism, and does accumulate in the presence of AKI and chronic kidney disease (CKD). However, there are many conditions that can also result in an elevated [BUN] unrelated to renal function, including (1) states of protein catabolism (e.g., corticosteroid therapy, sepsis); (2) excessive protein intake; or (3) increased reabsorption (e.g., dehydration, gastrointestinal bleeding). Conversely, patients who cannot synthesize urea (e.g., liver cirrhosis) or have inadequate protein intake may have misleadingly low BUN concentrations even in the presence of substantial kidney dysfunction.

Although s[Cr] is accepted as the standard test to monitor renal function, it is imperfect. Steady-state s[Cr] is influenced by age, gender, and muscle mass. Severe decrements in renal function can be present even while the s[Cr] remains within the laboratory's specified "normal range,"[18] especially among elderly females. For example, a s[Cr] of 1.2 mg/dL in a 90-year-old female with a body mass of 50 kg may underrepresent GFR, whereas the same s[Cr] in a 25-year-old black male with a body mass of 100 kg may be normal. Formulas such as the Cockcroft-Gault or Modification of Diet in Renal Disease (MDRD) calculations (Table 52.3) were developed to normalize demographic variations in muscle mass. Calculation tools are readily available online, and can be used to estimate renal function with reasonable accuracy. These imperfections are noted not to discourage use of [BUN] and s[Cr] for evaluation of renal function, but rather to highlight potential confounding factors that may have clinical import.

Emerging biomarkers may prove useful in the future for early detection of AKI. Potential biomarkers include both serum neutrophil gelatinase-associated lipocalin (NGAL) and cystatin C, and urinary NGAL, interleukin-18 (IL-18), and kidney injury molecule-1 (KIM-1).[19] Serum NGAL and cystatin C may be particularly useful in predicting AKI after cardiac surgery.[20] These biomarkers may also be important for drug development. With highly sensitive urinary biomarkers of kidney toxicity, drugs that have nonclinical signals of nephrotoxicity can be tested more safely in clinical trials.[21]

PREVENTION OF ACUTE KIDNEY INJURY

The best management strategy for AKI entails preventing its development. Certain patients have been identified clearly as being at high risk of developing AKI, including postoperative patients or those with sepsis, trauma, or hypovolemia,[22] including shock of any etiology. Patient groups also at risk include those receiving any nephrotoxic agents (e.g., iodinated radiocontrast medium, medications), those with CKD due to diabetes mellitus or hypertension, or patients with congestive heart failure, multiple myeloma, chronic infection (e.g., osteomyelitis), or a myeloproliferative disorder. Estimation of GFR using either the Cockcroft-Gault or MDRD GFR equation, or measurement of urine creatinine clearance (C_{Cr}) is especially important in such patients, as this may improve risk

TABLE 52.3

FORMULAS FOR ESTIMATION OF CREATININE CLEARANCE (eC_{Cr}) OR GLOMERULAR FILTRATION RATE (eGFR)

Cockroft-Gault Equation

$$eC_{Cr} = \frac{(140 - Age) \times Mass\,(in\ kilograms) \times [0.85\ if\ female]}{72 \times Serum\ Creatinine\,(in\ mg\,/\,dL)}$$

(when Cr is expressed in mg/dL)

$$eC_{Cr} = \frac{(140 - Age) \times Mass\,(in\ kilograms) \times Constant}{Serum\ Creatinine\,(in\ \mu mol\,/\,L)}$$

(When Cr is expressed in micromol/L, where constant is 1.23 for males and 1.04 for females.

Modification of Diet in Renal Disease (MDRD) Formula
For creatinine in mg/dL:

$$eGFR = 186 \times Serum\ Creatinine^{-1.154} \times Age^{-0.203} \times [1.212\ if\ Black] \times [0.742\ if\ Female]$$

For creatinine in μmol/L:

$$eGFR = 32788 \times Serum\ Creatinine^{-1.154} \times Age^{-0.203} \times [1.212\ if\ Black] \times [0.742\ if\ Female]$$

Creatinine levels in micromol/L can be converted to mg/dL by dividing them by 88.4. The 32,788 number above is equal to $186 \times 88.4^{1.154}$.

The MDRD equation has been validated in patients with CKD, but underestimates the GFR in healthy patients with GFRs over 60 mL/min (From Madaio M. Post-infectious glomerulonephritis. In: Schrier RW, ed. Diseases of the Kidney. Boston, MA: Little Brown; 1997:1579–1594; Prakash J, Sen D, Kumar NS, et al. Acute renal failure due to intrinsic renal diseases: review of 1122 cases. Ren Fail. 2003;25:225–233.) The equations have not been validated in AKI. These MDRD equations are to be used only if the laboratory has NOT calibrated its s[Cr] measurements to isotope dilution mass spectroscopy (IDMS). When IDMS-calibrated [sCr] is used (which is about 6% lower), the above equations should be multiplied by 175/186, or 0.94086. These formulas do not adjust for body mass, therefore, relative to the Cockroft-Gault formula, they underestimate eGFR for heavy people and overestimate it for underweight people. See text for abbreviations.

stratification regarding administration of procedures, medications, or imaging tests. Whereas all hospitalized patients must have their intravascular volume status monitored to some degree, these at-risk patients require particularly close monitoring to ensure that hypovolemia is avoided and that exposure to nephrotoxins is minimized or avoided. Consequently, high-risk patients may need frequent measurements of vital signs, central venous pressure, serum [lactate], urine output, or short-duration (e.g., 8–12 hours) C_{Cr}.

Furthermore, medications that are not overtly "nephrotoxic" but that do affect glomerular blood flow, such as angiotensin-converting enzyme inhibitors (ACE-I) and NSAIDs, should be used with caution, especially in populations prone to AKI. For instance, in patients with cardiac or liver disease, or patients who may be volume underresuscitated, prostaglandin-mediated afferent arteriolar dilation or angiotensin II–medicated efferent arteriolar constriction may be crucial in maintaining filtration pressure. Blockade of one or both of these mechanisms with a NSAID or ACE-I can result in an abrupt decrease in GFR.

Several interventions may prevent AKI in certain patient groups. Nondiabetic cardiac patients may have a diminished risk of AKI after cardiac surgery, according to the RIFLE criteria, by maintaining tight perioperative blood glucose control. In one study, nondiabetic patients undergoing cardiac surgery had glucose concentrations controlled by insulin infusion at either a trigger of >140 mg/dL, or in a range of 80–111 mg/dL. The observed overall incidence of postoperative AKI or acute postoperative RRT was lower in the group controlled more tightly, who also demonstrated a lower mortality rate.[22] Patients with septic shock appear to be at particularly high risk for AKI. These patients may be severely hypovolemic and may also be subject to nephrotoxicity from cytokine-mediated renal vasoconstriction as part of the proinflammatory response. Notably, delays in antibiotic therapy in this cohort of patients may be particularly predictive of AKI.[23]

Certain intravenous medications have been suggested to prevent the occurrence of AKI. Historically, low-dose dopamine (1.5–3.0 mcg/kg/minute) has been used most commonly.[24] D'Orio et al. demonstrated that dopamine (3 mcg/kg/minute) caused isolated renal vasodilation, resulting in increased diuresis, natriuresis, increased renal blood flow, and enhanced GFR, without activating either alpha- or beta-adrenergic receptors.[25] The institution of low-dose dopamine in critically ill patients will augment C_{Cr} by 25% or more in individual patients,[26] but large studies have failed to demonstrate benefit to prevent development of AKI or mitigate it postonset. Marik performed a meta-analysis of 15 trials (970 patients) looking at the absolute change of s[Cr] with the use of low-dose dopamine, and found no difference.[27] Bellomo et al., through the Australian and New Zealand Intensive Care Society (ANZICS) Clinical Trials Group, performed the largest multicenter randomized trial of low-dose dopamine (by studying critically ill patients with signs of systemic inflammatory response syndrome and clinical evidence of early AKI). This trial of 328 patients in 23 ICUs found that neither the primary outcome (peak s[Cr]) nor any of the secondary outcomes (hourly urine output, requirement for RRT, duration of mechanical ventilation, duration of ICU or hospital stay, or mortality) were altered among patients treated with low-dose dopamine.[28] Currently, low-dose dopamine may be used to promote diuresis in select patients with adequate preload, as many patients do respond with increased urine output. However, low-dopamine does not alter the outcome or avert the development of AKI in critically ill patients.

Fenoldopam, a potent dopamine D_1 receptor agonist that increases blood flow to the renal cortex and outer medulla, has also been utilized to prevent AKI, but may induce hypotension. Indications for fenoldopam in critical care are not well defined, but it may be beneficial when hypertension must be treated while preserving renal perfusion. In a study using perioperative fenoldopam with N-acetylcysteine, investigators found the combination abrogated an early postoperative decrease of renal function in cardiac surgical patients with CKD, but did not affect other outcomes.[29] A meta-analysis of fenoldopam to prevent AKI in postoperative cardiac patients showed that

fenoldopam reduced the need for RRT and perioperative mortality.[30] Another meta-analysis of randomized, controlled trials (RCTs) of fenoldopam to prevent or treat AKI in postoperative or intensive care patients demonstrated that mortality and the need for RRT were both decreased by fenoldopam.[31] However, the second meta-analysis included only small single-center studies, and doses were variable. Data are insufficient presently to support widespread use of fenoldopam for prevention or management of AKI.

SPECIAL POPULATIONS

Rhabdomyolysis

Certain patient populations are at extremely high risk of developing AKI, and warrant special consideration. Rhabdomyolysis is due most commonly to crush injury, but it can also occur with high fever or other clinical syndromes[32] (Table 52.4).

An unusual, recently described cause of rhabdomyolysis is propofol-related infusion syndrome, a complex syndrome characterized not only by rhabdomyolysis but also by metabolic acidosis, arrhythmias, myocardial failure, AKI, hepatomegaly, and death.[33] Propofol inhibits mitochondrial electron transport via the upregulation of malonyl coenzyme A, which inhibits activity of carnitine palmitoyltransferase I, thus preventing long-chain free fatty acids (FFA) from entering the mitochondria (Fig. 52.1). Beta-spiral oxidation of FFA is uncoupled and the electron transport chain is disrupted, preventing the utilization of medium- and short-chain FFAs, which leads to myocytolysis. Accumulation of FFAs may cause arrhythmias, whereas uncoupling of oxidative phosphorylation antagonizes adrenoceptor binding by β-agonists and myocardial calcium channels, thereby depressing myocardial contractility. Increased catecholamine requirements to overcome the adrenoceptor blockade (or circulating as a result of traumatic brain injury or the proinflammatory stress response) may increase propofol requirements (via increased clearance owing to the increased cardiac output), or cause direct myocyte toxicity. The negative inotropic effect of propofol, resulting in

increased catecholamine requirements, could create a "vicious circle" of propofol and catecholamines driving each other to progressive myocardial depression.

Another increasingly prevalent cause of rhabdomyolysis is prolonged immobilization in the bariatric setting, which may be prevented by careful padding on the operating table at all pressure points, frequent changes of patient position intraoperatively and postoperatively, or performance of certain bariatric operations in two stages.[34]

Sometimes AKI in the setting of rhabdomyolysis may be multifactorial. Factors predictive of AKI in this setting, determined by multiple logistic regression analysis, include the degree of elevation of serum creatine phosphokinase (CPK), $[K^+]$, or $[PO_4^{3-}]$, the magnitude of decrease of serum [albumin], dehydration at presentation, or sepsis as the underlying cause.[35]

The pathophysiology of rhabdomyolysis contributing to AKI has been studied extensively, and is due to renal ischemia, direct renal toxicity, and tubular obstruction. Hypotension and shock impair glomerular filtration due to reactive renal vasoconstriction, which results in decreased renal perfusion. Hypovolemia is initiated by capillary leak syndrome and extravasation of plasma into damaged muscle. As a result, oxygen delivery is reduced and renal tubular cell dysfunction impends. Likewise, tubular obstruction by cast formation (myoglobin with Tamm-Horsfall protein) can occur, resulting in oliguria.[32] Myoglobin itself is a direct tubular toxin but serum [myoglobin] peaks well before AKI is apparent, and thus is seldom measured. Myoglobin is catabolized to ferrihemate, generating reactive oxygen species (ROS) (at urine pH <5.8, both moieties are nephrotoxic) that are the likely cause of tubular toxicity.[32] The CPK may correlate with the extent of renal tubular damage, as the amount of myoglobin elaborated is also correlated.[36]

The treatment of rhabdomyolysis to prevent or minimize AKI is multifaceted. Initial therapy is focused on treating the underlying cause and resuscitating the patient. Muscle fascial compartments should be decompressed with fasciotomy and dead muscle debrided if needed, to avoid compartment syndromes. Offending toxins or drugs should be withdrawn. Intensive care unit monitoring with central venous pressure measurement and aggressive hydration optimizes intravascular volume. The next concern is to prevent AKI from myoglobinuria, especially if the serum (CPK) exceeds 5,000 U/dL, or myoglobinuria persists.[37] For these scenarios, treatment is by enforced alkaline diuresis with $NaHCO_3$ administration and an agent such as mannitol (25 g q6h being a standard dose), which is also a scavenger of ROS. Loop diuretics should be avoided as they tend to acidify the urine, which can exacerbate ROS generation and the direct toxic effects of the ferrihemate. For lesser elevations of CPK, aggressive diuresis with isotonic saline is sufficient. Many authorities recommend maintaining urine pH ≥ 6.0 by the continuous infusion of $NaHCO_3$. To maintain isotonicity, 150 mL of 8.4% $NaHCO_3$ (three standard amps of 8.4% $NaHCO_3$) is added to 850 mL D_5W to create the solution for infusion. Some authorities administer mannitol concurrently to enforce diuresis until pigmenturia disappears or [CPK] decreases, but both mannitol and $NaHCO_3$ are controversial for prevention of pigment-induced (i.e., myoglobin) nephropathy.[38]

TABLE 52.4

MAJOR ETIOLOGIES OF RHABDOMYOLYSIS

Crush injury
Prolonged immobilization
Muscle ischemia (prolonged hypoperfusion from hypovolemia or sepsis, extremity arterial occlusion)
Reperfusion injury
Compartment syndrome
Profound temperature elevation (high fever, heat stroke, malignant hyperthermia syndrome)
Severe exertion or muscle stimulation (marathon running, neuroleptic malignant syndrome)
Infection (*Clostridium* spp., *Streptococcus pyogenes*, Influenza A and B, Coxsackie virus)
Electrolyte disorders (hypophosphatemia, hypokalemia)
Drugs (statins or other lipid-lowering agents, daptomycin, propofol)
Toxins (alcohol, cocaine, heroin)
Genetic disorders

Contrast Nephropathy

Patients at high risk of AKI also include those who have CKD and require iodinated radiocontrast medium for a diagnostic test. Patients who have baseline s[Cr] >1.5 mg/dL, or baseline C_{Cr} < 30 mg/dL, are at high risk of superimposed AKI. There is no sure-fire means of preventing contrast nephropathy. Some

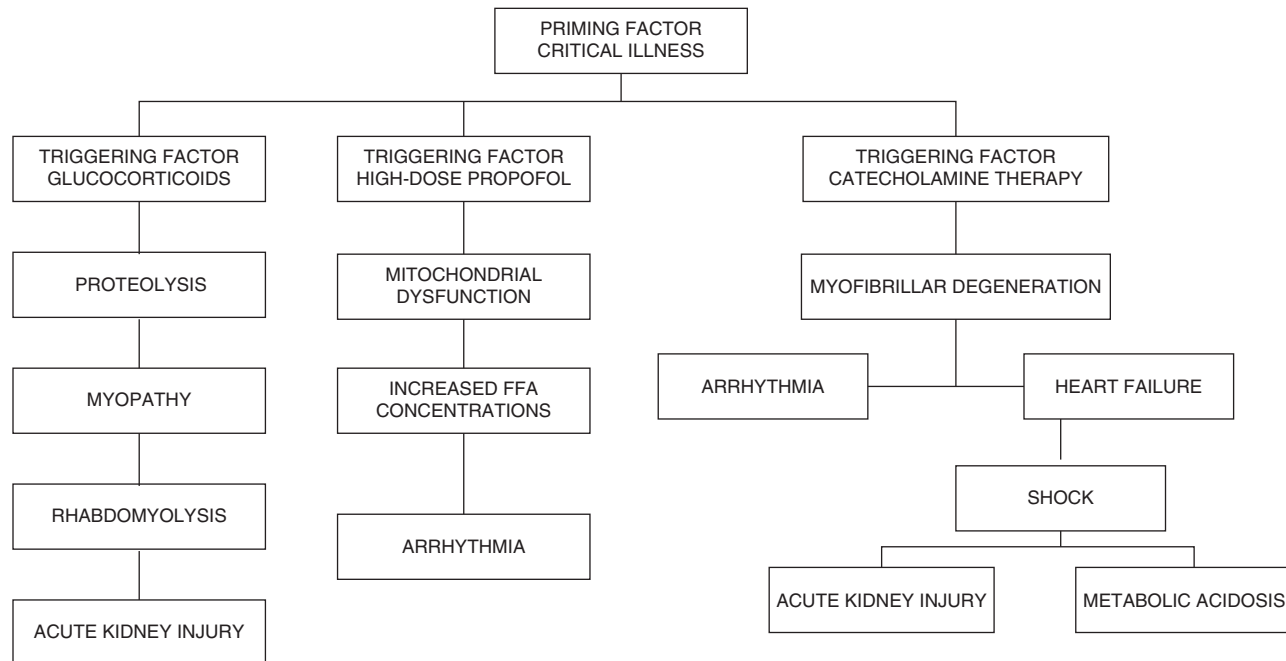
PATHOPHYSIOLOGY OF PROPOFOL INFUSION SYNDROME


FIGURE 52.1. Pathogenesis of propofol infusion syndrome. FFA, free fatty acids.

investigators have suggested that patients at risk should receive a $NaHCO_3$ infusion (50 mL of 8.4% $NaHCO_3$ added to 950 mL D_5W) at 100 mL/hour for 1 hour prior to the contrast administration and for 6 hours thereafter. When $NaHCO_3$ is employed, patients are placed at risk of developing pulmonary edema, and consequently need careful monitoring.[39] However, whether $NaHCO_3$ infusion prevents AKI in high-risk patients is controversial. In one study, all patients who underwent cardiac catheterization with an estimated GFR < 60 mL/minute were randomized to hydration with $NaHCO_3$ versus isotonic NaCl. Neither group differed in terms of the rates of mortality, RRT, myocardial infarction, or cerebrovascular events at 30 days or 6 months.[40] This finding was corroborated in part by a meta-analysis evaluating $NaHCO_3$ infusion compared to NaCl infusion for AKI prophylaxis in high-risk patients.[41] In that study, Brar et al. found that the benefit of $NaHCO_3$ for prevention of AKI was limited to small trials of lower methodological quality; no evidence of $NaHCO_3$ was noted among larger, better-quality trials. A recent systematic review on the same topic reached the same conclusion.[42] Nonetheless, our practice is to use $NaHCO_3$ administration for prophylaxis of contrast nephropathy owing to the smaller volume of fluid.

A variety of other agents have been employed to decrease the incidence of AKI following intravenous contrast, including *N*-acetylcysteine with either NaCl or $NaHCO_3$. In a meta-analysis of 10 studies combining *N*-acetylcysteine and $NaHCO_3$, Brown et al. found this combination to be more effective than *N*-acetylcysteine plus NaCl for patients undergoing cardiac catheterization.[43] Recently, the prostaglandin analogue iloprost was found to decrease the frequency of contrast-induced nephropathy (CIN) and maintain GFR compared to controls in patients undergoing coronary angiography.[44] Atrial natriuretic peptide (ANP) has also been studied to prevent AKI from CIN. A recent Cochrane review revealed that after major surgery there was a significant reduction in RRT requirement with ANP in prevention studies, but not in treatment studies; there was no mortality difference regardless.

Other interventions aimed at improving renal blood flow, such as dopamine[45] and fenoldopam[46] infusions (see above), are also of no benefit.

Low-volume nonionic low-osmolar or iso-osmolar contrast preparations have been suggested to decrease CIN when compared to high-osmolar agents. In a recent retrospective study, gadolinium was used in high-risk patients and yielded a decreased frequency of CIN when compared to standard contrast.[47] However, an RCT of 526 subjects with impaired baseline renal function and diabetes mellitus, undergoing diagnostic or therapeutic coronary angiography, showed that the renal effects of the nonionic, iso-osmolar agent iodixanol and the nonionic, low-osmolar agent iopamidol were comparable.[48] These two agents have emerged as the contrast media of choice in patients at risk of CIN who require imaging with parenteral contrast.[49]

BASIC PRINCIPLES OF TREATMENT OF ACUTE KIDNEY INJURY

Early intervention and prevention remain the optimal strategies in managing AKI, as no treatment has been proved effective in RCTs for established AKI. Nevertheless, delayed treatment of AKI may lead to worsened organ dysfunction. Although mild AKI may develop in isolation, all patients with severe AKI invariably manifest the multiple organ dysfunction syndrome (MODS). The most common pitfalls in AKI management are delay in diagnosis, incorrect assessment of the cause(s) of AKI, and failure to recognize and treat not only its complications, but also its precipitant and the other manifestations of MODS. If uncorrected, the precipitant is more likely to cause death than the AKI itself.

The most important step in diagnosing and treating AKI involves determining whether the etiology of the AKI

is prerenal, renal, or postrenal (see above).[50] However, once AKI develops, the clinician must treat the underlying cause concurrently with treatment or prevention of any related complications. For example, trauma and sepsis may contribute to the development of AKI by multiple mechanisms. In trauma, blood loss and the concomitant proinflammatory response from tissue injury can lead to hypovolemia and prerenal AKI, whereas the rhabdomyolysis of trauma or the use of iodinated contrast to detect injuries can lead to intrinsic AKI. Sepsis may be the most common cause of AKI in the ICU, where it may be present in up to 50% of cases.[51] In sepsis, hypovolemia can lead to prerenal AKI but bacterial toxins, vasoconstrictor proinflammatory cytokines, or the antibiotics used to treat sepsis may contribute to intrinsic causes of AKI.

Evaluation of Oliguria

The most common manifestation of the development of AKI is oliguria, defined as urine output insufficient to excrete the daily solute load, which in patients with normal renal concentrating ability (up to ~1,200 mOsm/L) eating a normal solute diet (~600–900 mOsm/day) equates to <0.5 mL/kg/hour based on ideal body weight or <400–500 mL urine output in a 24-hour period. This more nuanced definition is important; in patients who have a high solute load (e.g., patients receiving a high protein diet for wound healing or aggressive crystalloid resuscitation) or impaired renal concentrating ability, even a daily urine output of > 1 L may be relative oliguria.

Postoperative oliguria is most likely to be due to hypovolemia or other prerenal causes. Surgical evaluation begins with a focused history and physical examination for likely causes, but if the cause is unknown or obscure, a detailed evaluation must follow. Examination of the skin may reveal petechiae, purpura, ecchymosis, or livedo reticularis, which can provide clues to inflammatory and vascular causes of AKI. Ocular examination may find evidence of uveitis suggestive of interstitial nephritis or necrotizing vasculitis, whereas ocular palsy may indicate ethylene glycol poisoning or necrotizing vasculitis. Findings suggestive of severe hypertension, atheroembolic disease, or endocarditis may be observed by fundoscopy.

The most important part of the physical examination for surgical patients is the assessment of cardiovascular and volume status.[52] Vital signs taken both supine and standing (if possible), and careful examination of the heart, lungs, jugular venous pulse, skin turgor, mucous membranes, and extremities (for peripheral edema) are essential. Accurate daily records of fluid intake and urine output and daily measurements of patient body mass are crucial. Medications must be reviewed, and doses adjusted if necessary.

Abdominal examination findings can be useful to detect obstruction at the bladder outlet (postrenal AKI). The presence of an epigastric bruit suggests renovascular hypertension. Abdominal distention may suggest intra-abdominal hypertension and abdominal compartment syndrome (ACS). Foley catheters and other urinary conduits or stents should be inspected for patency and proper positioning, and intravesical pressure measured for suspected ACS (see below).

After this initial assessment, it must be determined whether oliguria is due to prerenal or other causes.[53] Confirmatory tests may include central venous or pulmonary artery pressure monitoring or a chest radiograph (Table 52.5). Notably, the detection of pulmonary edema in critically ill patients by standard anterior–posterior chest radiography lacks sensitivity and specificity. Thus, if available, invasive monitoring with either a central venous pressure catheter or a pulmonary artery catheter may assist in determining intravascular volume status, although outcomes may be unaffected.[54]

TABLE 52.5

DIAGNOSTIC TESTS TO DISTINGUISH PRERENAL AND RENAL AKI

■ INDEX	■ PRERENAL CAUSES	■ RENAL CAUSES
FeNa	<1%	≤2%
Urine [Na]	<10 mmol/L	>40 mmol/L
Urine/plasma osmolality	>1.5	1–1.5
Renal failure index	<1	>2
BUN:creatinine	>20	<10

BUN, blood urea nitrogen; FeNa, fractional excretion of sodium.
Calculation of FeNa: [urine sodium × plasma creatinine]/[plasma sodium × serum creatinine] × 100.
renal failure index: urine sodium × urine creatinine/plasma creatinine.

Urine electrolytes should be measured to determine whether tubular function is intact. In general, ATN results in disruption of tubular Na and solute reabsorption, whereas prerenal causes of AKI do not. The most commonly measured urine indices include the fractional excretion of sodium (FeNa) and the fractional excretion of urea (FeUrea). If one considers that a normal daily GFR is approximately 180 L/day and that serum [Na] is approximately 140 mEq/L, then the daily filtered load of Na = 25,200 mEq. As such, the normal response of the renal tubular system is to reabsorb more than 99% of the filtered sodium (i.e., FeNa < 1%); otherwise, a diet extraordinarily high in sodium would be required in order to avoid severe negative Na balance. Thus, in an oliguric patient, a FeNa of <1% implies that the tubular Na reclamation mechanisms remain intact, and therefore unlikely that tubular necrosis is responsible for the decrease in urine output or increase in s[CR]. Conversely, if an oliguric patient is found to have a FeNa > 2%, it is likely that tubular function has been compromised, and that prerenal factors alone are not responsible for the clinical picture. If urine [Cr] is unavailable, urine [Na] < 10–20 mg/dL is also consistent with a prerenal etiology.

Whereas the FeNa is a useful tool, it may be confounded by multiple factors, including diuretic therapy, whose purpose is to induce renal sodium wasting. In these patients, the calculation of the FeUrea may be more useful. Urea excretion, as with Na excretion, decreases in prerenal azotemia, but is not affected by the vast majority of diuretics in acute clinical use (loop and thiazide diuretics). As such, a value of FeUrea <35% also suggests that tubular concentrating ability remains intact and that oliguria may be prerenal.[55]

The measurement of serial C_{Cr} may also be useful in assessing the functional status of the kidneys. These values accrue more importance if the baseline C_{Cr} is known or the patient undergoes a change in C_{Cr}. Importantly, a full 24-hour C_{Cr} is not necessary and may even be inaccurate (and therefore misleading) in patients with dynamic changes of renal function.[56] A renal ultrasound should be ordered to evaluate for hydronephrosis, and may also be useful to estimate renal blood flow. As noted above, urology and renal transplant patients pose unique diagnostic problems; the former may be leaking urine intraperitoneally and have apparent renal failure due to reabsorption of urea and creatinine, whereas the latter may have vascular complications. These cases may require measurement of [creatinine] in drain fluid, or scintigraphy to assess perfusion. Eosinophils in urine sediment may suggest a drug reaction causing AKI, most frequently from a beta-lactam antibiotic.

In certain patients, the diagnosis of ACS must be excluded. In ACS, intra-abdominal pressure exceeds renal capillary perfusion pressure, resulting in oliguria. Patients at highest risk for ACS include those with large fluid resuscitation volumes (generally >8 L), large-volume hemorrhage (generally 2 L or more), ascites, severe bowel edema, or patients with abdominal packs in place to stanch hemorrhage. Intravesical pressure is a reasonable surrogate for intra-abdominal pressure; a simple method to measure intravesical pressure is to occlude the Foley catheter after the instillation of at least 50 (preferably no more than 100) mL of saline, and then transducing the pressure via the sampling port proximal to the clamp. Measurement does carry an increased risk of nosocomial bacterial cystitis. Any measurement in excess of 20–25 mm Hg is consistent with intra-abdominal hypertension, which in the proper setting can be diagnostic for ACS. Prompt decompression of the abdomen by laparotomy is the standard treatment for patients with high suspicion of ACS. However, bladder pressure values by this method must be interpreted cautiously in patients with CKD, neurogenic or small-volume bladders, bladder cancer, recent bladder injury, or active bacterial cystitis.

Treatment of AKI of Prerenal Etiology

The management of AKI is predicated on its cause (Table 52.3). A prerenal cause is the most common etiology of AKI after surgery, due usually to severe hypovolemia if not incipient or overt shock. Treating prerenal AKI mainly entails optimizing perfusion to the kidneys and treating the cause of the hypoperfusion or shock regardless of etiology. Whereas hypovolemia is the most common etiology of shock in surgical patients, cardiogenic shock from myocardial infarction, pulmonary embolism, tension pneumothorax, or pericardial tamponade may alternatively or also be present. Other cardiac causes are manifold, including pump failure, cardiac valvular disease, or intrinsic cardiac shunts. Neurogenic shock occurs most commonly after spinal cord injury, but can also occur from epidural local anesthesia. Other forms of distributive shock from etiologies such as medication or transfusion reaction should also be considered. Whereas most of these causes require volume replacement and treatment of the underlying cause, in left ventricular pump failure, the patient may paradoxically have decreased renal perfusion but requires diuretics with afterload reduction for successful management.

Management of AKI from Intrinsic and Postrenal Causes

Regardless of the etiology, management of AKI must avoid any further insult to renal function (particularly so for intrinsic AKI) and iatrogenic complications such as fluid overload. Many patients develop secondary pulmonary dysfunction from hypervolemia, usually due to overzealous fluid administration. One important goal in AKI is to maintain euvolemia so as to avoid an additional or superimposed prerenal insult. Fluid overload in the setting of AKI can be catastrophic, resulting in endotracheal intubation and prolonged mechanical ventilation, and convert a patient with single organ failure to MODS and a propensity for nosocomial infections and substantially increased risk of mortality. Potassium and chloride should be removed from intravenous solutions, and minimized in enteral feedings and oral diets to preempt hyperkalemia and minimize metabolic acidosis. Frequent monitoring of serum electrolyte concentrations is crucial.

Presuming the point of obstruction has been identified in postrenal AKI, a decision must be made as to how to relieve the obstruction. The approach is individualized depending on the site and nature of the obstruction, the condition of the patient, and the degree of renal impairment. For critically ill patients, urinary diversion is often preferred. Options include ureteral stents, suprapubic cystostomy, or percutaneous nephrostomy, depending on the level of obstruction.

If the patient has AKI, is deemed to have adequate preload, and is making some urine, the patient may be a candidate for diuretic therapy. Diuretics are more useful if the patient has decreased ventricular function, a history of prior use, or signs of hypervolemia such as hypoxemia, rales, tachypnea absent marked metabolic acidosis, or dyspnea. Loop diuretics (e.g., furosemide, bumetanide) are generally the diuretics of first choice. Lower doses of furosemide (i.e., 10–40 mg) may be ineffective in patients with more severe AKI (s[Cr] > 4.0 mg/dL), but patients may respond to higher doses (i.e., 80–200 mg) of furosemide or bumetanide (2–5 mg; approximate furosemide:bumetanide dosage 40:1). If an oliguric patient does not respond to an initial high dose, there is little benefit to another dose. High doses of loop diuretics are ototoxic, and should not be used repeatedly if the patient is anuric and unresponsive to diuretic therapy. Importantly, diuretics do nothing to alter the natural history of the AKI, but may facilitate the management of volume and nutrition, avoid the need for RRT, or obviate the need for prolonged mechanical ventilation if some urine output is restored. Loop diuretics can cause hypokalemia, hypomagnesemia, and metabolic alkalosis, especially after large-volume diuresis, so electrolytes should be monitored closely. When a patient has oliguria and hypervolemia in the presence of metabolic alkalosis or a mixed picture of alkalosis and acidosis, loop diuretics should be used with caution, as they can exacerbate alkalosis. For patients with a serum $[NaHCO_3] > 28$ mmol/dL, acetazolamide (250–500 mg once or twice daily) is effective, provided serum [K] and [Mg] are normal and the patient still has some renal function ($C_{Cr} > 25$–30 mg/dL). For patients with severe metabolic alkalosis refractory to acetazolamide, intravenous HCl 1% is the next agent of choice prior to RRT. Infusion of HCl must be administered by central venous catheter because of a high risk of chemical phlebitis (or tissue necrosis should the solution extravasate), and may cause or worsen hyperkalemia.

Complications of Acute Kidney Injury

Deranged renal function impairs the maintenance of electrolyte homeostasis and the excretion of water-soluble toxins, thus complications of AKI are generally associated with these perturbations (Table 52.4). Anemia may ensue as production of erythropoietin ceases during moderate-to-severe AKI. Consequently, AKI can potentially result in fluid overload, electrolyte abnormalities, and impaired clearance of toxins such as urea. Anemia may manifest cardiovascular complications in patients with coronary artery disease, or impair oxygen delivery in patients with cardiac or pulmonary disease. Chest pain, myocardial ischemia, hypoxemia, hyperkalemia, acidosis, or uremia (avoidable if RRT is instituted timely and appropriately) is possible. Unchecked, any of these entities may be life threatening, as they may lead to arrhythmias, myocardial infarction, pericarditis, or coma. Due to the potential lethality of these complications, timely RRT is especially important for critically ill patients.

Renal Replacement Therapy. The decision to institute RRT is generally made jointly by the managing inpatient service and the consultant nephrologist. In cases of immediate life-threatening complications such as severe hyperkalemia (peaked T waves by electrocardiography, serum [K] > 6.5 mEq/dL), or pulmonary edema causing hypoxemic respiratory

TABLE 52.6

COMPLICATIONS OF AKI REQUIRING POTENTIALLY EMERGENT RRT

Fluid overload
Metabolic acidosis
Drug intoxications (dialyzable drugs)
Electrolyte abnormalities (e.g., hyperkalemia)
Uremic encephalopathy
Uremic pericarditis

failure, the decision is obvious. In other cases the timing of RRT may be subtle, depending on the clinical status of the patient.[57] Unfortunately, there are no widely accepted criteria regarding the optimal start time for RRT, as data are conflicting. Nevertheless, the strongest evidence for early initiation of dialysis (i.e., at [BUN] ~70 mg/dL, or oliguria post-CABG) is in the perioperative period[58] (Table 52.6).

The most common indications for RRT in surgical patients are hypervolemia and metabolic acidosis, two conditions that affect ventilated patients adversely in particular by increasing the risk of prolonged mechanical ventilation and consequent nosocomial pneumonia. After the indication for RRT has been determined, the modality and intensity of the RRT must be chosen (Table 52.7). Standardized methods of RRT include continuous RRT (CRRT) and intermittent hemodialysis (IHD). Peritoneal dialysis has distinct disadvantages to intravenous RRT as it is less effective in the ICU setting due to inferior clearance,[59] and it is contraindicated by recent abdominal surgery.

Both blood filtration modalities pose their own particular risks and benefits. Intermittent HD has been the traditional first-line modality for RRT in patients with AKI or end-stage renal disease (ESRD). Maintenance of outpatient IHD is often scheduled on a thrice-weekly regimen. However, in the acute setting, many patients are so catabolic that daily RRT is required, particularly at the onset. Nevertheless, because IHD only lasts 3–4 hours, it is more feasible than CRRT for critically ill patients from a nursing perspective. Furthermore, because the patient is not physically connected to the machine other than during the treatment, scheduling of imaging tests,

TABLE 52.7

INDICATIONS, ADVANTAGES, AND DISADVANTAGES OF IHD AND CRRT

■ MODALITY	■ INDICATIONS	■ ADVANTAGES	■ DISADVANTAGES
IHD	• Emergent electrolyte abnormalities (hyperkalemia and acidosis) • Emergent fluid removal (i.e., volume-related respiratory distress) • Emergent drug or intoxication treatment (i.e., ethylene glycol) • Hemodynamically stable • <3 L/d obligate fluid intake	• Superior short-term solute, acid–base, and volume control • Relatively low complexity • No extra RN requirement • Medication dosing well understood • Less risk of filter clotting and blood loss • Patent not bed-bound except during 3–4 h treatment	• Less well tolerated hemodynamically • Limited medium- and long-term solute/volume control capacity
Continuous renal replacement therapy (CRRT[a])	• Hemodynamically unstable • >3 L/d obligate fluid intake • Severe volume overload	• Superior medium- and long-term solute, acid–base, and volume control • Less hypotension during fluid removal • CVVH (continuous hemofiltration) may be associated with superior middle-molecule clearance than CVVHD	• Limited ability to rapidly correct electrolyte and acid–base abnormalities • More complex for nursing staff • Higher RN workload • Higher cost • Increased risk of filter clotting and circuit blood loss • Medication dosing less well understood • Patient continuously bed-bound • CVVH may require higher blood flows and as such may need higher access quality than CVVHD
Slow continuous ultrafiltration	• Hemodynamically unstable • Severe diuretic-resistant volume overload without renal dysfunction sufficient to require dialysis • >3 L/d obligate fluid intake • Heart failure resistant to attempts at conventional diuresis	• Superior volume control irregardless of quantity of obligate fluid intake • Less hypotension during fluid removal as compared with IHD	• Minimal solute clearance • Patient continuously bed-bound • Higher RN workload

[a]CRRT encompasses CVVH, CVVHD, and CVVHDF. There are no clearly defined outcome differences between the three modalities, and the choice of modality may be center- and program-specific
RN, registered nurse.

procedures, physical therapy, and such is relatively easy. Intermittent HD is clearly the modality of choice if rapid effect is desired. For instance, patients who have life-threatening hyperkalemia are best served with rapid reduction in serum [K]. Similarly, for marked hypervolemia and respiratory failure, IHD would be the appropriate modality to remove fluid quickly. However, these same qualities may also lead to adverse outcomes, most notably hypotension from overaggressive ultrafiltration (especially in patients with vascular leak or hypoalbuminemia).

CRRT is a basket term of continuous dialysis modalities that encompasses continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF) (Table 52.7). There are no concrete differences among the various CRRT modalities in terms of outcomes, although techniques involving hemofiltration are believed to improve "middle molecule" clearance (itself, of unclear clinical importance). The main difference between CRRT techniques and "regular" dialysis is the efficiency of clearance. Because IHD was designed for stable outpatients, the goal is high-efficiency clearance in as little time as practicable to maintain reasonable clinical outcomes. On the other hand, CRRT is intended for critically ill patients with marginal or unstable hemodynamics. Many of these patients cannot tolerate rapid fluid and solute shifts, and will become hypotensive with IHD if not already, due to their underlying disease. Continuous RRT provides low efficiency clearance (15–20 mL/minute), but because it is a 24 hour/day treatment, it can accomplish much greater solute and water clearance over time. For example, even hemodynamically stable patients may have difficulty tolerating an ultrafiltration rate >1 L/hour, and so removing more than 3–4 L/3.5 hour IHD treatment may be challenging. On the other hand, most patients with adequate preload will easily tolerate an ultrafiltration rate of 200 mL/hour; if this is continued over a 24-hour CRRT treatment, 4.8 L can be removed with little hemodynamic detriment. In patients with high obligatory fluid intake (e.g., patients on total parenteral nutrition, medications such as polymyxin B that require a large-volume diluent), CRRT may be the only modality that can maintain or improve overall fluid balance. Consequently, hypotensive or vasopressor-dependent patients may be better candidates for CRRT than IHD.[60]

Despite superior filtration characteristics, CRRT does carry major disadvantages when compared with IHD[61] (Table 52.7). First, during CRRT the patient generally requires 1:1 nursing care continuously, which has implications for staffing. Second, because CRRT, by definition, entails constant connection to the dialysis machine, transport for operative procedures or diagnostic tests outside the critical care setting may be difficult. Third, the extracorporeal circuit of CRRT is more prone to clotting than IHD, likely due to prolonged contact of blood with nonbiologic dialysis membranes and tubing, even if blood pressure is maintained and anticoagulant therapy is administered. Clotting of the CRRT circuit is detrimental, as it interrupts therapy, causes the loss of approximately 200 mL blood each time, and is costly. To decrease clotting, regional or systemic anticoagulation may be employed, but clotting can still occur in the presence of therapeutic anticoagulation. Newer CRRT protocols use citrate anticoagulation rather than heparin in the extracorporeal circuit, which may be safer for the critically ill patient than systemic anticoagulation, but this method is not widely available and can lead to hypocalcemia and metabolic alkalosis.[62,63]

The intensity of the RRT has been studied.[64] Some early single-center data indicated that more intensive RRT yields better outcomes in terms of dialysis dependence and mortality,[65-67] but the issue remains controversial as larger, multicenter studies have been nonconfirmatory.[68,69] As such, there is currently no consensus on "dialysis dosing" in AKI. Although it seems plausible that higher clearances should translate to better outcomes, possible reasons for the failure of CRRT to show benefit include actual irrelevance of higher clearances to clinical outcomes in critically ill patients with MODS, or the unintended clearance of beneficial molecules such as antibiotics, anti-inflammatory cytokines, or nutrients.

Medication Dosing in Acute Kidney Injury

Consideration of the appropriate dosing of therapeutic medications is of paramount importance in patients with AKI, as both under- and overdosage may have serious consequences. Drugs that have substantial renal clearance either via glomerular filtration or tubular secretion may require either smaller doses or prolonged dosing intervals, or both. Drug clearance by both filtration or secretion can be estimated using measured or estimated C_{Cr}, although caution should be taken when dosing medications in patients whose renal function is changing dynamically, as often occurs in AKI.

Extracorporeal drug losses during RRT (both IHD or CRRT) can be substantial. Because dialysis membranes have pores that are size-exclusionary, dialytic clearance of drugs depends primarily on the molecular weight of the drug and its protein-binding characteristics. Drugs <500 kDa in size generally will require supplemental doses after dialysis, whereas extensively protein-bound drugs may require no particular adjustment.[70] A list of commonly used drugs that require supplemental dosing posthemodialysis can be found in Table 52.8.

Dosing of medications during CRRT is especially problematic due to the lack of standard CRRT protocols. For instance, the majority of published guidelines for dosing of antibiotics in CRRT patients draw on pharmacokinetic studies completed prior to the widespread adoption of high-clearance CRRT (i.e., 35 mL/kg/hour therapy fluid flow rate).[71,72] Inadvertent underdosing of antibiotics may be one factor that contributes to the lack of benefit of CRRT as compared with IHD. This may be true of nutrition as well; some studies have indicated that protein intakes in excess of 1.5–2 g/kg may be necessary to maintain positive nitrogen balance[73] Similarly, trace element replacement may be indicated, although the clinical importance is unclear.[73] Thus, in critically ill patients on CRRT, it is essential that the care team work closely with nephrology, pharmacy, and nutrition consultants to ensure proper dosing of medications and nutrients.

COMMONLY USED DRUGS THAT REQUIRE POSTHEMODIALYSIS DOSING
Aminoglycosides
Carbapenems
Beta-lactams (penicillin derivatives, cephalosporins)
Aztreonam
Beta-blockers
Fluconazole
Chloramphenicol
ACE inhibitors
Procainamide
ACE, Angiotensin-converting enzyme.

PROGNOSIS OF ACUTE KIDNEY INJURY

The prognosis of patients with AKI is related directly to the cause of renal injury and, to some extent, to the duration of AKI prior to therapeutic intervention. Mortality rates range from 31% to 80% depending on the patient population.[74] Predictably, patients who have more severe AKI generally have a worse prognosis. For patients who require dialysis and survive hospitalization, there remains a substantive risk of dialysis dependence at discharge, especially among patients with preexisting CKD (16%–32% of patients dependent)[75] as compared with patients with previously normal function (3%).[76] Renal function may continue to improve long after the end of dialysis dependence, with optimal kidney function generally being reached between 3 and 6 months after discharge. If one also includes AKI episodes not requiring dialysis, patients without CKD generally have complete recovery assuming they survive the AKI episode, with >90% of patients enjoying "full" recovery (defined as s[Cr] below threshold for RIFLE criteria or estimated GFR >60 mL/minute). However, patients with CKD may only experience full recovery in two-thirds of cases and partial recovery in approximately 30% (defined as persistent s[Cr] above threshold for RIFLE criteria).[77]

CHAPTER 53 ■ HYPOTHERMIA: TREATMENT AND THERAPEUTIC USES

MATTHEW C. BYRNES AND GREG J. BEILMAN

There is a clear distinction between hypothermia due to environmental exposure and hypothermia associated with injury. Hypothermia due to exposure can be lethal when it is extreme and persistent, such as that experienced by soldiers during the Napoleonic invasion of Russia; however, with modern medical care, patients without injury have an 80% survival when the depth of hypothermia is between 28°C and 32°C.[1] The effect of hypothermia on injured patients, however, is profound. In one large series, no patient with an initial core body temperature of <32°C survived.[2] This distinction clearly indicates that a different approach is needed for injured patients compared to medical patients suffering from hypothermia.

The triad of hypothermia, coagulopathy, and acidosis has been widely described as an important risk factor for death among injured patients.[3,4] Each component of the triad influences the other components. For instance, hypothermia can lead to worsened coagulopathy, which in turn can lead to acidosis. The presence of hypothermia worsens the physiologic condition of most patients with multisystem trauma. For decades, hypothermia has been treated aggressively in order to optimize outcomes. More recent data suggest there may be a role for induced hypothermia in certain types of injuries. This chapter reviews the physiologic aberrations that are seen with hypothermia and subsequently reviews basic science and clinical studies that guide the current clinical practice of treating injured patients with subnormal core body temperatures.

DEFINITIONS AND MEASUREMENT

There are a variety of definitions of hypothermia. The normal human core body temperature is 37°C; however, there is a normal circadian shift of ±0.5°C–1°C.[5,6] Several authors have defined hypothermia as a core body temperature of <35°C, while others have referred to hypothermia as a core body temperature of <36°C.[3,7-10] Yet another defined hypothermia as a core body temperature of <37°C.

The traditional classification of hypothermia was developed for patients with environmental exposure rather than patients with multiple injuries.[9] The traditional classification of hypothermia labels core body temperatures above 32°C as mild and core body temperatures below 28°C as severe. Profound hypothermia has been defined as core body temperature of 6°C–10°C and ultraprofound hypothermia as temperatures ≤5°C.[10] The lowest known temperature among adult survivors with environmental hypothermia is 13.7°C.

The combination of hypothermia and severe injury is associated with increased risk of death and complications. The key threshold associated with increased morbidity and mortality in injured patients appears to be 34°C.[2] The risk of mortality is further increased with temperatures below 32°C. As such, a different classification system should be utilized with injured patients. It is most appropriate to consider temperatures of 34°C–36°C as mild, 32°C–34°C as moderate, and <32°C as severe hypothermia. The existence of multiple classification

systems can create confusion when interpreting descriptions of the depth of hypothermia. Whenever possible, we have described absolute temperature levels rather than qualitatively labeling the depth of hypothermia.

There are a variety of methods available to evaluate core body temperature (Fig. 53.1). The gold standard for evaluating core body temperature is the pulmonary artery catheter; however, this method is infrequently available during early evaluation and is less commonly utilized in current practice.[11] Additionally, in patients with severe hypothermia (<28°C–30°C), this catheter has the potential to induce life-threatening arrhythmias. We recommend the use of bladder or tympanic temperature probes for routine temperature evaluation in acute care surgical patients. Bladder temperatures are measured using a Foley catheter with a thermistor at its tip. Tympanic temperature is readily measurable using current technology; however, many electronic thermometers do not allow measurement of temperature below 34°C. Esophageal temperature monitoring can be used but carries no advantage over the other methods.[12] Rectal monitoring is slightly more invasive and is not as responsive to changes in core body temperature. While oral temperature probes are appropriate for healthy patients, these probes are not useful for multiply injured patients or intubated patients. Finally, axillary temperature monitoring is the most inaccurate method and has no real utility in evaluation of hypothermia in acute care surgical patients.[3]

PREVALENCE AND RISK FACTORS

Hypothermia is common in patients suffering traumatic injury. Trauma patients represent a frequent source of hypothermia.[8,9,13] The average temperature of patients in one large trauma center was 35°C.[14] Contrary to expectations, there was no seasonal variation, so hypothermia is a consideration regardless of the time of year. Previous reports have estimated that about one-half of seriously injured patients are hypothermic on presentation.[13] Patients with prolonged extrications or entrapment are at increased risk, as they often have prolonged environmental exposures. Patients at extremes of age are at increased risk, as their ability to endogenously maintain their core body temperature is reduced. Administration of anesthesia predisposes to hypothermia as these agents inhibit endogenous reflexes that increase core body temperature. Increased injury severity itself is also a risk factor for hypothermia. Submersion is a considerable risk factor, as heat losses are 32 times greater among patients submerged than patients exposed to air.[15,16]

PHYSIOLOGY

There are physiologic effects of hypothermia on nearly every organ system (Table 53.1). There is increase in metabolic activity at very mild levels of hypothermia (35°C–36°C). Beyond this level, there is a slowing of metabolic activity at the cellular level and quiescence of signs of life at the extremes of

707
FIGURE 53.1. Current methods of measuring body temperature. A: Electronic thermometer configured for oral/rectal use. B: Electronic thermometer for tympanic measurements. C: Foley catheter with temperature-sensitive thermistor. D: Pulmonary artery catheter with temperature-sensitive thermistor.

hypothermia. In fact, the overall rate of metabolism decreases by 8% for every 1°C reduction in core body temperature.[17] Acute care surgeons must understand these physiologic changes in order to optimize treatment of patients who require either induction of hypothermia or institution of warming.

The hypothalamus is responsible for integrating signals from the body that relate to core body temperature.[18] The hypothalamus emits efferent signals that result in peripheral vasoconstriction in order to preserve heat to the body core. Shivering is induced with mild hypothermia (35°C–37°C) and can produce up to five times the normal metabolic heat production. Metabolic activity increases in order to generate heat. These mechanisms, however, are impaired as hypothermia deepens to 34°C, and they are also impaired in the multiply injured or intoxicated patient. As a result, injured patients have a reduced ability to endogenously correct hypothermia.

TABLE 53.1

PHYSIOLOGIC CHANGES ASSOCIATED WITH
HYPOTHERMIA

■ ORGAN SYSTEM	■ PHYSIOLOGIC CHANGES
Neurologic	Reduction in intracranial pressure Reduction in metabolism
Respiratory	Bronchorrhea Inhibition of cilia Reduced respiratory rate
Renal	Cold diuresis
Gastrointestinal	Ileus
Cardiovascular	Arrhythmia Bradycardia Negative inotropy
Endocrine	Hyperglycemia
Coagulation	Reduced enzyme function Reduced platelet function

Respiratory system. The respiratory system is stimulated at temperatures above 34°C–35°C. This leads to tachypnea and can result in bronchospasm. As the core body temperature falls below 34°C, the respiratory drive diminishes. There is also an increase in secretions and inhibition of bronchial cilia.[8] Upon rewarming, there is often development of pulmonary edema. As core body temperature decreases below 30°C, apnea may result.

Cardiovascular system. Mild hypothermia is associated with cardiac stimulation.[8,18] The hypothalamus responds to mild hypothermia by transmitting signals that result in sympathetic activation. This results in tachycardia, peripheral vasoconstriction, and increase in cardiac output. Temperatures below a threshold level (~32°C) result in cardiac depression.[9] Negative inotropy is seen with subsequent reductions in cardiac output. Bradycardia ensues, and the myocardium becomes progressively arrhythmogenic.[17] Ventricular fibrillation (VF) may occur spontaneously at temperatures below 25°C–28°C.[19] Resuscitation from asystole or fibrillation can be difficult, if not impossible, until the patient is warmed. These arrhythmias are often resistant to chemical or electrical cardioversion until the core body temperature is raised above 28°C. Additionally, there is a reduced response to catecholamines with appreciable degrees of hypothermia.[17,20]

Neurologic. There is a temperature-dependent reduction in consciousness associated with progressive hypothermia.[21] Confusion can be expected at mild degrees of hypothermia. This will eventually give way to a comatose state at temperatures <28°C–30°C. There is a reduction in cerebral blood flow and cerebral metabolism, which leads to a reduction in intracranial pressure. Motor reflexes become diminished and ultimately become absent.[9] These cerebral effects have led to a great deal of interest in utilizing hypothermia as a therapeutic entity for conditions associated with neurologic compromise. This is described in greater detail later in the chapter.

Renal/electrolytes. "Cold diuresis" is the most obvious effect of hypothermia on the renal system.[17,22] This is seen at mild and moderate degrees of hypothermia (>32°C). This is due to increased renal blood flow and to alterations in tubular membranes. The pH measured by arterial blood gas analysis will be artificially low if the blood is warmed before the analysis is conducted. Hyperglycemia can occur as a result of reduced insulin sensitivity and decreased pancreatic secretion

of insulin. Electrolytes, including potassium, phosphorus, and magnesium, can become depleted.[23]

Gastrointestinal. Bowel function in the presence of hypothermia is reduced.[17] If a nasogastric tube is inserted for an ileus in a hypothermic patient, extreme caution should be taken. Gastric intubation, along with other methods of patient manipulation, can lead to VF in patients with a core body temperature <28°C.[9]

Coagulation. Coagulation disorders represent the most important physiologic disturbance concerning hypothermic acute care surgical patients. These disorders are also the most extensively studied issues in injured patients.[24-35] Hypothermia leads to coagulopathy. Ongoing hemorrhage from coagulopathy leads to further hypothermia and acidosis. This "bloody vicious cycle" first reported by Kashuk et al.[36] has been confirmed in multiple subsequent studies. Warming hypothermic patients is a critical component to arresting this cycle.

The effect of hypothermia on standard laboratory values of prothrombin time/activated partial thromboplastin time/International Normalized Ratio (PT/PTT/INR) has been extensively reported. Cosgriff et al.[29] prospectively evaluated patients who required a massive transfusion, which was defined as transfusion of at least 10 units of blood. Coagulopathy was defined as a PT greater than two times the normal value and was present in 47% of the patients. In multivariate analysis, hypothermia was a significant risk factor for coagulopathy, with an odds ratio of 8.7. These clinical results have been confirmed by a number of laboratory studies. Reed et al.[31] submerged anesthetized rats in a water bath to achieve a core body temperature of 25°C–37°C. They observed a prolongation of the PTT and the PT when the blood was not warmed prior to analysis. When they warmed the blood *ex vivo*, the prolongation of the coagulation parameters was no longer seen. This suggests that laboratory analysis that is conducted after warming the blood *ex vivo* is likely to underestimate the degree of coagulopathy.

Rohrer and Natale[32] evaluated pooled human plasma that was known to have normal levels of clotting factors. They performed coagulation studies on the blood at temperatures ranging from 28°C–41°C. The PT in the normothermic samples was 11.8 seconds and increased to 16.6 seconds in the samples cooled to 28°C–34°C. The PTT was 36 seconds in the normothermic samples and increased to 57 seconds in the hypothermic samples. These results were confirmed clinically by Watts et al.[33] They evaluated 112 trauma patients with an injury severity score ≥9 points. They evaluated the core body temperature and performed coagulation studies. They found that 34°C was the threshold point, below which coagulation enzyme activity decreased.

Another study compared the effect of hypothermia to various clotting factor deficiencies.[30] Standard plasma was evaluated at temperatures between 25°C and 37°C, and plasma with specific clotting factor deficiencies was evaluated for comparative purposes. They found that plasma with normal factors at temperatures <33°C was functionally similar to normothermic plasma with factor deficiencies.

Hypothermia in an injured patient is often seen in combination with shock. In an animal model, hypothermia and shock were additive in their effects on coagulopathy.[28] In a human series, coagulopathy was also more common when hypothermia was paired with an increased injury severity and shock.[29]

Platelet function is also reduced in hypothermic patients. Valeri et al.[35] noted that a reduction in core body temperature in baboons was associated with a prolonged bleeding time. A similar study was conducted in healthy human volunteers. The bleeding time of hypothermic skin was significantly prolonged. This appeared to be mediated by a down regulation of P-selectin and thromboxane B_2.[34]

Whereas the most common and standard method of evaluating coagulation abnormalities involves measuring the PT/PTT/INR, Martini et al.[25] reported that thromboelastography

(TEG) is a more sensitive analysis in determining hypothermic coagulopathy. This point-of-care test evaluates the entire coagulation system in whole blood. TEG may be more accurate than are standard tests for evaluation of multiple aspects of the coagulation cascade and in directing therapy. TEG is becoming more available but has not currently been broadly adopted.

Two reports have evaluated pharmacologic manipulation of hypothermic coagulopathy.[26,27] Given that factor levels are normal, treatment with fresh frozen plasma would not be expected to reverse the coagulopathy. The administration of recombinant factor VIIa (rFVIIa), however, improved coagulation parameters of plasma that was artificially cooled. In a model of hypothermic/hemorrhagic shock, the administration of rFVIIa reduced overall blood loss. This suggests that rFVIIa can be used as an adjunct to warming when ongoing hemorrhage is severe.

In summary, there is a clear effect of hypothermia on the clotting cascade. This coagulopathy is caused by an alteration in platelet function and enzymatic activity rather than an alteration in the quantity of clotting factors. This effect is temperature-dependent, with deeper levels of hypothermia being associated with more substantial coagulopathy. Furthermore, common laboratory tests do not reflect the true degree of coagulopathy if the blood is warmed *ex vivo* prior to performing the test, as is commonly performed by most labs. The treatment of hypothermic coagulopathy is rapid warming rather than administration of blood products or supplements.

CLINICAL CONSIDERATIONS

Given the many physiologic effects of hypothermia on mammals, it is important to understand the clinical ramifications of reduced core body temperatures. There are certain responses to hypothermia that may be beneficial to acute care surgical patients, such as a reduction in metabolic rate and cerebral protection. There are other responses to hypothermia that are clearly harmful, such as coagulopathy and myocardial irritability. There is considerable of literature evaluating the effect of hypothermia on injured patients. The majority of the experimental studies have reported a beneficial effect of hypothermia on outcomes in injured patients, whereas most of the human studies have reported on a detrimental effect of hypothermia.

Numerous animal models have touted the benefit of hypothermia in injured patients.[37-43] Wu et al.[40] evaluated a model of hemorrhagic shock in pigs by creating a splenic laceration. Animals were subsequently cooled to 34°C or maintained at normothermia. Survival was greater in the hypothermic animals, and increased bleeding was not seen in the hypothermic animals. In another similar study using a model of prolonged hypotensive resuscitation, George et al.[44] demonstrated improved survival in hypothermic animals with associated decreases in resuscitation fluid requirements, organ injury, and lactate concentrations. Takasu et al.[41] reported similar findings in a rat model. Animals subjected to hemorrhagic shock that were cooled to 32°C or 34°C had a greater 72-hour survival. Another study also reported the benefits of hypothermia during hemorrhagic shock but also noted that these benefits were not realized with localized gut cooling.[38] In a rat model of hemorrhagic shock, Lee et al.[43] reported that induced hypothermia was more beneficial than spontaneous hypothermia. Another report confirmed that spontaneous hypothermia did not result in increased long-term survival.[45]

Specific organ function has also been evaluated in animal models. Severe hypothermia (28°C) in conjunction with hemorrhagic shock was associated with ventricular irritability.[46] The effect of shock on liver adenosine triphosphate (ATP)

concentrations was reported by Johannigman et al.[47] In a rat model of hemorrhagic shock, ATP fell steadily with warm shock but not hypothermic shock.

The process of warming has also been evaluated in animal models. In rat and mouse models of hemorrhagic shock, there was a considerable inflammatory response associated with the warming phase.[48,49] Warming improved cardiac and hepatic function in a rat model of hemorrhage.[50] Survival was greatest among pigs that underwent a "medium" rate of warming compared with slow and fast rates of warming.[42]

In contrast to the animal data, much of the human data suggest that hypothermia in injured patients is harmful.[2,51-54] A sentinel study was reported by Jurkovich et al. in 1987. They evaluated the effect of hypothermia on a group of patients with major trauma. Mortality progressively rose with reductions in core body temperature.[2] No patients in this series survived if their core body temperature was below 32°C. Wang et al.[52] conducted a multivariate analysis of risk factors of mortality after injury and noted an odds ratio for death of 3.03 associated with hypothermia. Shafi et al. attempted to discern if hypothermia was a marker of complications or a true risk factor for death in injured patients. They evaluated nearly 40,000 patients from the National Trauma Data Bank (NTDB) and performed a multivariate regression analysis.[53] They found that hypothermia (≤35°C), independent of other factors, was associated with increased mortality. Another large review of the NTDB noted that mortality began to increase at temperatures below 36°C.[55] All of these studies were retrospective analyses. In one prospective analysis, approximately 300 seriously injured trauma patients were studied, and effects of hypothermia on outcome were evaluated.[56] Hypothermia within the first six hours of arrival was not independently associated with mortality but did predict development of multiple organ failure. In the one randomized prospective study published to date, Gentilello et al.[51] randomized patients to rapid rewarming with continuous arteriovenous rewarming (CAVR) versus standard rewarming. Patients in the CAVR group experienced faster rates of warming. Early mortality, as well as 24-hour fluid requirements, were improved in patients randomized to CAVR. However, this benefit did not result in improved survival to hospital discharge. These studies together suggest that hypothermia is harmful in injured patients.

The distinction between elective hypothermia and trauma-related hypothermia was reported by Seekamp et al. They measured plasma ATP concentrations in patients undergoing elective hypothermia during coronary artery bypass surgery and in hypothermic trauma patients.[57] They noted that there was a preservation of ATP levels in elective hypothermia but decreased level of ATP in hypothermic injured patients. This suggests that hypothermia in injured patients is due to energy exhaustion rather than being a method of energy preservation.

Several reports have noted the effect of hypothermia on injured patients who require operative intervention.[58-60] An increase in mortality was noted among hypothermic patients who required a laparotomy. Blood loss was also related to the depth of hypothermia. Notably, the degree of hypothermia was more important than the abdominal injury score in determining the amount of intraoperative blood loss.

The distinction between human and animal studies likely relates to the type of studies that have been performed. Nearly all of the human studies have been retrospective analyses. Given the uniformity of the results, surgeons have been unwilling to randomize multiply injured patients to hypothermia or normothermia in a prospective study. The animal studies have generally not involved multi-system trauma. It is unclear if single-organ models of hemorrhagic shock in animals apply to the injured patients that acute care surgeons regularly encounter. Additionally, animal models generally involve active cooling of an otherwise normothermic animal. Human studies evaluated

patients who were hypothermic on presentation. Finally, animal models induce hypothermia shortly after the time of injury or before the injury. Given that there are inherent delays in transport of human trauma, it is not clear that these models are applicable to clinical settings.

Although the evidence is incomplete, we recommend warming multiply injured patients to normothermic levels. There is interesting experimental evidence suggesting that hypothermia may be beneficial during the course of injury, especially when associated with prolonged periods of hypotension,[44] but the application of this evidence is currently unclear. The bulk of the human evidence demonstrates that hypothermia is harmful to injured patients. Until the animal models are replicated in human studies, acute care surgeons should consider hypothermia to be a complicating factor in the management of their patients.

REWARMING

There are a number of methods to rewarm injured patients. These methods should be instituted early in the treatment of injured patients, as it is far easier to prevent further hypothermia than it is to treat hypothermia. An injured patient's metabolic rate may be sufficient to prevent further heat loss, but it is insufficient to produce overall warming.[61] Accordingly, the majority of severely injured patients will require adjunctive warming measures.

An average adult with a temperature of 32°C has a massive heat deficit of 300 kCal.[61] Oxygen consumption would have to increase dramatically to overcome this heat deficit, and severely injured patients generally do not have the physiologic reserve to respond to this challenge. The human body has a high specific heat (amount of energy required to raise 1 kg of material by 1°C). This, along with ongoing heat losses, makes warming injured patients challenging.

Methods of Rewarming

Methods of rewarming can be broadly categorized as passive or active (Table 53.2). Passive methods consist of blankets and a warm environment. Active methods can be characterized as either invasive or noninvasive. Noninvasive methods include forced air rewarming, circulating water blankets, radiant heat lamps, and resistive heating blankets. Invasive methods include tracheal insufflation with warmed gas, cavity lavage, cardiopulmonary bypass, and arteriovenous rewarming.

Passive Rewarming

Passive rewarming consists of provision of a warm room and blankets in order to prevent further heat loss. This modality is only appropriate for patients who are hemodynamically stable, are mildly injured, and are only minimally hypothermic. Any patient with a core body temperature <35°C and a major injury should undergo active rewarming. The effect of hypothermia on uninjured patients is much less profound. Patients without injury who become hypothermic secondary to environmental exposure can undergo passive rewarming as a long as the core body temperature is above 32°C.[62]

Active Rewarming

The majority of multiply injured patients will require some form of active rewarming. In general, the invasive methods result in more rapid warming but are also subject to more

TABLE 53.2

METHODS OF WARMING

■ METHOD OF WARMING	■ RATE OF TEMPERATURE RISE
Passive	
Blankets, warm room	0–0.5°C/h
Active noninvasive	
Forced air rewarming	1–2.4°C/h
Resistive heating blankets	1–2.5°C/h
Radiant heating lamps	Variable
Circulating water blanket	1.5–2°C/h
Active invasive warming	
Warmed tracheal insufflation	0.5°C/h
CPB	2°C/5 min under optimal conditions; usually slower in clinical settings
CVVR	3°C/h
CAVR	8°C/h
Cavity lavage	1–4°C/h
Intravascular warming	1.5°C/h

CPB, cardiopulmonary bypass; CVVR, continuous veno-venous rewarming; CAVR, continuous arteriovenous rewarming.

complications. The method of choice for any individual patient depends upon the degree of hypothermia as well as the urgency of the situation. A variety of warming devices are illustrated in Figure 53.2.

The most basic method of active warming is the infusion of warmed IV fluids. The maximum amount of heat transfer, however, is limited by the volume that physicians are willing to infuse. We recommend using warmed IV fluid to 40°C as a preventive rather than a therapeutic measure. Banked blood is stored at 4°C. Accordingly, infusion of several units of banked blood can accentuate hypothermia. We recommend using an infuser with a counter-current heating mechanism, so the blood products are warmed prior to infusion. There are a number of commercial fluid warmers/infusers available. Forced air rewarming has become the modality of choice for noninvasive active rewarming in most surgical centers. One of the most commonly utilized devices is the Bair Hugger (Arizant Inc., Eden Prairie, MN). This system provides convection heating to rewarm patients.[63] It consists of a paper/plastic interface that circulates heated air over a patient. The benefits of forced air rewarming include the ease of use, the ready availability, and the noninvasive nature of the treatment.

A number of studies have demonstrated the efficacy of forced air surface rewarming. Steele et al.[63] conducted a prospective study evaluating the effect of forced air rewarming versus regular blankets. They randomized patients to forced air rewarming at 43°C or standard blankets. They noted a temperature rise of 2.4°C per hour among patients with forced air rewarming versus 1.4°C per hour among patients treated with standard blankets. This modality is generally recommended for mild to moderate forms of hypothermia, as peripheral vasoconstriction can limit the ability of surface warming to transmit heat to the body core. Nonetheless, severe hypothermia has been successfully treated with surface air rewarming. Kornberger et al.[64] evaluated 15 severely hypothermic patients with a presenting core body temperature of 24°C–30°C. All of the patients were successfully warmed with an average warming rate of 1.7°C per hour. None of the patients with a prehospital arrest survived, but the remaining patients were

long-term survivors. We do not recommend this method for severely hypothermic patients with ongoing hemorrhage, as they require rapid rewarming in order to effect hemostasis.

Other methods of noninvasive warming include resistive heating blankets and circulating water mattresses. The carbon fiber resistive heating blanket has performed well in published studies. Negishi et al.[65] compared the effects of a circulating water mattress, forced air rewarming, and a resistive heating blanket on perioperative hypothermia. They found the greatest degree of heat conservation in the resistive blanket group. The touted advantage of the resistive heating blanket is the ability to cover a greater body surface area. Forced air rewarming is generally limited to the thorax while a laparotomy is being performed. Circulating water bath mattresses have the advantage of using water, which has a high specific heat and thus, the ability to transfer large amounts of heat to the patient. These mattresses, however, are generally placed posteriorly. This limits the efficacy of the mattress, as patients lose more heat anteriorly.

Another benefit of resistive heating blankets is their ease of use during transport. One study randomly allocated patients to foil blankets or resistive heating blankets during transport.[66] The patients allocated to resistive heating blankets increased their core body temperature by 0.8°C per hour, whereas the patients allocated to the foil blankets dropped their core body temperature by 0.4°C per hour.

A number of centers having access to water tanks for treatment of burn patients have described rewarming of appropriately stabilized patients (i.e., endotracheal intubation, no active surgical issues) by placing the patient in the warm water tank until warmed, but his type of warming is not widely available.

Radiant heating lamps do not serve a large role in the effort to rewarm injured patients. They can interfere with the exam of the patient or even cause a thermal burn if they are positioned too close to the patient. They are not more effective than other noninvasive methods of rewarming, and their drawbacks outweigh their benefits.

Cavity lavage was the first invasive warming technique that was widely available. This technique requires access to the peritoneal cavity or the pleural cavities. It can also be accomplished through a nasogastric tube in the stomach. The peritoneal cavity can be accessed with a peritoneal lavage catheter. The pleural cavity can be accessed with large-bore chest tubes.[67] Many liters of intravenous fluids warmed to 40°C can be instilled and withdrawn through the drainage tubes. Peritoneal warming can be more difficult to accomplish, as the rate of fluid return is often suboptimal. Pleural warming is easier to accomplish, as chest tubes are simple to place and they have a larger bore, so the rate of fluid return is much more rapid. Pleural warming also carries the benefit of directly warming the heart, which can be important in patients with clinically significant arrhythmias. Gastric lavage carries the risk of aspiration. The rate of warming with cavity lavage varies between 1°C and 4°C per hour.

Tracheal insufflation with warmed air is the least invasive method of the core rewarming modalities.[16] It is also the least effective. It is accomplished by administering warmed air through an endotracheal tube. This modality can be used as an adjunct but should not be used as the sole warming modality. The average rate of warming is 0°C-0.5°C per hour.

Extracorporeal warming is the fastest, yet most invasive, method of warming hypothermic patients.[61,68,69] Cardiopulmonary bypass can be initiated via a sternotomy or by femoral

FIGURE 53.2. (*Continued*) C: Rapid fluid infusion device with intrinsic fluid warmer. D: Fluidized external blanket device (This device and others of similar design can be used for both warming and cooling patients). E: Cardiopulmonary bypass apparatus.

access. Blood is warmed (and can be oxygenated) extracorporeally. This will warm the majority of patients within 1–2 hours regardless of their degree of hypothermia. In fact, in optimal settings, core body temperature can be raised by 2°C every 5 minutes.[70] Cardiopulmonary bypass has the additional benefit of supporting the circulation in patients with hypothermia-induced cardiac arrest. Cardiopulmonary bypass is limited by the invasiveness of the procedure as well as the need for systemic heparinization.

To combat the limitations associated with cardiopulmonary bypass, circuits have been designed to provide either CAVR or continuous venovenous rewarming (CVVR).[70-72] This technique is accomplished by inserting large-bore catheters in the femoral vessels. CAVR utilizes the patient's blood

pressure to pump blood through a warming circuit. It is then returned to the venous system. CVVR utilizes a mechanical pump to circulate venous blood through a warmer and back to the patient. This modality is similar to continuous dialysis, which can also accomplish core rewarming. The advantage of this setup compared with cardiopulmonary bypass is the lack of need for systemic heparinization and the ease of setup compared with bypass. This system can warm patients at rates of 3°C–8°C per hour.

Another technique recently developed utilizes an intravascular catheter to directly warm the blood *in vivo*. This system was developed in order to induce hypothermia as a therapeutic maneuver after cardiac arrest; however, the system also has a warming mode. A single catheter is inserted into the femoral

vein, and warmed fluid is pumped through a balloon in the exterior of the catheter, directly warming the venous blood. Taylor et al.[73] reported an average warming of 1.5°C per hour with this technique.

Frostbite

Frostbite represents an additional consideration of rewarming patients. Frostbite is characterized by freezing of tissues and most often occurs in the distal extremities.[74] This can lead to tissue necrosis and potentially amputation. Whereas the adage "life over limb" always holds true, the acute care surgeon should attempt to salvage this tissue whenever possible. The most successful method of warming frostbite in the hands or feet is by submersion in warmed water (37°C–40°C). After 30–45 minutes, the temperature in the tissue will generally increase to normothermic levels, which may prevent further tissue loss. Early debridement outside of severely infected cases is not recommended, and surgery is normally delayed for a period of months.

Afterdrop

The core body temperature may initially decrease during the course of the warming process. This is referred to as the "afterdrop" phenomenon. It is likely caused by a redistribution of cooled peripheral blood to the core during the initial phases of warming. Afterdrop in patients with environmental hypothermia has been associated with cardiac arrest, as the cold, acidemic blood of the periphery is returned to the core circulation. Cardioversion is frequently not successful in this setting until the patient is warmed to a temperature above 32°C. In this setting, active core warming should take place in conjunction with cardiopulmonary support (CPR or cardiopulmonary bypass) until the patient has been warmed above 32°C, at which time cardioversion should be attempted.

THERAPEUTIC USES OF HYPOTHERMIA

The majority of this chapter has focused on the adverse effects of hypothermia and therapeutic measures to rewarm patients. There are, however, specific clinical circumstances in which hypothermia may be beneficial. These conditions are all linked by the need to minimize neurologic injury after isolated traumatic brain injury (TBI) or cerebral anoxia primarily from cardiac arrest or drowning.

Traumatic Brain Injury

The most important benefit of hypothermia revolves around cerebral protection. As such, the majority of clinical studies evaluating the efficacy of hypothermia in injured patients have focused on patients with TBIs. Unfortunately, the results of these studies have been mixed at best.

TBI evolves from the primary injury to secondary and tertiary insults.[75] The primary injury occurs at the time of the initial trauma and is unalterable. Accordingly, all interventions are aimed at preventing secondary and tertiary progression of the brain injury. These efforts focus on maintaining oxygenation and perfusion to the injured brain and to minimizing intracranial pressure. Experimental studies have revealed benefits and drawbacks to inducing hypothermia to the injured brain. An intracranial hemorrhage could theoretically expand

as a result of hypothermic coagulopathy. Further, hypothermia could induce hypotension, which could worsen the injured penumbra. In contrast, however, there are a number of potential benefits. Hypothermia reliably reduces metabolic rate and cerebral oxygen demand. It also reduces excitatory neurotransmitters, which could reduce excitotoxicity to the injured brain. Other potential benefits of hypothermia include a reduction in edema formation, a reduction in intracranial pressure, and calcium antagonism. Given these experimental findings, clinicians theorized that hypothermia would improve functional outcomes after TBI.

Initial trials in the 1990s reported a benefit to inducing hypothermia in patients with TBI. On the basis of these results, a large phase 3 trial was conducted by Clifton et al.[76] in 2001. Patients were randomized to normothermia or hypothermia at 33°C for 48 hours. A poor outcome was seen in 57% of patients in both groups. Accordingly, the authors recommended against the routine use of hypothermia for TBI. Of note, however, intracranial pressure was more effectively lowered in the hypothermic patients. Hypotension and bradycardia were more common in the hypothermic patients, which may have mitigated any benefit that hypothermia may have attained. Subset analysis showed an improved outcome among patients treated with hypothermia who were already hypothermic on presentation. It is unclear if this was a result of random statistical analysis or evidence that hypothermic patients with a TBI should not be actively warmed.

Shiozaki et al.[77] evaluated the use of hypothermia for the treatment of TBI without elevated intracranial pressure. Patients were eligible for inclusion if their intracranial pressure was <25 mm Hg with standard therapeutics. Patients were randomized to receive either normothermia or hypothermia at 34°C for 48 hours. The clinical outcomes at 3 months were similar between the groups. The authors noted that infectious complications were more common among the hypothermic patients. This suggests that hypothermia is not an effective modality when intracranial pressure can be controlled with other interventions.

A phase 3 trial was conducted to evaluate hypothermia for treatment of TBI in children. The target temperature was 32.5°C and was maintained for 24 hours.[78] No benefit to neurologic function was noted in this trial.

The data on the utility of hypothermia for TBI has been summarized by six different meta-analyses.[79-84] The first four meta-analyses were conducted between 2002 and 2004, and all concluded that there was no compelling evidence to recommend the use of hypothermia. The Brain Trauma Foundation and the American Association of Neurological Surgeons have created guidelines for the management of TBI. The guideline on hypothermia was based on a subsequent meta-analysis conducted in 2008.[80] This report evaluated two additional randomized trials. They noted a reduction in mortality and an improvement in functional outcomes among patients treated with hypothermia. As a result, the guidelines include a level 3 recommendation to cautiously consider hypothermia for TBI. The most recent meta-analysis was conducted by the Cochrane group in 2009.[81] These authors found no benefit to hypothermia.

These studies have raised more questions than they have answered. The bulk of the clinical evidence argues against the routine use of hypothermia for treatment of TBI. Even if hypothermia as a general principle is beneficial, the optimal degree of hypothermia as well as the duration of treatment is unclear. It is also not clear if there is a difference between inducing hypothermia in a normothermic patient versus failing to warm a hypothermic patient. Further, patients with TBI represent a heterogeneous group of patients. It is possible that hypothermia would be beneficial in certain subgroups, such as those with diffuse axonal injury, and harmful in other groups,

such as those with massive intracranial bleeding. Data to fully answer these questions are not available.

We do not routinely treat patients with TBI with hypothermia. The results of the clinical trials are mixed at best. We consider utilizing hypothermia in patients with refractory intracranial hypertension, although this is the group of patients with the most guarded prognoses. The optimal duration of hypothermia is probably at least 48 hours, and the optimal depth of hypothermia is probably around 34°C. We avoid hyperthermia as a general rule, as hyperthermia is a clear factor in increasing intracranial pressure. In most settings, our temperature goal is normothermia. We aggressively warm patients with abdominal or thoracic hemorrhagic foci. We are currently less aggressive about rapidly warming patients with isolated TBI who present with a core body temperature of <37°C.

Post–Cardiac Arrest Conditions

The rate-limiting step in the resuscitation of patients after a cardiac arrest is the eventual neurologic outcome. Whereas Advanced Cardiac Life Support (ACLS) measures are effective in resuscitating cardiac rhythms, patients are often left in a state of neurologic devastation. Permanent neurologic injury can be seen as soon as 5 minutes after cardiac arrest.

There were two landmark trials published in 2002 that demonstrated the benefit of therapeutic hypothermia.[85,86] Bernard et al. randomized 77 patients to normothermia or hypothermia at 33°C. Patients who had an out-of-hospital arrest associated with VF were eligible for enrollment. Hypothermia was achieved within 2 hours of resuscitation and was maintained for 12 hours. Good neurologic outcome was more common among patients treated with hypothermia (49% vs. 26%, $p = 0.046$). Another study evaluated 273 patients randomized to normothermia or hypothermia at 32°C–34°C for 24 hours. This study also limited the scope of patients to out-of-hospital VF arrest and also demonstrated a benefit to hypothermia.

As a result of this study, American and international guidelines have recommended therapeutic hypothermia for out-of-hospital VF arrests.[87] Unfortunately, a number of issues remain undefined. Patients with pulseless electrical activity (PEA) or asystole have a much worse prognosis, and it is not clear if hypothermia is beneficial in these patients. Since the time of the landmark trials, a variety of smaller studies and case series have emerged. One review has suggested that hypothermia should be induced after all cardiac arrest events regardless of initial rhythm (assuming exclusion criteria are not met).[88] Unfortunately, the warrant for this claim is based on much weaker evidence than what is described above, and additional randomized trials evaluating other rhythms or clinical scenarios are unlikely to be conducted.

The vast majority of patients included in trials of postarrest hypothermia were medical patients. There is sparse data to guide clinicians on the management of patients with acute care surgical conditions who develop a cardiac arrest. In our opinion, there are four main conditions associated with acute care surgical anoxia that can be considered for therapeutic hypothermia: hanging, traumatic asphyxia, drowning, and post-operative arrest.

Hanging carries a grim prognosis when the presenting neurologic condition is coma. The data on the use of hypothermia for the treatment of hanging victims is limited to case reports and a single case series. The largest case series consists of eight patients, so no conclusions can be drawn.[89] We believe that it is reasonable to consider therapeutic hypothermia in hanging patients who are comatose, are hemodynamically stable, and have no evidence of hemorrhage or a vascular injury on CT scan.

Cardiac arrest in the perioperative period is a challenging complication. This event can be caused by a multitude of factors, such as sepsis, pulmonary embolism, hemorrhage, and respiratory failure. As such, the data on out-of-hospital VF arrest have little to no application to postsurgical patients. These patients are also at a higher risk of hemorrhage from coagulopathy if hypothermia is induced. As such, we cannot make any firm recommendations on the use of hypothermia in this setting. Given the dismal prognosis of prolonged cardiac arrest, it is certainly a tempting modality to consider.

Traumatic asphyxia occasionally occurs without major additional injuries. We consider using hypothermia in this setting after all sources of hemorrhage have been ruled out with computed tomography (CT) scanning. This consideration, however, is based on animal studies of asphyxia rather than good clinical data.[90]

Drowning

Drowning victims represent a unique consideration. Again, there are no data to derive any firm recommendation on their treatment. These patients are nearly always hypothermic on presentation. They have also almost always aspirated, which is important given the effect of hypothermia on immune function. In the absence of concurrent hemorrhage and arrhythmias (and in the absence of any strong supporting data), it seems reasonable to allow these patients to passively warm slowly over 12–24 hours.

Institution of therapeutic hypothermia requires the ability to induce and maintain hypothermia and subsequently rewarm the patient. Simple measures for inducing hypothermia include ice packs and cooling blankets.[88] Infusion of 30 mL/kg of 4°C saline will drop the core body temperature by 2°C–4°C. A number of commercial devices are available that include an integral autoregulatory circuit. This provides for more precise temperature control with less nursing effort. External cooling devices include the Arctic Sun (Medivance, Louisville, CO) and others. These devices have cooling pads that are connected to the skin and have a feedback loop connected with a thermometer that maintains the temperature within a set range. Also available for internal cooling are intravascular cooling catheters (Alsius, Zoll Medical Corporation, Chelmsford, MA). This catheter is inserted in the femoral vein. Chilled water is circulated around the exterior of the catheter to directly cool venous blood. The device is connected to a temperature probe, which is able to autoregulate the core body temperature within a very narrow range. Internal devices have been demonstrated to result in more rapid cooling of patients. Current recommendations are to cool patients to 32°C–33°C for 24–48 hours. The rewarming phase must be conducted slowly—no faster than over an 8-hour period. If shivering occurs, it can be minimized by meperidine, benzodiazepines, or neuromuscular blockage. Given the propensity of these patients to develop seizures, EEG monitoring should be considered if prolonged neuromuscular blockade is instituted.

Spinal Cord Injury

Given the similarity in tissue types between the spinal cord and the brain, there has been considerable interest in treating spinal cord injuries with hypothermia. The initial neurologic damage with a spinal cord injury is irreversible; however, there is often progressive cellular injury that occurs after the initial insult. Proponents of hypothermia have suggested that reducing the core body temperature can limit the progression of neurologic deficits after the initial injury.

Initial studies in this area were conducted in the 1960s with mixed results. Many of the initial studies evaluated local hypothermia induced directly on the spinal cord during surgical procedures. More recent experimental studies have demonstrated positive outcomes. In fact, a recent review noted that 16 out of 17 experimental studies reported positive results.[91] Recent studies have utilized systemic hypothermia rather than local hypothermia. In particular, Lo et al. reported their results with a rat model. They induced systemic hypothermia at 33°C 5 minutes after inducing a spinal cord injury. Both clinical and histologic outcomes were improved in animals treated with hypothermia.[92]

Unfortunately, there are minimal clinical data to support the use of hypothermia in human beings. There are no phase 3 trials. In fact, almost all the human clinical reports were published in the 1970s. National guidelines have indicated there is not enough evidence to support the use of hypothermia for spinal cord injuries. Experimental models that induce hypothermia within 5 minutes of injury are not applicable to clinical settings, as hypothermia can almost never be induced that rapidly. This treatment received national attention after an American professional football player with a cervical spinal cord injury was treated with hypothermia and subsequently regained the ability to walk.[93] Nonetheless, we do not believe the evidence is compelling enough to recommend routine use of hypothermia.

Emergency Preservation and Resuscitation

Physicians have known for many years that neurologic recovery is possible even after an hour or more of asystole if profound hypothermia is present. This is generally seen in cases of submersion injury. Cold-water exposure induces a "diver's reflex" and is responsible for preservation of brain function during periods of prolonged circulatory arrest. Whereas postarrest studies have employed hypothermia after resuscitation, it is clearly more efficacious to achieve hypothermia before arrest. Hemorrhagic shock can lead to multiple organ dysfunction and cardiac arrest. There are certain injuries that may be reparable but not within the time frame necessary to avoid cardiac arrest. As such, the concept of the diver's reflex was introduced to injured patients. This concept involves inducing profound hypothermia, inducing circulatory arrest, repairing the injury, and resuscitating the patient.

This concept was initially referred to as "suspended animation" and subsequently became known as "emergency preservation and resuscitation," or EPR. EPR has been used in a variety of animal models.[10] It consists of inducing a core body temperature of 5°C–10°C followed by a period of circulatory arrest and resuscitation. Overall survival and cognitive function have been directly linked to the depth of hypothermia. It is possible that pharmacologic agents could induce a state of hibernation that could serve as an adjunct to hypothermia or completely replicate the benefits of hypothermia without requiring temperature modification.[94,95]

Although there is mounting evidence of the efficacy of EPR in animals, there are sparse human data. The use of EPR in humans has been limited to case reports of injuries to the inferior vena cava that were otherwise irreparable.[56] The authors of these manuscripts noted that EPR allowed them to repair retrohepatic vena cava injuries in a bloodless field. Deep hypothermia has been used in elective cardiac and neurosurgical operations, but these settings are clearly different than the patient population the acute care surgeon encounters. Accordingly, it is not clear that these results can be transferred to human settings.

In summary, EPR is a method of resuscitation that could be used at some future time period. It is not designed for most injured patients; rather, its use would be limited to injuries causing a severe state of hemorrhagic shock that are otherwise irreparable.

SURGICAL CRITICAL CARE

CHAPTER 54 ■ NOSOCOMIAL INFECTIONS

PAMELA A. LIPSETT

In order to help the clinician make decisions about empiric antibiotic selection, the classification of infections has typically been divided into the site of infection (i.e., lung, skin and soft tissue, urinary tract, and intraabdominal) and the location of the patient at the time the infection occurs.[1-3] Historically, location has been divided into community- and hospital-onset, with hospital-acquired infections (HAIs) occurring after 72 hours of hospitalization, but patient demographics, risk factors, and pathogens have changed substantially over the last two decades, making this classification schema no longer informative. Bacterial resistance to antibiotics after exposure to the health care setting, and the potential for infection due to cross-contamination from the environment or from transmission from other patients, must now be considered in the initial choice of antibiotics. Because of these changes in epidemiology, infections are now classified as health care-associated, hospital-acquired, or community-acquired.[1]

HAIs remain a leading cause of morbidity and mortality, occurring in as many as 10% of hospitalized patients. Hospitals vary substantially in rates and types of HAIs, which may relate to coding, referrals, patient demographics, use of devices and procedures, as well as actual quality of patient care.[1,4] From January 2006 to October 2007, 28,502 HAIs were reported to the National Hospital Surveillance Network (NHSN): 10,064 (35.3%) were cases of central line-associated blood stream infection (CLABSI), 8,579 (30.1%) were cases of catheter-associated urinary tract infection (CAUTI), 4,524 (15.9%) were cases of ventilator-associated pneumonia (VAP), 5,291 (18.6%) were cases of surgical site infection (SSI), and 44 (0.2%) were cases of postprocedure pneumonia.[1]

Patients in intensive care units (ICUs) suffer a disproportionally high percentage of HAI when compared with patients in non–critical care areas.[1,5-9] For example, ICU beds account for 5%–10% of all hospital beds, yet 45% of CLABSIs occur in ICUs. Thus, the clinician must consider not only the individual patient risk factors but also the location of the patient in determining the probability and source of infection.[5]

This chapter discusses some of the common HAIs encountered in surgical patients, including pneumonia, CLABSIs, and UTIs, and to a lesser extent intraabdominal infections (IAIs), emphasizing epidemiology, pathogenesis, prevention, and treatment. SSIs are discussed in detail elsewhere (see Chapter__).

PNEUMONIA

Pneumonia is one of the most common nosocomial infections of hospitalized patients.[1,6] Health care-associated pneumonia (HCAP) occurs among patients hospitalized for 90 days; who live in nursing facilities; who have received antibiotics, chemotherapy, or wound care recently; or who undergo hemodialysis.[3] These patients are at risk for the same pathogens as patients who have hospital-acquired pneumonia (HAP), which by definition occurs after 48 hours of inpatient care in previously healthy patients. Distinguishing HAP from community-acquired pneumonia (CAP) is important, as patients with HAP are susceptible to pneumonia from different, potentially more virulent pathogens. VAP is a subset of HAP that occurs among patients after more than 48–72 hours of mechanical ventilation. Each day the patient remains on mechanical ventilation, the risk for development of VAP increases.

Because the cost (increased length of stay) of VAP and HAP is substantial, prevention has become an important focus for quality improvement and pay-for-performance reporting activities.[10,11] Clear recognition of the risk factors and understanding of the probable factors in disease development can lead to rational preventive strategies. Moreover, knowledge of varying diagnostic and treatment regimens may lead to improvements in patient care and outcomes.

Epidemiology

HAP is one of the most common nosocomial infections. At a rate of 3–10 cases per 1,000 hospital admissions, HAP may increase a patient's hospital stay by more than 1 week, resulting in up to $40,000 in additional cost.[1,9-12] A large and important subset of HAP, the risk of VAP is estimated at 3% per day for the first 5 days of mechanical ventilation, 2% per day for days 6–10, and 1% per day thereafter, with each day of mechanical ventilation adding incremental risk.[12]

Pathophysiology

The pathogenesis of HAP is multifactorial; several patient and treatment risk factors have been identified (Table 54.1). Most cases of HAP are secondary to microaspiration of infected material into the normally sterile lung parenchyma.[14] Thus, patient risk factors, the amount of pathogens delivered into the respiratory tree, and the virulence of infecting pathogens influence the probability of developing HAP and potentially the severity of the disease.

Classifying pneumonia into CAP and HAP recognizes that the causative pathogens differ and even change during hospitalization.[12] Because expected pathogens differ and successful outcome depends on appropriate initial treatment, general recommendations for empiric treatment depend on whether the patient has CAP or HAP (or HCAP), and the duration of the current hospitalization.[1,14-16] Distinguishing HCAP and CAP, broad-spectrum initial treatment of HCAP followed by de-escalation, has not led to measurable changes in mortality in prospective studies. Early HAP (<5 days into the hospital course) is associated with a better prognosis than late-onset HAP (arising ≥5 days into a hospital course).[1] These two categories can then be subdivided further into patients with and without prior antibiotic exposure.

Early-onset HAP in patients with no prior antibiotic exposure tends to mirror CAP, and patients generally have susceptible pathogens. The most common pathogens include Enterobacteriaceae, *Haemophilus influenzae*, *Streptococcus pneumoniae*, and methicillin-sensitive *Staphylococcus aureus* (MSSA).[14,15] Patients with no prior antibiotic exposure who develop late-onset HAP are infected by similar bacteria; however, occasionally these patients present with gram-negative bacilli (GNB) resistant to first-generation cephalosporins. Late-onset HAP in patients with prior antibiotic exposure

TABLE 54.1

RISK FACTORS FOR THE DEVELOPMENT OF VENTILATOR-ASSOCIATED PNEUMONIA

■ HOST DEFENSES	■ INCREASED BACTERIAL LOAD	■ VIRULENT PATHOGENS
Nasogastric tube	Bacterial colonization, recent viral infection	Prolonged antibiotics
Endotracheal tube	Gastric colonization	Length of stay
Supine position	Re-intubation	Chronic obstructive pulmonary disease
Head injury	Sinusitis	Poor infection control techniques
Sedation	Contaminated equipment	
Malnutrition		
Steroids		
Tobacco smoking		

presents a greater problem in both the prediction and empiric treatment of likely pathogens. As many as 40% of such patients present with potentially multi–drug-resistant (MDR) pathogens, including *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, and methicillin-resistant *Staphylococcus aureus* (MRSA).[15]

Gram-positive Bacteria. The common gram-positive cocci causing pneumonia in hospitalized patients are *S. pneumoniae* and *S. aureus*.[14-16] Patients with traumatic brain injury and early HAP may be infected with *S. aureus*. Whereas these pathogens are often seen in early-onset pneumonia, *S. aureus* can cause pneumonia at any point of the hospitalization, and MRSA is typically observed later in the hospital course. Risk factors for MRSA pneumonia include chronic obstructive pulmonary disease (COPD), longer duration of mechanical ventilation, prior antibiotic exposure, prior use of corticosteroids, prior bronchoscopy, colonization with MRSA, and adjacency to a patient identified to harbor MRSA.[16]

Gram-negative Bacteria. Gram-negative bacteria associated with early-onset HAP include *H. influenzae* and lactose-fermenting GNB such as Enterobacteriaceae, including *Escherichia coli*, *Klebsiella* species, and *Enterobacter* species.[14-16] Overgrowth of these organisms can be associated with prior antibiotic therapy, and their virulence may increase in critical illness. Enterobacteriaceae are increasingly demonstrating extended-spectrum beta-lactamase (ESBL) activity.[17,18] Whereas these organisms were treated frequently with broad-spectrum beta-lactam antimicrobials, plasmid-mediated resistance to these agents is increasing, and major outbreaks of VAP secondary to ESBL-producing pathogens have been identified.[17,18] Stains that produce ESBL are resistant to all beta-lactam agents and exhibit high-level resistance to fluoroquinolones, making carbapenems the recommended first-line agents for ESBL-producing strains.[17,18]

P. aeruginosa is the most common MDR GNB causing HAP/VAP,[1,16] and the most frequent VAP isolate in patients on mechanical ventilation for more than 4 days.[19] Resistance to one or more antibiotics is common and patients with MDR *P. aeruginosa* are at increased risk of severe sepsis and death.[20] *A. baumannii*, an aerobic, non–lactose-fermenting GNB that has intrinsic resistance to many antibiotics, can cause nosocomial infections that may spread rapidly among hospitalized patients[16,21-23] Due to its ability to acquire resistance rapidly to many drugs, prior antibiotic exposure is a major risk factor for resistance.[24]

Prevention

Patients scheduled for elective surgery may be identified to be at increased risk for postoperative pneumonia, and may be candidates for risk modification.[25,26] The respiratory risk index is a scoring system that categorizes patients as low-, medium-, or high risk for postoperative respiratory failure, based on factors such as emergency and complex operations, as per American Society of Anesthesiologists (ASA) score (see Chapter 10), and patient comorbidities (e.g., COPD, ascites, chronic kidney disease).[26] Potentially modifiable risk factors are indicated in Table 54.2.[27-73] The use of "ventilator bundles," such as those promulgated by the Institute for Healthcare Improvement (IHI), and similar quality improvement efforts have decreased the incidence of VAP by more than 50%.[27,28] However, the IHI paradigm contains two measures not likely to decrease the incidence of VAP (prophylaxis of stress-related gastric mucosal hemorrhage and venous thromboembolic disease, whereas other measures such as the effect of topical chlorhexidine used for oral hygiene, and recommendations about specific endotracheal tubes (e.g., silver-coated tubes) are not included in current bundles.

Diagnosis

Clinical Evaluation. The method of establishing the diagnosis of HAP remains controversial, undoubtedly due to difficulty establishing the differences among colonization, tracheobronchitis, and HAP. Neither radiological nor microbiological features in isolation can establish the diagnosis of HAP. The U.S. Centers for Disease Control and Prevention (CDC) and the NHSN have developed criteria for the diagnosis of nosocomial pneumonia, taking into account clinical factors, such as fever and leukocytosis, as well as radiological criteria, including persistent new findings on chest radiography[2,74] (Table 54.3). The controversy about whether to use clinical, noninvasive, or invasive measures to establish a diagnosis continues today.[75-91] An invasive diagnostic strategy does not alter mortality, but if antibiotic use is protocolized, the total duration of antibiotics may be lowered.[77,87,89,90]

RISK FACTOR REDUCTION AND PREVENTION FOR VENTILATOR-ASSOCIATED PNEUMONIA

■ RISK FACTOR	■ MODIFICATION
Smoking	Stop 8 wk prior to surgery when possible[29-33]
Asthma/chronic obstructive pulmonary disease	Optimize peak flow with bronchodilators and/or steroids[29]
Congestive heart failure	Optimize fluid status and blood pressure[29]
Postoperative pain control	Neuraxial anesthesia may reduce risk by 20%[34]
Aspiration risk	Head of bed elevation >30 degree[1,10,39,40]; remove nasogastric tubes[10,13,35-40]
Oral contamination	Selective decontamination[41]; mouth care, tooth-brushing, "stress ulcer" prophylaxis[39,42-49]
Intubation route and type	Nasotracheal intubation higher risk than endotracheal; type and presence of endotracheal tube; subglottic suction ("hi-lo") endotracheal tube; silver-coated endotracheal tube[50-55]
Ventilator circuit and suctioning	Endotracheal tube suctioning.[56-60] Circuit changes only when tubing is visibly soiled and (of course) between patients[36,51,61-67]
Duration of mechanical ventilation	Shorter time on ventilator lowers risk; maximal benefit to spontaneous breathing trials linked to sedation "holidays." Protocols effective[1,68-71]
Ineffective depth of respiratory effort	Incentive spirometry, cough and deep breathing exercises[72,73]

U.S. CENTERS FOR DISEASE CONTROL AND PREVENTION. SURVEILLANCE DEFINITION OF PNEUMONIA FOR A NON–IMMUNO-COMPROMISED ADULT PATIENT[a]

Radiology:
Two or more serial chest radiographs with at least ONE of the following:
- New or progressive AND persistent infiltrate
- Consolidation
- Cavitation

(In patients with no underlying pulmonary or cardiac disease, ONE DEFINITIVE radiograph is acceptable)

Signs/symptoms/laboratory:
At least ONE of the following:
- Fever (>38°C or >100.4°F) with no other recognized cause
- Leukopenia (<4,000 WBC/mm^3) OR leukocytosis (>12,000 WBC/mm^3)
- For adults ≥70 years old, mental status changes with no other recognized cause

AND

At least TWO of the following:
- New onset of purulent sputum, or change in character of sputum, or increased respiratory secretions, or increased suctioning requirements
- New onset or worsening cough, or dyspnea, or tachycardia
- Rales or bronchial breath sounds
- Worsening gas exchange (PaO$_2$:F$_1$O$_2$ ≤ 240), increased oxygen requirements, or increased ventilation demand

WBC; white blood cell count.

The Clinical Pulmonary Infection Score (CPIS)[78] includes both clinical and radiological factors that indicate an increased likelihood of the presence of pneumonia. Point values are assigned to each criterion and the total is summed. Traditionally, a threshold score of >6 points has been considered diagnostic of pneumonia[79] (Table 54.4). The clinical utility of the CPIS has been evaluated extensively, with both proponents and detractors.[78-81] In the original dataset, when the CPIS was ≤6 points, no patient satisfied microbiologic criteria for pneumonia.[79] Other investigators suggest that the CPIS, while sensitive, lacks specificity and leads to unnecessary antimicrobial treatment. Among 201 patients who underwent an invasive diagnosis of pneumonia, there was no difference in the CPIS score of patients with and without VAP. Importantly, therapy based on resolution of the CPIS would have led to 840 days of empiric antibiotics as compared to 424 days based on invasive specimen collection.[79]

Whereas most studies indicate that clinical evaluation is sensitive in identifying VAP, the specificity is low. Clinical diagnosis combined with short-course antibiotic therapy may be reasonable especially if a low [≤6 points] CPIS score is achieved after day three of treatment.[81] In a 2000 study, Singh et al.[81] examined short-course empiric therapy for patients in the ICU with suspected VAP. The rate of antimicrobial resistance or superinfection was significantly higher in patients receiving standard therapy. The duration of therapy was significantly lower in the experimental group, with no difference in mortality.

Bacteriologic Evaluation. The diagnosis of pneumonia can be established by a number of methods, including noninvasive and invasive means for sputum specimen collection and qualitative or quantitative microbiology.[82-91] Blind tracheobronchial aspiration (TBAS) is a noninvasive technique accomplished by inserting a flexible suction catheter into the distal trachea via the endotracheal tube to obtain sputum for quantitative culture.[86] The typical threshold for diagnosis of pneumonia is growth of >10^5 cfu/mL. This technique is simple

TABLE 54.4

MODIFIED CLINICAL PULMONARY INFECTION SCORE

	■ 0 POINTS	■ 1 POINT	■ 2 POINTS
Temperature (°C)	36.5–38.4	38.5–38.9	≤36.4 or ≥39
Peripheral WBC	4,000–11,000	<4,000 or >11,000 > 50% bands: add one extra point	
Tracheal secretions	None	Non-purulent	Purulent
Chest x-ray	No infiltrate	Diffuse or patchy infiltrate	Localized infiltrate
Progression of infiltrate from prior radiographs	None		Progression (ARDS or CHF believed unlikely)
Culture of endotracheal tube aspirate	No growth/light growth	Heavy growth Some bacteria on gram stain: Add one extra point	
Oxygenation (PaO$_2$:F$_1$O$_2$)	>240 or ARDS		≤240 and no ARDS

ARDS, acute respiratory distress syndrome; CHF, congestive heart failure; WBC, white blood cell count.

but does not allow specific lung segments to be sampled, and the catheter is contaminated easily.

Bronchoalveolar lavage (BAL) allows sampling of specific lung segments suspected to be involved with pneumonia, and supports quantitative microbiology. Bacterial growth of >10^4 cfu/mL is typically accepted as being most accurate for diagnosis of VAP, although some authors[1,89] argue that the use of 10^5 cfu/mL provides fewer false-positives and a lower likelihood of inappropriate antibiotic therapy.[90]

Specimen collection with a protected specimen brush (PSB) involves a telescoping catheter brush that is advanced blindly or through a bronchoscope, into the suspected distal airway. A diagnostic cutoff of >10^3 cfu/mL is typically accepted as being consistent with HAP.[1,91] Complications such as bleeding or pneumothorax may be more frequent with PSB.

Proponents of invasive diagnostic means for pneumonia suggest that fewer and more selective antibiotics be used when BAL or PSB is used to collect quantitative cultures.[89,90] Direct examination of BAL fluid for intracellular organisms (>5 cells) has overall sensitivity and specificity of 93.6% and 91.5%, respectively, for the diagnosis of VAP, with only 12% of patients receiving incorrect empiric therapy.[85] With early appropriate antibiotic therapy being an important predictor of mortality, a technique that facilitates early guidance of therapy may be useful clinically. In a randomized trial comparing PSB versus TBAS and thus quantitative versus qualitative techniques, Ruiz et al.[86] were unable to demonstrate any differences in ICU length of stay, length of mechanical ventilation, 30-day mortality, or attributable mortality between groups. However, the cost difference between groups was $368 versus $29.[86] Similarly, the Canadian Critical Care Trials Group randomized 740 patients with a clinical suspicion of pneumonia to BAL on mechanical ventilation for >4 days to quantitative culture versus TBAS, with qualitative culture controlling for the timing of empiric antibiotics.[87] The authors reported no difference in 28-day mortality. Additionally, there were no differences in the secondary outcomes of hospital and ICU length of stay, duration of mechanical ventilation, and ICU and hospital mortality.

On the other hand, Fagon et al.[88] randomized 413 patients to invasive versus noninvasive diagnosis of VAP, and found decreased 14-day mortality, improved organ function scores, and fewer days of antibiotic therapy among patients undergoing the invasive diagnosis. Interestingly, they also identified alternative infectious diseases that required intervention when pneumonia was not verified. The greatest support for the use of invasive techniques may be reflected by reducing antibiotic utilization or by more accurate use.[89,91] Shorr et al.[91] evaluated four randomized trials of diagnostic techniques, and found that invasive strategies do not affect the mortality of VAP, likely because empiric antibiotic choices must be made before results of quantitative cultures become available.

Treatment

Empiric Therapy and De-escalation of Treatment. The most important factor influencing the mortality of HAP is prompt and adequate empiric antibiotic therapy.[1,93,94] Treatment should be instituted immediately after specimen collection and should be directed against likely pathogens. The choice of antimicrobial agent(s) should account for risk factors such as current length of hospital stay, prior exposure to antibiotics, duration of mechanical ventilation, previous culture results, known antibiotic resistance locally among patient, contacts, and unit-specific microbiota, and host immunosuppression.[94,95] Several guidelines have been published suggesting agents that could be utilized for empiric antibiotics for CAP, HAP, VAP, and HCAP.[1,26,92,96,97-102] If the patient is considered low-risk by all criteria, single-agent therapy is a reasonable choice (Table 54.5).[1,26] On the other hand, patients who have risk factors as noted above should be considered for double- or triple-drug initial empiric therapy for VAP (Table 54.6).[1,26,99,100]

Whereas vancomycin is the agent used most commonly to treat MRSA in hospitalized patients, considerable debate has emerged about whether vancomycin should be used empirically as agent for suspected MRSA infection. The minimum

EMPIRIC ANTIBIOTIC CHOICES FOR LOW-RISK PATIENTS WITH VENTILATOR-ASSOCIATED PNEUMONIA

Third-generation cephalosporin (e.g., ceftriaxone)

Extended-spectrum fluoroquinolone (e.g., moxifloxacin, levofloxacin)

Aminopenicillin (e.g., ampicillin/sulbactam)

Narrow-spectrum carbapenem (e.g., ertapenem)

SURGICAL CRITICAL CARE

TABLE 54.6

EMPIRIC ANTIBIOTIC SELECTION IN HIGH-RISK
PATIENTS WITH SUSPECTED VAP

■ TRIPLE THERAPY FOR EMPIRIC INITIAL THERAPY IN HIGH-RISK PATIENTS WITH SUSPECTED VAP	
Antipseudomonal coverage by beta-lactam	Cefepime or ceftazadime, imipenem or meropenem or doripenem, piperacillin-tazobactam
Antipseudomonal fluoro-quinolone OR aminogly-coside	Ciprofloxacin or levofloxacin OR gentamicin, tobramycin, or amikacin
MRSA coverage	Linezolid or vancomycin
Therapy should be modified based on culture results as soon as possible, stopping unnecessary or overly-broad agents. De-escalation of therapy should occur within 72 h.	

MRSA, methicillin-resistant *S. aureus*.

inhibitory concentration (MIC) for vancomycin has been increasing among clinical isolates, and in a recent study, 73% of MRSA isolates had a MIC > 1.5 μg/mL.[103] Use of vancomycin as the primary agent for empiric use to treat high-risk patients with suspected VAP is also problematic because vancomycin has poor penetration of lung tissue.[104,105] Based on these trends, it is unclear whether vancomycin should remain the drug of choice for treating MRSA pneumonia, or whether linezolid should be considered as a first-line agent.[106-108] When compared to pneumonia caused by MSSA, MRSA is associated with prolonged ICU length of stay and increased hospital cost despite appropriate initial therapy.[108]

The decision to treat high-risk adult patients with suspected HAP/VAP with three agents (one against MRSA; two against MDR GNB) is based on the concern that MDR pathogens may be etiologic and that longer time to initial appropriate antimicrobial therapy has been linked to mortality. However, extended, overly broad antimicrobial therapy will lead to the development of additional resistance.[109,110] Some pathogens may be particularly difficult to treat; for example, as many as 50% of *Acinetobacter* isolates may be resistant to all antimicrobial agents except the polymyxins.[111,112] There is some evidence that treatment with intravenous or inhaled polymyxin E (colistin) may be safe and effective for patients with MDR *Acinetobacter* pneumonia.[111,113]

In many institutions, *P. aeruginosa* is the most common isolated pathogen responsible for VAP or HAP. In addition, the percentage of isolates sensitive to single-agent antipseudomonal therapy can be <50%.[114] This fact, along with the *in vitro* synergy observed with two-agent therapy (traditionally a beta-lactam and an aminoglycoside) has led to the suggestion that using two agents to cover possible MDR *Pseudomonas* is prudent,[108] albeit with considerable debate on the point.[115-121] Among trauma patients, Croce et al.[118] found that patients treated with a combination of a third-generation cephalosporin and gentamicin actually had increased rates of treatment failure and superinfection compared to those treated with the cephalosporin alone. However, recent investigations suggest that patients treated with initial combination therapy are more likely to receive appropriate empiric therapy, with associated improved mortality.[116,119-121] Heyland et al.[120] randomized patients with suspected VAP to empiric monotherapy versus combination therapy, and found no reduction of mortality from combination therapy. However, the percentage of patients treated effectively by combination therapy

was significantly higher. Moreover, patients with one or more MDR organisms were treated adequately 84% of the time by combination therapy, versus only 19% of the time by empiric monotherapy. For these reasons, current treatment guidelines recommend initial empiric double coverage for MDR GNB for critically ill patients with suspected HAP/VAP.[1,99,100,121-123]

De-escalation of therapy should be considered within 72 hours of initiating empiric therapy and is accomplished by: (1) changing to antibiotics with a narrower spectrum; (2) eliminating unnecessary antibiotics from the treatment regimen; or (3) changing to oral therapy.[124,125] Importantly, de-escalation has not been associated with decreased response rates, higher mortality, or longer hospital or ICU lengths of stay.[124,125]

Duration of Therapy. Recommendations for duration of antimicrobial therapy for nosocomial pneumonia have evolved in recent years, with an overall trend to decrease duration of therapy. In the seminal paper by Chastre et al.,[126] patients with VAP were randomized to 8 versus 15 days of antimicrobial therapy. All-cause mortality was similar between groups (18.8% for 8 days vs. 17.2% for 15 days, risk difference 1.6, 95% confidence interval [CI], −3.7 to 6.9). Additionally, there was no difference in recurrence rate (28.9% vs. 26.0%, risk difference 2.9 [CI −3.2 to 0.1]) of VAP. In a retrospective evaluation of the same population, pneumonia secondary to non–lactose-fermenting GNB and MRSA were both independently associated with recurrence.[127] Whereas concern for recurrence exists when treating MDR infections, these results[126,127] indicate that many patients may be treated safely and effectively with shortened courses of antibiotics.

The question remains: What is the shortest course of antimicrobial therapy appropriate for nosocomial pneumonia?[131] Serial BAL has been used as a method of assessing response to therapy and allowing for a shorter duration of therapy.[82] Discontinuation of appropriate therapy after 4 days in patients with decreased bacterial growth on repeat BAL decreases antibiotic duration and total antibiotic days, with no effect on mortality, length of stay, ventilator-free days, relapse rate, or rate of superinfection,[82] indicating that shortening of antibiotic courses may be accomplished safely in appropriate patients.

Outcomes

HAP has a substantial impact, both medically and economically, with incremental cost attributed to a single episode of HAP of up to $50,000.[2,5,10] Specifically, ICU patients with VAP experience longer ICU and hospital lengths of stay, which is a major driver of cost.[2,5,10] Prevention of HAP is therefore the focus of quality improvement efforts, and is, in part, why use of ventilator "bundles" for both prevention and therapy has blossomed.[106,128-130] However, the effect of VAP on mortality is unclear. In trauma and in patients with acute respiratory distress syndrome (ARDS), VAP does not appear to increase mortality, thus mortality is not a valid endpoint in studies of prevention of VAP.[132]

CATHETER-RELATED (-ASSOCIATED) BLOOD STREAM INFECTION

Definitions, Epidemiology, and Risk Factors

Central venous catheters are used commonly in patients for hemodynamic monitoring and administration of fluids and drugs, total parenteral nutrition, and blood products, and renal replacement therapy. The main complication of catheter use is infection, which can occur at the site of insertion, within

the blood stream, or result in metastatic infection.[133] Central line-associated BSI is defined from a surveillance perspective if a catheter is present within 48 hours of the culture and bacteremia occurs, irrespective of whether the catheter itself has been identified as a causative vector.[134] A laboratory-confirmed BSI (LCBSI) is defined when a patient has one of two possible conditions: (1) a recognized pathogen cultured from one or more blood cultures that is not related to infection at another site; and (2) signs and symptoms of infection and positive laboratory results not related to infection at another site; common skin contaminants must be cultured in blood from two or more sites, cultured on separate occasions.[134] These surveillance definitions overestimate the true incidence of infection because they do not account for a bacteremia from an undocumented source, such as an IAI. On the other hand, a catheter-related BSI (CRBSI) is confirmed when the catheter (cultured by the semi-quantitative "roll-plate" technique; >15 cfu—see below) and blood have identical pathogens. In the United States it is estimated that 250,000 BSIs occur annually, with rates ranging between 1.3 and 5.5 infections per 1,000 catheter-days.[135]

Catheters can become colonized or infected by two primary routes: (1) endogenous contamination from the skin alongside the catheter, causing catheter colonization and blood stream infection; or (2) endoluminal contamination from biofilm, a contaminated hub, or injection of infected fluid.[136] Catheter design and logistics must be understood to assess the associated risk.[136] For example, the catheter can be designated by the type of vessel it occupies (e.g., peripheral venous, central venous, or arterial); its intended life span (e.g., temporary or short-term vs. permanent or long-term); the insertion site (e.g., subclavian, femoral, internal jugular, or peripheral vein, peripherally inserted central catheter [PICC]); the pathway from skin to vessel (e.g., tunneled vs. nontunneled); its length; or some special characteristic of the catheter (e.g., cuffed or uncuffed, impregnation with heparin, antibiotics, or antiseptics, and the number of lumens).

Traditionally, the diagnosis of a CRBSI is established when both the catheter and blood stream yield the same pathogen.[136] A catheter may be cultured using the semi-quantitative "roll-plate" technique, whereby a 5-cm segment of catheter is rolled onto an agar plate; growth of >15 cfu is considered meaningful.[137] Pooled data suggest a sensitivity and specificity of 85% and 82%, respectively.[138] A more labor-intensive method intended to account for endoluminal pathogens subjects the catheter segment to sonication before plating. Growth of >10^3 cfu/mL is then considered diagnostic, with sensitivity and specificity of 83% and 87%, respectively.[138] However, both methods require catheter removal, thus alternatives have been considered. Simultaneous quantitative blood cultures can be drawn peripherally and through the catheter. A diagnosis of catheter-related infection is considered if the growth from the catheter is fivefold greater than the periphery. This method has sensitivity and specificity of 93% and 97% for long-term catheters.[138] Furthermore, if blood drawn from catheter turns positive more than 2 hours before blood drawn simultaneously from a peripheral site, CLASBI is confirmed with sensitivity and specificity of 90% and 72%.[138]

Data from the NHSN indicate that the most common pathogens isolated from CLABSIs were coagulase-negative staphylococci (34.1%), *Enterococcus* spp. (15.0%), *Candida* spp. (11.8%) and *S. aureus* (9.9%). Depending on local patterns, the frequency of resistant pathogens can vary widely, with more than one-half of *S. aureus* isolates being MRSA, 79% of *E. faecium* isolates being vancomycin-resistant (VRE), and up to 30% of *Pseudomonas* spp. resistant to more than one antimicrobial agent. More recently, *K. pneumoniae* and *Enterobacter* spp. may be resistant to cephalosporins via production of an ESBL.[139] Moreover, *A. baumannii* and *Klebsiella* spp. may be carbapenem-resistant, which can be transmitted rapidly to other GNB.

Prevention

Substantial progress has been made in preventing BSIs by implementing care bundles, including simple measures such as education, improved hand hygiene, use of full barrier precautions for catheter insertion, chlorhexidine skin antisepsis, avoidance of femoral sites, and prompt removal of unnecessary catheters.[28,140-144] After these measures proved to reduce infection substantially at Johns Hopkins, deployment in State of Michigan ICUs decreased rates of CLABSI and CRBSI from 7.7 to 1.4/1,000 catheter-days at 16–18 months.[144]

In addition to processes of care and bundles designed to reduce infection, technological advances such as catheter coatings with antiseptics or antimicrobials reduce infections when the catheter is in place for an average of 5–12 days [0.40, 95% CI, 0.27–0.58], but not 13–20 days [0.69, 0.42–1.14].[145] Ethanol lock solutions have been investigated for both prevention and treatment because resistance is unlikely and cost is modest. However, the concentration of ethanol, the dwell time, and the effect on the catheter all require elucidation.[146,147]

Antimicrobial locks have also been used in both clinical trials and in selected clinical conditions, such as in patients with tunneled hemodialysis catheters,[148-151] where CLABSI and hospitalization were reduced by 52% and 69%, respectively, albeit with concern for possible increased resistance to gentamicin in coagulase-negative *Staphylococcus* isolates.[148] Antimicrobial lock solutions are not recommended currently for routine use.[136]

The role of catheter dressings in reducing infections lacks clear recommendations as to the preferability of gauze or transparent dressings despite more than 20 years of study.[152-156] More recently, chlorhexidine gluconate-impregnated sponges have been shown consistently to reduce catheter and skin colonization, albeit with an increase in local skin reactions, especially notably in low-birth-weight infants (<1,000 g).[157-163]

URINARY TRACT INFECTION

Definitions, Epidemiology, and Risk Factors

Urinary tract infection (UTI) is the single most common HAI, representing more than 30% of all HAIs reported by acute-care hospitals.[1,2] The gold standard for diagnosis is the detection of a pathogen in the urine of a symptomatic patient. Traditionally, the microbiological quantification of a UTI has been the isolation of >10^5 cfu/mL from a mid-stream urine collection. However, this definition was proposed from healthy female outpatients, not from catheterized inpatients.

Several guidelines may assist clinicians in the prevention, identification, and management of UTIs.[164-169] However, sufficient evidence is lacking to support a clear definition of CAUTI versus the far more common (and often inappropriately treated) asymptomatic catheter-associated bacteriuria. In the recent guidelines of the Infectious Diseases Society of America (IDSA),[170] the term *catheter-associated asymptomatic bacteriuria* (CA-ASB) is retained, but it is omitted from the NSHN definitions (Table 54.7), and is considered by NHSN as a disease only when bacteremia ensues.[164] According to the IDSA guidelines[170]:

"Signs and symptoms compatible with CAUTI include new onset or worsening of fever, rigors, altered mental status, malaise, or lethargy with no other identified cause; flank pain; costovertebral angle tenderness; acute hematuria; pelvic discomfort; and in those whose catheters have been removed, dysuria, urgent or frequent urination, or suprapubic pain or tenderness."

Furthermore, patients with spinal cord injury may present with a compendium of complaints that include spasticity,

TABLE 54.7

NHSN DEFINITION OF CAUTI

■ TYPE OF INFECTION	■ DEFINITION
Catheter associated urinary tract infection	A CAUTI occurs in a patient who had an indwelling urethral catheter in place within the 48-h period before the onset of the UTI.
Symptomatic urinary tract infection	**Criterion 1a:** Patient had an indwelling urinary catheter in place at the time of specimen collection or a catheter removed within 48 h *and* at least one of the following signs or symptoms with no other recognized cause: fever (>38°C), suprapubic tenderness, or costovertebral angle pain or tenderness *and* a positive urine culture of ≥10^5 colony-forming units (cfu)/mL with no more than two species of microorganisms **Criterion 1b:** Patient did not have an indwelling urinary catheter in place at the time of specimen collection nor within 48 h prior to specimen collection *and* has at least one of the following signs or symptoms with no other recognized cause: fever (>38°C) in a patient that is ≤65 years of age, urgency, frequency, dysuria, suprapubic tenderness, or costovertebral angle pain or tenderness *and* a positive urine culture of ≥10^3 cfu/mL with no more than two species of microorganisms **Criterion 2:** Patient had an indwelling urinary catheter in place at the time of specimen collection or removed within the previous 48 h *and* at least one of the following signs or symptoms with no other recognized cause: fever (>38°C), suprapubic tenderness, or costovertebral angle pain or tenderness *and* a positive urinalysis demonstrated by at least one of the following findings: (a) positive dipstick for leukocyte esterase and/or nitrite; (b) pyuria (urine specimen with ≥10 white blood cells [WBC]/mm³ or ≥3 WBC/high power field of unspun urine); (c) microorganisms seen on gram stain of unspun urine *and* a positive urine culture of ≥10^3 and <10^5 cfu/mL with no more than two species of microorganisms **Criterion 2b** Patient did not have an indwelling urinary catheter in place at the time of specimen collection nor within 48 h prior to specimen collection *and* has at least one of the following signs or symptoms with no other recognized cause: fever (>38°C) in a patient that is ≤65 y of age, urgency, frequency, dysuria, suprapubic tenderness, or costovertebral angle pain or tenderness, *and* a positive urinalysis demonstrated by at least one of the following findings: (a) positive dipstick for leukocyte esterase and/or nitrite; (b) pyuria (urine specimen with ≥10 WBC/mm³ or ≥3 WBC/high power field of unspun urine); (c) microorganisms seen on gram stain of unspun urine *and* a positive urine culture of ≥10^3 and <10^5 cfu/mL with no more than two species of microorganisms
Asymptomatic bacteremic urinary tract infection (ABUTI)	Patient with or without an indwelling urinary catheter has no signs or symptoms (i.e., no fever (>38°C) for patients ≤65 y of age[a]; and for any age patient no urgency, frequency, dysuria, suprapubic tenderness, or costovertebral angle pain or tenderness, OR for a patient ≤1 y of age, no fever (>38°C core), hypothermia (<36°C core), apnea, bradycardia, dysuria, lethargy, or vomiting) *and* a positive urine culture of >10^5 cfu/mL with no more than two species of uropathogen microorganisms[b] *and* a positive blood culture with at least one matching uropathogen microorganism to the urine culture.

[a]Fever is not diagnostic for UTI in the elderly (>65 y of age) and therefore fever in this age group does not disqualify from meeting the criteria of an ABUTI.
[b]Uropathogen microorganisms are: GNB, *Staphylococcus* spp., yeasts, beta-hemolytic *Streptococcus* spp., *Enterococcus* spp., *G. vaginalis*, *Aerococcus urinae*, and *Corynebacterium* spp. (urease positive).

autonomic dysreflexia, or a "sense of unease".[170] The symptoms typical of a CAUTI are those identified also in noncatheterized patients; aside from fever, symptoms in a catheterized patient may be difficult to elicit, especially if critically ill.

Asymptomatic bacteriuria (ASB) is present when >10^5 cfu/mL is identified in two consecutive cultures from an asymptomatic patient. In outpatient females, ASB increases with increasing age, reaching a prevalence of 20% in those women older than 80 years.[171] In contradistinction, ASB is unusual in males before the age of 60 and is present among only 5%–10% of men older than 80 years.[172] In institutionalized older adults, as many as 50% will have ASB, which may persist for years without consequences. ASB is benign and not associated with negative outcomes.[169,173] Furthermore, the presence of pyuria is not sufficient to distinguish between asymptomatic or symptomatic UTI and does not indicate symptomatic infection.[171,173] However, absence of pyuria in a symptomatic UTI is unusual. Neither does the appearance or odor of the urine suggest presence of UTI.[174] To reiterate, ASB is not important clinically,

and treatment is unlikely to confer benefit.[169,173] Moreover, inappropriate treatment leads to potential resistance, drug side effects, and increased cost. Among 510 trauma patients, fever, leukocytosis, or both were not associated with a UTI, which occurred in 42 patients (16 episodes/1,000 catheter-days).[174]

The prevalence of CAUTI is highest in ICUs, where urinary catheters are used routinely to assess urine output. According to NHSN data from 2006 to 2008, rates range from a median of 3.4 infections per 1,000 catheter-days in surgical ICUs to 6.2 infections per 1,000 catheter-days in burn ICUs.[1] Rates on general care wards tend to be higher, ranging from 6.1 infections per 1,000 catheter-days in solid-organ transplant units to 14.5 infections per 1,000 catheter-days in rehabilitation units.[1]

Perioperative use of urinary catheters is common, but this practice is being scrutinized given that a urinary catheter is the single most important risk factor for the development of a UTI, related to usage itself and duration of use.[170] The National Surgical Infection Prevention Project revealed that 86% of patients undergoing major operations had indwelling

urinary catheters in the perioperative period, with one-half of the patients remaining catheterized for more than 2 days.[174] As expected, catheterization for more than 2 days was a significant risk factor for UTI (9.4% vs. 4.5%; $p < 0.004$).[175]

Additional risk factors for the development of a UTI include female gender, advanced age, diabetes mellitus, anatomic abnormalities, ureteral stents, and having had a solid-organ transplant,[165-180] In addition, conditions under which the catheter was inserted and maintained contribute to risk if not in conformance with standard infection control practices.

Pathogenesis and Microbiology

The pathogenesis of UTI can be classified according to whether infections are caused by endogenous or exogenous contamination.[170] Endogenous contamination occurs typically from contamination from the perineum and rectum by pathogens such as *E. coli*, *Klebsiella*, *Enterobacter*, and other Enterobacteriaceae. Exogenous contamination occurs via breaks in technique during insertion or aftercare. The pathogens can be typical nosocomial flora transferred to patients via contamination of the internal lumen of the catheter.

Biofilm may develop both on the internal and external surfaces of urinary catheters, and serves as a protective environment for pathogens, because antimicrobial agents penetrate poorly.[176] Biofilm can be an important factor in both forms of contamination, and is the reason why a catheter should be removed as soon as possible when a UTI is suspected, or changed if still necessary when a CAUTI is diagnosed or suspected.[171] Common nosocomial UTI pathogens are shown in Table 54.8,[139] but many may be colonists rather than pathogens. Staphylococcal UTIs may be associated with bacteremia. In a study of 102 patients with a urinary catheter and *S. aureus* bacteriuria, 33% had a CAUTI, and 13% were bacteremic. *S. aureus* bacteriuria can persist for months before causing bacteremia; bacteriuria may also reflect hematogenous pyelonephritis and urinary shedding. Therefore, all patients with *S. aureus* UTIs should be evaluated for bacteremia and possibly endocarditis (especially if blood cultures are positive.[177]

Treatment

Treatment of symptomatic CAUTI should include replacement or removal of the catheter if it has been in place for at least 1 week. Initial empiric antimicrobial therapy should be based on local epidemiologic data regarding pathogens and antimicrobial resistance patterns.[170,171] Once culture results are available, antibiotics should be adjusted accordingly, typically de-escalated and favoring an agent that is concentrated in urine. Whereas good clinical evidence is lacking regarding duration of therapy, guidelines recommend 7 days of therapy for patients who respond promptly to treatment and 10–14 days of therapy otherwise.[169] One study demonstrated that 5 days of levofloxacin treatment was sufficient if a patient was not seriously ill. Moreover, a 3-day course is recommended for females <65 years old without upper tract symptoms if the catheter has been removed.[170]

Prevention

The most important tactics in decreasing UTI is limiting exposure to urinary catheters and duration of their use.[165-171] Noninvasive means to measure bladder volume may reduce the "elective" use of urinary catheters during routine surgery. Specialized anti-infective catheters are not effective when catheter duration *in situ* is more than 1 week.

Because many patients become colonized with bacteria with an indwelling catheter, antibiotic prophylaxis at the time of discontinuation of a urinary catheter has been studied prospectively. A randomized trial of 239 patients given trimethoprim-sulfamethoxazole (three doses) versus placebo at the time of catheter removal demonstrated fewer infections (5/103, 4.9% vs. 22/102, 21.6%, $p < 0.001$), with only six patients requiring treatment.[178] Nevertheless, antibiotic prophylaxis of catheter removal is not recommended in the current IDSA guidelines.[170]

INTRA-ABDOMINAL INFECTION

Peritonitis

Peritonitis is a common diagnosis in surgical ICUs, often leading to severe sepsis.[179] Peritonitis is classified into three groups — primary, secondary, and tertiary, with secondary peritonitis subclassified into community- and HAIs. Primary peritonitis, previously called spontaneous bacterial peritonitis, arises without any anatomic cause, is typically mono-microbial, and is associated with ascites or peritoneal dialysis. Secondary peritonitis is most common and occurs when the peritoneal cavity is infected following perforation of a hollow gastrointestinal viscus, development of an intestinal fistula, anastomotic dehiscence, ischemic necrosis, or other injuries to the gastrointestinal tract.[179,180] Source control of the infectious focus and reduction of the bacterial inoculum are primary goals of surgical therapy, thereby allowing intraperitoneal host defenses to recover. More detailed discussion is presented elsewhere in this volume (see Chapter__).

The definition of tertiary peritonitis is controversial, but is generally considered as IAI that persists following multiple (at least two) interventions to control peritonitis. Patients with tertiary peritonitis are typically critically ill.[180-183] When compared with secondary peritonitis patients, patients with tertiary peritonitis have a higher APACHE II score (12.4 vs. 20.7 points), a greater number of organ failures (3.5 vs. 6.3 organs), and severe sepsis/septic shock (65.5% vs. 100%).[179] The mortality rate of tertiary peritonitis is quite high (30%-64%). Unlike secondary peritonitis, the microbial flora is not typically from enteric sources (e.g., *E. coli*, *Klebsiella* spp., other Enterobacteriaceae, *Bacteroides fragilis* group), but rather the common opportunistic and nosocomial facultative pathogenic bacteria and fungi (e.g., coagulase-negative staphylococci, enterococci, *P. aeruginosa*, *Candida* spp.)[179,181]; many are MDR organisms. Debate continues as to whether

---

TABLE 54.8

COMMON PATHOGENS OF THE URINARY TRACT

■ PATHOGEN	■ PERCENT OF INFECTIONS
Escherichia coli	15%–25%
Enterococci	14%–18%
Candida spp.	14%–25%
Pseudomonas aeruginosa	10%–17%
Klebiella pneumoniae	5%–10%
Enterobacter spp.	4%–8%
Coagulase-negative staphylococci	1%–5%
Staphylococcus aureus	1%–4%
Acinetobacter baumannii	0.5%–2%

the presence of these microbes represents colonization of the peritoneal cavity, invasive infection, or a marker of failure of host defenses. Factors that contribute to the development of tertiary peritonitis are listed in Table 54.9.[184]

Because tertiary peritonitis is considered as a continuum of disease from secondary peritonitis, the diagnosis can be difficult to establish.[181,183] Evans et al.[183] utilized a broad definition of tertiary peritonitis that included both localized (abscess) and generalized peritonitis following inadequate surgical source control (persistent infection resulting from lack of initial source control for secondary peritonitis does not define tertiary peritonitis). Thus, it is important to determine whether the surgical team believes that adequate source control has been achieved, which is typically possible in 80%–90% of cases.

Whereas a planned "second-look" re-laparotomy has been popular in the past, it is no longer recommended to diagnose tertiary peritonitis. Computed tomography (CT) is utilized when a postoperative patient with peritonitis fails to improve (especially when fever and leukocytosis are present), or manifests continued or worsening organ dysfunction.[182,185,186] If a localized fluid collection suspicious for an abscess is identified, percutaneous drainage is preferred. Some patients with focal signs of peritonitis may need to undergo re-laparotomy, but imaging usually demonstrates the feasibility of nonoperative management as a primary tactic. Supportive care with ongoing organ support and directed antimicrobial therapy is essential.

NOSOCOMIAL DIARRHEA

Nosocomial diarrhea is defined as developing after 3 days of hospitalization. The incidence of nosocomial diarrhea varies between 6% and 30% of hospitalized patients and is most common in ICUs and geriatric wards.[187] Diarrhea can be caused by medications that affect gut mucosa such as chemotherapy, anti-inflammatory agents, and agents that increase gastrointestinal motility. Nosocomial diarrhea related to noroviruses, rotaviruses, and adenoviruses has been reported.[188] Whereas antibiotic use and infectious causes explain some cases of nosocomial diarrhea, the most common cause of nosocomial diarrhea is the enterotoxin-producing *Clostridium difficile*, which may be responsible for up to 10%–20% of all cases. Other bacteria suspected to cause antibiotic-associated diarrhea include *S. aureus*, *C. perfringens*, and *K. oxytoca*,[189] but because these bacteria are part of normal fecal flora of healthy adults, a causative role in antibiotic-associated diarrhea has not been established firmly.

Clostridium difficile

The clinical spectrum of *C. difficile*-associated disease (CDAD) varies widely, ranging from an asymptomatic carrier state to life-threatening full-thickness pan-colitis.[190,191] There has been a recent dramatic increase in the incidence of *C. difficile* infections in US hospitals, from 30 to 40 cases per100,000 admissions in 2001, to 84 per 100,000 in 2005.[192] Furthermore, CDAD has been occurring with increased severity and virulence, due to the recent emergence of a epidemic strain characterized as restriction enzyme analysis type BI, North American Pulsed-Field Type 1 (NAP1), and PCR ribotype 027, or NAP1/BI/027.[193]

Antibiotic use alters gut microbiota and proliferation of *C. difficile*. However, for colitis to develop, the bacteria must attach to colonic mucosal cells to which nonpathogenic bacteria are normally adherent. Even though binding sites may be freed by antibiotic use that inhibits growth of normal fecal flora, *C. difficile* bacteria must also move through a dense mucus layer before attachment can occur.[194] Once attachment occurs, then toxins A and B (TcdA and TcdB) are produced, potent enzymes that damage mucosa by causing cytoskeletal disorganization. In addition to TcdA and TcdB, the hypervirulent strain NAP1/BI/027 produces the binary toxin *C. difficile* transferase (CDT), and lacks a regulatory protein (tcdC) that suppresses toxin production, allowing elaboration of 10-fold more toxin than wild-type strains.[194] The NAP1/B1/027 strain also is resistant to most fluoroquinolones, a pattern not seen before 2001. Moreover, subinhibitory concentrations of clindamycin, ampicillin, metronidazole, and vancomycin can enhance *C. difficile* colonization, spore germination, vegetative cell growth, and toxin production.[195-198]

The diagnosis of CDAD must be suspected in any patient who has recently (<2 months) been exposed to antibiotics. The clinical syndrome of CDAD is so varied that the presence or absence of any one clinical sign or symptom is unreliable to establish the diagnosis, including the presence of diarrhea (ileus may be present in severe cases).[191,199,200] The best test for diagnosis, a cell culture cytotoxin assay that has reported sensitivity of 94% and specificity of 99%, has a turnaround time of 24–48 hours, and is expensive.[191] Stool culture, although more sensitive, allows the recovery of bacteria for typing but does not allow identification of toxin production *in vivo*, and also takes 24–48 hours for results, and therefore is used seldom. Enzyme immunoassays have been used routinely for diagnosis because they screen for the presence of toxin, most notably TcdA, and are available quickly (within 4 hours). However, sensitivity is low (40%–75%). One method used increasingly is to screen a fresh stool sample using the common-antigen (glutamate dehydrogenase [GDH]) test. Because *C. difficile* produces GDH constitutively, the test is sensitive, can be completed rapidly (<1 hour), and is inexpensive.[201] Samples that screen positive can then undergo testing by a toxin assay, because the GDH assay only identifies the likely presence of *C. difficile*, and not whether toxin is produced. False-negative tests are thus rare.

In some cases, alternative diagnostic methods may be used.[191,201] Colonoscopy may identify mucosal changes, especially the formation of pseudomembranes, which are nonspecific and present in about one-half of cases. Sigmoidoscopy may miss disease confined to the ascending colon (up to 20% of cases). Moreover, endoscopy should be used cautiously with suspected toxic megacolon, as perforation may occur.

CT may identify suggestive findings, and may be used when other etiologies of abdominal infection must be ruled out. Characteristic CT features after oral and intravenous contrast include colon wall thickening, pericolic stranding, the "accordion sign," the "double-halo sign" (also known as the "target sign"), and ascites.[202] Wall thickening may be severe; "thumb-printing" and near-total occlusion of the lumen may be identified. The accordion sign shows oral contrast with high attenuation in the colonic lumen alternating with inflamed mucosa with low attenuation. The double-halo

TABLE 54.9

PATHOGENESIS OF TERTIARY PERITONITIS

Degree of bacterial contamination-bacterial inoculum
Virulence and synergy of involved species
Presence of adjuvants supporting microbial growth:
Intestinal contents, foreign material (barium), fibrin, blood
Adequacy of host response to infection
Appropriateness of medical interventions, especially surgical source control

sign shows varying degrees of attenuation attributable to mucosal hyperemia and submucosal inflammation after intravenous contrast. There should be no small bowel involvement; *C. difficile* is typically restricted to the colon.

Treatment. Treatment of *C. difficile* should be confined to symptomatic disease and distinguished between mild and severe manifestations.[202-205] Whereas oral metronidazole and oral vancomycin have generally similar efficacy, metronidazole has been preferred for initial therapy owing to lower cost and decreased likelihood of emergence of vancomycin-resistant enterococci.[203] However vancomycin was more effective for severe disease (97% vs. 76% for metronidazole) in a randomized trial, while in mild disease the antibiotics had similar outcomes.[206] The crucial element in therapy is delivery of drug to the lumen of the colon, where it can eradicate *C. difficile*.[206] Oral vancomycin is not absorbed and reaches colon intraluminal concentrations more than 100-fold higher than the MIC for *C. difficile*. Normally, oral metronidazole is absorbed completely by the proximal gut and does not appear in feces. However, in the presence of decreased transit time associated with diarrhea, metronidazole does appear in the stool.[201] Vancomycin enemas have been recommended in cases where ileus is present, but drug may still be delivered inadequately to the proximal colon. Repopulation of fecal flora with stool enemas is marginally effective and decidedly unattractive. The use of probiotic therapy is unproved, and there is concern that systemic illness may ensue in the setting of damaged mucosal barriers seen with CDAD.

In patients with severe CDAD, a total abdominal colectomy may be indicated.[203-207] Absolute indications for surgical intervention have not been determined, and advanced surgical judgment is required to balance appropriateness and timing of colectomy. Development of organ dysfunction, signs of hypoperfusion, and the need for vasoactive agents to support blood pressure are signs associated with mortality, therefore as predictors of the need for surgery, they manifest too late.[204,207] Neither any specific degree of leukocytosis, serum [lactate], nor any combination of clinical signs and symptoms has been validated prospectively to inform surgical decision-making. Retrospective data suggest that a white blood cell count $>50 \times 10^9$/L, [lactate] >5 mmol/L, and vasopressor use are associated with a high mortality rate when compared with WBC $< 20 \times 10^9$/L, [lactate] <2.1, and no use of vasopressors.[208] If surgery is performed, total abdominal colectomy is the procedure of choice, because segmental resection has been associated with increased mortality.[204-208] One author has suggested laparoscopic creation of an ileostomy as an alternative to colectomy,[209] allowing instillation of medication directly into the bowel and ameliorating the problem of impaired colonic transit due to ileus and profound mucosal edema, but this approach is unvalidated.

SURGICAL CRITICAL CARE

CHAPTER 55 ■ THROMBOEMBOLIC DISEASE

ELLIOTT R. HAUT AND EDWARD E. CORNWELL

Venous thromboembolism (VTE) disease, the composite term for deep vein thrombosis (DVT) and pulmonary embolism (PE), is a complication that deserves a prominent place in the mind of any surgeon caring for acutely ill or injured patients. As concepts of rapid triage and resuscitation accomplish their goals of optimizing the numbers of surgical patients surviving their initial physiologic insult, an ensuing challenge is represented by the attendant risk of these potentially lethal complications disproportionally seen in those who are immobilized and recuperating. The specter of the problem has reached sufficient magnitude to prompt the U. S. Congress to designate March as DVT Awareness Month[1] and the Surgeon General in 2008 to issue "A Call to Action to Prevent Deep Venous Thrombosis and Pulmonary Embolism."[2]

This chapter discusses VTE from the standpoint of incidence, risk factors, and screening philosophy and impact on "quality."

Virchow's triad composed of venous stasis, endothelial injury, and hypercoagulabilty, is the well-known classic explanation for the basic underlying pathway toward DVT. Once DVT occurs, there are many different natural outcomes that may follow. At one end of the spectrum, the body's normal fibrinolytic system can prevent propagation and lyse the clot, potentially even before the patient becomes symptomatic. At the other end of the spectrum would be the case of a large DVT traveling through the vascular system and causing sudden death from a large saddle pulmonary embolus. Other frequent scenarios include DVT that are clinically apparent with significantly swollen extremity and the potential for long-term sequelae of postthrombotic syndrome and/or PE that become symptomatic with pleuritic chest pain, shortness of breath or hypoxia requiring immediate treatment.[3]

Multiple patient populations treated by acute care surgeons are at exceedingly high risk of VTE. ICU admission is often suggested as an independent risk factor for VTE, although those patients quite likely also have multiple other well-accepted risk factors. In a study of 110 mechanically ventilated ICU patients, nearly 25% were diagnosed with DVT when the group was liberally screened with duplex ultrasound, in spite of appropriate VTE prophylaxis. In addition, 11.5% of patients with DVT in this study were diagnosed with PE as well.[4] In trauma patients, VTE remains an important clinical problem,[5] with the DVT rate as high as 58% if only high risk patients are considered in the risk pool and aggressive diagnostic surveillance is applied.[6] However, the reported rates are often lower than 1%, especially when registry data are used.[7-9] Within the field of general surgery, historical data, from the years before VTE prophylaxis was used, sheds some light on the underlying risk of VTE in certain populations. Within the group of untreated general surgery patients, the risk of DVT and PE were 19.1% and 1.6%, respectively. The rate for fatal PE was a remarkable 0.87%.[10] Even in the current era in which we frequently use prophylaxis, VTE rates of over 2.5%–3.5% are reported after some major general surgery and surgical oncology cases.[11]

Many different factors can increase a patients' risk of developing VTE.[12] Once a patient has VTE diagnosed, he/she is always at elevated risk for recurrent VTE, especially if provoked by an acute event or new diagnosis. These varied risk factors can be categorized by the patient's primary diagnosis category (i.e., trauma, cancer), other medical conditions (i.e., congestive heart failure), treatments performed (i.e., central line placement), hypercoaguable state (hereditary or acquired), or other predisposing conditions (i.e., obesity, advanced age). Some of the commonly accepted risks are listed in Table 55.1. In addition, these risk factors seem to be additive such that the more risk factors an individual patient has, the higher their risk of VTE.[12,13] Many procedures commonly performed on acute care surgery patients are also associated with elevated VTE occurrence rates including central line placement (femoral is highest risk location), major surgical procedures, chemotherapy administration, and fracture immobilization. Nearly every diagnosis that increases the odds of VTE by >10-fold is commonly treated by the acute care surgeon: fracture (hip or leg), major general surgery, major trauma, and spinal cord injury[12,13] (see Table 55.2). Additional factors specific to VTE risk in trauma patients are included in Table 55.3.

In addition to clinical impact on individual patients affected by VTE, there are significant financial implications of VTE occurring both during and following hospitalization. In one study of orthopedic surgery patients, mean hospital length of stay was more than doubled for patients with VTE compared to those without VTE. The study also reported the mean total costs of inpatient care nearly twofold higher for the VTE patients.[14] A study of cardiovascular surgery patients had similar findings; VTE patients had 14% higher inpatient costs and 68% longer length of stay as compared with those patients not having a VTE.[15] The economic burden of having DVT or PE as a secondary diagnosis during hospitalization is estimated to be $7,594 and $13,018, respectively.[16] In addition, this same study showed a high rate of readmission (14%) for patients with a secondary diagnosis of DVT or PE.[16]

VTE PROPHYLAXIS

According to the Agency for Healthcare Research and Quality, VTE prophylaxis in the appropriate patient populations is a top safety priority for hospitalized patients. Evidence-based guidelines published by specific specialty groups (e.g., The Eastern Association for the Surgery of Trauma [EAST][17] and The American College of Chest Physicians [ACCP])[18] utilize risk stratification to suggest which patients are at what level of risk and allow for appropriate suggested protocols for VTE prophylaxis.

The attached risk stratification tool (Algorithm 55.1) and algorithm-based prophylaxis regimen is one example for trauma patients that takes into account several concepts from the surgical literature: (1) enoxaparin, a low molecular weight heparin (LMWH), demonstrates an efficacy advantage over unfractionated heparin in a prospective randomized trial with trauma patients with ISS ≥ 9. (2) Normal ambulation (when appropriate) is an excellent adjunct in prophylaxis. (3) No regimen is 100% effective to prevent all VTEs,[19] suggesting some role for diagnostic surveillance in some high risk patients.[20]

Prophylaxis, in general, is divided into two main categories. The first is chemical or pharmacologic prophylaxis, including unfractionated subcutaneous heparin or LWMH given prophylactically to patients. In surgical patients, there

TABLE 55.1

RISK FACTORS OBSERVED IN 1,231 CONSECUTIVE PATIENTS TREATED FOR ACUTE DVT AND/OR PE

■ PATIENT RISK FACTOR	■ (%)
Age over 40 y	88.5
Obesity	37.8
History of venous thromboembolism	26.0
Cancer	22.3
Bed rest over 5 d	12.0
Major surgery	11.2
Congestive heart failure	8.2
Varicose veins	5.8
Fracture (hip or leg)	3.7
Estrogen treatment	2.0
Stroke	1.8
Multiple trauma	1.1
Childbirth	1.1
Myocardial infarction	0.7
1 or more risks	96.3
2 or more risks	76.0
3 or more risks	39.0

TABLE 55.2

RISK FACTORS FOR VTE

■ STRONG RISK FACTORS (ODDS RATIO > 10)
Fracture (hip or leg)
Hip or knee replacement
Major general surgery
Major trauma
Spinal cord injury

■ MODERATE RISK FACTORS (ODDS RATIO 2–9)
Arthroscopic knee surgery
Central venous lines
Chemotherapy
Congestive heart or respiratory failure
Hormone replacement therapy
Malignancy
Oral contraceptive therapy
Paralytic stroke
Pregnancy/, postpartum
Previous venous thromboembolism
Thrombophilia

■ WEAK RISK FACTORS (ODDS RATIO < 2)
Bed rest 3 d
Immobility due to sitting (e.g., prolonged car or air travel)
Increasing age
Laparoscopic surgery (e.g., cholecystectomy)
Obesity
Pregnancy/, antepartum
Varicose veins

Modified from Anderson FA Jr, Spencer FA. Risk factors for venous thromboembolism. *Circulation*. 2003;107(23 suppl 1):I9–I16.

is also some proven benefit that the preoperative dose, given 1–2 hours before surgery, is important to help with the prevention of clots. Although there maybe some associated elevated risk of bleeding with the prophylaxis, this small elevated risk is far outweighed by the substantial drop in symptomatic VTE events and PE-related death. In the current era, nearly all admitted surgical patients will have at least some risk factors warranting pharmacologic prophylaxis. Extended prophylaxis (beyond hospitalization) is also recommended for some surgical populations treated by acute care surgeons—specifically those undergoing cancer surgery[21-24] and major abdominal and pelvic surgery.[25,26]

Mechanical prophylaxis includes sequential compression devices, intermittent pneumatic compression devices, and graduated compression stockings. These mechanical devices also have a benefit in reducing the risk VTE and are especially helpful in patients who have a specific contraindication to chemical prophylaxis and cannot get either unfractionated or LMWH. Even with the accepted improvement in VTE rates with mechanical devices, studies have shown they cannot be used in some trauma patients due to wounds, casts, immobilizers, or external fixators[27] and that compliance with these devices on surgical patients is poor even without any specific contraindications.[28]

In orthopedic surgery specifically, there are multiple other types of prophylaxis that has been recommended. There are very good data that long-term prophylaxis for up to 6 weeks with warfarin in patients after hip replacement surgery has been shown to decrease event rates for both symptomatic DVT as well as PE.[18] It is suggested that aspirin may be used for prophylaxis in certain orthopedic patient populations, although there is still much ongoing debate, and many hematologists and thrombosis experts believe that this is likely inappropriate.

The prophylactic use of IVC filters for prevention of PE in patients without proven DVT remains controversial. The use

of these filters in trauma patients who are deemed to be of very high risk for PE has increased in recent years in the hopes that these prophylactic inferior vena cava filters can prevent massive PE and sudden cardiac death.[29] There is no consensus on exactly what patient population such filters should be used in, although in clinical practice they are placed for this specific indication in many trauma patients every year. There are temporary IVC filters that can be safely deployed by vascular and/or trauma surgeons in addition to interventional radiologists with a plan to remove them after the period of highest risk has ended. However, there is still ongoing concern that even with the planned removal of the devices, many filters remain *in situ* as trauma patients often lack appropriate follow up to have the filters taken out.[30]

Even with the large amount of strong evidence suggesting prophylaxis against VTE, the routine use of acceptable prophylaxis is surprisingly low both in the United States and around the world.[31-34] In surgical patients, rates of guideline-compliant prophylaxis often hover around 50%. In an attempt to increase this low compliance with best practice prophylaxis, many approaches have been taken[35] including computerized decision support[36] and electronic alerts.[37]

SURGICAL CRITICAL CARE

TABLE 55.3

RISK FACTORS INDEPENDENTLY ASSOCIATED WITH DVT IDENTIFICATION IN INDIVIDUAL TRAUMA PATIENTS BASED ON A MULTIVARIABLE LOGISTIC REGRESSION MODEL

	■ ODDS RATIO (OR)	■ 95% CONFIDENCE INTERVAL
Treatment at "Screening" vs. "NonScreening" Trauma Center	2.16	1.07–4.34
Age ≥ 40 y	2.00	1.74–2.30
Extremity injury (AIS ≥ 3)	1.96	1.68–2.30
Head injury (AIS ≥ 3)	1.53	1.22–1.92
Ventilator days ≥ 3	5.14	3.66–7.22
Venous injury	2.85	1.97–4.13
Major surgery	4.79	4.08–5.62

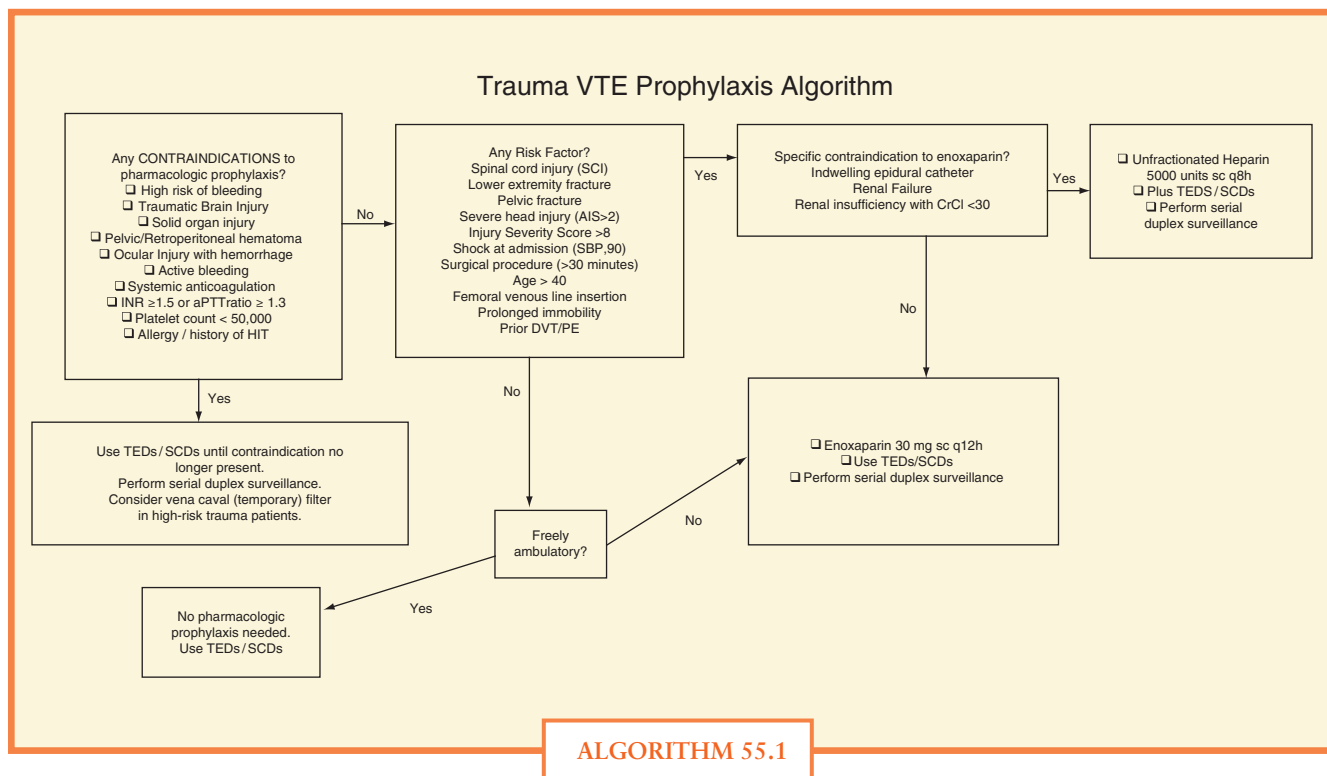
Adapted from Haut ER, Chang DC, Pierce CA, et al. Predictors of post-traumatic deep vein thrombosis (DVT)—hospital practice vs. patient factors: an analysis of the National Trauma Data Bank (NTDB). *J Trauma*. 2009;66(4):994–999.

Diagnosis

Even as recently as 20 years ago, DVT was a difficult diagnosis to make because the test, contrast venography, was difficult to perform, invasive, painful, and likely caused more DVTs at a later date. However, presently, the duplex ultrasound is now the well-accepted standard of care for diagnosis of DVT.[17] This relatively inexpensive, noninvasive test has also likely increased the overall numbers of DVTs identified since it can be looked for more easily, even in the patient with a relatively low index of suspicion.

The Diagnosis of Pulmonary Embolism

Historically, before the modern era of diagnostic imaging, many pulmonary emboli were identified only at autopsy and were not suspected premortem. The earliest test for diagnosing a PE was pulmonary arteriogram, which was an invasive technique performed by interventional radiologists or cardiologists, whereby, contrast was injected directly into the pulmonary artery via right heart catheterization. Invasive pulmonary arteriogram gave way to the V/Q or ventilation/perfusion mismatched scan, upon which many of the major early studies regarding diagnosis of PE (i.e., PIOPED study) were based.[38]

Currently, computed tomography (CT) pulmonary angiogram is clearly the most commonly performed test to identify PE, and this test has proved appropriate for the majority of patients except for patients who cannot get IV contrast due to renal dysfunction or allergy to the contrast material for whom ventilation-perfusion scanning remains an option.[39] In addition, patients need to travel to the CT scanner for this diagnostic test, which can also be a problem for the hemodynamically unstable patient in the ICU. In this patient population, echocardiogram has been suggested to be the ideal test of choice. Echocardiogram findings of a dilated right heart and pulmonary hypertension are relatively specific for PE in the hemodynamically unstable patient. Serum testing of D-dimer levels serves as an excellent adjunct role in the diagnosis (specifically to help rule out DVT/PE) in the outpatient and emergency department settings.[39] However, in the acute inpatient


ALGORITHM 55.1

ALGORITHM 55.1 Algorithm.

setting, D-dimer levels are frequently elevated in postsurgical patients as well as in those who are systemically ill, making this test less useful.

Treatment

The mainstay of treatment for patients with all VTE is medical in the form of anticoagulation. Even as recently as just a few years ago, treatment was always in a hospital setting. Patients would receive days of intravenous heparin drip with a bridge period until they were therapeutic on their warfarin, the major vitamin-K antagonist oral anticoagulation. However, there has been a major paradigm shift in that patients with VTE are now routinely treated with either once or twice a day dosing of LMWH, and then bridging that to warfarin, which can be safely performed on an outpatient in many patient populations. It is important to remember that when a patient is started on warfarin, there must always be an overlap period with some heparin (either unfractionated or LMWH) since there may be a short period of hypercoagulability immediately after vitamin K antagonists, that is warfarin, are given. Other anticoagulants can be used specifically in patients with a history of or active heparin-induced thrombocytopenia. In this case, direct thrombin inhibitors are utilized for treatment of DVT and/or PE. Many suggest that in these complex cases, consultations with specialists such as a hematologist who are well versed in the wide range of anticoagulants are to be implemented.

Duration of Treatment for Patients with VTE or PE

Although there has been recent debate on the needed length of therapy for DVT/PE, new evidence-based guidelines from the American Heart Association have attempted to streamline expert opinions. Length of therapy should be short (3 months) for those with a first DVT episode provoked by a major risk factor. Longer treatment (at least 6 months) is suggested for patients with recurrent or unprovoked DVT. It remains unclear exactly which patients should be screened for inherited hypercoagulable states (i.e., Factor V Leiden, antithrombin deficiency, protein C or S deficiency). However, if one is identified, this may change the suggested length of therapy. There are suggestions that repeat duplex ultrasound to confirm resolution of the clot is beneficial before stopping the anticoagulation.

Some hospitalized patients with DVT/PE cannot receive first line treatment with anticoagulation due to specific contraindications. These will include recent neurologic or ophthalmologic surgery, trauma patients with solid organ injury and/or retroperitoneal hematoma), preexisting coagulopathy or thrombocytopenia, or those at significant risk for recurrent falls. In these patients, IVC filter placement is the classically accepted treatment to prevent PE, although it will not help treat the underlying DVT.

Patients with PE and hemodynamic instability present a difficult treatment decision. Fibrinolysis, or thrombolytic therapy (i.e., Alteplase), is suggested for the treatment of massive PE in patients without contraindications. This treatment may break the PE into smaller pieces and allow better blood flow to potentially resuscitate the patient, such that they can move on to the next step of therapy. If thrombolytic is going to be given, it should be done immediately as soon as possible once the diagnosis of PE is either identified definitively or in a patient with cardiac arrest and significant risk factors. In patients with submassive PE, the evidence is less clear and clinical judgment is warranted to balance the risk/benefit ratio.[40]

In patients with submassive PE, there may be a role for either catheter-directed therapies such as embolectomy/fragmentation (usually performed by vascular interventional radiologists) or potentially an open surgical pulmonary artery thrombectomy (Trendelenberg procedure). The performance of this procedure is beyond the scope of this book, as it will routinely be performed by a cardiothoracic surgeon, through either a median sternotomy or anteriolateral thoracotomy. The decision to proceed down one or the other paths should be made in team consultation and will depend on local expertise with these procedures.[40]

SCREENING PHILOSOPHY AND QUALITY

Since injured patients are at elevated risk for DVT, many authors suggest that high-risk asymptomatic patients be screened for lower extremity DVT using duplex ultrasound. However, other authors have suggested that this process may not be cost effective as it has not been proven to improve patient outcomes. Recently published data show wide variability in trauma surgeons' opinions and trauma center practices regarding the use of screening duplex ultrasound in asymptomatic trauma patients.[20] Our policy of aggressive screening is driven by a desire to identify VTE as a DVT rather than a PE; however, recent federal government health policy decisions prompts reconsideration of this approach. In this section, we offer constructive criticism of the Center for Medicare and Medicaid Services' (CMS) decision to treat DVT as a "never event"[41] and the attendant thrust to use hospital DVT incidence rates as a marker for quality of care.[19]

We have previously reported evidence for surveillance bias in DVT reporting on a national level using the National Trauma Data Bank (NTDB), as well as at a single institution.

Our first exploratory analysis of the hypothesis that DVT rates reported may be related to rates of screening asymptomatic patients for DVT with duplex ultrasound was a retrospective review of trauma registry and hospital discharge data from a single academic level 1 trauma center.[42,43] Patients admitted to the Adult Trauma Service were divided into two groups, those admitted before versus after implementation of a written guideline for DVT prophylaxis and duplex ultrasound screening of asymptomatic high-risk patients. Data were compared between these two groups. Significantly more duplex ultrasound exams were performed in the later period (20.9 vs. 81.5 per 1,000 trauma admissions, $p < 0.0001$). This outcome was expected based on the implementation of our new guideline. The proportion of patients with DVT diagnosed increased 10-fold from 0.7 to 7.0 per 1,000 admissions ($p = 0.0024$). The incidence of PE or mortality did not change significantly, but proportionately more VTEs were identified as DVTs rather than PEs.

Our next study was a hospital-level analysis of duplex ultrasound and DVT rates in the largest trauma database available, the NTDB.[44] We divided hospitals into quartiles based on their rates of duplex ultrasounds per trauma patient admission and compared the DVT rates reported from hospitals in each quartile. Hospitals in the highest quartile by duplex rate reported a DVT rate sevenfold higher than the average DVT rate in the first three quartiles (1.52% vs. 0.22%, $p < 0.001$) (see Fig. 55.1). One plausible explanation for the large disparity in DVT and ultrasound rates between quartiles was practice variation between hospitals in screening asymptomatic trauma patients. The DVT rate increased significantly and correlated with duplex ultrasound rate at hospitals that had a 2% or greater ultrasound rate.

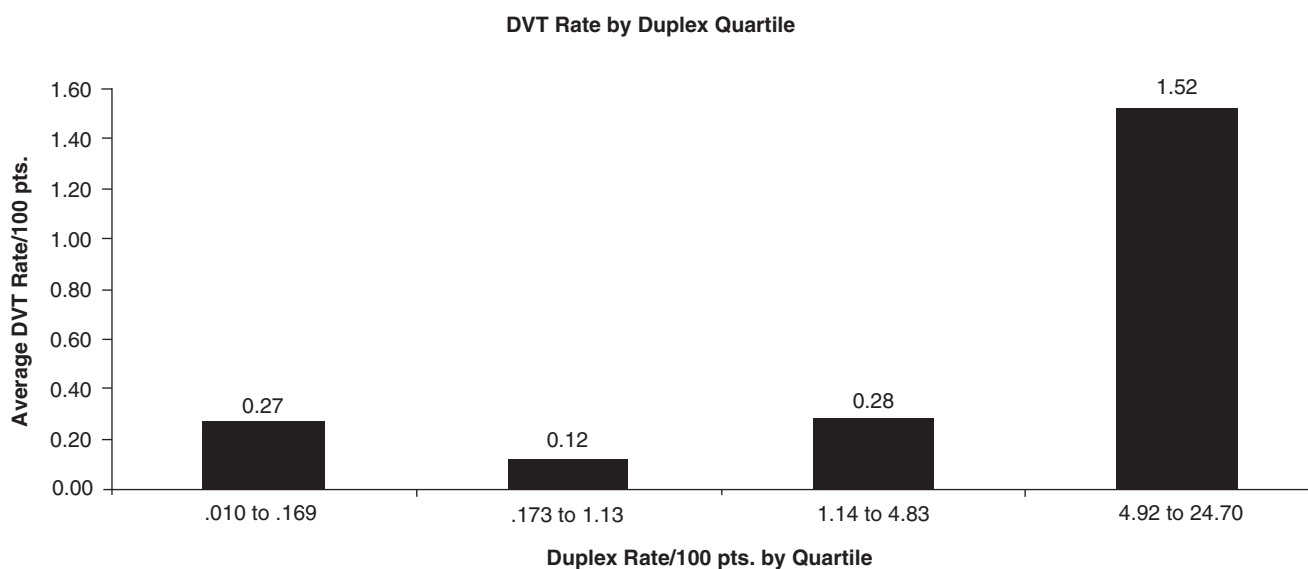
DVT Rate by Duplex Quartile


FIGURE 55.1. Hospital DVT rates in each quartile of hospitals. Raw data of the average hospital DVT rate per 100 admitted patients by duplex rate quartile. From Pierce CA, Haut ER, Kardooni S, et al. Deep vein thrombosis surveillance patterns in the National Trauma Data Bank: the more we look, the more we find. *J Trauma*. 2008;64:932–937.

We then used a multilevel analytical approach combining patient- and hospital-level characteristics within the NTDB to examine the outcome of reported DVT while controlling for differences in patient populations and individual patient characteristics that may influence rates of DVT after trauma.[8] As NTDB contains no data on hospital duplex surveillance practice, we defined "screening" trauma centers as those performing ultrasound on over 2% of patients. Multiple logistic regression was performed, using patient-level risk factor covariates (such as age, gender, injury severity score, injury mechanism, procedures, and comorbidities) as well as hospital duplex rate to compare odds of DVT diagnosis for patients at "screening" versus "nonscreening" centers. Unadjusted DVT rate was threefold higher for patients treated at "screening" trauma centers (1.18% vs. 0.35%, $p < 0.001$). Admission to a "screening" trauma center was independently associated with a twofold increased risk of having DVT reported, even after controlling for patient risk factors (odds ratio 2.16, 95% CI 1.07–4.34, $p = 0.03$) (Table 55.3).

This sequence of research suggests that DVT rates reported by trauma centers are inherently biased due to variations in local screening patterns and likely mislead rather than truly identify the quality of trauma care and should not be used for benchmarking purposes. A Journal of the American Medical Association (JAMA) editorial suggested that "aggressive screening strategies can markedly increase case-finding rates without an effect on quality of care. The absence of a standardized surveillance system could lead to a spurious association between more preventable harm and lower-quality care."[45]

We take this opinion a step further and suggest that if we ignore the issue of surveillance bias and decide to report and compare biased complication rates, there is a potential for unintended consequences to cause individual patient harm.[46] Patients may be put at elevated risk from providers who do not perform appropriate diagnostic testing in an attempt to avoid reporting complications. In the case of DVT, if the diagnosis is not considered, an ultrasound is not performed, and the DVT is not identified, the hospital may have few events to report. However, patients could be directly harmed since these DVTs may not be identified early on and intervened upon with anticoagulation to prevent propagation or PE.[19] This potential

for unintended consequences was most eloquently described by Alam and Velmahos; "So if your intubated polytrauma patient develops asymptomatic DVT and you are diligent enough to screen and detect it, you are at a risk of punishment and of not being reimbursed. On the other hand, if you do not bother investing in expensive technology, developing screening protocols, or battling with the radiology department for better patient care, you are gold. No screening, no DVT, no punishment."[44]

Our ability to clearly prove harm from the CMS policy is clouded by inaccuracies in estimating which duplex exams were truly "screening," and by relatively small numbers of patients with fatal PE's in any single registry. Nonetheless, it is clear that many, if not most, patients who develop DVTs do so despite appropriate prophylaxis, and other patients escape developing a DVT despite receiving no prophylaxis. Therefore, we strongly believe that the quality marker that should be used in federal health care reimbursement policy should consider compliance with DVT prophylaxis guidelines, not merely the incidence of DVT alone.[46,47] We are hard pressed to identify a rebuttal to this premise—other than inconvenience.

SUMMARY

The experience with risk stratification, prophylaxis, diagnosis, and treatment of VTE has allowed consensus management guidelines to be generated. More work is needed, however, to achieve consensus on the utility of an aggressive screening regimen, and to resolve the controversy over the use of DVT occurrences as a marker for quality of care.

CHAPTER 56 ■ THE IMMUNOCOMPROMISED PATIENT

UROGHUPATEI P. IYEGHA AND GREGORY J. BEILMAN

Immunocompromised patients present a special challenge to the acute care surgeon. Although transplant recipients, human immunodeficiency virus (HIV)-infected individuals, and chemotherapy patients are the most poignant examples, much more common are the immunocompromised states imposed by advanced age, malnutrition, chronic disease, and critical illness. As modern medicine continues to improve outcomes for such patients, they will continue to be an increasingly important part of the population that may eventually require emergency surgery. Therefore, knowledge of the various immunocompromised states and their management is of considerable importance to the acute care surgeon.

THE IMMUNE SYSTEM

As our knowledge of the immune system has grown, it has become clear that it is an extremely complex system with multiple dimensions that we are only beginning to understand. A detailed description of the immune system and our current state of knowledge is beyond the scope of this chapter. However, some basic premises remain true even if the full knowledge of the mechanisms behind them is still forthcoming. The immune system can be divided into two broad categories: innate and adaptive immunity. The innate response is the initial inflammatory response to infection or injury and is designed to proceed in a nonspecific manner. The adaptive immune system is tailored to the inciting pathogen and results in immunologic memory. While it is useful to categorize the immune system in this way, it should be pointed out that the two systems are closely integrated and each enhances the efficacy of the other. For example, the complement system as well as the host of inflammatory cytokines (tumor necrosis factor-alpha (TNFα), interferon-gamma (INFγ), interleukin (IL)-1, IL-2, etc.) play roles in both systems and illustrate their interdependence. The cells important for innate immunity are neutrophils, macrophages, natural killer (NK) cells, and dendritic cells. Mast cells, basophils, and eosinophils play a role in innate immunity as well, although their actions are classically demonstrated by type I hypersensitivity reactions. Neutrophils and macrophages phagocytose pathogens and/or cells infected with pathogens, while NK cells attack host cells that have been infected. TNFα and IL-1, primarily produced by macrophages, are the major inflammatory cytokines, and are implicated in many of the manifestations of the systemic inflammatory response syndrome.

Dendritic cells, positioned in tissues that are exposed to the external environment, link the innate immune response to the adaptive immune response by participating as antigen presenting cells (APCs). Via the major histocompatibility complex (MHC) class II, APCs present exogenous antigens to CD4+ (helper) T lymphocytes, which subsequently secrete cytokines such as INFγ, IL-2, and IL-4, which increases the activity of macrophages, CD8+ (cytotoxic) T lymphocytes and B lymphocytes, respectively. Cytotoxic T lymphocytes recognize and target cells presenting endogenous antigen (such as viral proteins) via MHC class I present on all nucleated cells. B lymphocytes recognize antigens bound to cell surface antibodies and subsequently differentiate into plasma cells that secrete antigen-specific antibodies. Perhaps the most important distinction to be made between the innate and adaptive immune response is that the adaptive immune response results in immunologic memory. Circulating memory B lymphocytes that secrete antigen-specific antibodies as well as circulating antigen-specific helper and cytotoxic T lymphocytes manifest this memory. The presence of antigen-specific immune cells allows for a much more rapid and robust response to an antigen if it is encountered again.

PROFOUND IMMUNOCOMPROMISE VERSUS RELATIVE IMMUNOCOMPROMISE

Immunocompromised patients can generally be separated into two broad categories: those with profound and those with relative immunocompromise. The most prominent example of profound immunocompromise is post solid-organ transplant immunosuppression. However, bone marrow transplantation, immunosuppressive therapy for autoimmune disorders, cancer chemotherapy resulting in neutropenia, and HIV infection/acquired immunodeficiency syndrome (AIDS) are also common etiologies of profound immunocompromise. Furthermore, an increasing number of genetic disorders, referred to as primary immunodeficiency disorders have been and continue to be elucidated (Table 56.1). While the individual conditions in this category may be rare, the aggregate should not be considered so.[1] Profoundly immunocompromised patients have a markedly increased susceptibility to infection as well as a considerable inability to combat infection once it is established. On the other hand, relative immunocompromise has many etiologies and is more difficult to quantify. Chronic illness such as diabetes mellitus, cancer, alcoholism, and drug abuse are associated with impaired innate and adaptive immunity. Advanced age and malnutrition, often synchronous with chronic disease, are also associated with impaired immune function and make up a growing portion of the general population. Additionally, intensive care units across the nation are filled with critically ill patients with immune dysfunction related to their acute illness. Similar to those with profound immunocompromise, these patients exhibit increased susceptibility to infection and demonstrate increased postoperative morbidity and mortality.

ORGAN TRANSPLANTATION

Over 20,000 organ transplants are performed annually in the United States (http://optn.transplant.hrsa.gov). The kidney is by far the most commonly transplanted organ followed by liver, heart, and lungs. A large part of the modern success of

organ transplantation has come from the development of more effective immunosuppressive agents. As organ transplantation continues to improve and becomes an increasingly viable option for a myriad of disease processes, the population of transplant recipients is likely to increase. It is well established that the rate-limiting factor in transplantation is donor availability. This observation underscores the reality that the acute care surgeon should expect to encounter transplant recipients in his or her practice and be prepared to manage them appropriately. A basic working knowledge of immunosuppressive regimens is

crucial to providing proper management of transplant patients. The field of immunosuppression has undergone many changes over recent decades driven by a much better understanding of the immune system. This knowledge has allowed for the development of targeted therapies with increased efficacy. Today, most patients will receive a combination of agents to prevent rejection. While traditional corticosteroid therapy remains an integral part of immunosuppression, modern therapy includes a multiplicity of agents including antimetabolites, calcineurin inhibitors, and lymphocyte-activation inhibitors. Other agents frequently used for induction and to combat rejection include antilymphocyte antibodies and IL-2 receptor antagonists. A summary of these agents with mechanisms of action and side effects is provided in Tables 56.2 and 56.3. Corticosteroids are the most commonly encountered class of immunosuppressive agents, although arguably they are more frequently used outside of transplantation. Corticosteroids inhibit cytokine release and impair neutrophil chemotaxis, rendering patients susceptible to infection. In addition, fibroblast function, collagen production, and angiogenesis are impaired, which negatively impact wound healing. Animal data clearly demonstrate impaired wound healing with corticosteroid therapy and limited human studies have correlated increasing doses of corticosteroids with impaired wound healing and increased postoperative infectious complications.[2,3] Unfortunately, patients receiving chronic corticosteroid therapy do not have the luxury of halting therapy as this places them at risk for adrenal insufficiency due to a depressed hypothalamic–pituitary–adrenocortical (HPA) axis. For this reason, supplemental corticosteroid therapy is commonly administered during periods of acute stress.

In effect, all immunosuppressive therapy places patients at risk for infectious complications. Up to 63% of solid-organ transplant recipients experience an infectious complication within the first year of transplant.[4] The risk of infection is highest during the first 6–12 months, corresponding to the period of most intensive immunosuppression. The risk of infection also increases with treatment of rejection. The most frequent infections seen early and late after transplantation are presented in Table 56.4. Infectious complications in the first month after transplantation are frequently caused by the

TABLE 56.2

IMMUNOSUPPRESSIVE AGENTS AND MECHANISM OF ACTION

■ AGENT	■ USES	■ MECHANISM OF ACTION
Corticosteroids (prednisone, methylprednisolone)	Induction Maintenance Rejection	Redistribution of lymphocytes, block T-cell proliferation, IL-2 synthesis
Antilymphocyte antibodies (antithymocyte globulin, OKT-3)	Induction Rejection	Lymphocyte depletion
Humanized antibodies (Basiliximab, daclizumab)	Induction Rejection	Specific targets: IL-2 receptor
Calcineurin inhibitors (cyclosporine, tacrolimus)	Maintenance Rejection	Inhibit IL-2 production, inhibits expansion and differentiation of T cells
Proliferation signal inhibitors (sirolimus/rapamycin, everolimus)	Maintenance	Block cytokine-driven cell cycle progression
Antimetabolites (azathioprine, mycophenolate mofetil)	Maintenance	Inhibit RNA/DNA synthesis

SURGICAL CRITICAL CARE

TABLE 56.3

SIDE EFFECTS OF COMMON IMMUNOSUPPRESSIVE AGENTS

Antithymocyte globulin	Fever, leukopenia, thrombocytopenia, serum sickness
Azathioprine, mycophenolate mofetil	Leukopenia, thrombocytopenia, anemia, diarrhea, abdominal pain, hepatotoxicity, pancreatitis
Basiliximab, daclizumab	Hypersensitivity (anaphylaxis), fever
Corticosteroids	Hyperglycemia, osteoporosis, impaired wound healing, hypertension, Cushingoid facies, Addisonian crisis (from rapid withdrawal)
Cyclosporine	Nephrotoxicity, neurotoxicity, drug interactions, hypertension, hyperkalemia, hirsutism, gingival hyperplasia
Sirolimus Everolimus	Hyperlipidemia, myelosuppression, impaired wound healing, diarrhea, arthralgia, pneumonitis
Tacrolimus	Nephrotoxicity, neurotoxicity, drug interactions, hypertension, hyperkalemia, diarrhea, diabetes, tremor
OKT-3	Pulmonary edema, fevers, rigors, diarrhea, headache, bronchospasm, increased CMV infection, risk of PTLD

same organisms common to immunocompetent hosts. Thereafter, opportunistic infections predominate, correlating with the highest degree of immunosuppression. Included among the most common problems are viral infections such as cytomegalovirus (CMV) and opportunistic fungal infections such as *Candida* and *Aspergillus* species.[5] A key component to treatment of infection in transplant patients is decreasing and/or ceasing immunosuppression, allowing the host immune system a chance to respond and increasing the prospects of clearing the infection. In the balance, of course, remains the risk of developing rejection in the transplanted organ. Consequently, close collaboration with the transplant team is required to appropriately manage immunosuppressive therapy and to prevent and/or detect signs of rejection.

TABLE 56.4

RISK OF INFECTION AFTER TRANSPLANT WITH RESPECT TO TIME AFTER TRANSPLANT

■ WITHIN 6 wk	■ 6 wk TO 6 mo	■ ≥6 mo
Viral Herpes simplex Hepatitis B, C	CMV (pneumonia) Hepatitis B, C EBV Varicella zoster Influenza Respiratory syncytial virus Adenovirus Polyoma (BK) virus	CMV (retinitis, colitis) Hepatitis B, C Papillomavirus Posttransplant lymphoproliferative disorder
Bacterial Nosocomial infection (e.g., line, pneumonia, wound, urinary tract infection)	Nocardiosis Listeriosis from Listeria monocytogenes Tuberculosis	Listeriosis Tuberculosis
Fungal Candidiasis	Candidiasis Aspergillosis Cryptococcosis Coccidioidomycosis Histoplasmosis	Cryptococcosis Coccidioidomycosis Histoplasmosis
Parasitic	*P. jiroveci* infection Strongyloidosis Toxoplasmosis Leishmaniasis *Trypanosoma cruzi* infection	*P. jiroveci* infection Strongyloidosis

AUTOIMMUNE DISORDERS

A multitude of chronic inflammatory and autoimmune disorders require anti-inflammatory, immunomodulating, and occasionally, immunosuppressive therapy for adequate symptom and disease control. Well-known examples include rheumatoid arthritis, systemic lupus erythematosus, and inflammatory bowel disease. Pharmacologic treatment ranges from nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX-2) inhibitors to corticosteroids, disease modifying antirheumatic drugs (DMARDs), and biologic response modifiers such as TNFα inhibitors (see Table 56.5).[58,59] By nature of their varying mechanisms of action, these drugs contribute to problems with surgical wound healing and increase rates of postoperative infectious complications. However, cessation of therapy for surgical procedures often leads to disease flares and worsening symptoms, which can decrease functional status and retard postoperative recovery. This conundrum poses a challenge to physicians and patients alike when it comes to surgical decision making.

Unfortunately, surgical outcome data in patients with chronic inflammatory and autoimmune disorders receiving various pharmacotherapies is limited. Animal studies have clearly demonstrated that NSAIDs negatively impact wound healing. However, selective COX-2 inhibitors have not been shown to negatively impact wound healing in animal models.[3] There is a paucity of human data for either class of drugs and current recommendations are based on extrapolations from the animal data. Although concerns exist regarding applicability of this data, it is generally recommended that NSAIDs be withheld for 3–4 days prior to surgery involving soft tissue and tendons. This recommendation has little applicability to the acute care surgeon, however.

There is also modest data regarding surgical outcomes and some of the more potent agents such as methotrexate, azathioprine, and other DMARDs as well as TNFα receptor inhibitors such as infliximab. Two small studies in the orthopedic literature, one retrospective review, and one prospective study, demonstrated that continuing methotrexate in rheumatoid arthritis patients in the perioperative setting is associated with increased infectious and wound healing complications. However, several other small studies, both retrospective and prospective, failed to demonstrate the same results, finding no significant difference in complication rates in patients who stopped methotrexate prior to surgery compared to those who continued methotrexate treatment perioperatively.[3] Similarly, there is conflicting data regarding outcomes in patients with inflammatory bowel disease being treated with biologic agents who are undergoing surgery. Several small studies have demonstrated equivalent postoperative complication rates in patients being treated with infliximab and other immunosuppressive agents such as azathioprine and 6-mercaptopurine for Crohn's disease and chronic ulcerative colitis compared to those who either had their medications discontinued before surgery or were not being treated with these agents.[6–9] However, multiple additional studies have noted an increased postoperative infectious complication rate in patients receiving infliximab preoperatively for

TABLE 56.5

DMARDS AND BIOLOGIC RESPONSE MODIFIERS USED IN TREATMENT OF AUTOIMMUNE AND OTHER INFLAMMATORY DISORDERS

■ AGENT	■ MECHANISM OF ACTION
Acetylsalicylic acid (ASA)	Irreversibly inhibits cyclooxygenase
NSAIDS (ibuprofen, naproxen, ketorolac, etc.)	Nonselective inhibition of cyclooxygenase
COX-2 inhibitors (celocoxib, rofecoxib, etc.)	Selective inhibition of COX-2
Corticosteroids	Specific mechanism of action unknown
Methotrexate	Folic acid analog, inhibits dihydrofolate reductase, inhibits de novo purine synthesis
D-penicillamine	Chelating agent, promotes urinary excretion of copper, mercury, zinc and lead
Gold sodium thiomalate	
Sulfasalazine	Specific mechanism of action unknown
Hydroxychloroquine	Impairs handling of heme
Azathioprine	Inhibits de novo purine synthesis
TNFα inhibitors (Infliximab, Etanercept, Adalimumab)	Prevent binding of TNFα to its receptor Infliximab—anti-TNFα monoclonal antibody Etanercept—Fused ligand binding portion of human TNFα receptor and Fc portion of human IgG_1 Adalimumab—anti-TNFα recombinant human IgG_1 monoclonal antibody
Rituximab	Chimeric monoclonal antibody against CD20 B-cell antigen
Anakinra	Recombinant IL-1 receptor antagonist
Abatacept	T-cell costimulation modulator—binds CD80 and CD86 on APCs preventing CD28 binding to T cells

Data from Brunton LL, Lazo JS, Parker KL, eds. *Goodman & Gilman's The Pharmacological Basis of Therapeutics*. 11th ed. New York: McGraw Hill; 2006; Katzung BG, Masters SB, AJ Trevor, eds. *Basic and Clinical Pharmacology*. 11th ed. New York: McGraw Hill; 2009.

treatment of Crohn's disease and ulcerative colitis.[10–13] One particular study noted that the risk of postoperative infectious complications, most notably sepsis, was mitigated by the presence of a diverting stoma in patients undergoing ileocolonic resection for Crohn's disease.[10] As a whole, these studies are small, underpowered, and possess confounding variables such as concomitant use of corticosteroids and other immunosuppressive medications. Though the authors generally attempt to compensate with multivariate analyses, the small study sizes of current reports do raise concerns about adequately detecting differences.

Despite its deficiencies, it is this data that is extrapolated to provide recommendations for other clinical scenarios. Obviously, the luxury of discontinuing immunomodulating therapy preoperatively is not typically available to acute care surgeons. The problem that most surgeons will face will revolve around the potential increased risk of postoperative infectious and wound healing complications as well as perioperative management of the primary disease state for which anti-inflammatory and immunomodulating therapy was intended. Clear guidelines are lacking given the current state of knowledge. In elective surgery, the recommended approach is to thoroughly assess risk factors and individually weigh risk versus benefit.[3,14] In some semielective instances that are encountered in acute care surgery, this approach is reasonable. In those patients in whom therapy is continued during the perioperative period, caution and vigilance is advised to detect postoperative complications early and initiate appropriate treatment in a timely fashion. When the risks clearly outweigh the benefits (e.g., intra-abdominal catastrophe), immunomodulatory therapy should be withheld until infectious concerns have subsided.

NEUTROPENIA

The most significant problem that acute care surgeons encounter in patients receiving chemotherapy is neutropenia. Defined as an absolute neutrophil count (ANC) of <1,500 cells per mL, neutropenia significantly inhibits the ability to combat bacterial infection. Moderate (ANC 500–1,000 cells per mL) and severe (ANC < 500 cells per mL) neutropenia impart the greatest risk compared to milder degrees of neutropenia. While chemotherapy is a common etiology, radiotherapy, leukemias, myelodysplastic disorders, and severe viral infections can also cause neutropenia. Neutropenic patients may experience fever and can develop life-threatening sepsis from transient bacteremia that would otherwise be clinically silent in an immunocompetent host. Common sources include the skin and oral cavity. The vast majority of infectious problems can be resolved with antimicrobial agents and cessation of the inciting agent until neutrophil counts increase. Often, granulocyte colony stimulating factor (G-CSF) has been administered to help stimulate a rise in neutrophil counts. Recently, the American Society of Clinical Oncology Update committee expanded recommendations for the use of colony stimulating factors (CSFs) to include prevention of febrile neutropenia in high-risk patients and to allow a modest to moderate increase in dose density and/or intensity of chemotherapy regimens.[15] While this decision-making process will likely fall to oncologists and hematologists, surgeons should be aware of the potential for use of CSFs in the perioperative management of neutropenic patients. Typically, surgeons become involved in the management of these patients when a gastrointestinal source is suspected for neutropenic fever or when patients complain of abdominal pain. The differential diagnosis can range from common entities such as calculous cholecystitis, peptic ulcer disease, appendicitis, diverticulitis, and bowel obstruction to less common conditions such as neutropenic enterocolitis, spontaneous intestinal perforation, and acalculous cholecystitis.

HUMAN IMMUNODEFICIENCY VIRUS/ACQUIRED IMMUNODEFICIENCY SYNDROME

HIV is a blood borne retrovirus that targets the CD4 lymphocytes of the host. It uses reverse transcriptase to translate its viral RNA into DNA in the host cell, which thereafter enables the cell to manufacture millions of viral particles. These particles are released systemically after lysis of the host cell and are free to target other CD4 lymphocytes. The end result is massive depletion of CD4 lymphocytes and subsequent host immunosuppression, referred to as AIDS. Modern antiretroviral drug therapy has improved outcomes and prolonged survival in patients with HIV infection; however, a significant portion will go on to develop AIDS, the most advanced stage of HIV infection.[16] Clinically, this corresponds with a state of profound immunosuppression and is defined by the development of an AIDS-defining illness or when CD4 counts drop to <200 cells per mm^3 (Tables 56.6 and 56.7).[16]

According to Center for Disease Control estimates, more than 1 million people in the United States are infected with HIV, one-fifth of which are unaware of their infection. Each year in the United States, an estimated 56,300 new HIV infections occur and approximately 36,000 people are newly diagnosed with AIDS. In 2007, an estimated 455,636 people were living with AIDS in the United States (http://www.cdc.gov). While the numbers are striking, they pale in comparison to the global crisis affecting millions of people.

A recent review highlighted the current state of surgical care in HIV/AIDS patients.[17] The advent of antiretroviral drug therapy has improved the overall outcomes for these patients and has concomitantly decreased the number of operations for AIDS-related surgical illnesses. However, these patients will continue to require surgical intervention for a number of intra-abdominal problems. The authors highlight that although AIDS-related conditions (CMV gastroenteritis, typhlitis, GI lymphoma and Kaposi sarcoma, mycobacterial infection, etc.) should remain in the differential diagnosis in HIV patients undergoing evaluation for abdominal pain, illnesses common in non-HIV patients and unrelated to the immunocompromised state (appendicitis, diverticulitis, peptic ulcer disease, etc.) should also be considered and are often the most likely etiology of the patient's complaints. As with any immunocompromised patient, the physical and laboratory findings may be blunted in AIDS patients. Typical findings such as peritonitis and leukocytosis may be diminished or absent. Occasionally, CD4 counts are absent or outdated and may not be available in the acute situation to impact clinical decision making. In this instance, total lymphocyte count (TLC) has been shown to be a reasonable predictor of absolute CD4+ count (specificity 97% for CD4+ count < 200 per μL when TLC <1.0 × 10^9 per L) and may be useful in the acute setting to gauge the degree of immunosuppression.[18] This is typically used as prognostic information as low CD4+ counts have been correlated with increased postoperative morbidity and mortality.[19,20] However, recent reviews have not found a correlation with low CD4+ counts and adverse postoperative outcomes although an increase in postoperative pneumonia and overall 12-month mortality was noted in a cohort of HIV+ patients, irrespective of CD4+ count.[21,22] In the trauma literature, it has been recently demonstrated that no major difference in mortality exists for patients with HIV, although this

TABLE 56.6

AIDS-DEFINING CONDITIONS

- Candidiasis of bronchi, trachea, or lungs
- Candidiasis, esophageal
- Cervical cancer, invasive[a]
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 mo duration)
- CMV disease (other than liver, spleen, or nodes)
- CMV retinitis (with loss of vision)
- Encephalopathy, HIV related
- Herpes simplex: chronic ulcer(s) (>1 mo duration); or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 mo duration)
- Kaposi's sarcoma
- Lymphoma, Burkitt's (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, any site (pulmonary[a] or extrapulmonary)
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *P. carinii* pneumonia
- Pneumonia, recurrent[a]
- Progressive multifocal leukoencephalopathy
- *Salmonella septicemia*, recurrent
- Toxoplasmosis of brain
- Wasting syndrome due to HIV

patient population had a higher risk of infectious complications and a longer hospital length of stay.[23]

HEMATOPOIETIC CELL TRANSPLANTATION

Hematopoietic cell transplantation, commonly referred to as bone marrow transplantation, is achieved by ablation of a recipient's hematopoietic and immune systems with cytotoxic chemotherapy with or without radiation (known as conditioning) prior to intravenous delivery of hematopoietic stem cells obtained from bone marrow, peripheral blood, or umbilical cord blood. It is used for treatment of bone marrow failure, malignancies such as leukemia, lymphoma, and multiple myeloma, immunodeficiency syndromes and inborn

TABLE 56.7

CD4+ T-LYMPHOCYTE STAGES

Stage 1	≥500 cells/μL[a]
Stage 2	200–499 cells/μL[a]

[b]With or without AIDS defining condition.

errors of metabolism. The treatment produces a profound state of immunocompromise in the recipient and a markedly elevated risk of infection. The timeline of immunocompromise can be divided into three risk periods: the preengraftment period (defined from the onset of conditioning to recovery of neutrophil counts), the early postengraftment period (defined by neutrophil recovery extending until day 100, which approximates the onset of B- and T-lymphocyte functional recovery), and the late postengraftment period (which is defined by day 100 until normal immunity is achieved). Each of the periods is associated with increased risk for specific infections and necessitates appropriate prophylaxis. Bacterial infections predominate during the early time points while viral and fungal infections become more prominent as time elapses in the postengraftment period.[24] In the unfortunate circumstance of a surgical emergency prior to achievement of normal immunity, a high morbidity and mortality is anticipated.

AGING AND MALNUTRITION

Aging is associated with a phenomenon referred to as immunosenescence—age related changes in immune function initially conceptualized as a global immune hyporesponsiveness. Although the mechanisms of these changes are extremely complex and are still being elucidated, multiple *in vitro* and *in vivo* studies in mice and humans have demonstrated impairment of both innate and adaptive immunity. Defects in multiple effectors of the immune response have been demonstrated, including neutrophil and macrophage phagocytic activity, antibody production, B and T lymphocyte proliferation, and IL-2 production.[25–27] However, aging is also associated with an increase in proinflammatory mediators resulting in a state of chronic low-grade inflammation. Several studies have demonstrated increased proinflammatory cytokines such as TNFα and IL-6 as well as an overall decrease in B and T lymphocyte receptor repertoire diversity.[28,29] As a result, immunosenescence is now thought to reflect overall dysregulation of the immune system rather than simply impaired function. The end result is an increased risk of infections, autoimmune disorders, and malignancy in elderly patients.[30–32] Complicating the issue is the synchronous issue of malnutrition in the elderly. Poor nutritional status is also recognized as a cause of immune dysfunction and a risk factor for increased mortality in elderly hospitalized patients.[33] The specific mechanisms have yet to be defined; however, studies have suggested that malnutrition impacts neutrophil chemotaxis and lymphocyte counts although this may not be reversed by improving nutrition in elderly patients.[34–36] The data is difficult to interpret in light of the complex environmental influences such as comorbid conditions, functional status, etc. Consequently, the interaction between malnutrition and the aging process that results in the immune phenotype we see clinically is still poorly understood. Despite the evidence for immune dysfunction, the impact on

surgical outcomes is difficult to quantify specifically. A practical approach is to recognize age as an additional risk factor, along with the patient's nutritional state and comorbid conditions, for an impaired inflammatory response and subsequently, increased postoperative infectious complications and poorer outcomes.

BURNS/CRITICAL ILLNESS

Thermal injury is associated with an increased risk of infection that goes beyond the loss of normal barrier function of the skin. Numerous alterations in innate and adaptive immunity occur leaving the patient susceptible to infection, sepsis, and multiorgan dysfunction. Indeed, after the early postburn period, infectious complications are the leading cause of mortality. The observed immune dysfunction is postulated to be a result of alterations in the cytokine expression. Recent work has implicated macrophage hyperactivity and leads to a shift in Th-1/Th-2 balance.[37] The exact mechanisms are complex and have yet to be fully elucidated. Even in the absence of thermal injury, critical illness such as sepsis and multiorgan failure is associated with immune dysfunction. One proposed mechanism is the immunomodulating effects exerted by the sympathetic nervous system via catecholamines, which include increased IL-6 and TNFα production, depressed neutrophil function, and decreased cellular adhesion to the endothelium. Furthermore, catecholamines have been shown to increase growth of several bacteria including *Escherichia coli* and *Staphylococcus epidermidis in vivo*, purportedly because of their ability to supply iron to bacteria via interactions with iron-laden transferrin and lactoferrin.[38] Clearly, critically ill patients as a result of burns or sepsis represent an extremely complex environment with multiple concomitant factors that precludes simple description. Fortunately, heightened awareness for infectious complications is well integrated into the practices of those that care for this patient population.

SUBSTANCE ABUSE

Substance abuse has been shown to be associated with increased infection risk. While intuitively this may be attributed to the risk-taking behavior associated with substance abuse, emerging data demonstrate that the agents of abuse themselves have immunomodulatory effects. Opiates have been shown, in both animal models and human studies, to have immunosuppressive effects, likely mediated by direct action on immune cells via opioid receptors. Cannabinoids are also thought to have a receptor-mediated immunosuppressive effect, with animal and human studies implicating HPA axis and autonomic nervous system pathways. Increased susceptibility to bacterial and viral pathogens has been demonstrated in animal models. Similarly, nicotine is thought to impact the HPA axis, although via nicotinic acetylcholine receptors rather than cannabinoid receptors. Very little is known regarding the immunomodulating effect of cocaine but a receptor-mediated mechanism is also suspected. Alcohol's effect on the immune system, in contrast, is not thought to be receptor mediated, although it is associated with global depletion of circulating lymphocytes and decreased cytokine production. Animal models have demonstrated increased susceptibility to bacterial infection, and observational data suggest an increased risk of viral infection in humans who abuse alcohol.[39] Taken as a whole, substance abuse should be considered an additional risk factor for impaired immunity and increased susceptibility to infection.

DIABETES

Diabetes mellitus is associated with an increased susceptibility to infection. Diabetic patients develop infections at a higher rate and are at increased risk for severe infections such as necrotizing soft tissue infections.[40] Poor glucose control indicated by persistent fasting hyperglycemia has been linked to abnormalities in innate immunity. Specific alterations included increased basal cytokine secretion, impaired neutrophil chemotaxis, phagocytosis, and bactericidal activity, and impaired monocyte/macrophage function. In addition, the hyperglycemic environment has been shown to enhance the virulence of certain organisms including *Candida albicans* and *E. coli*.[41] Conflicting data exist on whether cell-mediated adaptive immunity is significantly affected. Even so, diabetes mellitus should not be discounted as a risk factor for severe, complicated infections and postoperative infectious complications. The data also underscores the importance of maintaining normoglycemia in the perioperative setting, especially in critically ill patients.

GENERAL CONSIDERATIONS

Diagnosis

Surgeons must possess a high degree of suspicion when evaluating for surgical pathology in the immunocompromised patient as many of the local and systemic signs of inflammation are blunted. Notoriously, immunocompromised patients may fail to demonstrate peritonitis despite significant intra-abdominal pathology. In the case of soft tissue pathology, local findings such as erythema, induration, or purulence may not correlate with the severity of infection. Patients may or may not demonstrate fever and may simply present with changes in vital signs (e.g., tachycardia and hypotension) and metabolic acidosis. White blood cell counts may be elevated, but are often normal or low. In fact, a normal white blood cell count may actually represent a relative leukocytosis in a patient who is normally leukopenic. While the physical exam is often unreliable, positive findings should be taken seriously and should prompt a vigorous workup. Radiographic imaging plays a significant role in the evaluation of abdominal complaints in these patients (Fig. 56.1). The mainstay is computed tomography (CT) scanning. As mentioned above, significant intra-abdominal pathology such as abscess or intestinal necrosis or perforation may be present without the diffuse generalized peritonitis observed in immunocompetent patients. For invasive soft tissue infection, pursuit of radiographic imaging to assist with diagnosis may cause unnecessary and dangerous delays in appropriate surgical management. If severe infection necessitating surgical debridement is suspected, prompt operative exploration is warranted and serves as a diagnostic maneuver as well as potentially life-saving intervention.

Preoperative Management

Once the decision to intervene surgically has been made, the priorities in preoperative management remain unchanged from that of immunocompetent patients. The patient should receive prompt, appropriate fluid resuscitation, invasive hemodynamic monitoring if necessary, and broad-spectrum antibiotics where applicable. Antimicrobial therapy should be directed toward the most likely etiologic organisms based on the pathophysiology of the disease process; however, the hospital-specific antibiogram and patterns of microbial resistance should play a role in antimicrobial selection. In addition,

empiric antifungal therapy should be considered given the propensity of immunocompromised patients to fungal infection. Perhaps the most important consideration specific to immunosuppressed patients is for those who are receiving chronic corticosteroid therapy. These patients should receive stress dose steroids perioperatively to prevent the sequelae of adrenal insufficiency. As with immunocompetent patients, immunocompromised patients should receive appropriate surgical intervention for acute surgical conditions as rapidly as possible. Unnecessary delays in proceeding to the operating room should be avoided.

Operative Considerations

For the majority of disease processes requiring surgical intervention, the operative procedure itself changes very little in immunocompromised patients compared to immunocompetent patients. Invasive soft tissue infection should be debrided back to healthy tissue, abdominal explorations should be complete and thorough, and ischemic or infarcted bowel should be resected. If a large amount of bowel remains in question and not obviously necrotic, temporary abdominal closure with return to the operating room for a "second look" in 24–36 hours is appropriate. When bowel resection is required, the surgeon faces the decision of whether to perform a primary anastomosis or divert the fecal stream. If the patient falls into the category of profoundly immunocompromised, the patient is at increased risk of anastomotic leak and dehiscence due to impaired wound healing. The immunocompromised state further exposes the patient to increased morbidity and mortality from intra-abdominal abscess and sepsis. In these cases, fecal diversion is recommended. Similarly, cases in which significant peritoneal contamination is present, such as colonic perforation with fecal peritonitis, typically require formation of a diverting stoma. In select patients, there remains the possibility of electively reestablishing intestinal continuity after the patient has recovered from the acute process. Primary anastomosis may be considered in cases in which there is minimal peritoneal contamination or the patient only has risk factors for relative immunocompromise. In this instance the surgeon's clinical judgment is paramount. Factors such as the patient's overall presentation, comorbid conditions, operative course, and hemodynamic state play a role in the decision-making process. While frequently fecal diversion is justified based on the above factors, primary anastomosis with or without proximal diversion of the fecal stream is a viable option as well in select patients with minimal risk factors.

Abdominal closure presents another challenge in the operative management of the immunocompromised patient. These patients are at increased risk for postoperative wound infection and fascial dehiscence secondary to impaired wound healing. While closing the abdominal wall, particular attention must be paid to the strength and integrity of the fascia. Immunocompromised patients often demonstrate a thin, attenuated fascia with decreased tensile strength. Conversely, patients may have normal-appearing fascia that is still at risk for dehiscence due to an impaired inflammatory response that is essential for normal wound healing. Patients at greatest risk are those who are profoundly immunosuppressed, such as transplant recipients and cancer patients receiving chemotherapy. Likewise, elderly and/or malnourished patients and those receiving chronic corticosteroid therapy are at increased risk for poor fascial healing. If such risk factors are present or considerable concern exists over the integrity of the fascia, retention sutures may be used to prevent the catastrophic event of evisceration, should a large fascial dehiscence occur during the patient's convalescence. Postoperative incisional hernia is a predictable complication in this setting and likely represents partial fascial dehiscence during the recovery process. If the surgical wound is contaminated, standard skin closure should be avoided. In this instance, leaving an open wound to heal by secondary intention, either with daily dressings or vacuum-assisted closure is the conservative approach. Unfortunately, impaired wound healing consigns the patient to a chronic wound that may take months to heal. Alternatively, partial skin closure and delayed primary closure are both wound management strategies geared toward minimizing the postoperative wound infection risk while simultaneously attempting to decrease the size of the wound. Obviously, signs of a wound infection in a wound that is closed or partially closed should prompt immediate opening of the wound and initiation of antimicrobial therapy if considerable cellulitis is present.

Postoperative Management

Management for immunocompromised patients in the immediate postoperative period differs little from that of immunocompetent patients. Resuscitation should proceed with typical endpoints of restoring end-organ perfusion as indicated by blood pressure and urine output. Ventilatory management, invasive hemodynamic support, and pharmacologic support should proceed according to established guidelines, similar to that of immunocompetent patients. For patients who receive chronic corticosteroid therapy, stress dose steroids (typically hydrocortisone 50–100 mg intravenously every 8 hours) should be continued in the postoperative setting and gradually tapered over several days down to their preoperative dosing regimen.

Immunocompromised patients are at increased risk for postoperative infectious complications. While wound infections and intra-abdominal abscess are vivid examples, these patients are also at increased risk for pneumonia, catheter-related infection and sepsis, urinary tract infection, and antibiotic-associated diarrhea and colitis. Consequently, immunocompromised patients must be closely monitored and any indication of infectious complications should prompt a thorough workup to determine the source. Empiric antimicrobial therapy should be tailored to specific organisms based on preoperative or intraoperative culture results as soon as these are available. An abrupt decline in clinical

FIGURE 56.1. Massive retroperitoneal air extending medial to the bilateral kidneys secondary to descending colon perforation in a lung transplant recipient.

SURGICAL CRITICAL CARE

status in which infection is suspected usually warrants broadening of the antimicrobial spectrum until the specific etiology is found.

Fungal Infections

The immunosuppression associated with solid-organ transplantation increases the risk of fungal infection. The incidence of these infections may also be increased because of the use of broad-spectrum antimicrobial agents. Agents that are useful for treating fungal pathogens include amphotericin B, azoles, and echinocandins. Amphotericin B acts to prevent fungal growth by binding to fungal cell wall sterols and causing cell death via lysis. Azoles inhibit the cytochrome P450 enzyme responsible for ergosterol synthesis. Echinocandins inhibit glucan synthesis, disrupting cell wall structure. Often the different mechanisms of action of the echinocandins and azoles are utilized simultaneously by administering dual therapy. A recent report of transplant recipients with invasive aspergillosis receiving combination therapy of voriconazole and caspofungin showed improved survival in patients with either renal failure or *Aspergillus fumigatus* infection compared to those receiving a lipid formulation of amphotericin B.[42]

The most common fungal pathogens seen in immunocompromised patients are *Candida* species. The widespread use of fluconazole has likely contributed to the increased incidence of species resistant to this agent. Suspected fungal infection should be treated initially with a broad-spectrum antifungal agent such as caspofungin or voriconazole. Unfortunately, approximately 1% of transplant patients develop infection with *Aspergillus* species and this possibility should be considered in patients who fail to respond to initial therapy. If suspected, empiric therapy is warranted rather than waiting for a definitive diagnosis as invasive aspergillosis is associated with mortality as high as 60%.[43]

Other Infectious Concerns

Viral infections are important causes of morbidity and mortality in solid-organ transplant recipients. Endemic viruses of little concern to the immunocompetent population may be life threatening in the immunosuppressed host. CMV is a common pathogen in the transplant population affecting nearly 50% of kidney transplant recipients.[44] Donor seropositivity (in seronegative recipient), high dose immunosuppression, and repeated treatment for rejection are all risk factors for CMV infection.[45] The range and severity of infection with CMV is large and the lungs, gastrointestinal tract, liver, retina, and pancreas can all be affected. CMV antigen in blood or body fluid confirms diagnosis and treatment typically consists of intravenous ganciclovir followed by oral valganciclovir (Table 56.8).

Polyoma (BK) virus has a worldwide prevalence of about 98% in the general population with near universal exposure during childhood. In kidney transplant recipients, reactivation of the virus, which typically resides in latent form in the kidney, can result in inflammatory interstitial nephritis progressing to renal failure known as BK or polyoma-associated nephropathy. Thus far, this development has only been observed in kidney transplant patients. Risk factors for reactivation include tacrolimus use and recent treatment for rejection. In patients with unexplained renal failure after renal transplant, the presence of BK virus should be evaluated using polymerase chain reaction on urine and blood samples. Patients with a viremia should undergo reduction of immunosuppression.

Pneumocystis jiroveci, previously known as *Pneumocystis carinii*, is a common cause of pneumonia in immunosuppressed patients and should be considered in any patient presenting with respiratory symptoms who is not receiving prophylactic therapy. Empirical therapy with intravenous trimethoprim/sulfamethoxazole or pentamidine is necessary before established diagnosis due to an associated high mortality with delays in treatment.

TABLE 56.8

EMPIRICAL AGENTS FOR EARLY TREATMENT OF INFECTION IN TRANSPLANT PATIENTS

■ CLASS OF AGENT	■ AGENT	■ DOSE[a]
Broad-spectrum antibiotic agents[b]	Piperacillin/Tazobactam	3.375 g IV q6h
	Meropenem	0.5–1 g IV q8h
	Imipenem/cilastatin	0.5–1 g IV q6–8h
Gram-positive agents[c]	Vancomycin	1–1.5 g IV q12–24h
	Daptomycin[d]	4–6 mg/kg IV daily
	Quinupristin/dalfopristin	7.5 mg/kg IV q8h
	Linezolid	600 mg IV q12h
	Tigecycline[e]	100 mg IV load, 50 mg IV q12h
Antifungal agents	Voriconazole	6 mg/kg IV q12h × 2, then 4 mg/kg IV q12h
	Posaconazole	Oral only: 200 mg 3–4 times daily
	Caspofungin	70 mg load, 50 mg IV daily
	Anidulafungin	200 mg load, 100 mg IV daily
	Liposomal amphotericin B	3–10 mg/kg IV daily
Antiviral agents[f]	Ganciclovir	2.5–5 mg/kg IV q12h
	Foscarnet	90 mg/kg IV q12h

[a]Please note that doses given do not account for renal or hepatic insufficiency common in critically ill patients. Prior to choosing an empirical antibiotic regimen, the clinician should carefully consider the patient scenario and medication side effects related to the specific patient.
[b]Rather than a single agent, combination agents covering both gram-negative organisms and anaerobes may be chosen (e.g., fluoroquinolone plus clindamycin or metronidazole). For cases with a strong suspicion for *Pseudomonas aeruginosa* infection, additional *Pseudomonas* coverage should be added (e.g., fluoroquinolone or aminoglycoside).
[c]When vancomycin-resistant *Enterococcus faecium* infection is suspected, one of the latter four choices should be employed.
[d]Daptomycin is not indicated for treatment of pneumonia (package insert).
[e]Tigecycline is not indicated for treatment of hospital-acquired pneumonia (package insert)
[f]Antiviral agents directed toward herpesvirus family (most commonly CMV). Adjust for other viruses.

Rejection

Rejection remains a constant concern in the management of the transplant patient in whom immunosuppression has been held or decreased in order to manage infection. Indeed, this is often the case given the spectrum of pathology the acute care surgeon encounters. Particular attention must be paid to the transplanted organ in order to detect early signs of rejection. Renal allografts are monitored with serum creatinine and blood urea nitrogen determinations although these may be elevated as a result of acute renal failure secondary to the acute illness. Likewise, cardiac dysfunction, respiratory failure, liver dysfunction, and hyperglycemia all represent issues that accompany critical illness but may also be attributed to developing rejection of that particular transplanted organ. Consequently, it is imperative that the patient's transplant team be involved in the care of the patient to help with decision making in this regard. Rejection is definitively diagnosed by biopsy and histopathologic examination although empiric therapy to combat rejection may be initiated if the patient's overall condition allows and the diagnosis is strongly suspected. High-dose corticosteroids and antibody therapy are commonly used to treat rejection.

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

In general, surgical care in patients with HIV/AIDS should proceed similar to the patient without HIV. While CD4+ counts may offer prognostic information, this data may not always be available although TLC may be a useful predictor. Regardless, a high index of suspicion must be corroborated with adjunctive studies and vigilance must be exercised if delays in appropriate surgical care are to be avoided. Both disease processes common to HIV/AIDS patients and those unrelated to HIV/AIDS must be considered in the differential diagnosis. Postoperatively, infectious complications should be sought and treated aggressively. Collaboration with infectious disease/HIV specialists is crucial to ensure appropriate management of antiretroviral therapy postoperatively. Antiretroviral therapy should not be interrupted for any period longer than necessary since viral replication begins shortly after interruption of therapy.[46] Finally, while surgical care of this patient population does expose caretakers to the possibility of HIV transmission, the average risk is very low. The average risk of transmission after exposure to HIV-infected blood has been estimated to be 0.3% for the percutaneous route and 0.09% for mucous membrane exposure.[47,48] Care must be taken to minimize exposure; however, excessive measures are likely to be unnecessary. Exposures should be reported immediately so that post exposure prophylaxis can be initiated in a timely fashion.

SURGICAL DISEASE PROCESSES RELATED TO THE IMMUNOCOMPROMISED STATE

Posttransplant Lymphoproliferative Disorder

Posttransplant lymphoproliferative disorder (PTLD) refers to a spectrum of uncontrolled B-cell proliferation linked to Ebstein-Barr virus (EBV) infection that ranges from simple benign hyperplasia to lymphoma. This disorder is associated with increased morbidity and mortality to immunocompromised hosts, typically solid-organ and bone marrow transplant recipients. PTLD typically occurs during times of most intensive immunosuppression. The incidence of PTLD is low in renal and pancreas transplantation compared with other solid-organ transplants (2.6% at 10 years). (http://optn.transplant.hrsa.gov). The clinical presentation of this disorder can vary widely. Many patients present with nonspecific symptoms such as malaise, fever, and weight loss. Others present acutely with hemodynamic instability and markedly elevated serum lactate level that is refractory to aggressive fluid resuscitation. Patients may even present emergently with perforation, obstruction or hemorrhage requiring surgical intervention, although this represents a minority of patients.

Evaluation for suspected PTLD should include imaging of the brain, chest, and abdomen, with targeted biopsies to obtain a tissue diagnosis. Treatment of patients with PTLD has not been well standardized but includes reduction of immunosuppression, surgical resection, or radiotherapy for localized disease, or treatment with chemotherapy and/or anti–B-cell antibody (rituximab) for more extensive or refractory disease. Other treatment options include administration of antiviral therapy and interferon-α, although these modalities are under investigation.[49–51] Patients receiving chemotherapy or rituximab for gastrointestinal PTLD may suffer perforation during treatment secondary to tumor lysis and require emergent laparotomy.[52]

Neutropenic Enterocolitis

The most common gastrointestinal source of infection related to neutropenia is neutropenic enterocolitis, also known as typhlitis. The exact etiology is unknown but is postulated to be multifactorial, involving intestinal mucosal injury, neutropenia, and impaired mucosal defense against gastrointestinal microorganisms. The mucosal injury may be a direct cytotoxic effect of chemotherapy or radiotherapy or may be related to neutropenia itself in the absence of cytotoxic therapy. The mucosal injury leads to loss of gut barrier function and allows translocation of bacteria and unchecked invasion of the intestinal wall. This leads to inflammation, edema, and ultimately perforation. Treatment with antibiotics is typically sufficient but early diagnosis is imperative. CT is the mainstay of diagnosis and demonstrates sensitivity as high as 92%. Diagnostic imaging is crucial since physical exam findings are typically minimal due to the inability of neutropenic patients to mount a substantial inflammatory response and thus demonstrate peritonitis (Fig. 56.2). When present, findings may be diffuse or localized to the right lower quadrant, as the terminal ileum is the most common site of pathology. In the absence of hemodynamic instability, generalized peritonitis or imaging findings suggestive of perforation, antimicrobial therapy targeted toward gram-negative and anaerobic organisms is the standard treatment. G-CSF should be administered to normalize neutrophil counts. Surgical intervention is mandated for imaging findings suggestive of intestinal perforation, in unstable patients demonstrating shock, and in patients who fail medical management. Diverting stoma formation is obligatory in most cases if intestinal resection is required.[53]

Gastrointestinal Cytomegalovirus Infection

Profoundly immunosuppressed patients are at risk for development of upper and lower gastrointestinal tract involvement with CMV, leading to abdominal pain, bleeding, and rarely, perforation. While historically seen in patients suffering from AIDS and those receiving immunosuppressive therapy for inflammatory disorders, the rise of solid-organ transplantation has provided a growing population of susceptible patients.
FIGURE 56.2. CT scan showing inflammation of the terminal ileum consistent with typhlitis in a neutropenic patient. Inset highlights the inflamed terminal ileum.

Initial CMV infection most commonly occurs within about 6 months of transplantation, correlating with the highest immunosuppressive load. CMV infections are more common in serologically negative patients who received organs from a CMV positive donor. CMV-related problems are also more common among patients with known CMV infection and those treated with relatively high doses of immunosuppression.[45] As a result, routine prophylaxis against CMV infection has been included in the first few months of post-organ transplantation protocols in many centers nationwide, while others perform routine surveillance for CMV for weeks to months following transplantation. While these strategies have decreased early development of CMV infection, late infection can still occur.[45] Diagnostic endoscopy should be performed early in patients with suspected gastrointestinal involvement with CMV, tissue biopsies of the stomach and/or colon should be obtained to evaluate for the presence of CMV. Initial treatment consists of intravenous ganciclovir or foscarnet, with a switch to maintenance therapy by oral agents as tolerated for a period of weeks to months. Refractory bleeding and perforation are obvious indications for surgical intervention, although intervention in the patient population susceptible to this disease process is associated with high morbidity and mortality.

Necrotizing Soft Tissue Infection and Invasive Fungal Infection

Necrotizing soft tissue infection is an entity well known to the acute care surgeon and is described in detail elsewhere in this text. Necrotizing soft tissue infection as a complication of immunosuppression such as in transplantation is a rare event, but has been reported.[54] It is associated with significant morbidity and mortality and, as in immunocompetent patients, should be treated with emergent surgical debridement and systemic antimicrobial therapy. Fungal etiologies must be considered and appropriately covered in the antimicrobial regimen if suspected. Necrotizing fasciitis caused by *Candida* species has been reported and a series of primary deep cutaneous opportunistic mycoses secondary to multiple organisms including *Alternaria*, *Aspergillus*, *Histoplasma,* and *Blastomyces* species has been published.[55–57] If not treated promptly, systemic dissemination may occur, a frequently fatal development. Timely intervention relies on early diagnosis and intervention, which is predicated on including fungal etiologies in the differential diagnosis.

Conclusion

The immunocompromised patient certainly presents a challenge that acute care surgeons must be prepared to confront in clinical practice. Patients may present with profound immunocompromise secondary to immunosuppressive medication, chemotherapy, or AIDS. It is more probable, however, that surgeons will encounter those who are relatively immunocompromised such as the diabetic, elderly, malnourished, or critically ill. Often, multiple risk factors for relative immunocompromise may be present simultaneously. While distinguishing between profound and relative immunocompromise is useful for generally assessing the risk of complications related to a compromised immune response, it also has clinical utility in formulating the differential diagnosis in patients in which the diagnosis is unclear. A high index of suspicion is necessary to treat these patients in a timely and appropriate manner. Broad-spectrum antibiotics should be instituted without delay, appropriately tailored based on culture results, and discontinued when clinically indicated. Agents active against viral and fungal pathogens should be included in the selection of antimicrobial therapy if significant risk for these pathogens exists. Likewise, surgical intervention should proceed promptly to achieve source control as rapidly as possible. Intraoperatively, special consideration must be given to the wound healing capability of the patient. Fecal diversion is indicated for those who are profoundly immunocompromised and should be considered in the relatively immunocompromised patient if additional risk factors are present. Retention sutures may also be used if fascial dehiscence is of particular concern. The postoperative care of the immunocompromised patient requires vigilance in monitoring for the development of infectious and/or wound healing complications as presenting signs may be minimal. Stress dose steroids should be administered to those patients who receive chronic corticosteroid therapy or demonstrate adrenal insufficiency. Close collaboration with specialists in transplant and HIV/AIDS patients is mandatory, as these patients will need to resume immunosuppressive or antiretroviral therapy postoperatively and the decision regarding timing may be difficult. Ultimately, as the specialty of acute care surgery expands and our ability to care for critically ill patients continues to improve, the capacity to provide safe acute care surgery services to the immunocompromised patient population should also continue to improve.

CHAPTER 57 ■ SUPPORT OF THE ORGAN DONOR

DAVID M. KASHMER, SUZANNE A. FIDLER, AND MICHAEL D. PASQUALE

The gap between the availability of organs and the demand for transplantation is large. The number of potential organ donors in the United States has been estimated to be more than 10,500 per year,[1] and, clearly, not all potential donors progress to organ procurement. As of July 22, 2006, the United Network for Organ Sharing (UNOS) stated that the number of patients awaiting transplantation in the United States was 92,450. Looking at data for the period 1997 through 1999, only 50% of health care agents who were proxies approached regarding donation agreed to proceed,[1] yielding a donor conversion rate of 42%. Factors affecting procurement include the number of families approached regarding organ donation, families' perception of the donor process, religious or spiritual beliefs, cosmetic appearances, and the difficulty regarding change in provider focus from the health of their patient to the health of an unseen patient at a different location. Steps being taken to decrease the gap between demand and availability include the use of living donors, expanded criteria donors (ECDs), and donation after cardiac death (DCD, or non–heart-beating donor). As critical care surgeons, it is vitally important to understand this demand as well as our potential role in maximizing opportunities for organ procurement. At the same time, we must remain focused on the care of our patients and their families, as well as being respectful of their wishes.

In this chapter we explore the roles that the acute care surgeon plays in support of the potential organ donor. We will also examine issues surrounding the declaration of brain death, non–heart-beating donors, and medical–legal implications surrounding organ donation.

ROLES OF THE ACUTE CARE SURGEON IN CARING FOR POTENTIAL ORGAN DONORS

Determination of Death

Due to the nature of acute care surgery, surgeons practicing in this field will often be required to assist in the determination of death. This is often difficult as the focus now changes from preservation of the patient's life to declaration of death and possible salvage of a patient unknown to the surgeon. With regard to patient death and donation, one source of uncertainty that is important to manage is the application of brain death criteria or criteria for DCD.

One of the important guiding principles of organ transplantation is the "dead donor rule." This rule, a general ethical principle in organ transplantation, declares that organ procurement should occur only when the patient is dead. The Uniform Determination of Death Act (UDDA) defines death based on either the irreversible cessation of: (1) circulatory and respiratory functions, or (2) all brain functions, including the brain stem.

In 1968, an Ad Hoc Committee of Harvard Medical School defined brain death as "the irreversible cessation of all brain functions," thereby permitting transplant surgeons to harvest organs from a donor whose heart and lungs were still functioning.[2] The following are the guidelines for the determination of brain death in adults:

1. The patient must be in a deep unresponsive coma, there must be no movement or responses to stimulation, and there must be a clear understanding as to the etiology of the coma.
2. The patient must have a core temperature that is at least 32°C (90°F)
3. Drug intoxication and poisoning must be excluded.
4. There are no medical conditions that may confound the clinical assessment of brain death (e.g., no severe electrolyte, acid-base, or endocrine disturbances)
5. The patient must be apneic and must not recover spontaneous respiratory function during an apnea test.

Apnea Test:

   a. Core temperature 36.5°C (97°F)
   b. Systolic blood pressure 90 mm Hg
   c. Corrected diabetes insipidus or positive fluid balance in past 6 hours
   d. Patient on 100% oxygen at appropriate intermittent mandatory ventilation (IMV) for pCO_2 36–45 mm Hg, pH 7.35–7.44 for 30 minutes; blood gas just prior to apnea test to confirm pCO_2 36–45 mm Hg
   e. Place on continuous positive airway pressure (CPAP) at FiO_2 100% or place on T-piece 100% FiO_2 at >6 L/min
   f. Note the presence or absence of spontaneous respiration during or at the conclusion of 10-minute period of observation
   g. Check arterial blood gases (ABG) after the 10 minutes to confirm $pCO_2 \geq 60$ mm Hg (Note: if the pCO_2 is 60 mm Hg or 20 mm Hg above baseline, the apnea test supports the clinical diagnosis of brain death.

6. Two physicians must record the declarations of Brain Death in the progress notes and must sign, date, and time both declarations and document that the patient is brain dead. The clinical examinations may be up to 6 hours apart. The second clinical declaration is considered the legal time of death. The two physicians who independently determine brain death are not permitted to participate in the procedures for procuring or transplanting an organ or other body part from the patient.
7. Cranial nerve reflexes and responses:

   a. Pupils midposition (4 mm) to dilated (9 mm), fixed, and unresponsive to light.
   b. Absence of corneal reflexes.
   c. No oculocephalic reflex
   d. No deviation of the eyes to irrigation in each ear with 50 mL of ice water
   e. No swallowing or yawning
   f. No gag reflex
   g. No cough response or bradyarrhythmia to bronchial suctioning

Donation after Cardiac Death

In light of the aforementioned shortage of available organs for transplantation, DCD has emerged. Determining irreversibility depends on the circumstances; irreversible cessation of circulatory and respiratory functions may mean that the heart cannot be restarted spontaneously or that the heart cannot be restarted because of the decision to forego resuscitative measures.[2]

A "do-not-resuscitate" (DNR) order prevents the physician from engaging in resuscitation so that the patient's state of death is legally irreversible.

DCD practices pose additional legal considerations because the timing for declaring irreversible cessation of circulatory and respiratory function varies across transplant programs. Therefore, DCD protocols should clearly indicate which time period the hospitals and organ procurement organizations (OPOs) will follow, such as waiting between 2 and 5 minutes after the cessation of cardiopulmonary function before organ procurement.[2]

UNOS, which operates the Organ Procurement and Transplantation Network (OPTN), has developed rules regarding DCD, which were finalized in March 2007 and became effective on July 1, 2007, requiring that all OPOs and transplant centers must incorporate "model elements" in their DCD protocols.[2] These model elements address the withdrawal of life-sustaining measures and pronouncement of death as described below[3]:

Withdrawal of Life-sustaining Measures/ Patient Management

1. A time-out is recommended prior to the initiation of the withdrawal of life-sustaining measures. The intent of the time-out is to verify patient identification and the respective roles and responsibilities of the patient care team, OPO staff, and organ recovery team personnel.
2. No member of the transplant team shall be present for the withdrawal of life-sustaining measures.
3. No member of the organ recovery team or OPO staff may participate in the guidance or administration of palliative care, or the declaration of death.
4. There must be a determination of the location and process for withdrawal of life-sustaining measures (e.g., endotracheal tube removal, termination of blood pressure support medications) as a component of the patient management.

In pronouncing death for DCD, the physician who is authorized to declare death must not be a member of the OPO or organ recovery team, and the method of declaring cardiac death must comply in all respects with the legal definition of death by an irreversible cessation of circulatory and respiratory functions before the actual pronouncement of death.

PATHOPHYSIOLOGY OF BRAIN DEATH

Donor management begins with the neurologic determination of death (NDD, or "brain death") and consent to organ donation, and culminates in surgical organ procurement. Understanding the pathophysiology of brain death provides an important opportunity to enhance multiorgan function during this period of time and thereby improve organ utilization. It is important to realize that the resuscitation of the cardiopulmonary system benefits function of all organs and it is important to take time in the intensive care unit (ICU) to optimize organ function to improve transplant outcomes. Hence, reversible organ dysfunction can be addressed with aggressive resuscitation; once organ function is optimized, surgical procurement should be arranged emergently. The temporal changes in organ function after NDD demand flexibility in identifying the optimal time for procurement.[4]

The earliest manifestation of increased intracranial pressure (ICP) is characterized by hypertension, bradycardia, and altered breathing. When the brainstem becomes compressed as it is pushed against the foramen magnum, ischemia will result. This results in increased local neuronal activity that produces an increase in sympathetic outflow and an elevation in blood pressure in order to maintain cerebral blood flow. The hypertension will additionally produce reflex bradycardia. Herniation,

however, is associated with a massive increase in catecholamines that produces hypertension and tachycardia. The catecholamine surge, which can lead to coronary vasoconstriction, subendocardial ischemia, and focal myocardial necrosis, is believed to be one of the contributing factors to cardiac dysfunction in potential organ donors. Additionally, the catecholamine surge may lead to increased filling pressures, increased afterload, and an elevated pulmonary wedge pressure (PWP), which then leads to "neurogenic pulmonary edema." The sympathetic storm lasts for only a brief period of time and is then followed by a prolonged phase of severe hypotension secondary to decreased sympathetic outflow. The hypotension may be further compounded by ventricular dysfunction requiring use of inotropes and vasopressors to maintain organ blood flow. The deterioration of cardiovascular function associated with intracranial hypertension varies with the rapidity of increase in ICP, time after herniation, and etiology of brain injury.[5] There is also evidence that brain death induces an inflammatory response and subsequent endothelial injury, which can lead to impaired graft function and graft vasculopathy.

On a cellular level, there is global mitochondrial dysfunction and a change from aerobic to anaerobic metabolism with reduced energy stores in the myocardium. This, combined with the ischemic time and ischemia–reperfusion injury, contributes to graft dysfunction. From an endocrine standpoint, there is a reduction in antidiuretic hormone (ADH, vasopressin) secretion and thyroid dysfunction. The decrease in ADH leads to the development of diabetes insipidus (DI) whereas the thyroid dysfunction generally manifests as hypothyroidism. There is data to suggest that proinflammatory cytokines may inhibit the conversion of thyroxine (T4) to the active form of thyroid hormone, tri-iodothyronine (T3). T3 via binding to specific receptors, increases oxygen utilization, the uptake of glucose and amino acids, mitochondrial size/number, and promotes a conversion to aerobic metabolism. Additionally, T3 will increase cardiac output and decrease systemic vascular resistance.

From a hematologic standpoint, release of thromboplastin from the ischemic brain can cause disseminated intravascular coagulation while the systemic inflammatory response syndrome response activates humoral and cellular components that add to the coagulopathy. As mentioned earlier, a sympathetic storm occurs during herniation which is rapidly followed by a depletion of catecholamines that can lead to significant hypothermia due to loss of central temperature control and vasodilation. Hypothermia can further exacerbate myocardial depression and further compromise oxygen delivery.

OPTIMIZATION OF THE POTENTIAL ORGAN DONOR

Subsequent to the pronouncement of death, the donor management period begins. During the donor management period, the acute care surgeon and organ procurement coordinator should focus on optimizing the patient for donation. Appropriate organ donor management then should address the pathophysiologic changes mentioned previously to optimize the number of organs transplanted per donor (OTPD). The main goals are to maintain cardiac function, minimize the deleterious effects that occur with brain death, and maintain adequate oxygen delivery to the vital organs. These goals can be met by optimizing hemodynamics with the judicious use of fluids, inotropes, and vasopressors, preserving lung function by paying close attention to mechanical ventilation and pulmonary toilet, preventing infection, and by utilizing specific measures shown to maintain and improve cardiac function. Detailed standing orders released by the Canadian Council for Donation and Transplantation are shown in Table 57.1. Note

TABLE 57.1

DATA COLLECTED FROM UNOS REGION 5 DONOR MANAGEMENT GOALS (DMG)

■ ADULT DONORS

Standard monitoring
- Urine catheter to straight drainage, strict intake and output
- Nasogastric tube to straight drainage
- Vital signs every hour
- Pulse oximetry, 3-lead ECG
- CVP
- Arterial line pressure
- Optional PAC

Laboratory investigations
- ABGs, electrolytes and glucose q4h and as needed
- Complete blood count q8h
- Blood urea nitrogen and creatinine q6h
- Urine analysis
- Aspartate aminotransferase (AST), alanine aminotransferase (ALT), bilirubin (total and direct), INR (or PT) and PTT q6h

Hemodynamic monitoring and therapy
General targets: heart rate 60–120 bpm, systolic blood pressure >100 mm Hg, mean arterial pressure ≥70 mm Hg
- Fluid resuscitation to maintain normovolemia, CVP 6–10 mm Hg
- If arterial blood pressure ≥ 160/90 mm Hg, then: Wean inotropes and vasopressors and, if necessary, start
  - Nitroprusside: 0.5–5.0 mcg/kg/min or
  - Esmolol: 100–500 mcg/kg bolus followed by 100–300 mcg/kg/min
- Serum lactate concentration q2–4h
- Mixed venous oximetry q2–4h; titrate therapy to MVO_2 ≥60%

Agents for hemodynamic support
- Dopamine: ≤10 mcg/kg/min
- Vasopressin: ≤2.4 U/h (0.04 U/min)
- Norepinephrine, epinephrine, phenylephrine (caution with doses >0.2 mcg/kg/min)

Indications for PAC
- 2-Dimensional echo ejection fraction ≤ 40% and/or

- Dopamine >10 mcg/kg/min (or equivalent), or
- Vasopressor support (not including vasopressin if part of hormone therapy), or
- Escalation of support

Glycemia and nutrition
- Routine intravenous dextrose infusions
- Initiate or continue enteral feeding as tolerated
- Continue parenteral nutrition if already initiated
- Initiate and titrate insulin infusion to maintain serum glucose level at 4–8 mmol/L

Fluid and electrolyte targets
- Urine output 0.5–3 mL/kg/h
- Serum Na 130–150 mmol/L
- Normal ranges for potassium, calcium, magnesium, phosphate

Diabetes insipidus
Defined as:
- Urine output >4 mL/kg/h associated with
- Increasing serum sodium ≥145 mmol/L and/or
- Increasing serum osmolarity ≥300 mosm or
- Decreasing urine osmolarity ≤200 mosm

Therapy (to be titrated to urine output ≤3 mL/kg/h):
- Intravenous vasopressin infusion at ≤2.4 U/h, or
- Intermittent D DAVP, 1–4 mcg IV then 1–2 mcg IV q6h (there is no true upper limit for dose; should be titrated to desired urine output rate, usually < 100 mL/h)

TABLE 57.1

DATA COLLECTED FROM UNOS REGION 5 DONOR MANAGEMENT GOALS (*Continued*)

Combined hormonal therapy
Defined as:
- Thyroxine (T4): 20 mcg IV bolus followed by 10 mcg/h IV infusion (or 100 mcg IV bolus followed by 50 mcg IV q12h)
- Vasopressin: 1 U IV bolus followed by 2.4 U/h IV infusion
- Methylprednisolone: 15 mg/kg (≤1 g) IV q24h

Indications:
- 2-Dimensional echocardiographic ejection fraction ≤40% or
- Hemodynamic instability (includes shock, unresponsive to restoration of normovolemia and requiring vasoactive support [dopamine > 10 mcg/min or any vasopressor agent])
- Consideration should be given to its use in all donors

Hematology
- Optimum hemoglobin: 90–100 g/L; for unstable donors, lowest acceptable level is 70 g/L
- For platelets, INR, PTT, there are no predefined targets; transfuse in cases of clinically relevant bleeding
- No other specific transfusion requirements

Microbiology
(baseline, daily and as needed)
- Daily blood cultures
- Daily urine cultures
- Daily sputum cultures
- Administer antibiotics for presumed or proven infection

Heart-specific orders
- 12-lead ECG
- Troponin I or T, q12h
- 2-Dimensional echocardiography
  - Should only be performed after fluid and hemodynamic resuscitation
  - If ejection fraction ≤40% then, insert PAC and titrate therapy to the following targets:
- PCWP: 6–10 mm Hg
- Cardiac index: >2.4 L/min/m^2
- SVR: 800–1,200 dyn/sec/cm^5
- LVSWI: >15 ml/kg/min
  - PAC data are relevant for hemodynamic therapy and evaluation for suitability of heart transplantation independent of echo findings
  - Consider repeat echocardiography at 6–12 h intervals.
- Coronary angiography

Indications:
  - History of cocaine use
  - Male > 55 years or female > 60 years
  - Male > 40 years or female > 45 years in the presence of two or more risk factors
  - Greater than or equal to three risk factors at any age.
Risk factors:
  - Smoking
  - Hypertension
  - Diabetes
  - Hyperlipidemia
  - Body mass index > 32
  - Family history of the disease
  - History of coronary artery disease
  - Ischemia on electrocardiogram
  - Anterolateral regional wall motion abnormalities on electrocardiogram
  - 2-dimensional echocardiographic assessment of ejection fraction ≤40%
Precautions:
- Ensure normovolemia
- Administer prophylactic *N*-acetylcysteine, 600–1,000 mg enterally twice daily (first dose as soon as angiography indicated) or IV 150 mg/kg in 500 mL normal saline over 30 min immediately before contrast agent followed by 50 mg/kg in 500 mL normal saline over 4 h
- Use low-risk radiocontrast agent (nonionic, iso-osmolar), using minimum radiocontrast volume, no ventriculogram

(Continued)

SURGICAL CRITICAL CARE

TABLE 57.1

DATA COLLECTED FROM UNOS REGION 5 DONOR MANAGEMENT GOALS (*Continued*)

Lung-specific orders
- Chest radiograph q24h and as needed
- Bronchoscopy and gram staining and culture of bronchial wash
- Routine endotracheal tube suctioning, rotation to lateral position q2h
- Mechanical ventilation targets:
  - Tidal volume: 8–10 mL/kg, PEEP: 5 cm H_2O, PIP: ≤30 cm H_2O
  - pH: 7.35–7.45, $PaCO_2$: 35–45 mm Hg, PaO_2: ≥80 mm Hg, O_2 saturation: ≥95%
- Recruitment maneuvers for oxygenation impairment may include:
  - Periodic increases in PEEP up to 15 cm H_2O
  - Sustained inflations (PIP at 30 cm H_2O times 30–60 s)
  - Diuresis to normovolemia

It is important to take the necessary time in the ICU to optimize organ function to improve transplant outcomes. Resuscitation and reevaluation can improve reversible organ dysfunction (myocardial and cardiovascular dysfunction, oxygenation impairment related to potentially reversible lung injury, invasive bacterial infections, hypernatremia) and evaluate temporal trends in hepatic AST, ALT, and creatinine or any other potentially treatable situation. This treatment period can range from 12 to 24 h and should be accompanied by frequent reevaluation to demonstrate improvement in organ function toward defined targets. Once organ function is optimized, surgical procurement procedures should be arranged emergently. There are no demographic factors or organ dysfunction thresholds that preclude giving consent for donation and offering organs for transplantation.

Reprinted with permission from CMAJ. 2006;174(6):S27.

ABGs, arterial blood gases; CVP, central venous pressure; DDAVP, 1-desamino 8-D arginine vasopressin (desmopressin); ECG, electrocardiogram; INR, International Normalized Ratio; LVSWI, left ventricular stroke work index; MVO_2, mixed venous oxygen saturation; PAC, pulmonary artery catheter; PEEP, positive end-expiratory pressure; PIP, peak inspiratory pressure; PT, prothrombin time; PTT, activated partial thromboplastin time; PWP, pulmonary wedge pressure; SVR, systemic vascular resistance; SWI, stroke work index; IV, intravenous

that the placement of invasive monitoring (central venous pressure [CVP], arterial catheter, Foley's catheter) is typically required.

The most frequent hemodynamic problem is hypotension due to either hypovolemia, neurogenic shock due to decreased sympathetic outflow, or myocardial dysfunction. Treatment begins with optimizing preload (CVP 6–10 mm Hg) with the most appropriate fluid (crystalloid, colloid, or blood product). If hypotension persists despite adequate filling pressures, an inotrope should be considered. If inotropes are initiated, consideration should be given to the placement of a pulmonary artery catheter (PAC) to assess preload, afterload, and cardiac performance. Simply stated, an escalation of support should be accompanied by escalation in monitoring. Subsequently, if inotrope dosing has to be increased due to persistent hypotension, an investigation into the exact cause must be undertaken. Echocardiography can be used to evaluate cardiac function and if this demonstrates adequate ventricular function and volume status, then severe vasodilation is the most likely cause. In such cases, a vasoconstrictor would be considered as the agent of choice. Vasopressin has been shown to be very useful in this setting because it acts synergistically with catecholamines and may allow a reduction or even discontinuation of them. Vasopressin is a special agent because it can be used in a variety of applications, i.e., hemodynamic vasopressor support, DI therapy, and hormone therapy. Second-line agents for hemodynamic support include norepinephrine, epinephrine, and phenylephrine. Escalation of doses of catecholamines should be guided by PAC data realizing that a reduction in inotropes is desired as it will reduce myocardial oxygen consumption and thereby help maintain myocardial energy stores. Optimization of these parameters, along with attention to acid-base and electrolyte balance, hematocrit, oxygenation and ventilation, and hormone supplementation has been shown to improve potential organ donor salvage.[6]

Hypoxemia can result in cardiovascular instability and may be due to pneumonia, aspiration pneumonitis, pulmonary contusions, pulmonary edema, ventilator-associated lung injury, and oxygen toxicity. The lowest inspired oxygen concentration, peak inspiratory pressure (PIP) and positive end expiratory pressure (PEEP) compatible with acceptable oxygenation should be used. The quality of donor lungs can be improved with endotracheal suctioning, bronchodilators, steroids, chest physiotherapy (PT), bronchoscopy and lavage, and judicious small-volume colloid resuscitation.

From an endocrine standpoint, central DI occurs in 50%–80% of brain dead patients. Central DI is characterized by decreased secretion of ADH, which gives rise to polyuria and polydipsia by diminishing the patient's ability to concentrate urine. This results in a loss of intravascular volume and electrolyte abnormalities. Treatment with desmopressin (1-desamino-8-D-arginine vasopressin [DDAVP]) loading followed by an infusion can reduce the volume losses and help correct the electrolyte issues. Due to the multiple endocrine abnormalities, it is now recommended that a hormonal "cocktail" consisting of T3, vasopressin, and methylprednisolone be administered to potential organ donors.[7] The weight of currently available evidence in a large retrospective cohort study by the United Network for Organ Sharing in the United States suggests a substantial benefit of triple hormone therapy with minimal risk. This study showed substantial increases in kidney, liver, and heart utilization from donors receiving triple hormonal therapy as well as improvements in 1-year kidney and heart graft survival.[8] Glycemic control should be achieved, if necessary by insulin infusion. Additionally, routine enteral feeding should be initiated or continued as tolerated, and discontinued on call to the operating room for harvesting, whereas parenteral nutrition should not be initiated, but may be continued if it had already been started.

IMPLEMENTATION OF THE ORGAN DONOR MANAGEMENT PROTOCOL

Multiple studies suggest that the use of guidelines and protocols to identify and care for the potential organ donor are effective in improving both organ donation rates and the number

of OTPD.[9–15] These guidelines and protocols must provide clinical management guidance incorporating the principles mentioned previously, as well as the social support necessary to accomplish the task of obtaining consent and supporting the family and friends of the potential donor.

The clinical component of the management protocol should include early identification with admission to a monitored setting and resuscitation in accordance with the principles mentioned earlier. The combination of a clinical management protocol like the one shown in Algorithm 57.1, with standing orders as shown in Table 57.1, will facilitate the implementation of a program for aggressive organ donor management. Multiple studies have shown that adherence to these aggressive management protocols will decrease the incidence of cardiopulmonary failure and increase the number of organs recovered per donor as well as the function of the transplanted organs.[9,16–18] DuBose and Salim[19] demonstrated that adherence to their aggressive management protocol (Fig. 57.1) was associated with an 82% increase in the number of donors, a 71% increase in the number of organs recovered, and an 87% decrease in the number of donors lost due to cardiopulmonary instability. In a separate report published by the Midwest Transplant Network in 2009,[20] the number of OTPD was notably higher ($p = 0.06$) and the percentage of lungs transplanted was significantly higher ($p < 0.01$) among donors who underwent optimization by critical care providers. Finally, in an unpublished report from University of Pittsburgh Medical Center (UPMC), it was noted that use of critical care providers to support potential DCD donors in the prerecovery phase of the procurement process allowed these donors to progress to donation more comfortably and more quickly.

In addition, the social aspects of the organ donation process must be addressed. Historically, consent to donation has been the largest impediment during the transplantation process, and it has been suggested that the strongest predictor of donation decisions may be the family's initial response to the request for donation.[21] Further, it has been shown that a substantial number of families deciding against organ donation cite an inadequate explanation of the process of brain death, leading to a lack of understanding of the process.[22] This stresses the involvement of critical care physicians who have a good relationship with the patient's family, are seen as advocates for the patient and family, and have a good understanding of brain death, cardiac death, and the process of organ procurement. Additionally, utilization of transplant coordinators has been shown to be useful in coordinating the efforts to facilitate both consent and refocusing of care to organ preservation and harvest. Alternatively, fully trained staff members from the regional OPOs may be used to facilitate this process. The goal is to provide consistent family support and act as liaisons between the family and the health care providers. Implementation of such programs (In-House Coordinator or IHC) has led to significant improvements in conversion and consent rates in a full range of hospital settings.[23–25]

PATHOPHYSIOLOGY OF ORGAN PRESERVATION

At least two key concepts are required to understand current thoughts regarding organ preservation: (1) warm ischemia and (2) cold ischemia. Warm ischemia is that time period when oxygen delivery (DO_2) to an organ is substantially decreased and yet that organ remains at or near a state of normothermia. An important example of warm ischemia occurs during the DCD donation process, where a patient may be extubated as part of comfort measures and becomes hypoxic,

but yet is near or actually normothermic. This warm ischemia time is an important issue regarding eventual graft function and should be minimized without diminishing the important, careful respect addressed to patient comfort. In short, no matter how much warm ischemic time may be detrimental to eventual graft function, care must be taken to clearly respect patient and proxy wishes as the disease process progresses and the patient is kept comfortable prior to any declaration of death.

Tolerance for warm ischemia differs greatly across tissue types. Cornea and skin may tolerate several hours of warm ischemia, whereas the brain suffers an irreversible loss of function within a few minutes of onset.[26] Modern organ preservation methods, followed from the necessity of extending ischemic times over which organs maintained viability. Modern techniques have, prolonged the viability of grafts for transport, by utilizing cold ischemia.

Cold ischemia, describes the period of time where the temperature of an eventual graft is lowered to diminish metabolic activity, oxygen demand, and the sequelae of hypoxia that lead to irreversible cell death. The key, is cooling the eventual graft via a temperature-controlled bath and a hypothermic preservative flush solution. Cooling serves the aforementioned purposes of restraining oxygen demand as well as decreasing oxygen free radical creation, where by the preservative solution used has many important effects including pH maintenance, metabolic supply, prevention of cellular edema, and modification of intracellular calcium.[26] Cold ischemia is not simply slowing of all metabolic functions, but rather consists of both slowing those systems and preventing their discordance. Interestingly, metabolism does occur during cold storage.[27]

In order to obtain a sense of scale with regard to cold preservation techniques, consider that simple surface cooling of the kidney allows ischemia to be tolerated for 12 hours[28] whereas cooling via flush with a preservative solution allows preservation for 12–120 hours depending upon the solution used.[29] In short, cooling alone functions in an important capacity, but cooling in conjunction with flushing allows significant preservation times. Multiple different solutions are available to be used as agent for performing a cold flush of allografts.

Table 57.2 demonstrates some important solutions utilized in the cold preservation of organs: Euro-Collins solution, histidine–tryptophan–alphaketoglutarate (HTK) solution, and University of Wisconsin (UW) or ViaSpan ([DuPont Merck Pharmaceutical, Wilmington, DE]) solution are three of the most widely used agents. Each has important characteristics that may influence eventual graft outcome. For example, the potassium content of UW is substantial, and in larger solid-organ allografts, UW may yield a substantial cardioplegic effect owing to the elevated potassium content. Therefore, before reperfusion (if not earlier), it is important that the surgical and anesthesia team have some plan to offset that important, potentially deleterious effect. In the case of pancreas allografts, some centers have become concerned regarding the viscosity of HTK solution with respect to any potential influence on allograft thrombosis. These are just a few of the many important considerations regarding which flush type is used during retrieval and preservation of the allografts.

Another important consideration exists with respect to allograft storage: static versus perfusion storage. With static storage, the organ is cold-flushed as previously described and is submerged in the cold preservative solution for transport, etc. In perfusion storage, more frequently performed with renal allografts, kidneys are continuously perfused with a volume of preservative solution. Cold preservation, in the case of renal allografts, also allows potentially implanting surgeons to learn important characteristics of the organ's flow dynamics. Data from the perfusate pump, such as resistive index, are an

important factor that may be used to determine the likelihood that an organ will exhibit delayed graft function post-implant. It seems, however, that preservation by perfusion is effective for approximately 3–5 days, as substantial injury to the vascular endothelium may occur with longer intervals.[30]

Those, then, are many of the practical points regarding modern organ preservation. Clearly, important messages for anyone delivering care to the potential donor exist: warm ischemia time must be minimized where possible, and cold flush via a static or perfusate system should be used. Several important consequences may act as headlines regarding the pathophysiology of organ preservation for the acute care surgeon: (1) kidney damage, for example, is predictably reversible only if renal warm ischemia time is <30 minutes,[31] and (2) recovery is rapid after 10 minutes of warm ischemia, but recovery can take ≥1 week if >30 minutes of warm ischemic time is incurred. On balance, warm ischemia is tolerated much worse than cold ischemia time.

NECESSARY INTERVENTIONS IN THE POTENTIAL ORGAN DONOR

In terms of scope of practice, surgeons are trained to recover the groin lymph nodes necessary for human leukocyte antigen (HLA) typing to begin prerecovery. Other technical interventions such as bronchoscopy, central venous catheter placement, endotracheal tube repositioning, and major vessel cannulation are reimbursed by the OPO. Some state laws mandate that a driver's license that relates a person's wishes to be an organ donor allows for the postmortem procurement of that person's organs. Therefore, as briefly described previously, it is possible that a patient who presents to the trauma bay as a "trauma code," is deemed to have a nonsurvivable injury and is declared dead may be treated as a donor owing to that patient's expressed wishes. An acute care surgeon could be contacted to heparinize that patient, cannulate the infrarenal abdominal aorta, clamp the aorta at the level of the right crus of the diaphragm, cold-flush the viscera with preservative solution, incise the inferior vena cava (IVC) in the chest to allow efflux of blood, and pack the abdomen in ice. Just as with the DCD situation, the inferior mesenteric vein need

not be cannulated; a portal flush could be performed on the back table if deemed necessary at all. The process could take <10 minutes and may be performed in the trauma bay. The process could be adapted to recover more than abdominal viscera where appropriate. The potential grafts would then be preserved according to the donor's wishes as expressed via the driver's license.

In practice, this avenue is often not explored (as mentioned previously) despite frequent conjecture on the part of the procurement teams. Some OPOs across the country express concern that, despite the license's clear expression of the patient's wishes, the patient's family may potentially believe that everything was not done for the patient so the physicians could "take their organs." Whereas most physicians would bristle at the suggestion that they would withhold any care in order to enhance organ harvesting, the importance of maintaining and encouraging public perception regarding the positive nature of organ donation is commonly valued over the increased number of grafts available by procuring in this manner.

This mind-set may be changing. One OPO determined that positive public perception regarding the benefits of organ donation may be maintained (or improved) and at the same time the opportunity for increased recovery could be taken. A new dynamic has been introduced by one bellwether OPO, called Condition T. This breakthrough system honors the patient's wishes as expressed on the driver's license, such that any patient presenting as traumatically injured, or otherwise, is a candidate for cannulation and organ preservation after that patient's premanagement physician has pronounced death. Care is taken to keep separate the physician who declares death from the donation process. It is only after the patient's physicians have done all that they reasonably can for a patient that death is declared per routine. It is only after the patient has died that any consideration of Condition T is instituted.

Currently, an emergency room physician is trained to cannulate the femoral artery and begin cold flush in a specially prepared room. Other technical details regarding venting blood and effluent (via cannula or some other method) were not available at the time of publication. The donor is cooled via external techniques in addition to the flush procedure. The procurement team is called and the process is technically similar to standard retrieval in the DCD example, with one of the exceptions being that the flush has occurred.

This situation is an obvious opportunity for acute care surgeons. Cannulation and venting may be achieved via the femoral vessels or, should there be some issue, the abdomen may be opened for the more traditional aortic cannulation. The clear message is that surgeons, should they choose to participate in the process, are well equipped to manage the acute, technical nature of Condition T should the program spread across the country.

MEDICOLEGAL AND ETHICAL CONSIDERATIONS

Surgeons in the acute care setting involved in managing potential donors may encounter medicolegal issues pertaining to organ procurement. These issues include obtaining the appropriate consent to donate from the potential donor, or more often the surrogate decision maker, ensuring that the potential donor's advance directives are respected and at the same time permitting the necessary interventions for determining medical suitability to donate and preserving organs, and balancing end-of-life care with managing the prospective organ donor to maximize organ procurement.

The possibility of legal problems may create some trepidation for providers who might engage in organ transplantation

opportunities. Providing some legislative support for the donation process, the National Conference of Commissioners on Uniform State Laws in 1968 drafted the Uniform Anatomical Gift Act (UAGA), which was amended in 1987 and revised in 2006. Although not all states have adopted the most recent version of the UAGA, the Act supports the organ transplantation process and creates immunity for participants.[32] Presently, the limited legal cases involving organ transplantation demonstrate that courts generally follow the legislative intent of the UAGA to promote organ donation and expand the donor pool.

The UAGA addresses who may consent to providing an anatomical gift, the interpretation of donor cards and documents for permitting an anatomical gift, the necessity for interventions to a potential donor to determine medical suitability of organs, the recognition of individuals agreeing to make an anatomical gift regardless of the jurisdiction in which the gift was initiated, and the authorization for procurement organizations to access donor registries and medical records for the purpose of coordinating organ procurement.[32] State legislation modeling the UAGA defines a framework to follow in the organ transplantation process.

Consent for organ donation is satisfied when an individual has previously signed a designation on a legal document such as a driver's license or in a donor registry. The revised UAGA in 2006 reinforced the legallybinding nature of the donor card by indicating that the donor consent for organ donation becomes irrevocable and does not require consent from anyone after the donor's death.[32] Thus, OPOs may procure organs even when families refuse donation. However, the application of the UAGA also requires a transparent process for the voluntary consent of the organ donor. Moreover, the Consolidated Omnibus Reconciliation Act of 1986 requires hospitals accepting Medicare and Medicaid to "discuss organ donation with families of deceased patients who were potential donors."[33] Requiring familial consent for donation undermines the authority of donor cards and patient autonomy and poses a conflict in those instances where the surrogate contradicts the donor's previously signed donor document. Part of the practice for obtaining consent from the family arises from the unwillingness to create tension with the family and fear of litigation from discontented family members.

A current OPO practice is to accept a presigned organ donor card or registry as legally binding regardless of family consent. Condition T, described previously, is a rapid-response protocol designed for those individuals designated as organ donors who fail resuscitative efforts. Family consent is not required, but the donor designation status must be unambiguous.[34]

Under Condition T, in the presence of a valid document for an anatomical gift, this organ procurement practice is legal and consistent with the general requirement of abiding by legally binding documented authorization.

The revised UAGA requires law enforcement officers and emergency rescue personnel to make a reasonable search for organ donation authorization and requires hospitals to cooperate in the transplantation process.[34] In the event that there is no donor card or donor registry, the UAGA specifically designates who may make an anatomical gift on behalf of the deceased based on priority: spouse, adult son or daughter, parent, adult sibling, guardian, or medical examiner.[34] Although not all in a class must be queried to exclude an objection, consent may be negated if a next of kin of the same class objects.[35] When consent from a surrogate is required, the UAGA has defined "reasonably available" as "able to be contacted by a procurement agency without undue effort and willing and able to act in a timely manner consistent with existing medical criteria necessary for making anatomical gifts," allowing hospitals to expeditiously locate a surrogate for consent.[2] The immunity protections of UAGA apply so that "persons who fail to discharge their duties to search for a donor document or discuss

the option of donation with the family are not subject to criminal or civil liability."[36] But administrative actions may apply and if the behavior is truly egregious such as lying to obtain the organs, the court will not uphold the immunity protections.[37] And, because the UAGA takes effect only after death has been declared, it does not provide protection to the pronouncement of death; failure to properly declare brain death may demonstrate bad faith.

Nonetheless, the UAGA provides immunity from civil and criminal liability to those professionals involved in organ transplantation to encourage health care professionals' participation in the organ donation process.

It is generally accepted that acting in "good faith" will shield from liability those who act in accordance with the law when obtaining consent for organ recovery. Courts broadly interpret "good faith" as in *Nicoletta v. Mayo Clinic* (1987) where the court defined "good faith" as "honest belief, the absence of malice, and the absence of design to defraud or seek an unconscionable advantage."[2]

The recently revived procurement process implementing DCD, which the Institute of Medicine endorsed in 2006 to expand the donor pool, poses questions as to whether the donor card reflects a sufficiently informed consent to this type of procurement. For individuals relying on procurement organization websites, they may not have received sufficient information specifically addressing DCD, involving a more complicated process and requiring additional intervention to the prospective donor than in a procurement following brain death. Thus, institutional policies and procedures addressing DCD ensure that the potential participants understand the process and that patient autonomy and surrogate decision making are respected.[2]

The revised UAGA overrides decisions about withholding or withdrawing life support outlined in an advance directive. To address the apparent conflict in situations where a patient wishes to forgo life-sustaining treatment but is a prospective donor, the revised UAGA of 2006 included sections 14(c) and 21(b) to permit the continuation of life support and necessary measures to preserve the opportunity to donor until OPOs complete their evaluation of the suitability of the prospective donor.[38] In accordance with section 14(c), the procurement organization may conduct any reasonable examination necessary to ensure the medical suitability of a potential donor and the "measures necessary to ensure the medical suitability of the part may not be withdrawn unless the hospital or procurement organization knows that the individual expressed a contrary intent."[38] Section 21(b) specifically addresses the conflict where a prospective donor has a declaration or advance health care directive that indicates the desire to decline life-sustaining measures and yet is a potential donor.[38] In this situation, the potential donor's attending physician and prospective donor or agent shall confer to resolve the conflict as expeditiously as possible. In the meantime, "measures necessary to ensure the medical suitability of the part may not be withheld or withdrawn from the prospective donor if withholding or withdrawing the measures is not contraindicated by appropriate end-of-life care."[38]

It is recommended that facilities devise advance care planning and a team that discusses with the potential donor where possible, or family, the use of life support once the clinical triggers are met to assist in the evaluation of the medical suitability of the donor. The local OPOs are authorized by the Health Care Financing Administration and UNOS to manage the procurement of organs in their region and are responsible for organizing and overseeing the identification of donors, evaluation of potential donors, confirmation of the diagnosis of brain death, arranging consent from family, clinical management of potential donors, obtaining permission for visiting transplant surgeons to procure organs at the donor's location, preservation and packaging of organs for transplant. The OPO assists with management of the donor by preparing guidelines.[39]

Implementing a collaborative process and integrating the attending surgeon's management of the prospective donor and the OPO's role in organ procurement will aid in navigating through issues that may evolve. Collaborative practices include contacting and timely coordinating with the OPO to assist in the organ transplantation process, avoiding conflicts of interest by requiring that the health care professional involved with the donor not participate with the transplant team, assigning appropriate staff and ancillary support roles and responsibilities in the organ donation process, facilitating communication with the family, utilizing trained personnel such as an OPO representative or third party to discuss possible donation in cases where no donor card is present, designating a physician who will declare death and following donor management guidelines.[2]

NEW TRENDS IN ORGAN RECOVERY

One important new trend in organ recovery involves the utilization of the acute care surgeon in the postmortem, predonation state. Currently, select OPOs are utilizing acute care physicians to resuscitate donors and optimize organs prior to donation. Frequently, this is a physician who did not participate in the care of the patient while he or she was alive. This emerging paradigm for utilizing critical care providers is beginning to yield some important data.

Consider the number of OTPD. In a recent report by the Midwest Transplant Network, OTPD was notably higher among those donors who underwent optimization by a critical care provider ($p = 0.06$).[21] Physician involvement in the postmortem state was associated with a larger number of available organs as adjusted for the number of donors. This is not the only evidence indicating that an important opportunity exists that may benefit multiple patients. A statistically significant difference ($p < 0.01$) was noted in the percentage of lungs transplanted when optimization was guided by an acute care provider.[21] Also, note the OTPD in the standard criteria donor (SCD) and ECD conditions (Table 57.3).

TABLE 57.3

FINDINGS OF 2007 REPORT FROM MIDWEST TRANSPLANT ALLIANCE TO AMERICAN SOCIETY OF TRANSPLANT SURGEONS

	■ INTENSIVIST	■ NO INTENSIVIST
OTPD	4.05	3.30
DMGs met (PTPD 4.31 vs. 3.23)	25 (58%)	10 (23%)
Hearts transplanted	20 (47%)	21 (49%)
Lungs transplanted	37 (43%)	12 (14%)
OTPD (SCD)	4.36	3.71
OTPD (ECD)	2.43	1.50
ATN rate	12%	24%

OTPD, organs transplanted per donor; DMGs, donor management goals; SCD, standard criteria donor; ECD, expanded criteria donors; ATN, acute tubular necrosis.

Another important point regarding the current state of organ recovery involves the fact that DCD donors do not always progress to donation after extubation or withdrawal of other futile life-prolonging measures. This leaves an Operating Room Recovery team that waits for a requisite amount of time (which varies by OPO), only to be unable to recover any viable organs or able to recover only a few of the potential grafts. Equally difficult is prolongation, in the DCD situation, of what is often called the phase 2 time (time when the donor is hypoxic postextubation but still near-normothermic) which may lead to poor graft quality. In either case, failure to progress or slow donor progression yields suboptimal results.

The UPMC currently has critical care physicians manage the prerecovery phase of the procurement process. Participating physicians report (unpublished data) that they have had no DCD donors fail to progress to donation. Again, by this report, DCD donors progress both more comfortably and more quickly.

This is only a small portion of the mounting evidence that indicates how acute care providers are already influencing the process of organ recovery to the benefit of potential recipients. Also by anecdotal report, prerecovery inflammatory levels as indicated by interleukin (IL)-6 concentrations may be decreased in situations where physicians lead donor optimization; this holds a possibility for improving graft quality. A final, important anecdotal report from the UPMC program indicates that many common factors including ventilator weaning, the use of vasopressors after adequate fluid resuscitation, the weaning of vasopressors when appropriate, and resuscitation to common endpoints are greatly improved in the area of physician-led prerecovery optimization.

In short, acute care surgeons are presented with the opportunity to widen their scope of practice so as to considerably impact the current recovery process. Data are already accumulating regarding the benefits of such involvement.

FUTURE OPPORTUNITIES

Final notes regarding the potential of this important situation include reimbursement issues and scope of practice. Physicians who currently optimize donors for an OPO are reimbursed by that OPO. Because recovery is improved, it is believed there is a reasonable break-even point on the expenditure by the OPO. More viable grafts are produced and thus the situation is more easily justified. Involved parties report little discernable pushback from the OPO donor coordinators, who have been described as pleased to have physician input and guidance in the process so as to reduce uncertainty regarding resuscitation and maximization.

CONCLUSIONS

The field of acute care surgery is presented with an opportunity to expand and participate in an important emerging discipline: donor optimization and recovery. Data exist that demonstrate how, when critical care-trained physicians are involved, an increased number of allografts are available to narrow the large gap between available organs and patient demand. Further, evidence exists that describes how intervention to defined, easy to understand donor management goals (DMGs) improves the number of OTPD (Table 57.4).

Critical care-trained surgeons are uniquely poised to assist in the important work of organ recovery, as they possess the requisite cognitive and technical skills necessary to intervene so as to improve physiologic endpoints while performing necessary interventions including bronchoscopy, lymph node procurement and, perhaps in the future, cannulation. The drive to provide patients with what they need in terms of transplantable organs, while respecting donors' rights, is a guiding principle that will likely continue to bring acute care surgery toward the forefront of donor management.

TABLE 57.4

REGION 5 DATA REGARDING OTDP WHEN DMGS MET

■ DMG DATA (SCDS ONLY, n = 255)	■ <4 OTDP (n = 132)	■ ≥4 OTPD (n = 123)	■ P VALUE

SURGICAL CRITICAL CARE

CHAPTER 58 ■ PALLIATIVE CARE

RONALD M. STEWART

In the face of critical surgical illness, palliative care focuses on a set of individualized goals aimed at reducing the suffering of the patient and family members.[1,2] Ideally, this process begins prior to the patient's illness with a personal expression of the person's end-of-life choices, and extends into the bereavement period following the patient's death. Realistically, patients rarely begin palliative care planning prior to becoming ill, and most often the process is initiated only after critical illness supervenes or the patient is considered terminal. Rather, palliative care should be integrated as a routine part of the continuum of care in the surgical intensive care unit.[3,4] Stated another way, relief of suffering and pain are essential to clinical cure, so the shift from curative to primarily palliative care is largely a change in the goals of therapy.

High-quality palliative care is usually interdisciplinary in nature, and is now a recognized medical specialty. Hospice and Palliative Care Medicine was recognized in 2008 by the American Board of Medical Specialties, with certification in hospice and palliative medicine issued by 10 cosponsoring boards, including the American Boards of Anesthesiology, Emergency Medicine, Family Medicine, Internal Medicine, Obstetrics and Gynecology, Pediatrics, Physical Medicine and Rehabilitation, Psychiatry and Neurology, Radiology, and Surgery.

Considering that palliative care involves crucially important decisions that can be difficult or emotionally wrenching to make, assisting critically ill surgical patients in the transition to palliative care can be challenging for the surgeon. The proposition is no easier for the patient. Thomas Finucane pointed out two fundamental issues that ensure that this transition will continue to be difficult for the patient and his or her family.[5] There is a near-universal and fervently held desire to remain alive. Second, in spite of concerted effort, caregivers cannot predict the future sufficiently to provide a meaningful, precise estimate of when death will occur.[5] The author would make two additional points: (1) most patients have strong and unique personal beliefs about the nature of death; and (2) from a purely surgical perspective, the surgeon has a strong clinical emotional investment in the patient's care, most often manifesting as a powerful motivation for the patient to survive the operation. This chapter provides an overview of palliative care as it relates to acute care surgery, trauma, and surgical intensive care.

HISTORY

An urologic oncologist, Balfour Mount, originally coined the term *palliative care* in the establishment of a clinical service at Montreal's Royal Victoria Hospital.[6] Doctor Mount took inspiration from Elisabeth Kubler-Ross and Cicely Saunders in London.[7] The focus of the newly created palliative care unit was to provide comprehensive care of the terminally ill patient.[8] This care was aimed at understanding, anticipating, preventing, and alleviating the suffering of the dying patient, which remain the goals of palliative care today.[9]

PRINCIPLES

The American College of Surgeons (ACS) Committee on Ethics developed a statement on the principles guiding care at the end of life, which was approved by the Board of Regents and published in the Bulletin of the ACS in 1998 (Table 58.1).[10] This statement is a solid resource to the global approach to palliative care. When one reads this statement of principles and reflects on its meaning, it is clear that several crucial points were emphasized: (1) The patient has the right to determine his or her own care, and the surgeon shall respect the patient's authority to make this choice (including the right to refuse care the surgeon may recommend). (2) The provision of care based on the patient's choices should address comprehensively pain, psychosocial, family, and spiritual issues. (3) The surgeon should forego treatments that are futile.

ETHICAL CONSIDERATIONS

Although this chapter is not a primer on medical ethics, it would be incomplete without a discussion of the general philosophical framework of the principles of both palliative and curative care. The principles may not be held universally by all cultures, but are viewed widely as being applicable universally to decision making relating to the ethical practice of medicine in Western, traditional medicine. The following principles underlie the ethical structure of medical practice and palliative care: 1) honesty; 2) autonomy; 3) beneficence/nonmaleficence; 4) dignity (Table 58.2).[11] In addition, several key ethical concepts are relevant to the discussion surrounding palliative care. These include the concepts of futility, informed consent, medical uncertainty, and the principle of double effect (Table 58.3).

Palliative care is often thought of as distinct from traditional curative or supportive care; however, because most modern intensive care is supportive, meaning care that supports organ function until the patient heals, there is a natural continuum whereby palliative care can be integrated into modern intensive care.[3,4] For individual patients there may be a clear point of transition from curative to palliative care; however, in some cases the continuum may lead to indistinction, rather than a clear demarcation. For the purposes of discussion, clear transition points serve to illustrate common dilemmas or questions in the intensive care unit (ICU).

When Should Care Be Shifted from Curative/Supportive to Palliation?

In patients who are critically ill or who have major, life-threatening, or debilitating surgical and medical problems, the surgical team is often faced with the question of how much curative or supportive care to provide, or alternatively should the goals of care initiate or change to exclusively palliative care?[12] In the clinical experience of the author, these questions most often revolve around the principles of autonomy, futility, and beneficence. When the patient has outlined clearly his or her wishes and opinions related to clinical care, the treatment plan should be consistent and respectful of the patient's wishes, unless care is deemed to be futile. In the case of futility, there is no obligation on the part of the physician to provide futile care. The concept of futility is well described; however, there is considerable disagreement among experts (and applicable laws

TABLE 58.1

ACS' STATEMENT ON PRINCIPLES GUIDING CARE AT THE END OF LIFE

- Respect the dignity of both patient and caregivers.
- Be sensitive to and respectful of the patient's and family's wishes.
- Use the most appropriate measures that are consistent with the choices of the patient or the patient's legal surrogate.
- Ensure alleviation of pain and management of other physical symptoms.
- Recognize, assess, and address psychological, social, and spiritual problems.
- Ensure appropriate continuity of care by the patient's primary or specialist physician.
- Provide access to therapies that may realistically be expected to improve the patient's quality of life.
- Provide access to appropriate palliative care and hospice care.
- Respect the patient's right to refuse treatment.
- Recognize the physician's responsibility to forego treatments that are futile.

TABLE 58.3

CONCEPTUAL FRAMEWORK FOR THE ETHICAL PRACTICE OF PALLIATIVE CARE MEDICINE

Double Effect: The concept that a treatment may have two effects (e.g., for opioids, that medication relieves pain, but may depress respiratory drive). In practical use, it is the intent of the treatment that is most important. Effective treatment of pain may lead to impaired respiratory drive; however, if the intent is to treat pain effectively, the treatment is ethical and warranted.

Futility: Futile care is care that provides no benefit to the patient. Practically, developing a working definition of what constitutes futile care is challenging, except at the extremes.

Informed Consent: The patient gives permission, usually in writing, to a given treatment following a thorough discussion of the risks, benefits, and alternatives.

Medical Uncertainty: Diagnoses, prognoses, and treatment decisions are based on probability, thus there is inherent uncertainty in many end-of-life situations.

Surrogate Decision Maker: The family member or significant other who is recognized to have authority to make decisions for the patient who lacks capacity for medical decision making, or there is ambiguity with respect to what the patient would have intended. Ideally, the health care agent is designated in advance by the execution of a durable power of attorney for health care, or "health care proxy." If no agent is designated, a hierarchy is defined, with the patient's spouse at the apex and children subordinate.

among the states) as to what constitutes futile care, except in extreme situations (e.g., brain death, anencephaly), so there is commonly disagreement over what constitutes futile care (Table 58.3).

What to Do When the Patient Wishes for Treatment, but Care Is Deemed Futile by the Physician?

This is an inherent conflict between the principle of autonomy and the concept of medical futility. The first course of action should be reassessment of the determination of futility. In most instances, futile care is assessed based on medical probability, for which there is inherent uncertainty. Oftentimes, what seems to be a disagreement over futile care is really a

TABLE 58.2

DEFINITIONS PRINCIPLES OF RELEVANCE TO PALLIATIVE CARE

Autonomy: The precept that the patient has the right to determine his or her care, or lack thereof.

Beneficence: The physician shall act uniformly in the best interest of the patient.

Dignity: A less well-defined term signifying that the patient has a right to respectful, ethical, and empathetic treatment.

Honesty: The precept that the patient has the right to know the truth about their condition and their planned treatment, including its likely outcome and risk.

Nonmaleficence: "First, do no harm." This is related to beneficence, but emphasizes the point that the most important principle is to not harm the patient.

disagreement over the goals of care, so the next course of action should be a respectful, thoughtful, and empathetic discussion between the physician and patient/surrogate(s) concerning the goals of care and a discussion of why the care is not beneficial to the patient. This discussion should include a self-reflective reassessment of the determination of futility, including an objective internal review of biases and potential conflicts (see below).

What to Do When the Patient Wishes No Further Treatment, but the Physician Believes the Care Is Beneficial?

In this situation, the conflict is between patient autonomy and practitioner beneficence—the patient is refusing a treatment that the surgeon considers indicated and beneficial. Again, the best first course of action is a careful self-reassessment. Provided the patient has the capacity to make medical decisions, there should follow an empathetic and respectful discussion between caregiver(s), to understand the patient's point of view, and patient/surrogate to understand the medical issues involved. For terminally ill patients, once this discussion has been held to the satisfaction of all parties, the patient's wishes should be followed, regardless of the point of view of the health care team. The patient has the right to make what the clinician may perceive to be an incorrect decision.[13]

In the author's experience, this situation is uncommon. Most often the surgical team and the patient/surrogate are in agreement as to when to transition from curative to palliative care. Even when there is disagreement initially, the parties can usually negotiate a mutually agreeable decision. Achieving this harmonious agreement should be a primary goal of the surgical team.

SURGICAL CRITICAL CARE

IDENTIFYING POTENTIAL BIAS AND CONFLICTS OF INTEREST

When there is disagreement, it is essential to perform an internal reassessment concerning one's own beliefs, potential biases, and potential conflict of interests. Even in the absence of any disagreement, it is beneficial to reexamine periodically one's own potential biases and conflicts of interest. Developing this habit assists with developing a "mindful practice".[14] One would suppose that compared to the patient and his or her family, this process would be easier for the educated, experienced surgeon or intensive care physician; however, sometimes this exercise can be more challenging than one might suppose. The most dangerous bias is one that is unrecognized by oneself. Outlined below are some of the more common potential biases of those working with critically ill patients.

Overconfidence in Predicting Outcome

"Medicine is a science of uncertainty and an art of probability."[15]

—Sir William Osler

The longer a doctor has practiced medicine, the less confident he is in his ability to predict the outcome of critical illness; any prognosticator would be well-advised to proceed with caution. Several pieces of data support this conclusion. A prospective, 1-year study of 206 critically ill French oncology patients who were considered for ICU admission found that 101 patients were not admitted: 54 because they were deemed "too sick," and 47 because they were deemed "too well."[16] Worrisome was that 17% of the "too sick" patients were still alive at 180 days, implying that this group was not terminally ill. Of the group of patients "too well" for admission, 22% were dead in 30 days. Thus the evaluators were not particularly adept at predicting either who would survive or who would not. That the data came from a group of cancer patients, for whom the end of life might seem to be easier to predict as compared to a general surgical or medical population, underscores the difficulty.

In a follow-up to the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT), a group of 2,954 critically ill, nononcology patients with chronic obstructive pulmonary disease, congestive heart failure, or end-stage liver disease were followed after hospital discharge.[17] The goal of SUPPORT was to include terminal patients who had an aggregate 6-month mortality rate of 50%. Of these patients, 347 died during the index hospitalization, leaving 2,607 patients who were followed as outpatients. Of these patients, 1,948 (66%) were alive at 6 months. None of the predictive models were accurate for the prediction of who would not survive for 6 months. Using a model predicting a <10% survival rate at 6 months, the actual survival was 41%.

The panoply of critically ill scoring and mortality prediction models (MPMs), including the Acute Physiology and Chronic Health Evaluation (APACHE), APACHE II, APACHE III, and APACHE IV scores; the Simplified Acute Physiology Score (SAPS) and SAPS II; the Sequential Organ failure Assessment (SOFA) score; and MPM and MPM II, should raise skepticism. Three points can be made about these mortality prediction tools: (1) Each of these models predicts mortality well for a population of patients. (2) From a temporal standpoint, each is more predictive the closer one comes to death. (3) Most (except APACHE III and SOFA) are not particularly useful to predict the outcome for an individual patient. Therefore, these predictive tools are not particularly helpful when trying to prognosticate for the individual patient.

Among those who care for critically ill patients, bias of overconfidence in predicting outcome can lead to an unjustified, overly pessimistic view or a similarly unjustified, overly optimistic assessment of prognosis. Based on the author's experience, a personal prognostication is offered: When physicians predict the future, one can usually predict accurately that they will be incorrect. Regardless of the author's opinion, scientific data clearly support a healthy skepticism concerning one's ability to predict the outcome of critically or terminally ill patients.

Covenant of Care

Surgeons perform operations upon patients. These operations have a permanent and immediate effect upon the patient's life. Surgeons and patients partner together to address the problem the operation is designed to remedy. As such, surgeons as a group are invested emotionally in the care of their own patients. Cassel and Buchman described this relationship as covenantal, as a simple promise: "I will care for you."[18–20] This covenantal relationship is obviously positive, and at least in the author's opinion, often makes the surgeon the most influential advocate for the patient's wishes. However, at the end of life, this relationship may lead the surgeon to push for curative care, even when it is against the patient's wishes. In a hypothetical case discussion regarding informed consent, a group of well-trained, respected, competent surgeons were asked what they would do in the following scenario[21]: A patient has a soft tissue infection of the foot that is limb-threatening. The consulting surgeon is informed by the patient that death is preferable to amputation, and operation is deferred. The surgeon is consulted again several days later after the patient has become comatose from sepsis and encephalopathy due to a necrotizing soft tissue infection, and lacks capacity to express his or her wishes or make medical decisions. The surgical panelists were unanimous in their agreement that they would amputate the lower extremity in order to save the patient's life. This was a theoretic panel discussion, but this desire to do the right thing for the patient may lead the surgeon to push curative care in contradistinction to the patient's expressed wishes. Even the language that is commonly used belies this authority—patients' "wishes," and doctors' "orders." When one is invested emotionally in the care of a patient, one should take time to reflect personally as to what the patient would choose, and then one should do what one can to honor those wishes. This may or may not be different from the surgeon's wishes or their perception of what is in the patient's best interest; clarifying any discrepancy beforehand is decidedly in the patient's best interest.

Caring for All—Distributive Justice

"Critical care resources are not only expensive, but also scarce."[18] Whereas the patient's surgeon may have an intensely personal bond with the patient, the acute care surgeon or intensive care physician caring for all patients in the ICU is often placed in the situation of determining the appropriate resource utilization for the case. Even at times of peak ICU utilization, when decision making can be particularly challenging, this responsibility must be recognized and accepted, and should not bias any decisions regarding palliative and curative care, except perhaps in mass-casualty situations. Intensive care is costly and not beneficial for every patient, but recognition of same should not bias care that is in the patient's best interest. The finite nature of resources is primarily a societal issue that must be addressed at the societal level.

Compassion Fatigue

Compassion fatigue, or "burnout," probably affects all providers of trauma and emergency care at one time or another.[22] It is common among those who provide care for terminally ill patients, particularly caregivers who are isolated and overworked. The condition tends to lead to cynicism, anger, and fatigue—a situational depression. If one is mindful of the problem, compassion fatigue can be prevented,[22] but when present it may lead to a bias in either direction. Palliative care is best provided by those fully engaged and committed to the comprehensive relief of patient suffering, which is almost impossible under conditions of burnout. A portion of the ACS Manual for the Resident on Palliative Care emphasizes self-care as a component of palliative care.[23]

The Unbiased Surgeon or Intensivist

The most dangerous bias is the unrecognized bias. Each of us has our own unique biases concerning curative and palliative care based on our own beliefs, values, previous experiences, and fund of knowledge. It is a grave mistake to consider oneself unbiased. This is well told by the late William F. Buckley, describing the story of a man without a country[24]:

> "… It told of a man at a bar who boasted of his rootlessness, derisively dismissing the jingoistic patrons to his left and to his right. But later in the evening, one man speaks an animadversion on a little principality in the Balkans and is met with the clenched fist of the man without a country, who would not endure this insult to the place where he was born."

So it must be with the unbiased surgeon or unbiased intensive care physician: Being mindful of our own predispositions is crucial to provide reliable guidance and advice for patients and their families when they need it most.

PROVIDING PALLIATIVE CARE IN PRACTICE

Cicely Saunders[25] and Balfour Mount[26] emphasized the concepts of the care of the whole patient and relieving all pain as essential elements of palliative care. This approach involves the more traditional domains of relief of symptoms, prevention and treatment of pain, and psychosocial support; however, the palliative approach extends beyond these domains into less traditional areas of spiritualism and existentialism. Eric Cassell broadened this view, emphasizing further that individual patient suffering is unique and is affected by a large number of holistic and subjective domains that extend beyond the typical medical assessment.[27]

As a tool to assist in addressing these domains in palliative and end-of-life care, several authors have developed tools to assist the clinician. One tool with documented effectiveness to improve care at the end of life is the PEACE Tool (Table 58.4).[28]

P reminds the practitioner to address pain and the wide range of physical ailments that afflict patients with serious medical and surgical illnesses. The acute care surgeon is well prepared to deal with this constellation of physical problems, but the important first step is a logical and systematic approach to identifying the complaints that are most distressing to the patient. Most pain management issues can be addressed by the surgeon, but consultation with a palliative care specialist or pain management practitioner is indicated when the patient's pain is not relieved completely.

TABLE 58.4

PEACE TOOL

Physical symptoms: Pain; gastrointestinal, urologic, or respiratory symptoms; skin breakdown/irritation; fatigue and energy level.
Emotive (and cognitive) symptoms: Depression, delirium, or anxiety.
Autonomy-related issues: Does the patient perceive that he/she is in control of their own care?
Communication, Contribution to others, and Closure of life affairs: Addresses relations with loved ones, one's legacy, and closure of one's personal affairs.
Economic burden and other practical issues: Addresses economic burden, care providers outside the inpatient hospital setting, insurance matters and paperwork.
Transcendent and existential issues: Is the patient at peace? Addresses issues of faith, spirituality, purpose, and what happens after death.

E is a reminder to address emotional and cognitive issues. Of these problems, the most common are depression, anxiety, and delirium. Preventing or addressing these issues requires a multifaceted approach. In particular, the identification of delirium can be challenging because as many as 70% of critically ill surgical or trauma patients may experience delirium during their hospitalization (which may persist for several days), but up to 60% of affected patients manifest a "hypoactive" delirium with no overt signs.[29,30] Validated assessment tools are available to assist the clinician, notably the Confusion Assessment Method for the Intensive Care Unit (CAM-ICU)[31,32] (Table 58.5). The CAM-ICU tool was designed for bedside use by ICU clinicians who have no psychiatric training. The assessment can be completed in as little as 2 minutes, with sensitivity, specificity, and interrater reliability all approaching 95%.[29–32]

If emotional or cognitive issues are identified, they are addressed by maintaining a relationship between patient and care providers that promotes a positive, encouraging environment, celebrating victories (past, present, and future) and allowing the patient their self-expression. The American poet Ted Rosenthal said, "Life is grim, but not necessarily serious." in his book *How Could I Not Be Among You?*, written while dying.[33] The goal is to help the patient "still smell the rose above the mould," as Osler, on his deathbed, reportedly quoted Thomas Hood repeatedly.[34] The same goals exist for the patient's family in the ICU, even when the patient is incommunicado

A is for autonomy and is a reminder to involve the patient and family in end-of-life care. It is important for the patient and family to be given voice, and to feel in control. This may be a point of friction with surgeons, who also usually have the same goals. The patient's and family's goals may not always be consistent with those of care providers, wishing (perhaps) that more aggressive care be provided than is logical or consistent with the patient's physical condition according to the medical team. As Finucane states lucidly: "The desire not to be dead coupled with an inevitable imprecision in estimates of survival for individuals makes it difficult for many severely ill patients to shift goals."[5] The author would also emphasize that the patient or their family may be correct and the medical team may be incorrect with respect to this conflict, and that it is important that the medical practitioner acknowledges with humility the uncertainty of his or her predictive powers.

TABLE 58.5

THE CONFUSION ASSESSMENT METHOD FOR THE
INTENSIVE CARE UNIT

Domain 1: Acute onset of mental status changes, or fluctuating course
- Is there evidence of an acute change in mental status, from baseline?
- Has abnormal behavior fluctuated in the prior 24 h?

Sources of data: Serial Glasgow Coma Scale scores or sedation scores; input for the patient's critical care nurse, or family

Domain 2: Inattention
- Does the patient have difficulty focusing attention?
- Is there reduced ability to maintain/shift attention?

Sources of data: Attention screening examinations by picture recognition or random letter test (neither requires an oral response and can thus be used to assess patients ventilated mechanically)

Domain 3: Disorganized thinking
- Is conversation rambling or incoherent? Is there unclear or illogical flow of ideas, or unpredictable switching among subjects?
- Is the patient able to follow questions and commands?

Source of data: Clinical assessment

Domain 4: Altered level of consciousness
- Is the level of consciousness anything other than "alert?" Examples include vigilant (hyperalert), lethargic (drowsy but arousable), stuporous (difficult to arouse), or comatose.

Source of data: Clinical assessment

The CAM-ICU tool was designed and validated for use by nonpsychiatrist clinicians at the bedside. Delirium is present when both Domains 1 and 2 are positive, plus either Domain 3 or 4. Modified from Ely EW, Margolin R, Francis J, et al. Evaluation of delirium in critically ill patients: Validation of the Confusion Assessment Method for the Intensive Care Unit (CAM-ICU). *Crit Care Med*. 2001;29:1370–1379.

Alternatively, a patient may wish for less aggressive care than the medical or surgical team wishes to provide. This choice may not be linear or logical—as an example, a patient may refuse definitive care, but wish for supportive care following this decision. A patient–physician–family relationship based on respect, communication, and cooperation is beneficial to all parties. The patient's wishes for autonomy should be granted insofar as possible, and when impossible, an empathetic and thorough discussion of the rationale behind the medical decision is mandatory.

Autonomy does not mean that the physician abrogates to the patient the responsibility for the transition to palliative care. Burdening the family solely with the decision to withdraw curative or supportive care as part of the transition to palliation is at once unwise and unfair. The decision to shift from curative to palliative care is made jointly by the physician, the patient, and his or her surrogate (if applicable). As a professional who is educated, trained, and experienced in these situations, the physician is central in guiding patient and family through this situation without making them feel unheard, guilty, or abandoned. Although the task is difficult, the reward is the patient and family are often grateful for the assistance.

C is for closure for the patient and their loved ones. As much as possible, it is important for patient and family to believe that there is no unfinished business and that death will occur with no regrets. Asking about unfinished business or unfinished communication with loved ones may be therapeutic for the patient. Circumstances may not permit for critically injured patients or patients who suffer a devastating acute illness; however, it is imperative that an opportunity for closure be found insofar as possible. This may mean forgoing a declaration of brain death for a brief period of time for the family to achieve closure, or to allow a loved one to arrive after a long journey. There may be substantial guilt surrounding a violent or sudden event. To the extent possible, the skilled acute care surgeon should minimize these feelings and help the patient and family to achieve closure, which may mean the family forgives the patient or themselves, or vice versa. Forgiveness is an important part of healing, and it should start at the bedside in the ICU. Similarly, organ donation may be a part of this tactic. Many loved ones who choose to donate organs find meaning in the gift and have something positive emerge from a tragic, unexpected death, as compared to those who either choose not to donate, or were not given the opportunity.

E is for economic and other practical issues. Dying in modern Western society is a complicated, expensive, and bureaucratic event. The expense of being seriously ill may be a primary stressor to the patient. To the extent possible, the medical team can address some of these concerns. Assistance with insurance forms, social services, and simply discussing these matters with the patient and his or her family can make a positive difference.

T is for transcendental and existential issues. Religion and spirituality are extremely important to most patients and their families during their illness and surrounding the patient's death. Most terminal cancer patients in a recent survey endorsed religion as important to their care and expressed concerns about the lack of spiritual support from medicine and their community.[34] Providing faith-based support and counseling is a crucial part of palliative care.[35, 36] This should be tailored to the patient's beliefs, not those of the medical team or any physician. This spiritual care is central to addressing each of the preceding first four domains: physical complaints, emotive symptoms, autonomy, and closure. Sensitivity to these concerns is an important role for the physician.

The PEACE Tool was designed for palliative/hospice care outside of the ICU; however, it is useful to remind the practitioner of the need for total and comprehensive care across domains that are not a typical part of a surgical treatment plan. The tool also is modified easily for use in the ICU, although many of the questions may be directed toward the patient's family and loved ones, rather than the patient him- or herself. Regardless of which tools are employed, the implementation of palliative care should address the domains of physical, psychosocial, economic, and spiritual/religious issues.

SELECTED LEGAL ASPECTS OF PALLIATIVE CARE

Alleviating Pain and Hastening Death?

In many instances it is possible to treat pain without undue risk of respiratory compromise or hastening death.[37] For the patient with severe pain, respiratory depression is a small risk due to a number of factors, including opioid tolerance with chronic use.[38] In situations where pain or distress cannot be treated without risk of respiratory compromise, palliative sedation is an option. This situation arises most commonly with respiratory distress when mechanical ventilation has been withdrawn or is not indicated due to a terminal condition. Higher doses of opioids, alone or in combination with an anxiolytic, are indicated in these situations, and may be used if the intent of their use is to prevent suffering.[37]

The United States Supreme Court has differentiated palliative sedation from euthanasia and physician-assisted suicide. Euthanasia is the administration of medication by a care provider with the intent of causing death, and is illegal everywhere in the United States. Physician-assisted suicide is illegal in all US jurisdictions except the State of Oregon, and is defined as prescribing or educating the patient in the use of medication, knowing that the patient intends to use these medications to commit suicide. Palliative sedation is the administration of medication with the intent of preventing pain or suffering, even if death may be hastened. The palliation should be indicated clinically and the intent of relieving pain and suffering for the benefit of the patient should be documented. Under the principles of beneficence and double effect, the Supreme Court has ruled that palliative sedation is both legal and ethical.[39,40] Justice O'Connor wrote in Vacco v. Quill:

> *"The parties and the amici agree that in the States a patient who is suffering from a terminal illness and who is experiencing great pain has no legal barriers to obtaining medication, from qualified physicians, to alleviate suffering, even to the point of causing unconsciousness and hastening death."[39]*

Some states go further still. Both California and Florida have statutory rules mandating effective pain management. In addition, there is potential civil liability for failure to provide effective palliation and treatment of pain. Civil courts have ruled in favor of plaintiffs on the grounds of malpractice, abandonment, and elder abuse when physicians have failed to provide adequate pain relief.[37]

In summary, comfort care should be provided for the purposes of preventing and treating suffering and pain. Palliative pain relief or sedation is both ethical and legal. The palliative care plan should be documented sufficiently that an external reviewer can determine the indication and intent, describing adequately the indication for palliation and that the physician's primary intent is to relieve pain and prevent suffering.

SUMMARY

In the context of critical surgical illness, palliative care focuses on a set of individualized patient goals aimed at reducing the suffering of the patient and his or her family. The ACS' Statement on Principles Guiding Care at the End of Life provides an ethical framework for the provision of palliative care to surgical patients (Table 58.1). A mindful self-assessment of personal beliefs, potential conflicts of interest, and potential biases is a good starting point for advising and assisting patients in the transition from curative to palliative care. High-quality palliative care is interdisciplinary and deals with the total patient. The palliative care plan addresses the holistic domains of physical afflictions, psychosocial concerns, economic burdens, and spiritual/religious issues. Even with a great care plan, effective medical leadership, and superb technical implementation of treatment measures, the transition from curative to palliative care will still be challenging, because patients almost without exception have a strong desire to be among the living; and physicians are imperfect in their ability to provide meaningfully precise prognostic information as to when death will occur. These challenges should not deter us from our responsibility of providing effective guidance throughout this transition in a manner that results in comfort, dignity, and respect for the patient and their loved ones.

CHAPTER 59 ■ EMTALA AND OTHER PRINCIPLES AFFECTING THE ACUTE CARE SURGEON

KENNETH L. MATTOX

The physician engaged in trauma management, emergency surgery, acute care surgery, or surgical critical care is intricately involved with patients with immediate life-threatening emergency conditions. Issues and decisions regarding receiving such patients, evaluation, management, consultation, and even transfer are all governed by the patient's clinical condition. These issues and decision nodes have been the subject of the many chapters of this book and will not be repeated here, although some of the regulations will be reviewed in this chapter to formulate rules, misperceptions, and policies regarding patients with critical conditions.

No profession in the world is more regulated than that of physicians in the United States. Surgeons are more regulated than other medical specialists, and an "acute care surgeon" who may or may not participate in trauma and surgical critical care is subject to more regulations than any other surgeon. The Emergency Medical Treatment and Active Labor Act (EMTALA) is both the epitome and a surrogate for a long list of regulations, rules, practice guidelines, policies, and outside manipulation as to how an acute care surgeon must function. The regulations were initially designed to protect persons interacting in health care, beginning with the patient in need. Others who need regulatory protection include surgeons, hospitals, custodians of medical records, hospital administrators, nurses, and many others.

The initial EMTALA was signed into law in 1986. Minor amendments were made almost every year, with a major revision in 2003, clarifying the roles of hospitals and physicians. Unfortunately, with revisions come new areas of confusion and new areas to allow manipulations at both the sending and receiving facilities. For all EMTALA regulations, it is the hospital that bears the responsibility for complying with the law, with the physicians as representatives of the hospital care. Surgeons voluntarily accept their responsibility as "agents of the hospital" when they accept call or referred patients, as well as when they transfer patients out or refuse transfer or referral for care.

EMTALA rules were developed to ensure that a patient with an immediate life-threatening emergency in an original location, which did not have the physical and personal resources to manage that emergency condition, would be transferred to a region that possessed a facility with the capacity of diagnosing and managing that emergency. The EMTALA never *intended* these rules to be used as an economic screen. Nor was there any intent that a patient without financial resources for medical payment would automatically be sent to a facility with a higher level of care, especially when patients with payment resources with that same immediate life-threatening emergency were often kept at the original sending institution. Likewise EMTALA was never intended to be a required referral source for specialized hospitals nor a mechanism for a hospital to refuse to receive a patient in referral for an emergency merely because that patient did not have financial resources or was outside the usual payment system or program of the hospital.

DEFINITIONS WITH EMTALA RAMIFICATIONS

A number of terms or phrases have direct bearing on EMTALA and the responsibilities and interpretations by hospitals, patients, doctors, families, and governmental agencies.

"Emergency" is a word with multiple meanings; its interpretation depends on the person using the word, the situation, the venue, and combinations of these and many other variables. An emergency may be modified by ethereal politics, ethics, economics, regulations, interpretations, past experience, gender, age, culture, and ethnicity. The same person may not meet an emergency with the same response however identical the situations might be. Two persons may anticipate or define the same situation as being either an urgent emergency or a nonemergency to be handled entirely at a discretionary time.

The motivation to seek assistance during an emergency is likewise variable. Such motivations may be time limited, economic limited, culturally limited, or influenced by a previous condition, either in ones memory of another, by previous education, or by past direct experience.

Modern Western culture has imprinted on society that everything is urgent, immediate, and therefore an emergency, which must be investigated and "taken care of" that very second. Very few conditions either in personal life, politics, religion, business, or even in health care are truly "emergencies" that require an immediate response.

Most misinformation regarding the emergency nature of a medical condition is secondary to funding and payment for services issues. With regard to a medical emergency, a patient or even a payer of medical services might attempt to make a case that a condition is an emergency, either to achieve an immediate evaluation and treatment or to alter the payment source or amount. Thus the attempt to define the emergency condition might be in the mind of the patient or personnel working for a funding agency, not the physician who is evaluating and treating the patient.

"Immediate life-threatening emergency" is a condition recognized to result in the death of a patient within a reasonably short period of time, usually perceived as being within 24 hours, or in some instances 1–3 days. Such conditions have recognizable staging and classification schemes that allow a reviewer to place such a patient in an immediate life-threatening emergency. Many "highest level of code" trauma conditions, and many acute care surgery conditions, such as a perforated viscus, necrotizing infection, acute occlusion of a major blood vessel, and similar conditions are indeed universally recognized as immediately life threatening. Many acute, subacute, and chronic medical, surgical, and mental health conditions will eventually result in the disability and death of a patient, but their mere presence is not an immediate life-threatening condition. Many conditions such as neoplasia, degenerative diseases, many infections, and most vascular conditions do not require an immediate hospitalization, or even a visit to an emergency center, unless that disease process has an immediate life-threatening complication that makes it such an emergency. The immediate life-threatening emergency should be defined by the medical community as being a condition that would be readily agreed upon to be such, not just a perception on the part of a patient.

"Hospital emergency department" is a location or locations, on or off the hospital main campus, which is licensed to provide emergency services; and up to one-third of the outpatient visits to that location are seen on an urgent basis. In such instances, the hospital advertises or appears to the public as a location providing emergency medical services.

"Acute surgical emergency" is a subset of immediate life-threatening emergencies that will require a surgical or procedural approach to reversing that emergency. Such an acute surgical emergency might require surgical, nonprocedural interventions, such as might be achieved by a surgical intensivist in a surgical intensive care unit.

"Trauma" is a subset of an acute surgical emergency, requiring a specialized trauma center immediately and available 24 hours a day. Trauma conditions can be categorized by both anatomic and physiologic derangement, and sometimes by the mechanism of injury. For each body area injured classification mechanisms have been developed by the American Association for the Surgery of Trauma and are readily available on the Eastern Association for the Surgery of Trauma (EAST) website (http://www.east.org/portal/) for immediate review. The mere presence of an injury does not require the presence of a trauma center. More than 90% of injuries are of a sufficiently minor nature that it has been recommended by the Advanced Trauma Life Support course of the American College of Surgeons that only <10% of patients with major trauma be taken to a designated trauma center.

"Dumping" is a term often used to designate a transfer to a regional health facility (with or without the prior knowledge and agreement of the receiving facility) for the purpose of moving an "undesirable" patient from a sending health facility. The reason for the undesirability may be financial, complexity of conditions, unfavorable diagnosis, or a long list of other excuses.

"Reversed Dumping" is a term referring to a receiving hospital using maneuvers to prevent a sending hospital from transferring an appropriate patient with an immediate life-threatening emergency to the appropriate regional facility, when that facility clearly has a duty to accept that patient in transfer. A patient without financial means of payment for an emergency service that can be rendered at the local hospital is *not* a reason in itself to send the patient to a higher level of care.

"Innovative Dumping" is a tactic to achieve a transfer of a patient to a regional emergency facility when under some usual circumstances, the sending hospital has the resources and personnel to manage the emergency. Apparently the most recent revisions to the EMTALA law have made provisions that have encouraged many local and nonreferral hospitals to develop means of transferring patients for a variety of conditions that are only managed electively at the sending hospital. For hospitals with a single or limited specialist on the medical staff roster, a hospital may elect to develop a limited call roster with important restrictions placed on the specialist on the call roster. Even though there are specialty services and an emergency room in a facility, a hospital is not under obligation to place such specialist on a daily call roster to respond to an emergency if placing him or her on such a recurring and frequent list would cause an unreasonable work schedule for that physician, and potentially produce an unsafe call condition.

"Warranty Work" is continuity of care concept that requires a physician who started a course of treatment for a patient with an emergency to complete that course of treatment. Many surgical conditions can undergo a variety of different acceptable approaches to procedural intervention. Once begun, a surgeon who initiates such a course should complete that course, including removing sutures, external fixation devices, and secondary staged surgery. Alternatively, such a surgeon may make mutually acceptable arrangements with a professional partner, associate, or even a surgeon at another facility to participate in follow-up care of a patient. For a surgeon to unknowingly be sent a patient whose course of treatment is not completed is not considered professional. Like many other aspects of society, a tradesman has a duty to satisfactorily complete a course of work, and to redo and repair faulty work under the concept of a warranty or assurance. For a patient who received a partial completion of an emergency surgical intervention to be sent to a regional facility to a different physician or physicians, without his or her knowledge and acceptance, is a form of dumping and is considered in some states as a violation of EMTALA.

OBLIGATIONS AND ASSUMPTIONS UNDER EMTALA

A physician working in an institution or location that receives a patient with an alleged emergency medical condition has a responsibility to participate in the evaluation of that patient to determine if indeed the symptoms, complaints, and findings in that patient are immediately life threatening. A chronic condition might be life threatening sometime in the distant future, such as controlled diabetes, controlled hypertension, atherosclerosis, or cancer. With most diseases or pathologic conditions, at some point in time, the disease itself or a complication of the disease might become immediately life threatening, with an ethical requirement to make a judgment between the patient and the physician about whether or not the condition or the disease will be treated. Conversely, all medical conditions that can result in a fatal or devastating complication at some point in time, if they are *not* immediately life or limb threatening as such, are not subject to the EMTALA regulations. As an example, atherosclerosis, which can occlude a coronary artery, might have been present as a fatty streak or a small athroma for several decades, but it is the acute coronary artery syndrome with its pain, electrocardiogram and cardiac enzyme abnormalities that announce the immediate presence of an impending fatal heart attack or cardiac arrhythmia. The duty of the physician is to evaluate the patient for such immediate life-threatening conditions and take a decision with the patient about the extent and location of immediate treatment.

Under EMTALA, a hospital has an obligation to clearly state the scope of their services and capabilities, particularly the level of emergency care and capabilities. Should a patient arrive with a presumed immediate life-threatening condition, by concern, symptom, or diagnosis, the hospital has an

obligation to provide the extent of the evaluation and services within its advertised limits, or to arrange for transport to a facility that can provide these services. This transport can be by prearranged transfer agreements or by communications via protocol through the hospital's transfer centers.

Hospitals, especially small hospitals with limited number of specialists on the staff who are capable of providing the emergency aspects of their specialty, are not required to have a "specialist on call" every night, weekend, and holiday. To demonstrate the extremes of such a circumstance, a single neurosurgeon, a single orthopedic surgeon, or a single general surgeon in a community with only one small hospital, but that does advertise that they take emergency patients, cannot expect the single surgeon to be available, much less operating 24 hours a day, 7 days a week. But a hospital is expected to have a published "call roster" indicating the days and hours that the specialist of that hospital who does respond to emergency calls, will indeed be on the call roster. When a hospital does not have a specialist on call, when there is such specialist on the staff of the hospital, that hospital should have prearranged methodologies for transfer of such emergency patients to another hospital.

When the need for an emergency treatment exists, a hospital might state that a transfer is required for a "higher level of care." The use of this phrase is often over used, or poorly understood. There are specific reasons that a hospital and its medical staff might not be able to provide the level of emergency care for the patient who exhibits immediate life-threatening condition, but the reasons and the details of the nonavailability should be clearly stated in the hospital's published "schedule of benefits" and/or the particular equipment, services, or personnel at a particular time. As an example, there should not be a quality difference in the general, urologic, orthopedic, or pediatric surgery available between a level 3 and level 1 trauma center. Differences between these two types of trauma centers are more in the fields of neurosurgery and thoracic surgery procedures requiring cardiopulmonary bypass. One that is often cited as needing a higher level of care is in hand and finger replantation. The skill and equipment required for replantation involves detailed microvascular surgery. However, a minor hand laceration or abrasion does *not* require the higher skills of a "hand surgeon" to evaluate such injuries, nor is a hand surgeon required to examine and treat a simple fracture of the fingers or metacarpal bones.

The status of the patient's immediate life-threatening condition and the availability of hospital and personnel resources to treat that condition should be the major driving force to prompt discussions regarding transfer to another facility. When immediate life threatening conditions exist, the availability of funding sources or methods of payment for hospital and physician services should never be the motivating factor for either keeping or transferring a patient. Over time, the economic profile of the patients transferred for emergency conditions to a facility that provides a higher level of care should be virtually identical to the overall economic profile of *all* the patients cared for in that facility.

A "DUTY" TO EVALUATE AND "DUTY" TO TREAT

A hospital whose facilities are licensed to provide emergency medical evaluation and treatment has a duty to a patient who either arrives or is transferred to this facility to evaluate that patient for the presence of that emergency condition. The operational term "EVAULATE" is key, and the extent of that evaluation must be commensurate with the ability for the physical examination, laboratory, and imaging to make a determination as to the complexity of the emergency condition

and to be able to communicate to the patient and/or to secondary physicians or facilities the details of the patient's condition. A decision as to whether an emergency facility and its staff, including the physicians, are able to render the requisite interventions is a function of many factors. These factors include: available resources, adequate numbers of personnel, capability and skills of the emergency personnel, infrastructure presence, and many others. Even in the absence of optimal resources, should there be no adverse outcome, the decisions made by the emergency caregivers are rarely questioned. Should the outcomes be adverse, the hospital, outside agencies, the family and the patient, and others often have questions regarding duty, judgment, technique, timing, and process, even if the skills and treatment exceeded a local and regional standard of care and all benchmarks were higher than the normal. Thus the duty and the decisions made often have ethical, economic, moral, medical, legal, and emotional overlay, impacting judgment. Regardless of the many decision nodes involved in an acute evaluation, decision, and treatment in a patient with an immediate life-threatening condition, the physician has a duty to adequately document all actions and the reasons behind the decisions.

Can a "Treatment" Be Less Than Complete Prior to Transfer?

The various regulations relating to patient evaluation and transfer, including those of EMTALA, focus on evaluation and making plans for therapy, with appropriate disclosure and communication. It is altogether appropriate for an integrated collaborative network of care to involve a number of levels of care with a network of communications and follow-up for quality assurance and performance improvement. The epitome of such an integrated collaborative network is the sequential care given to the current wounded warrior in a military conflict in Afghanistan or Iraq, who is treated at two to three levels of care in those countries, transferred to Landsthul Army Regional Hospital in Germany, and then later to a hospital in the Continental United States for continuing care. The Joint Trauma Treatment System with its Trauma Data Base, communicates to all members of the team at all levels ensuring that the care is informed and integrated. A "damage control" or "incomplete" treatment that is then continued in an agreed-upon plan of care is appropriate for any patient with any immediate life-threatening medical condition. This integrated collaborative network is totally outside the intent and specific details of the focus of the EMTALA and other regulatory documents.

Methods of Keeping out of EMTALA Trouble with Regulatory Agencies

Hospitals and physicians evaluating and caring for patients with emergent immediate life-threatening conditions have a strong motivation to stay within existing safety regulations, including EMTALA. A few simple principles will assure that concerns from outside regulatory agencies will be kept to a minimum and when they do occur, there will be ample information available to address the intent, policy, process, and outcome of the institution and its personnel that might come into question.

- Communicate—At all levels and in all hand offs, communicate honestly with all appropriate members of the treating team, especially the physicians caring for the patient at both sending and receiving hospitals

SPECIAL TOPICS

- Document—Record in the appropriate records, both the status of the patient, the evaluation and findings, the treatment rendered, and the communications among appropriate treating personnel. Document telephone and e-mail conversations.
- Transfer centers—Utilize at your facility a transfer center that assists in both communications and permanent recording of the exact nature of the care given, the higher level of care desired, and the specifics of the information known to those involved in any patient "hand-off."
- Do not overly advertise—For both hospitals and physicians, avoid hyperbole in describing the extent and focus of the emergency care that can be provided.
- Do your warranty work—Recognize that care rendered during emergency life-threatening conditions requires the same patient–physician–hospital relationship as during elective care, if not more stringent. Care that is given is subject to the same understanding for completing the work begun by a physician, unless there are understandings from a secondary facility and physician for continuing that care. Should a complication or an untoward event occur, full disclosure of such an event is the responsibility of those who were involved in the patients' care and arrangements are made, with the full understanding of the patient as to how and who will manage the continuing care. Such continuing care, with acceptance of such continuing responsibility, should be fully understood and agreed upon by all parties.
- EMTALA during disaster situations—The principles of EMTALA equally apply during times of disaster. During such times, it is important that rescue and EMS personnel, *not* over burden a major facility that routinely receives critically ill and injured patients, with persons only needing a shelter, but to preserve such facilities for that small percentage of surviving patients with immediate life-threatening conditions that can maximally benefit from the specially focused evaluation and care.
- Regional Review Process—Many hospital systems, as well as geographic areas, including multicounty emergency, trauma, acute care organizations (both governmental and volunteer) have successfully addressed a confidential regional peer review and performance improvement emergency medical process. Such regional reviews should markedly reduce a need for continually revising national regulatory processes.

CHAPTER 60 ■ INFORMED SURGICAL CONSENT

DAVID G. JACOBS

"*Patients should understand the indications for the operation, the risk involved, and the result that it is hoped to attain*"

—ACS Statements on Principles of the College[1]

A chapter devoted to the topic of informed consent may, at first glance, seem to be out of place in a textbook of acute care surgery. The deliberate, sometimes painstaking, process of informing and getting the consent of patients for surgical procedures hardly seems compatible with the fast-paced decision making required of both the surgeon and the patient when acute conditions arise. Yet, given the higher likelihood of adverse outcomes (death, complications, poor quality of life, etc.) in patients undergoing acute surgical procedures, the importance of the physician and the patient being "on the same page" with respect to the anticipated risks, benefits, and outcome of the planned operative procedure cannot be overestimated. Thus, it behooves all acute care surgeons to have some familiarity with the informed consent process under both elective and nonelective situations. Furthermore, since informed consent regulations may vary from hospital to hospital, and from state to state, some familiarity with these local requirements is desirable as well.

There are perhaps several reasons why the informed consent process might be undervalued by the acute care surgeon:

- Surgeon too busy with multiple simultaneous responsibilities (acute care surgery, trauma, surgical critical care)
- Surgeon's desire to get the patient to the operating room quickly
- Surgeon's inability to adequately inform the patient regarding operative procedure since actual operative findings would be unknown to the surgeon at the time of consent
- Urgent/emergent situation precludes development of strong surgeon–patient relationship
- Surgeon under the mistaken belief that informed consent is unnecessary for acute surgical procedures
- Surgeon unsure about validity of consent for acute surgical procedures due to patient factors such as pain, sedation from medications, and anxiety
- Difficulties establishing relationship with acute surgical patients due to language or cultural barriers

This chapter will briefly review the foundation, the principles, and the practice of informed consent as it applies to the *elective* surgery arena, and will then highlight some important aspects of the consent process that are unique to the *nonelective* surgical environment. In so doing, some of the above-listed obstacles to achieving true informed consent in acute care surgical patients will be addressed, and some recommendations for perhaps improving the currently existing consent process will be offered.

INFORMED CONSENT IN ELECTIVE SURGICAL PRACTICE

Foundation of Informed Consent

A comprehensive review of the informed consent process is beyond the scope of this chapter, but the interested reader is referred to several excellent recent reviews on the topic.[2-7] However, some basic understanding of the history, as well as

the components of the process, is necessary in order to place "emergent" informed consent into proper perspective. To begin with, it must be emphasized that informed consent is much more than obtaining a patient's signature on a consent form. True informed consent is a process wherein the patient is first *informed* by the surgeon of the risks, benefits, and intended outcomes of the proposed surgical procedure, followed by the patient's *consent* to undergo the procedure. Note here that it is the responsibility of the surgeon performing the procedure to both (1) inform the patient and (2) obtain the patient's consent, and that these responsibilities should not be abdicated to other members of the surgical team. Constraints of time and place occasionally preclude the surgeon from witnessing the patient's (or patient's surrogate) written signature on the consent form, especially when the procedure is being done on an emergent or urgent basis. Under these unique circumstances, it is permissible for a resident physician or nurse to obtain the patient's signature on the consent form, as the form itself is simply a legal document that attests to the fact that the informed consent process has been carried out by the surgeon. Indeed, signing, or even use of, the consent document is not a mandatory feature of the informed consent process from an ethical standpoint, although it may well be a legal requirement of a particular institution or state. All surgeons should therefore familiarize themselves with the requirements of the institutions and states within which they work. The content and structure of consent forms is discussed further elsewhere in this chapter.

Informed consent therefore really represents two separate processes and two separate tasks for the surgeon—inform and consent. In the United States, these two processes, though now inextricably linked, actually developed sequentially, separated by more than 40 years. The concept of *simple consent* was established first in 1914 in the case of *Schloendorff v. The Society of New York Hospital*.[8] In this case, consent had been obtained from the patient for an examination under ether anesthesia. However, while the patient was under anesthesia, the surgeon, without the patient's explicit consent, removed an abdominal tumor. Postoperatively the patient developed gangrene of the hand, which she claimed directly resulted from resection of the abdominal mass. The court ruled in favor of the patient, stating "*every human being of adult years and sound mind has a right to determine what shall be done with his body; and a surgeon who performs an operation without his patient's consent, commits an assault for which he is liable in damages.*"[7] Thus the concept of patient autonomy, a fundamental ethical principle and a fundamental underpinning of informed consent, was upheld by the court. No longer could surgeons unilaterally decide (and carry out) what they felt was in their patient's best interest—the patient's consent was first required. However, no further stipulations were made as to the quality of that consent until 1957, when, in *Salgo v. Leland Stanford Jr. University Board of Trustees*, the courts imposed a further duty on the surgeon to provide the patient with the information necessary to make an "intelligent" consent decision.[9] The patient in this case became paraplegic following performance, by his surgeon, of a translumbar aortogram, which involved injection of sodium urokon. This particular complication was a known, but quite rare, risk associated with this agent, one that Mr. Salgo's surgeon had not discussed with

him prior to performing the aortogram. Although the case was ultimately decided in favor of the physician, the court's opinion made it quite clear that the physician had a responsibility to inform the patient as part of the consent process—"*a physician violates his duty to his patient…if he withholds any facts which are necessary to form the basis of an intelligent consent by the patient to the proposed treatment.*" Although this new requirement of the physician to provide *any* necessary facts may seem vague or overly onerous, the same opinion also provided the physician with some room for judgment in informed consent discussions—"*In discussing the element of risk a certain amount of discretion must be employed consistent with the full disclosure of facts necessary to an informed consent.*"[4] The opinion in the *Salgo* case appears to represent the first documented use of the phrase "informed consent" and clearly ushered in a new era of physician responsibility in obtaining consent for medical treatments. Decades following *Salgo*, there is still not universal agreement as to how much actual discretion a physician must employ in informed consent discussions. This aspect of the informed consent discussion will be discussed in greater detail below.

Principles of Informed Consent

The process of informed consent requires several fundamental assumptions ([10]):

- The physician has provided adequate information with which to make a decision (adequate physician disclosure)
- The patient is competent to make a decision (patient competence)
- The patient indicates full understanding of the situation and the information imparted to him by the physician (patient understanding)
- The patient voluntarily consents to the proposed intervention (absence of undue influence)

Adequate Physician Disclosure. What constitutes adequate disclosure by the consenting physician? As discussed above, the *Salgo* ruling, which established the concept of informed consent more than 50 years ago, required physicians to provide "*any facts… necessary <for an> intelligent consent,*" but also allowed for some physician discretion in these discussions. In response to the ambiguity of the *Salgo* decision, three ethical standards have evolved over the years [2,11]

- *The Professional Standard* (also called the "Reasonable Physician Standard" or the "Professional Community Standard")—Requires the physician to disclose what a reasonably prudent physician with the same background, training, and experience, and practicing in the same community, would disclose to a patient in the same or similar situation
- The Materiality Standard (also called the "Reasonable Patient Standard" or the "Prudent Patient Standard"—Requires the physician to disclose what a reasonable patient in the same or similar situation would need to know in order to make an appropriate decision.
- The Subjective Patient Standard—Requires the physician to disclose what a particular patient, in his or her own unique set of circumstances and conditions, would need to know in order to make an appropriate decision.

From an *ethical* perspective, none of these standards is ideal. The Professional Standard has been criticized as being too physician-centered, in that it preferentially values what the physician, not the patient, thinks is important. The Materiality Standard fails to define what a "reasonable" patient is, and the Subjective Standard perhaps makes unreasonable demands of the physician to discern the particular values, interests,

and life circumstances of every patient who needs informed consent. From a *legal* perspective, most states have included language in their informed consent statutes that define which of the three standards described above is recognized in that particular state. The Encyclopedia of Everyday Law, available online, nicely summarizes these requirements for many of the 50 states, and the reader is advised to familiarize himself or herself with the standard currently being used in the particular state in which he or she practices.[11]

Although states may vary in the type of informed consent standard to which they hold physicians who practice within their borders, there does seem to be general consensus as to the basic elements of a proper informed consent discussion. In fact, several professional health care organizations have adopted formal informed consent standards for their respective organizations. The American College of Surgeons for example, in its Statement on Principles, outlines four specific items that should be included in informed consent discussions. These are

- The nature of the illness and the natural consequences of no treatment
- The nature of the proposed operation, including the estimated risks of mortality and morbidity
- The more common known complications, which should be described and discussed
- Alternative forms of treatment, including nonoperative techniques

The Joint Commission on Accreditation of Healthcare Organizations and the American Medical Association have established similar guidelines (Table 60.1). Finally, it is important to note that the health care provider is not obliged to disclose risks that are commonly understood, obvious, or already known to the patient.[12]

Patient Competence. In actuality, incompetence is a legal condition that can only be determined by the courts. Persons judged by the courts to be incompetent, by definition, are precluded from providing informed consent for themselves or for others. Similarly, minors, with very few exceptions, are legally prohibited from providing informed consent, although ethically, they should be included in informed consent discussions when they possess the maturity to do so.[10] Beyond legal considerations, and adult (nonminor) status, patients must possess adequate *capacity* for medical decision making. Capacity refers to the ability of the patient to process the information received and communicate a meaningful response, and is decision specific, so that a given patient may demonstrate capacity for medical decision making for one aspect of his or her care, yet lack decision-making capacity in other medically related areas.[6] Although there is no legal requirement for such, psychiatric consultation is frequently recommended when the loss of decision-making capacity in a given patient is suspected. However, the treating physician may actually be in the best position to assess capacity under these circumstances, since this physician likely has a better understanding of the patient's medical condition, as well as the risks, benefits, and alternatives to the proposed intervention, and is also in the best position to judge whether the patient's response to the circumstances is appropriate. Psychiatrists, however, may be helpful in working with the patient to restore capacity for medical decision making, although the time course of this restoration process may not be conducive to decision making in situations of acute surgical illness. In situations where the patient's decision-making capacity is confirmed to be lacking, or when patients have been deemed incompetent (including minors), and informed consent for a medical intervention is required, consent must be sought from the patient's surrogate. Most states have legislation that establishes the hierarchy of persons acting as a patient surrogate. Typically, a court-appointed guardian

TABLE 60.1

ELEMENTS OF INFORMED CONSENT

The Joint Commission

1. The nature of the proposed care, treatment, services, medications, interventions, or procedures
2. Potential benefits, risks, or side effects, including potential problems related to recuperation
3. The likelihood of achieving care, treatment, and service goals
4. Reasonable alternatives to the proposed case, treatment, and service goals
5. The relevant risks, benefits, and side effects related to alternatives, including the possible results of not receiving care, treatment, and services
6. When indicated, any limitations on the confidentiality of information learned from or about the patient

American College of Surgeons

1. The nature of the illness and the natural consequences of no treatment
2. The nature of the proposed operation, including the estimated risks of mortality and morbidity
3. The more common known complications, which should be described and discussed: the patient should understand the risks, as well as the benefits of the proposed operation; the discussion should include a description of what to expect during the hospitalization and posthospital convalescence
4. Alternative forms of treatment, including nonoperative techniques

American Medical Association

1. The patient's diagnosis, if known
2. The nature and purpose of a proposed treatment or procedure
3. The risks and benefits of a proposed treatment or procedure
4. Alternatives (regardless of their cost or the extent to which the treatment options are covered by health insurance)
5. The risks and benefits of the alternative treatment or procedure
6. The risks and benefits of not receiving or undergoing a treatment or procedure

From Raper SE, Sarwer DB. Informed consent issues in the conduct of bariatric surgery. *Surg Obes Relat Dis*. 2008;4(1):60–68.

heads the list, followed by a health care power of attorney. In the absence of either of these two individuals, consent would then need to be sought from spouses, adult children, parents, siblings, etc., although the precise order of these individuals in the hierarchy does vary from state to state. Once again, it is a good idea to become familiar with the regulations in force in the state in which one practices. This information can be accessed at http://new.abanet.org/aging/PublicDocuments/famcon_2009.pdf.[13]

As mentioned above, some exceptions to the "incompetent minor rule" do exist that allow for informed consent to be obtained from minors. Specifically, emancipated minors are legally permitted to provide informed consent for themselves. An emancipated minor is one who has assumed the responsibilities of adulthood, usually by willingly living apart from one's parents and by managing one's own financial affairs. Also included within this emancipated minor category are married minors and minors who are members of the armed services of the United States. These individuals are permitted to participate in the informed consent process as well. Also, minors who are parents are permitted to provide informed signature for their children. A final exception, the "mature minor doctrine" can be invoked, enabling a physician to act on the signature of a minor when parental signature cannot be obtained. Under these circumstances, the minor must be at least 15 years old, must appear capable of fully understanding the medical situation, must have received full disclosure of risks, and must grant consent to treatment.[6,14]

Patient Understanding. Even in situations where the patient's decision-making capacity is not in question, the patient may still not fully comprehend the nature of the procedure or treatment for which his/her consent is being sought. In addition to providing full disclosure, the surgeon also must ascertain whether the patient has an adequate understanding of the intervention to which he or she is being asked to consent. Several distinct thought processes have been identified in patients consenting to surgery that may interfere with their complete understanding of what their surgeons are telling them.[3] Some examples of these include

- A profound belief that surgery will result in cure
- Unrealistic expectations of the surgeon (or the institution) brought about via reputation, or by virtue of being a super-specialist (or a superspecialty hospital)
- Enhancement of physician trust as a result of being referred by family, friends, or other physicians
- Belief in medical expertise as opposed to medical information
- Resignation on the part of the patient to the risks of medical treatment
- Desire on the part of the patient to abrogate decision making to the surgeon ("do whatever you think is best, doc…")

Each of these attitudes that patients may bring with them to informed consent discussions may prevent the patient from fully engaging in, and thus fully understanding, even the most well-intentioned discussion of risks, benefits, and alternatives. Physicians need to be aware of these potential pitfalls and take the steps necessary to ensure their patient understands the information they have just imparted to them. This can be done by analyzing the types of questions being asked them by the patient, but also by asking probative questions of the patient as a means of identifying areas of incomplete comprehension. It is often helpful for the surgeon to ask patients to reiterate in their own words their understanding of the rationale, risks, and benefits of the procedure.

Absence of Undue Influence. Finally, it is also the responsibility of the surgeon to ensure that the consent obtained from the patient is voluntary and represents what the patient believes is in his or her best interest. Many external influences may exert themselves in the setting of surgical illness, particularly so under the conditions of acute surgical illness. Pain, fear, and anxiety can be powerful motivators of behavior and may propel patients to make decisions that they might not make under less stressful conditions. Steps should be taken to remove as many of these emotional and physiologic barriers to

true informed consent as possible, recognizing that the pharmacologic treatment of pain and anxiety may also potentially impair the patient's capacity for decision making.[6] In addition to these external influences, family and friends may occasionally, and possibly quite unintentionally, exert unwanted influence over the consent process. Obvious examples of this can be seen in patients contemplating cosmetic or even bariatric surgery, where perhaps the patient may be considering surgery not for his or her own benefit, but rather to please others.[7] Should the surgeon suspect that the patient is experiencing unwanted external influences such as these, a private discussion with the patient (and perhaps a separate private discussion with the "unwanted influences") provides the best opportunity to understand and implement the plan of action that maximizes the best interests of the patient.[2] Recognize, too, that the surgeon may, intentionally or otherwise, act as a coercive force when it comes to informed consent. Many patients are intimidated by the stereotypical strong-willed surgeon, or by the reputation that precedes even the first encounter with a surgeon. Some surgeons may actually express displeasure or dismay when a patient questions or declines the operative plan, thereby unwittingly contributing to the coercive atmosphere, and a less than informed consent situation. A more subtle form of surgeon coercion occurs when the surgeon, uninvited, offers an opinion as to the course of action the patient should choose, and in so doing, makes it more difficult for the patient to choose an alternate path. In general, such offerings should be avoided by the surgeon unless expressly invited by the patient, and even then, the surgeon must be sure to emphasize that a different course of action chosen by the patient will be respected and honored. Another well-recognized form of surgeon coercion is "framing," a process wherein the surgeon's word choices can exert unintended influences on the patient's decision making.[2,3] These word choices, intentionally or otherwise, either overemphasize the benefits (e.g., "you'll feel like a new man") or minimize the risks (e.g., "bleeding is *never* a problem with this type of surgery") of the proposed intervention, and may lead to unrealistic expectations on the part of the patient. Exaggerating the gravity of the patient's situation, referred to as "crepe hanging," is a particularly common and unethical form of framing that preoperatively sets falsely low expectations for the postoperative outcome in order to protect the reputation of the surgeon. If the postoperative outcome turns out to be good, the patient's appreciation of, and gratitude toward, the surgeon is intensified, whereas, in the unlikely event of a bad postoperative outcome, the surgeon escapes "blame," since a poor outcome has already been predicted. These subtle and not-so-subtle forms of framing are incompatible with the ethical principles of autonomy and beneficence that underlie informed consent, and they should be scrupulously avoided. One additional common practice that may unintentionally interfere with the goal of obtaining the patient's *voluntary* consent is that of waiting until the day of surgery to obtain consent. A consent discussion that occurs in the preoperative holding area, without adequate time for a detailed explanation of the risks, benefits, and alternatives, without adequate time for questions, without adequate time to read the informed consent document, and all perhaps performed after the patient has been administered a preoperative sedative can hardly be considered "informed." In addition, the patient's awareness that the operating room has been reserved, that the surgeon has blocked out the time on his or her operating schedule, and that family or friends have taken time off from work to accompany the patient, are all potentially coercive forces that may, perhaps subconsciously, influence a patient to sign a consent document for a procedure to which he is not entirely committed to undergoing. Whenever possible, the informed consent process should be initiated well in advance of the intended procedure, with the patient being given ample time to consider, or

even change, their decision. Unfortunately, this luxury of time, which works well for the informed consent process in elective surgery, is not feasible for patients needing to undergo urgent or emergent surgical procedures.

Exceptions to Informed Consent

"*If a surgeon is confronted with an emergency which endangers the life and health of the patient, it is his duty to do that which the occasion demands within the usual and customary practice among physicians and surgeons in the same or similar localities, without the consent of the patient.*"[15]

Under some conditions, informed consent may be neither possible nor necessary, and some of these conditions are particularly germane to patients with acute surgical conditions. Occasionally, treatment of a patient without his or her consent can be mandated by law if there is a perceived risk to public health and safety. However, most exceptions to informed consent benefit the patient directly by ensuring timely access to needed medical care for that individual patient. Informed consent can legitimately be waived under the following circumstances[11,12,16]:

- Medical emergencies
- Unanticipated conditions during surgery
- Patient waiver of consent
- The therapeutic privilege

Medical Emergencies. Medical emergencies constitute the largest category of exceptions to the informed consent requirement, but this well-recognized exception should not be invoked indiscriminately simply because the patient requires "acute" surgical intervention.[16] The guiding principle here is whether delay in treatment required to obtain consent would result in harm to the patient. Harm in this context is not necessarily limited to loss of life or limb, but refers to any major adverse outcome that may occur as a result of a delay in treatment. In general, the fact that the patient has presented to the health care facility is taken as evidence of presumed consent to emergency treatment. Frequently, these patients display impaired decision-making capacity due to alterations in mental status brought on by hemodynamic instability, sepsis, or direct Central Nervous System (CNS) insult or injury. Resuscitation, including intubation and mechanical ventilation, can, and should, be undertaken immediately in this patient population without concern for obtaining informed consent based upon the fact that these patients are inherently incompetent, and based upon the assumption that most reasonable individuals under the same circumstances would desire treatment. Of course, when an appropriate patient surrogate is identified, informed consent should be obtained for all subsequent procedures. This approach can also be extended to the perhaps less straightforward situation of the emergency surgery patient with impaired decision-making capacity due to intoxication, but documentation of the patient's lack of capacity is critical if suspension of the patient's informed consent rights is to be upheld. This principle is illustrated in *Miller v Rhode Island Hospital*, where an intoxicated trauma patient was subjected to a diagnostic peritoneal lavage procedure against his will, and sued the hospital for battery. In siding with the defendants, the court held that the determination of whether a patient's intoxication would render the patient incapable of giving informed consent would depend upon the circumstances, and that medical competency (whether the patient was able to reasonably understand the medical condition, and the risks and benefits of, and alternatives to, the proposed procedure) was the relevant standard for physicians to judge conscious patients in these circumstances.[17] Thus, in order for a physician to deny a patient his

or her informed consent rights on the basis of intoxication, the physician must first be absolutely convinced that intoxication has rendered the patient medically incompetent, since this is the standard required by the courts to successfully defend a charge of battery. One additional facet of the emergency exemption to informed consent that deserves mention is the issue of consent for blood transfusion. Here again, the issue of medical competency comes into play, since transfusing a medically competent patient against his or her will would clearly constitute battery. Patients deemed medically incompetent, whether due to injury, illness, or intoxication, can be transfused without their consent, even against the objections of the patient or patient's family under the compelling state interest standard.[18] The emergency exemption to informed consent also extends to the "incompetent" minor, such that the informed consent requirement can be waived when an emergency exists and immediate injury or death could result from the delay associated with attempting to obtain parental consent.[16] Emergent blood transfusion, without consent, for a minor patient has generally been upheld by the courts, even when the transfusion has been adamantly refused by the parents and the patient, again based upon the compelling state interest in preserving the life of a child. As stated in *Novak v Cobb County-Kennestone Hospital Authority*, "not even a parent has unbridled discretion to exercise their religious beliefs when the state's interest in preserving the health of the children within its borders weighs in the balance."[19] In all circumstances where the emergency exception is invoked, it is prudent to document in the patient record the nature of the emergency, and the rationale for proceeding without informed consent. If possible, a corroborating statement in the patient record from a second health care provider is also desirable.[14]

Unanticipated Conditions During Surgery. The courts have generally looked favorably on surgeons who have performed, on patients under general anesthesia, procedures for which they did not have explicit informed consent as long as (1) the procedure appeared to be in the patient's best interests and (2) there was not adequate opportunity for the surgeon to obtain consent. This is referred to as the "extension doctrine," and it assumes that the surgeon is using reasonable judgment. In order to meet the criteria for the extension doctrine, the condition must be one that was unforeseen, and the patient must not have expressly refused such an intervention.[12] These circumstances present themselves relatively frequently to the acute care surgeon when undertaking laparotomy for "peritonitis" of unknown origin. In *Barnett v Bacharach*, a patient who was thought to have an ectopic pregnancy consented only for the removal of the ectopic pregnancy itself. At laparotomy, however, the patient was found to have acute appendicitis and an appendectomy was performed. Following an uneventful recovery, the patient refused to pay for the surgical services provided because informed consent was not first obtained and thus the procedure was unauthorized. At trial, the court found that the surgeon acted properly because of the seriousness of the patient's condition.[20] However, in *Tabor v Scobee*, the court found that the surgeon had acted improperly when he removed the infected fallopian tubes from a patient who had given informed consent only for an appendectomy. Here the surgeon argued that serious harm or death could have resulted had the procedure been delayed for weeks or months, but this time frame did not fulfill the court's definition of a condition severe enough to warrant denial of the patient's informed consent rights.[21] Perhaps the patient's resulting sterility also played a role in the court's decision.

Patient Waiver of Consent. Occasionally, a patient will relinquish his or her right to informed consent by expressly waiving this right and specifically directing the physician to do what the physician thinks is in the patient's best interest.

This is a relatively unusual occurrence in this day and age, and this acquiescence on the part of the patient should be clearly documented by the surgeon in the patient record.

The Therapeutic Privilege. By law, a physician has no obligation to provide informed consent if he or she believes that the patients' emotional and physical condition could be adversely affected by full disclosure of the treatment risks.[22] This is referred to as the therapeutic privilege and, although a legitimate exception, must be invoked with great caution, and with abundant physician documentation in the patient record.

Problems with Informed Consent

Even in elective surgery situations, and even with the most well-intentioned physician, the informed consent process is far from perfect. Patients seem to comprehend little about what has been explained to them, and what little they understand, they fail to retain for any substantial period of time. Falgas recently conducted a review of 23 articles that assessed the quality of the informed consent process across a variety of surgical specialties. Several different consent discussion formats were represented in these 23 articles, including verbal explanations alone, written materials alone, use of audiovisual media, and various combinations of these formats. Patient understanding was judged as either adequate (more than 80% of the participants in the study had a level of understanding graded in the highest classification category), moderate (50%–80% of the participants in the study had a level of understanding graded in the highest classification category) or inadequate (<50% of the participants in the study had a level of understanding graded in the highest classification category). Based upon these definitions, "adequate" overall understanding of the information provided was demonstrated in only 29% of the patients examined, while only 36% of the patients demonstrated "adequate" understanding of the risks associated with surgery (Table 60.2). Although one may quibble with the definitions used in this review, it is nevertheless quite clear that, regardless of how the informed consent discussion is carried out (verbal, written, with or without audiovisuals), a substantial gap exists between the information that surgeons think they transmit to their patients, and the information that patients actually understand and retain.[23]

The retention of informed consent information over time is undoubtedly less important than the information comprehension issue discussed above, but considering that many patients will go through the informed consent process in the outpatient setting days to weeks before the surgery is actually undertaken, patients may well require reeducation when they re-present for their surgical procedure. Furthermore, the retention issue can become quite problematic should accusations of inadequate disclosure be brought against the physician and the patient be required to recall specifically what he or she was or was not told in advance about the surgical procedure in question. Those items that the patient believes were not properly disclosed by the surgeon may simply have been forgotten by the patient, emphasizing the need for the physician to maintain an accurate accounting of all of the information that was exchanged as part of the consent process. Hutson and Blaha described 38 orthopedic patients who were not allowed to sign their operative consent forms until they could correctly recall all items on a questionnaire. However, 6 months after the operation, only 16% of the risks could be recalled.[24] Similar results were noted by Lavelle-Jones in general surgery patients.[25] Some have advocated the provision of written materials as a way of improving information retention, but Lavelle-Jones found that giving the patient an operation information card at the time of consent did nothing to improve long-term recall.

TABLE 60.2

SYNTHESIS OF DATA FROM DIFFERENT STUDIES REGARDING THE EVALUATION OF THE VARIOUS COMPONENTS OF THE INFORMED CONSENT PROCESS FOR SURGERY OR PARTICIPATION IN CLINICAL TRIALS

■ COMPONENTS OF THE INFORMED CONSENT PROCESS	■ STUDIES SHOWING DIFFERENT LEVELS OF UNDERSTANDING OR SATISFACTION FOR THE COMPONENTS OF INFORMED CONSENT		
	■ ADEQUATE (%)	■ MODERATE (%)	■ INADEQUATE (%)
Evaluation of the amount of provided information	7/12 (58)	3/12 (25)	2/12 (17)
Understanding of given information	6/21 (29)	9/21 (43)	6/21 (29)
Understanding the risks of operation	5/14 (36)	5/14 (36)	4/14 (29)
Understanding the benefits of operation	2/6 (33)	3/6 (50)	1/6 (17)

From Falagas ME, Korbila IP, Giannopoulou KP, Kondilis BK, Peppas G. Informed consent: how much and what do patients understand? *Am J Surg.* 2009;198(3):420–435.

In hopes of improving the informed consent process in their neurosurgical practice, Konndziolka developed a procedure-based consent form to facilitate patient discussion. The consent form listed specific diagnoses, procedures, alternatives, and risk, and each point discussed was checked off by the surgeon. Immediate recall of information regarding the diagnosis and planned procedure was 100%, and was 98.1% for information regarding alternative treatments, and 97.4% for information regarding risks. More impressively, recall at a mean interval of 4.5 months was still 100% for the diagnosis and procedure and was 92.4% and 91.7% for alternatives and risks, respectively.[26] In addition to improved patient recall, the new consent form provided much better documentation of the consent process and hence, better legal protection for the physicians against future claims by patients of inadequate disclosure. Since this study did not include a control group, it is not possible to attribute the authors' success to the new consent form itself, since there are likely many factors that influence patient comprehension in the context of informed consent. Fink, in a multi-institutional study of patients undergoing total hip arthroplasty, carotid endarterectomy, laparoscopic cholecystectomy, or radical prostatectomy, examined 14 variables in an attempt to define independent factors associated with improved patient understanding during the informed consent process. Patients in this study were randomized to one of two consent formats—a standard informed consent discussion or standard discussion supplemented by the "repeat back" technique, wherein the patient, after being appropriately informed about the intended procedure, is asked to describe, in his or her own words, the diagnosis, procedure, anatomic location, the risks, the benefits, and the alternatives to the proposed procedure. Factors independently associated with comprehension in this study included race, ethnicity, education, age, operation type, use of the repeat back technique, and total consent time. Total consent time was the strongest predictor of patient comprehension, with maximal comprehension being achieved when informed consent took between 15 and 30 minutes.[27] Perhaps taking more time for our informed consent discussions is the key to achieving better comprehension in surgical patients, at least in the elective surgery setting. Patients requiring more urgent surgical procedures may not be able to afford this luxury of time, and perhaps other approaches are required in this patient population. This is discussed further below.

Another problematic area in surgical informed consent is determining just how much information a given patient *wants* to know. Earlier in this chapter, we alluded to those elements that a physician should (ethically), and must (legally) disclose to the patient as part of the informed consent process, but do these requirements in any way reflect what patients really want to get out of informed consent discussions? Although very little research has been done in this area, it appears, not surprisingly, that patients are quite heterogeneous when it comes to how much information they want their physicians to divulge in informed consent discussions. Losanoff conducted a study of 98 nonhernia patients from their outpatient clinic, asking them to imagine themselves as patients requiring inguinal hernia repair. They were asked to indicate their level of interest in being informed about several different aspects of hernia surgery, including hernia natural history, pathology, management, complications, and postoperative recovery (Table 60.3) (Although the overall level of interest in this group of patients was fairly high (interest score of 5.5 out of possible 7), there

TABLE 60.3

HERNIA INFORMATION SHEET ("WOULD YOU LIKE TO KNOW ABOUT…")

Information About the Risks for Hernia Formation
- Personal risk factors
- Asymptomatic hernias
- Long-term risk of hernia
- Predisposition to hernias
- Characteristics of hernia

Types of hernias
- Demographics of hernia distribution
- Annual number of hernias repaired in the United States
- Acquired causes of hernia
- Congenital hernias
- Weakness of the abdominal muscles in patients with hernia
- Possible hernia sites

TABLE 60.3

HERNIA INFORMATION SHEET ("WOULD YOU LIKE TO KNOW ABOUT…") (Continued)

Management of Hernia
- Not having the surgery (watchful waiting)
- Possibility of having a "difficult" operation
- Possibility of not undergoing the surgery for medical reasons
- Growth of the hernia in case of watchful waiting
- Possibility of having a strangulation
- Signs and symptoms of strangulation
- Chance for recurrence of the hernia

Hernia Operations
- Hernia surgery in general
- Hospital trajectory during the day of surgery
- Being disrobed and with clipped hairs for the surgery
- Preoperative scrubbing
- Possible urinary catheterization
- Number of incisions
- Types of surgical repair
- Technical details of accessing the site of the hernia
- Prior experience of the surgeon

Anesthesia For Hernia Surgery
- Prior experience of the anesthesiologist
- Type of anesthesia
- Aftermath of anesthesia

Who's Who?
- Who will be around you during the day of surgery?
- Who is going to operate on you?
- Who is going to give you the anesthesia?
- Who are the nurses in the operating room?
- Who are the surgical technicians in the operating room?
- Whether an anesthesiologist or a nurse anesthetist will be providing the anesthesia

Possible Complications
- Specific complications depending on the type of procedure
- Rate of your doctor's intra- or postoperative complications
- Nonsurgical complications related to your procedure
- Complications of anesthesia
- Possible delayed effect of anesthesia
- Postoperative bleeding
- Postoperative infection
- Postoperative retention of urine
- Postoperative intestinal obstruction

Postoperative Management
- Intravenous line for medication
- Asking the nurses for pain medication
- Scarring or tissue loss after surgery
- Ipsilateral postoperative numbness
- Chronic inguinal neuralgia
- Decreased sexual function
- Hernia recurrence

Long-Term Outcome of Laparoscopic *Vs. Open* Repair

From Losanoff JE, Litwinczuk KM, Ranella MJ, et al. Elective inguinal hernia repair: a unified informed consent, or who wants to know what? *Am Surg.* 2009;75(4):29–300.

was substantial variability within the group (range 1.5–7). Patients seemed most interested in details about the operation itself, and about the postoperative period, and least interested in details about hernias in general, and in the identities of the members of the operating team.[28] This latter finding is interesting in light of a recent government recommendation that patients be specifically informed if surgical trainees (residents, students) will be involved in their operations (see following paragraph). The authors also analyzed patient demographics to identify any patterns that might help to predict which patient types might desire more or less preoperative information. Neither patient age or race was predictive of interest in obtaining more information, whereas an advanced level of education (beyond high school) was positively correlated with a desire for more information regarding the technical aspects of the operation, details of anesthetic management, and the number and type of staff present in the operating room. Similar findings were noted in a study by Keulers et al. who, in addition to surveying patients about the issues in which they were most interested in being educated on, also surveyed 24 surgeons to determine what information they thought their patients would be interested in receiving. Physicians not only consistently underestimated their patients' desire for receiving extensive information but also were wrong about the types of information their patients wanted. Patients were much more interested in receiving information about the preoperative period, anesthesia, the operation itself, and the postoperative period, including postdischarge care, than they were about the disease process itself, its cause, and its prognosis. Complexity of the procedure had no impact on the amount or types of information the patients were interested in receiving.[29] These findings underscore the need for surgeons to ensure that the consent process is a true dialogue, where the patient's desire for information is heard and met.

A final problem with the informed consent process is the consent form itself. As discussed above, there is no legal requirement for a patient to sign a consent document prior to undergoing a surgical procedure. The purpose of the form is to simply provide documentation that the informed consent process has been carried out appropriately, although even a perfectly executed consent document may not necessarily provide legal protection to the physician should the patient bring suit on the grounds of inadequate disclosure. Consent forms, however, have become synonymous with the consent process itself, and paradoxically, neither physician nor patient may actually know what is contained within the form that both parties must ultimately sign. Until recently, there was considerable latitude in the content of informed consent forms for surgery, resulting in widely disparate amounts of information being transmitted, captured, and documented. Issa reviewed 204 consent forms for 2 urologic procedures (transurethral resection of the prostate, radical prostatectomy) carried out over a 6-year period of time at the Atlanta VA Medical Center. Information on the purpose and benefits of treatment was missing in 4.4% of forms, and deficient in 22.6%. Operative risks were poorly documented as well; risk of death was documented only 62% of the time, while bleeding, infection, and deep venous thrombosis were documented in only 31%, 31%, and 1% of forms, respectively. No documentation was present on any of the forms regarding the risk of pulmonary embolus. Alternative treatment options were missing in 49% of forms and significantly deficient in the remaining 51%.[30] This study exposes some very serious flaws in the documentation phase of the informed consent process, but does not identify the source of the problem. Are the physicians simply failing to fill in completely a perfectly adequate consent form, or is the consent form itself inadequate? The answer is probably both. Bottrell graded 540 different consent forms from 157 hospitals nationwide to determine whether the forms incorporated the four

basic elements of informed consent (nature of the procedure, risks, benefits, and alternatives). Only 26% of forms included all four basic elements, 35% contained three elements, 23% included two elements, 14% contained only one element, and 2% of forms included none of the four elements. Most documents, it appeared, existed to authorize treatment or to protect hospitals and caregivers from liability, as opposed to providing the patient with information that might be useful in decision making.[31] It is clear that a sizeable gap exists between the content of a good informed consent discussion and the content of most informed consent documents currently in use. Perhaps due to this fact, CMS (Centers for Medicare and Medicaid Services), in 2007, issued revised guidelines for informed consent documents.[32] Some of the more notable directives contained within these revisions include the following:

- A properly executed informed consent form should reflect the patient consent process.
- Except as specified for emergency situations in the hospital's informed consent policies, all inpatient and outpatient medical records must contain a properly executed informed consent form prior to conducting any procedure or other type of treatment that requires informed consent.
- A properly executed informed consent form contains … [a] statement that the procedure or treatment, including the anticipated benefits, material risks, and alternative therapies, was explained to the patient or the patient's legal representative; hospitals are free to delegate to the responsible practitioner the determination of which material risks, benefits, and alternatives will be discussed with the patient.
- A well-designed informed consent form might also include the following additional information:

  - Name of the practitioner who conducted the informed consent discussion with the patient or the patient's representative
  - Indication or listing of the material risks of the procedure or treatment that were discussed with the patient or the patient's representative
  - Statement, if applicable, that physicians other than the operating practitioner, including but not limited to residents, will be performing important tasks related to the surgery, in accordance with the hospital's policies and, in the case of residents, based on their skill set and under the supervision of the responsible practitioner
  - Statement, if applicable, that qualified medical practitioners who are not physicians who will perform important parts of the surgery or administration of anesthesia will be performing only tasks that are within their scope of practice, as determined under State law and regulation, and for which they have been granted privileges by the hospital

Including all of this information on the informed consent document will not achieve the purpose intended by CMS regulations—to educate the patient—if the form is not understandable to the patient or, worse yet, if the patient doesn't actually read the form. These forms should be written on a 12-year-old (seventh grade) reading level[7], but very few actually are.[33,34] And the study by Lavelle-Jones et al.[25] cited above found that 69% of their general surgery patients admitted to not reading the consent form before signing it. Electronic consent forms that allow patients to move through and digest the educational material at their own pace have been shown to improve patient comprehension, and the interactive nature of these programs can serve to document the requisite level of comprehension, thereby providing a greater degree of medical–legal protection to the physician.[5] Unfortunately, these are not in widespread use in the United States currently. Procedure-specific or practice-specific consent forms, as discussed above, have also been suggested as better methods of transmitting the information necessary to the patient for decision making, and better methods of documenting the informed consent process, but still may suffer from the "readability" issue and provide no proof that the patient has actually read the form or understands what he or she has read.[26,30]

INFORMED CONSENT IN ACUTE SURGICAL PRACTICE

Similar Principles: Different Process

Acute care surgeons must not fall into the trap of thinking that the informed consent process can be waived for *all* acute surgical procedures. As emphasized previously, this exemption can only be invoked under those circumstances where the delay required to obtain consent would pose an unacceptable risk to the patient's life or well-being. Surgeons should not rely upon this exemption to defend against a failure-to-disclose legal action, since the courts have tended to use a rather narrow definition of "life-threatening." In *Jackovach v Yocom*, a 17-year-old boy suffered a crushed elbow joint and a profusely bleeding scalp laceration when he jumped from a moving train. The boy was subsequently taken to the operating room to stop the bleeding from the scalp wound and, while under anesthesia, the physicians determined that the boy's arm needed to be amputated because of the immediate danger it posed to his life. After the arm was amputated, the boy and his parents brought a suit against the physicians, claiming that the procedure was performed without their informed consent. In holding for the defendant physicians, the court noted that terminating the operation in order to obtain informed consent from the boy's parents would have subjected the patient to greater risk of shock because of a necessary second anesthetic induction.[15] In contrast, in *Rogers v Sells*, the court found that a defendant physician was liable for not obtaining parental informed consent before amputating a 14-year-old boy's foot following a car accident. The physician had described the extremity as "crushed and mangled…the muscles, blood vessels, and nerves were torn and some of the nerves severed, and…the foot had no circulation." However, testimony indicated that neither life-threatening ischemia nor bleeding were present at surgery. Therefore, the court held that the situation was not an emergency with the danger of immediate harm and that the physician had an obligation to obtain informed consent.[35] Recent advances in trauma, specifically the damage control philosophy, might obviate the need for such difficult intraoperative decision making for today's practicing trauma surgeon. However, the vastly different court decisions arrived at in these two very similar clinical circumstances should serve as a strong reminder to all surgeons to consider very carefully whether a true emergent situation exists before invoking the emergency exemption to informed consent.

The intensive care unit (ICU) is another venue where a patient's informed consent rights might be inappropriately or inadvertently overlooked in the name of providing "life-saving" care. As inconvenient or inefficient as it may be, informed consent must be sought from the patient or, more likely in the ICU, the patient's surrogate unless a true-life-threatening emergency exists. Unfortunately, there are no universally accepted definitions of "medical emergency," and therefore, what constitutes an emergency is left to physician judgment. That judgment, however, is reviewable by the courts, and the physician's decision may be overruled,[14] as nearly occurred in *Liguori v. Elmann, Hunter*, et al.[36] In this case, the patient, in the course of recuperating from coronary bypass surgery, developed a large pneumothorax. A chest tube was placed approximately

30 minutes later by a surgical resident without first obtaining informed consent from the patient's family. Shortly thereafter, it was discovered that the chest tube had lacerated the patient's heart, a complication that ultimately led to the patient's demise. A wrongful death suit was brought by the patient's family, claiming, among other things, that the patient had been denied her rights to informed consent and that they would have not authorized the procedure had they known it was being performed by a surgical resident. The physician defendants prevailed, based upon the "emergency exemption" to informed consent, but the case was appealed several times, ultimately to the level of the state's Supreme Court, arguing that that since the chest tube had not been placed until 30 minutes after the diagnosis of pneumothorax was established, that the circumstances did not meet the criteria of a true life-threatening emergency, and that the courts "should instead adopt a rule of law that would require physicians to secure consent, even in the context of a medical emergency, unless it is truly impossible." Ultimately, the Supreme Court found for the physicians, writing, "Although some emergencies might well present physicians with sufficient time to seek consent, we decline to adopt plaintiffs' rigid formulation of the circumstances in which their failure to do so would be permissible."[37] Some have proposed a "blanket consent" approach for ICU procedures, wherein a single consent form would be sought from the patient or the patient's surrogate for several common ICU procedures (central venous lines, arterial catheters, chest tube placement, blood transfusion, etc.).[38] Such an approach would obviate the need to enter into a separate informed consent discussion each time one of these common ICU procedures was required. Others, however, have criticized this approach as being ethically unsound, since it denies the patient (or surrogate) the detailed risk/benefit/alternative information he or she is entitled to and needs in order to make a truly informed decision about the proposed procedure.[39] Since the vast majority of acute care surgical procedures do not qualify for the informed consent emergency exemption, the acute care surgeon must be knowledgeable about the informed consent process in general, and how the process may need to be modified for patients with acute surgical conditions.

The core informed consent principles outlined above for elective surgical patients apply equally to patients with acute surgical conditions, but the process may need to be altered for acute care surgical patients to accommodate the unique needs of this patient population. Decision making in acute care surgery, by the patient and by the physician, must be, by definition, much more rapid, and less deliberate, a major difference from elective surgery patients. The ideal 15–30 minute informed consent discussion alluded to above, carried out in the outpatient setting, with the opportunity for the patient to go home, consult with friends and family, search the Internet, deliberate further, and then change his or her mind about having the operation, is a scenario that is simply not available to the patient in need of an urgent operation. In addition, the presence of severe acute pain, and the sedative and judgment-altering effects of analgesics may impair the acute care surgical patient's ability to participate fully in an informed consent discussion. The surgeon may not be able to devote the amount of time needed by the patient or family for the consent process due to other pressing demands on the surgeon's time, or due to the patient's physiologic instability, and need for urgent surgery. And even if adequate time does exist, complete disclosure by the surgeon may not be possible since the full extent of the patient's pathology (and hence the intervention required) may not be known to the surgeon until the operative procedure is under way. For all of these reasons, both patients and physicians undertaking informed consent discussions for acute surgical procedures are at a distinct disadvantage compared to their counterparts in elective surgical scenarios. Several

studies, across a number of surgical disciplines, including trauma, illustrate the difficulties encountered in adapting the informed consent process to patients with acute surgical conditions. Oburo conducted postoperative interviews with 28 elective orthopedic surgery patients and 21 orthopedic trauma patients to determine any qualitative difference in the consent process.[40] All elective orthopedic surgery patients understood the nature of their operation compared to only 71% of the orthopedic trauma patients. 86% of the elective patients were knowledgeable about the possible complications of the operation, whereas only 48% of the trauma patients were familiar with this information. Only 57% of elective patients and 29% of the trauma patients had actually read the consent before signing it. All elective surgery patients had received a pamphlet preoperatively, outlining the proposed operation and its risks, whereas none of the trauma patients had access to this information. In addition, trauma patients had less contact preoperatively with senior surgeons than did elective patients and so, may not have been as completely informed about their impending surgery as were the elective patients. Finally, some trauma patients felt as if they had no choice but to sign the consent form given the circumstances of their injury. This may explain why so few of these patients actually read the consent form, since they had already resigned themselves to signing the form regardless of its content

Bhangu interviewed 41 consecutive elective orthopedic surgery patients (primarily total hip and total knee replacement) and 40 consecutive orthopedic trauma patients (primarily femur fracture) on their first postoperative day to assess the quality of the consent process[41]. Statistically significant differences were noted between the elective and the trauma patients in several different categories: knowledge of the operation performed (100% vs. 90%), recall of complications (62% vs. 22%), percentage of patients desiring more detailed information about their operation (12% vs. 30%), and the percentage of patients who wanted written information included in the preoperative consent discussion in addition to the verbal explanation (85% vs. 35%). Overall, 100% of the elective patients were happy with the consent process compared to only 90% of the trauma patients

Vessey and Siriwardena[42] carried out postoperative interviews on 49 patients who had undergone recent "urgent" abdominal surgery to determine the impact of pain and preoperative analgesia on informed consent comprehension. "Urgent" surgery was defined as "a procedure performed for a suspected acute abdominal condition where operation could not be deferred and was generally (but not exclusively) performed within 48 hours of admission." Even though all 49 patients had signed the consent document, one-third felt that preoperative pain had impaired their judgment to the point where they could not truly give informed consent, and 13% felt that preoperative analgesics had interfered with their ability to participate fully in an informed consent discussion. Sixteen percent of patients stated that inadequate exposure to, and disclosure by, the surgeon preoperatively impaired their ability to provide informed consent. Fifteen percent of patients claimed that they had not understood preoperatively why an operation was being performed, citing pain and insufficient time with the surgeon as the causative factors. Fifty-seven percent of patients stated that they had not been informed about any of the risks of, or potential complications from, the surgery, not because of pain or insufficient time with the surgeon preoperatively, but rather because the surgeon simply did not offer this information. A follow-up study performed at the same institution yielded very similar results.[43]

The largest emergency informed consent analysis to date was performed by Akkad and coworkers, who compiled 734 questionnaires received from patients undergoing either elective or emergency gynecologic surgery.[44] As in other studies,

emergency surgery patients were more likely to have *not* read the consent form (49% vs. 17%) and if they had read the form, not to have understood it (51% vs. 29%). In both groups, the two most common reasons for not reading the consent form were having had "a verbal explanation," and "trust in the doctor," but patients in the emergency group were significantly more likely to report "feeling too ill" or "not being given a chance" to read the form (Table 60.4). There were also major differences in the physical and emotional conditions of the two patient groups at the time of signing the form, with 69% of emergency patients experiencing pain, or feeling "unwell, drugged, tired, or exhausted," compared to only 19% of the elective patients (Table 60.5). Emergency patients were more likely to feel as though they had no option but to sign the consent form (40% vs. 24%), and 37% of emergency patients stated they would have signed the form no matter what was on it, compared to only 15% of elective patients. Having an opportunity to ask questions of the surgeon appeared to be important to all patients, but emergency patients were much less likely than elective patients to have been given this opportunity (29% vs. 11%). Overall, elective surgical patients were more satisfied with the consent process (80%) than were emergency patients (63%). The authors also gathered information regarding those factors associated with a positive informed consent experience. Compared to the elective surgery patients, the emergency surgery patients were less interested in detailed operative information but preferred to have the consent form read to them (as opposed to reading it themselves).

What can be learned from these studies in acute care surgical patients, and what can be done to improve the consent process for these patients? Overall, acute care surgical patients

- Are less content with the overall consent process
- Have less access to materials that might aid comprehension
- Have poorer comprehension of the intended surgical procedure and its risks
- Are less likely to have been offered information about risks
- Are less likely to have read the consent form
- Are more likely to want more detailed information
- Are more likely to want consent information *read to* them

- Are less likely to have been given the opportunity to ask questions of the surgeon
- Are more likely to have IC process impaired by pain, analgesia, or by insufficient time with the surgeon

Recognizing these fundamental differences in the acute care surgery patient population is the key to crafting an informed consent process that successfully addresses these shortcomings. While the constraints of time imposed by the nature of acute surgical illness may not allow as full a disclosure as elective surgical patients receive, acute care surgical patients can, and should, be made to feel comfortable about consenting to surgery. Tailoring the informed consent discussion to the information the patient thinks is important, rather than relying on a consent form (that the patient will likely not read) to educate the patient should be the focus of the informed consent discussion. This requires first discerning from the patient what he or she understands about the nature of the illness, and what needs to be done to remedy the situation. This will help the surgeon to identify gaps in the patient's knowledge base that will need to be filled in before the patient can fully participate in the consent process. In addressing these knowledge gaps, it may not be possible, nor advisable, to provide as detailed and comprehensive an accounting of all of the risks, benefits, and alternatives as might be provided to an elective surgical patient undergoing the same procedure, but certainly any information that the surgeon thinks might possibly impact the patient's decision making must be disclosed. Some have proposed providing the patient with just the minimal amount of information necessary at this stage, and then supplementing that information with more detailed discussions in the postoperative period.[2,4,14,45] Asking then the patient to repeat back to the surgeon, in his or her own words, the purpose of the proposed operation, its major risks, and complications should provide the surgeon with additional insight into the patient's level of understanding of the situation and point out the need for further clarifications if warranted. The use of audiovisual and computer-based educational strategies may provide for increased patient comprehension and retention of important information, but their role in emergent surgical situations has

yet to be elucidated.[10,46] Finally, the patient must be given an opportunity to ask any questions he or she might have, providing yet another opportunity to the surgeon to discern the patient's level of understanding of the situation, and the capacity of the patient to provide true informed consent. Once all questions have been answered to the patient's satisfaction, the consent form, if required by the medical facility, can then be offered for the patient's (or surrogate's) signature, as well as for the signature of a witness, who ideally has been present for the entire informed consent discussion. All major risks and complications that have been discussed with the patient should be listed on the consent form, and a copy of the form given to the patient after all parties have signed it. This provides an opportunity for the patient to review the form after surgery if desired, particularly if the patient chooses not to read the form preoperatively. Additional questions that occur to the patient in the postoperative period after reading the consent form can be addressed with the surgeon at that time in a less pressured environment.

CONCLUSION

Informed consent refers to a *process* wherein a physician provides to a competent patient sufficient information about the nature of the proposed intervention, its risks, benefits, and alternatives, to enable the patient to a make an informed decision about whether that intervention is in his or her best interest. As such, it is much more than obtaining a patient's signature on the consent form, and therefore, this important task should not be undervalued, or relegated to individuals (nurses, residents) who may not be as knowledgeable as is the physician concerning the details of the proposed intervention. Furthermore, since the ethical and legal underpinnings of informed consent vary across state lines and between institutions and continue to evolve over time, it would behoove all physicians to become familiar with those guidelines and regulations that could well have a direct impact on their practices. For the acute care surgeon, the informed consent process need not necessarily be altered or truncated in any way for patients requiring urgent or emergent surgical procedures unless the delay incurred in obtaining informed consent poses an immediate threat to the patient's life or well-being. The acute care surgeon should, however, recognize that pain, anxiety, sedatives and analgesics may impair the ability of the acute care

surgical patient to participate fully in informed consent discussions, and therefore, the consent process may need to be tailored to fit these unique circumstances. This may entail a more limited, but also more focused, discussion of the major risks and benefits, less reliance on written materials, or even turning to a patient surrogate to obtain consent. Most importantly, providing sufficient opportunity and time for all of the patient's questions and concerns to be addressed not only leads to greater patient satisfaction, but also allows the surgeon an additional opportunity to assess whether the patient actually comprehends the circumstances and the intervention to which he or she is about to consent.

CHAPTER 61 ■ ADVANCE MEDICAL DIRECTIVES

GRACE S. ROZYCKI AND WILLIAM R. SEXSON

Advances in medical care have led to life-saving interventions, but extending a patient's life in a severely compromised state may be associated with unnecessary suffering and burdensome financial consequences for the patient, family, and society. Additionally, depending upon the patient's clinical condition, prognosis, and social circumstances, the patient may not desire certain interventions, especially those that will prolong the dying process. Providing the best, yet appropriate care for a patient near the end of life requires planning and the input of multidisciplinary caregivers within the context of medical ethics principles.

Advance care planning is the process by which a patient, along with his or her physician, family members, or other close personal relations, plans for future medical care.[1] Engaging in this process eventually leads to a document called an "advance care directive" or "advance medical directive." This document provides vital information to help the patient, family, and health care provider converge on a plan to enhance the quality of end-of-life care for the patient. Although advance medical directives are not an end in themselves, they delineate the patient's preferences for medical care within a spectrum of reasonable clinical options.[1] This chapter discusses the basic terminology and evolution of advance care planning and highlights the relevant issues that the patient, physician, and family encounter when developing an advance medical directive. Also, this work discusses how the unique environment of the intensive care unit (ICU) and the unexpected medical crisis add a level of complexity to the implementation of an advance medical directive.

TERMINOLOGY

The principles of medical ethics that are most related to advance care planning include those of autonomy, informed consent, and beneficence. An understanding of these terms is important so that a quality advance medical directive can be produced that will empower the patient at the end of life (Table 61.1).

Autonomy

The principle of autonomy recognizes the rights of individuals to self-determination, that is, their ability to make informed decisions about personal matters. Over the past several decades, there has been a shift from the paternalistic physician–patient model to a more autonomous role of the patient.[3] In the paternalistic model, the physician presents selected information about an intervention or plan and encourages consent based on what the physician considers best for the patient.[3] This model is most appropriate during medical emergencies when the risk of delaying treatment to obtain informed consent outweighs the benefit to the patient. But, in nonemergent circumstances, the paternalistic model may not produce the most beneficial outcome for the patient as the physician and patient may have different values and hence, dissimilar goals of care. In contrast, the autonomous

physician–patient model emphasizes the concept of the patient's control over medical decision making. When the patient uses this model to express his or her desires about medical care, the best outcomes are expected if the patient has the capacity to understand the relevant medical facts and takes responsibility for his or her actions.[4] In either model, mutual trust between the physician and the patient is the cornerstone of the relationship and the patient's autonomy is best respected when decision making takes place with open communication and informed consent.[5]

Informed Consent or Informed Decision Making

This principle refers to the patient having an understanding of the medical care or intervention and its risks and benefits. Essentially, informed consent includes the information given and the consent of the patient.[6] But, for informed consent to be effective, the patient must be competent and able to make a decision without coercion.[7] Adults are presumed to be competent, and the term implies that the decision maker is capable of understanding and retaining relevant information and then formulating and communicating a choice. Only when sufficient understanding is present can the patient assess the options and make a decision that reflects his or her values and desires. The elements of informed consent are listed in Table 61.2. Although the physician is obligated to provide information about the risks and benefits of the procedure and those of the alternative options, patients should be encouraged to ask questions, to think carefully about their choices, and to be forthright with their physicians about their goals, values, concerns, and reservations.[8]

Beneficence

As a fundamental principle of medical ethics, beneficence deals with actions that best serve the interest of patients. In general, these actions involve the restoration of health and the relief from suffering. Restoring health may not be a reasonable goal in all cases, especially for the patient who is near the end of life but, the relief from suffering usually is attainable. Beneficence should be an integral part of a physician's practice and actions taken should be in concert with the patient's values and desires.

Communication. Clear communication lies at the heart of good decision making. In one recent review, communication problems were found in 25 of 31 cases referred for ethics consultation.[9]

For example, the comment by a physician that a condition is "treatable" may be heard by the patient or family as the condition is "curable." Similarly, a surgeon may tell a patient's family that a cardiac anomaly is "fixable" but fail to mention that the patient's congenital heart disease is due to a chromosomal anomaly. Another frequently used and misunderstood term is that a patient has a "poor prognosis." Physicians use

SPECIAL TOPICS

TABLE 61.1

TERMINOLOGY RELATIVE TO ADVANCE CARE PLANNING

■ TERM	■ DEFINITION
1. Advance health care directive or advance medical directive	A written instructional health care directive and/or appointment of an agent, or a written refusal to appoint an agent or execute a directive.
2. Agent	An individual designated in a legal document known as a power of attorney for health care. Makes health care decisions for the individual who granted the power. The agent is also referred to as durable power of attorney for health care or health care representative.
3. Instructional health care directive	A "living will." A written directive describing preferences or goals for health care, or treatment preferences or willingness to tolerate health states. Its purpose is to provide information to guide future health care.
4. Advance care planning	The process of discussing, determining and/or executing treatment directives and appointing a proxy decision maker.
5. Surrogate	Proxy by default; a person who, by default, becomes the proxy decision maker for an individual who has no appointed agent.
6. Capacity	An individual's ability to understand the significant benefits, risks, and alternatives to proposed health care and to make and communicate a health care decision. The term is frequently used interchangeably with competency, but is not the same. Competency is a legal status imposed by the court.
7. Minimally conscious state	A neurologic state characterized by inconsistent but clearly discernible behavioral evidence of consciousness and distinguishable from coma and a vegetative state by documenting the presence of specific behavioral features not found in either of these conditions.
8. Palliative care	Also called "comfort care," a comprehensive approach to treating serious illness that focuses on the physical, psychological, and spiritual needs of the patient. Its goal is to achieve the best quality of life available to the patient by relieving suffering, controlling pain and symptoms, and enabling the patient to achieve maximum functional capacity. Respect for the patient's culture, beliefs, and values is an essential component.
9. Permanent vegetative state	A vegetative state is a clinical condition of complete unawareness of the self and the environment accompanied by sleep–wake cycles with either complete or partial preservation of hypothalamic and brainstem autonomic functions. The persistent vegetative state is a vegetative state present at 1 month after acute traumatic or nontraumatic brain injury, and present for at least 1 month in degenerative/metabolic disorders or developmental malfunctions. A permanent vegetative state can be diagnosed on clinical grounds with a high degree of medical certainty in most adult and pediatric patients after careful, repeated neurologic examinations by a physician competent in neurologic function assessment and diagnosis. A patient becomes permanently vegetative when the diagnosis of irreversibility can be established with a high degree of clinical certainty, that is, when the chance of regaining consciousness is exceedingly rare.
10. Patient Self-Determination Act	An amendment to the Omnibus Budget Reconciliation Act of 1990, the law became effective December 1991 requiring most United States hospitals, nursing homes, hospice programs, home health agencies, and health maintenance organizations to provide to adult individuals, at the time of inpatient admission or enrollment, information about their rights under state laws governing advance medical directives, including: (1) the right to participate in and direct their own health care decisions; (2) the right to accept or refuse medical or surgical treatment; (3) the right to prepare an advance medical directive; and (4) information on the provider's policies that govern the utilization of these rights. The act prohibits institutions from discriminating against a patient who does not have an advance medical directive. The Act further requires institutions to document patient information and provide ongoing community education on advance medical directives.

this term when death is inevitable, but the subjectivity of the term makes it almost meaningless to the patient and the family. Difficulty with communication can also be rooted in the reading or comprehension level of the patient. The average reading level of adults in the United States is approximately at the eighth-grade level.[10] Mueller et al. reviewed advanced directive forms from all 50 states. Using the Flesch-Kincaid scoring system to assess the average readability of these forms, they found them to be at the eleventh-grade level and only five states had forms with readability at the eighth-grade level or lower. Hence, many patients may not be able to comprehend the information being presented in the form and this may explain, in part, why advanced directives are commonly not completed.

TABLE 61.2

ELEMENTS OF INFORMED CONSENT

- Assessment of decision-making capacity
- Understanding of the diagnosis
- Understanding of the proposed procedure or intervention
- Understanding of the alternatives to the proposed procedure or intervention
- Understanding of the risks and benefits of each of these
- Ability to form a reasoned opinion based on this understanding
- Ability to express the desire for or against the proposed procedure or intervention

THE EVOLUTION OF ADVANCE CARE PLANNING

History

Based on the nationally recognized inherent right of self-determination, the law requires the physician to obtain the patient's consent for invasive medical procedures. But, as medical technology advanced, it became clear that these tools had the potential to sustain life regardless of its quality. Patients' rights advocates became concerned about this issue and by the 1960s, the "living will" was developed in an attempt to address the negative impact of futile life-sustaining treatments.[11] As the earliest form of an advance medical directive, the living will was designed to empower individuals to make medical decisions at the end of their lives. Subsequently, on November 5, 1990, Congress passed the Patient Self-Determination Act.[2] This law was in response to the United States Supreme Court case Cruzan v Director, Missouri Department of Health and Human Services.[12] Ms. Cruzan sustained a severe traumatic brain injury in 1983 following a motor vehicle crash and remained in a persistent vegetative state for years. Her parents asked that their daughter's enteral nutrition be discontinued and after several years in litigation, the case went to the United States Supreme Court. They ruled that individual states had the right to determine the requirements for surrogate decision making regarding life-sustaining therapy. In response to this ruling, Senator Danforth of Missouri sponsored the Patient Self-Determination Act, which became law on December 1, 1991. The purpose of the Patient Self-Determination Act was to give patients the right to make decisions regarding their medical care, including the right to accept or refuse treatment, and to make an advance medical directive. The law requires all Medicare-certified hospitals to ask a patient whether he or she has an advance medical directive and to make the forms available to those who do not have one. The Patient Self-Determination Act acknowledged that the patient had the right to accept or refuse treatment but also protected the physician from litigation in the end-of-life decision making for the patient.[2] Currently, advance care planning is recognized throughout the United States as a way to identify preferences for life-sustaining care when patients no longer have decision-making capacity.

Advance Medical Directives

Advance care planning constitutes the activities that lead to the development of an advance care directive. This planning process includes deciding about future health care decisions, the exploration of treatment goals, and reflection on a patient's personal values and beliefs. The process as a whole was developed to ensure patient autonomy at the end of life through the production of a document known as the "advance medical directive."[11,13] Hence, through the planning process and the generation of the advance medical directive, the patient's autonomy can be translated into treatment decisions made by physicians and families on behalf of the incapable patient.

The methods by which an individual can indicate how treatment decisions will be made in the event of loss of decision-making capacity are the development of a living will, the appointment of a proxy, or through both of these mechanisms.[14] Hence, the living will and the proxy are two distinct methods to safeguard autonomous choice. Most states have living will statutes that provide that a person's directives regarding the use of artificial life support will be honored.[15] Patients may write their own living wills or use a template that is available at their state's living will statute web site.[16] Through the living will, the patient dictates the types of medical interventions and the conditions under which they should be used. In general, the living will becomes effective when the patient becomes incompetent yet the question remains as to whether it should guide almost all medical practice. Hence, there are some valid concerns about the generation, revision, and use of a living will.[17,18] For example, patients may be concerned that the decisions they make when the living will is created will be binding even if their values and interests change. This concern is understandable as patients in a stage of advanced illness may lack decision-making capacity and are no longer able to communicate these changes. If the living will is crafted with a narrow focus or with language that is too specific, it lacks the flexibility to address unanticipated medical or social circumstances that may arise in the future. Alternatively, if it is fashioned in a very general language, it may be too ambiguous and therefore not be useful to the patient or to the physician. For example, some documents have language such as, "terminal condition," or "seriously incapacitated" leaving the interpretation of such phrases to the physician's judgment. If the patient has had a discussion with the physician, then this ambiguity may be useful. If this discussion has not occurred, then the ambiguity may lead to uncertainty as to what course to follow. Another drawback of the living will is that as patients formulate this directive, even if done with the aid of a medical professional, most will have a limited understanding about the risks and benefits of current and future medical treatments and how they may apply to the patient's condition. Therefore, the patient, family, and caregivers need to recognize that the living will has practical limits on its use and cannot encompass all circumstances. Nonetheless, physicians should encourage patients to write a living will and to ensure that it is available to their families. Patients should also be encouraged to review the document annually or whenever a significant change occurs in their health status or family relationships.[19] For further clarification on some of the legal issues surrounding this topic, the American Bar Association's Commission on Law and Aging offers information for the lay person about the myths and facts regarding advance medical directives (Table 61.3).

Another alternative to the living will or a directive that works hand-in-hand with it is the designation by the patient of a proxy decision maker. The proxy may be a family member, friend, or other person who has the authority to make medical

TABLE 61.3

MYTHS AND FACTS ABOUT HEALTH CARE ADVANCE DIRECTIVES

■ MYTH	■ FACT
1. You must have a Living Will to stop treatment near the end of life.	Treatment can be stopped without a Living Will if everyone involved agrees. However, without some kind of advance directive, decisions may be more difficult and disputes more likely. The Durable Power of Attorney for Health Care is the more useful and versatile advance directive, because it applies to all health care decisions and empowers the person you name to make decisions for you in the way you want them made.
2. You must use your state's statutory form for your advance directive to be valid.	Most states do not require a particular form, but do require witnessing or other specific signing formalities. Even if your state requires a specific form, doctors still have a legal obligation to respect your treatment wishes, regardless of the form you use.
3. Advance directives are legally binding, so doctors must follow them.	Advance directive laws merely give doctors and others immunity if they follow your valid advance directive. Doctors can always refuse to comply with your wishes if they have an objection of conscience or consider your wishes medically inappropriate. However, they may have an obligation to transfer you to another health care provider who will comply.
4. An advance directive means "Do not treat."	An advance directive can express both what you want and don't want. Never assume it simply means "Do not treat." Even if you do not want treatment to cure you, you should always be kept reasonably pain free and comfortable.
5. If I name a health care proxy, I give up the right to make my own decisions.	Naming a health care proxy or agent does not take away any of your authority. You always have the right, while you are still competent, to override the decision of your proxy or revoke the directive. If you do not name a proxy or agent, the likelihood of needing a court appointed guardian grows greater, especially if there is disagreement regarding your treatment among your family and doctors.
6. I should wait until I am sure about what I want before signing an advance directive.	No. Most of us have some ambivalence about what we would want, and that's acceptable, because treatment near the end of life can be complicated. We can't predict all the facts and circumstances that may face us in the future, and treatment wishes may change. You can, at least, appoint your proxy if you have someone whom you trust.
7. Just talking to my doctor and family about what I want is not legally effective.	Meaningful discussion with your doctor and family is actually the most important step. The question of what is "legally effective" is misleading, because even a legally effective document does not automatically carry out your wishes. The best strategy is to use a good health decisions workbook to help you clarify your wishes; talk with your physician, health care agent, and family about your wishes; put those wishes in writing in an advance directive; and make sure everyone has a copy.
8. Once I give my doctor a signed copy of my directive, my task is done!	No, you have just started. First, make sure your doctor understands and supports your wishes. Second, there is no guarantee that your directive will follow you in your medical record, especially if you are transferred from one facility to another. You or your proxy should always double-check to be sure your providers are aware of your directive and have a copy. Advance planning is an ongoing PROCESS. Review your wishes yearly or anytime your health or family status changes, make appropriate changes, and communicate those changes as needed.
9. If I am living at home and do not want to be resuscitated by an EMS team if my heart or breathing stops, my advance directive must say so.	Your advance directive will usually not help in this situation. If someone dials 9–1–1, EMS must attempt to resuscitate you and transport you to a hospital, UNLESS you have a special out-of-hospital DNR form or bracelet used in your state. This is not the same as your health care advance directive. In most states, both the patient and doctor must sign the special form and the patient then wears a special identification bracelet or necklace.
10. Advance directives are only for old people.	It is true that more older, rather than younger, people use advance directives, but every adult should have one. Younger adults actually have more at stake, because, if stricken by serious disease or accident, medical technology may keep them alive but insentient for decades

Myths and Facts About Health Care Advance Directives. Available at: http://www.abanet.org/aging/pdfs/myths_and_fact_about_ HC_AD.pdf. Accessed April 19, 2010.

decisions for the patient. By understanding the patient's values, the proxy approaches medical decision making in accordance with the patient's desires and intents.[21,22] This process is commonly referred to as decision making by "substituted judgment." By appointing a proxy, there is less concern about the specificity or generality of the living will as the proxy will make medical decisions for the patient based on the patient's desires. A proxy may be appointed under a living will statute or through the creation of a durable power of attorney. In some states, the living will statute may restrict a proxy's authority to making health care decisions only in the setting of select clinical conditions such as terminal illness.[23] But, a proxy appointed as a durable power of attorney for health care has more authority and can take legally binding action on the patient's behalf. In this case, the proxy, also known as the "agent," can be a lawyer, family member, friend, or any competent adult. The durable power of attorney for health care has more authority than the living will or the proxy. For example, the durable power of attorney can be used to delegate authority for health care decisions in all cases of patient incompetence.[23] Also, the physician is able to rely on the agent's decision even when the patient's desires were not clearly expressed or did not take into account unforeseen circumstances. Although these advance medical directives are not without their drawbacks, they do provide some guidelines for the physician who needs to make difficult decisions about the care of critically ill patients with little or no chance of recovery.

To that end, the physician should plan to have an early dialog with patients about artificial life support and their treatment preferences. Despite the broad-based support for advance medical directives, few patients have them. Only about 25% of Americans have completed advance medical directives, yet studies indicate that most patients want a formal document regarding future health care and that they prefer to obtain that information from their physician.[24,25] Although this is time-consuming for physicians, studies show that one-on-one intervention with patients and brief episodic discussions seem to be the most effective strategies to increase the completion rates of advance medical directives.[26–28]

Table 61.4 lists the most common barriers to advance care planning. Discussions about advance medical directives should be rooted in the patient's values and goals for medical care, as well as the appropriateness of specific interventions. Effective measures to initiate these discussions include community education efforts and the provision of resources for the patient.[30,31] The physician can be directly instrumental in providing information such as, sample drafts of living wills, clarification of terminology, and web links where the patient can seek more information on the topic[32,33] (Table 61.5). Patients may desire more information on the ethical and legal aspects of withholding and withdrawing of life-sustaining treatments as this has been cited to be a point of confusion for patients as they develop an advance medical directive.[34] An example of a useful workbook is "Your Life, Your Choices, Planning for Future Medical Decisions: How to Prepare a Personalized Living Will."[35] This manual is a step-by-step guide that walks the patient through the process of advance care planning. Using some thought-provoking exercises and poignant questions, the authors provide useful information about the process of developing an advance medical directive including a section on how patients should articulate their desires and values to their physicians.

During an office visit, the topic of advance medical directives can be introduced in a nonthreatening way by simply asking the patient if he or she has a living will or has formally appointed a health care proxy.[24] The patient should know that advance medical directives can be revised or revoked while the patient is still competent, and that they will be implemented only when the patient is incapacitated and unable to participate in medical decision making. Understanding a patient's values is an important part of the dialog as this information will strongly influence the overall content of the document and the approach that the physician uses during a medical crisis. The importance of addressing the patient's values was highlighted in a prospective study conducted in five outpatient primary care practices in North Carolina and Pennsylvania.[36] The authors' audiotaped discussions between patients and their physicians about advance medical directives. During the discussions with their patients, all of whom were ≥65 years of age, the 56 physicians covered topics such as potential medical scenarios and their treatments, patient values, and surrogate decision makers. The authors found that the physicians covered the key areas of uncertainty and proxy well but, only 34% of them explicitly elicited information about the patient's personal values, goals for care, and reasons for

TABLE 61.4

BARRIERS TO ADVANCE CARE PLANNING

1. **Reluctance to discuss the issue.** Physicians may be reluctant to tell a patient that he or she is approaching the end of life. The patient may be in denial about their medical condition and therefore not receptive to hearing the information.
2. **Procrastination.** Patients in good health may find the discussion irrelevant.
3. **Time constraints.** End-of-life discussions with patients and families are time-consuming as they tend to be open-ended and ill-defined.
4. **Misunderstanding regarding resuscitation preferences.** Patients may not understand medical terminology and medical technology. Further, future medical technology and its applications are unknown.
5. **Unrealistic expectations.** Public awareness of CPR is promoted, but a parallel education about futile applications is not emphasized.

SPECIAL TOPICS

treatment preferences. The importance of this study was that it underscored the need for physicians to adhere to standard recommendations when discussing advance medical directives with patients so that the information obtained will be useful in future decision making. To ensure that the crucial components of advance medical directives are addressed, some authors recommend the patient and the physician go through a check list that can be included in the patient's annual history and physical examination update.[24] Finally, after the advance medical directive has been completed, the document should be reviewed annually or sooner if there has been a change in the patient's health status, family relationships (that affect the appointment of the proxy), or other pertinent social circumstances.

SPECIAL CIRCUMSTANCES

Decision Making During a Medical Crisis

Making end-of-life medical decisions long before a terminal condition ensues helps to ensure that the physician and family will act in the patient's best interest and in a timely manner especially at a time when the emotional component of the decision-making process intensifies. In preparation for this time, the patient should be aware that the terminal disease may create an immediate life-threatening emergency that may not be remedied. But, even if the patient can be treated for this medical emergency, the risks are greater and the benefits usually fewer due to the patient's weakened clinical condition. Equally challenging for the physician is when a terminally ill patient's period of clinical stability is interrupted by a worsening in his or her clinical condition.[37] For example, new metastases may be detected on a follow-up computed tomography scan indicating a poor prognosis. With recognition that death is approaching soon, the decision involves pursuing treatment aimed at prolonging life or adopting an approach focused on specific end-of-life goals and comfort. Patients should understand that "doing nothing" or withholding further treatment does not equate to abandonment and that efforts will continue to ensure comfort and support for the patient during the remaining time before death.

Important issues that factor into this decision matrix during this time include the following: (1) the patient's values, (2) end-of-life goals, (3) the emotional and financial burden for the family, (4) prognosis, (5) risk-benefit analysis of the proposed intervention, (6) current symptom burden, and (7) the patient's age and life stage.[38] Further, before any decision is made, the physician should assess the patient's physical, psychological, and spiritual needs, their support system, and their end-of-life goals.[38] For example, patients who are at peace with dying and those who have accomplished their goals in life will usually decline further interventions that would prolong life.[38] In contrast, patients who have yet to fulfill an important goal or who are in denial about their terminal condition are more likely to want additional life-prolonging treatments. Patients are expected to undergo a grieving process associated with the end-of-life condition and, potentially, even feel depressed. But, physicians can best help patients and their families or surrogates prepare and navigate through this difficult time by ensuring that they understand the risks and benefits of interventions at this stage of their medical condition, their prognosis, and the principles and processes of palliative care. After having physician–patient–family discussions to address the scenarios of future medical crises, the physician can more easily affirm the patient's choices and make appropriate recommendations.[38]

End-of-Life Care in the Intensive Care Unit

Making end-of-life medical decisions for the critically ill patient in the ICU presents several challenges for the caregivers and the family. The noisy environment, visitor restrictions, and multiple monitoring instruments augment the anxiety that families and patients are feeling. The diversity of diagnoses, the presence of family and surrogates, and the urgency and complexity of the decision-making processes contribute to the challenges, rewards, and risks associated with the practice of critical care medicine. In the ICU, death is a routine occurrence to caregivers but not to the patient and the family. Given the emotional impact of decisions surrounding death and dying, conflicts are expected and are disturbing to all parties.

In this setting, end-of-life medical decisions frequently involve withholding or withdrawing support that involves transferring the patient from the ICU to a step down or ward unit. This can be difficult if the patient and the staff have developed a mutually supportive attachment. Equally difficult is transferring the patient from the ICU to a palliative care facility. When aggressive physiologic support is no longer beneficial, then equally aggressive humane supportive (palliative) care must include emotional and behavioral components as well. Also, if the patient is no longer mentally competent, the physician must rely on advance medical directives and input from the family to guide treatment decisions. If the physician has already established a good rapport and trust with the patient's family and understands the patient's values, then conflict with the family is less likely and the decision making can be both expeditious and supportive.[39] But, such a case is unlikely as the patient's primary care physician is usually not the critical care intensivist and hence conflict may arise, especially over life-sustaining treatments. Without the preestablished trust between the physician and the patient or family, the intensivist's decisions may be challenged and legal or ethical consultants may be needed to mediate these issues. It is essential to emphasize to families that their input is valued and that the health care team is committed to the patient's well being.[40] The family–physician conflicts are particularly important in the ICU because the patient is often mentally incapacitated and thus, decision making ethically and legally rests with the patient's surrogate.

As disagreements arise, some authors have suggested using a "differential diagnosis" approach so that physicians will consider all the possible explanations for the disagreements rather than dealing emotionally with the problems.[41] As this approach unfolds, the contributing factors of these family–physician conflicts fall into three categories: family features, physician features, and organizational/social features.

Families may disagree with physicians because they do not understand the medical situation or because they have been given different information in the past or conflicting information by other clinicians. In such situations, it becomes especially important to have either a single person designated to talk to the family, or better, have routine multidisciplinary conferences where all the health care team members can discuss the patient's status and can arrive at a consistent way of expressing this to the family. The physician should ask the family members to put into their own words the patient's history, what they have been told by other health care providers, and their understanding of the patient's current clinical situation. Also, the family members or proxy should be given time to explain the choices that they desire for the patients. This approach can help identify incorrect information and allows the physician to assess the family's reasoning skills. Further, through open-ended questions, the physician can elucidate information about what the family believes to be the causes, consequences, and prognosis of their loved one's illness.

In this process, the physician may discover that the family or proxy is psychologically unprepared to hear the patient's diagnosis or prognosis or may need to hear the information stated more explicitly. In addition to open-ended questions, the physician should make an effort to listen intently, have nondefensive neutral responses, and encourage the family members to write down questions as they think of them. Even if the family is not in denial about the patient's medical condition, "bad news" is often poorly processed and imperfectly remembered.[41] Suggestions to improve communication and understanding between the family and the physician include the following: (1) repeating critical information; (2) providing the information in written and verbal forms; and (3) encouraging questions to improve the information transfer and retention.[42] Finally, it is common to have numerous physicians involved in the care of the patient, and so it is helpful to choose one health care professional to serve as the primary communicator or have regular scheduled meetings with the designated family member or proxy. Another issue for the family that factors into the complexity of making decisions while the patient is in the ICU is that of guilt. The basis of this guilt may be long-standing interpersonal family disagreements or the helplessness of dealing with a critically ill or injured child, just to name a few. Hence, the family may be unwilling to make particular kinds of decisions. In general, the physician, not the family, should take responsibility for the medical decisions. Open-ended questions such as, "What do you think your sister would want us to do?" helps the family to meaningfully participate in the decision process without the burden and guilt of owning responsibility for the medical decision making. Another way that the family can comfortably participate in the medical decision making is to help set some goals for the patient, such as, to maximize comfort and minimize pain. Through this common purpose, the bond among the family members and between the family and caregivers strengthens.

Throughout the time the patient is in the ICU, the physician may also struggle on multiple levels with making end-of-life decisions. These issues include concern about prognostic uncertainty, failure, and legal repercussions. For example, medical–legal risk may be increased for the physician because of the misuse of, or complications associated with, the sophisticated diagnostic and life-support technology. To compound that risk is the urgency, complexity, and invasive nature of the procedures. Further, the physician also feels the economic pressures associated with caring for critically ill patients as ICU beds are almost always in demand and in treating patients who are nearing death, expectations for cure are low. Throughout this process, good communication remains the cornerstone of successful interactions between the physician and the family.

SUMMARY

Notwithstanding the limitations, advance care planning is an important tool that should encourage communication among the patient, physician, and family with the goal of empowering the patient at the end-of-life. The process of advance care planning and the development of a living will and choosing a surrogate should be part of an ongoing discussion intrinsic to the doctor–patient relationship. Physicians should be proactive in education and encourage patients to pursue the process of advance care planning and provide information on advance medical directives. An important part of this process is for the patient to reveal his or her values, preferences, and goals to safeguard autonomous choices and ensure that desires are honored as death ensues. As the Terry Schiavo case demonstrated, even relatively young and healthy patients should be encouraged to think about these issues that surround treatment decisions in the event of terminal illness or permanent unconsciousness.[43]

CHAPTER 62 ■ ACUTE CARE SURGERY, ETHICS, AND THE LAW

CHARLES E. LUCAS AND ANNA M. LEDGERWOOD

The words *moral*, *ethical*, *virtuous*, and *righteous* are often used interchangeably to imply actions that are carried out "in accordance with principles or rules of right or good conduct."[1] Morality refers to personal behavior, especially in the sexual domain. Ethical behavior implies conformity with idealized standards of right and wrong, especially within medicine and the law. Virtuous behavior implies moral excellence or, more narrowly, chastity. Righteous behavior indicates freedom from guilt, such that outrage might be the justifiable response to an accusation of bad behavior. A more refined definition of ethical behavior was provided by Mark Twain:

> "*The fact that man knows right from wrong proves his intellectual superiority to other creatures; but the fact that that he can do wrong proves his moral inferiority to any creature that cannot.*"[1]

Ethical behavior is not absolute but depends upon one's rearing, education, religion, and socialization. Each culture develops its own ethic. Sanctioned behavior in an insular, parochial environment may be unacceptable in an open, cosmopolitan setting, and vice versa. This reflects the intricate balance between societal and individual rights. The United States has an open society that emphasizes individual rights, but the balance between social and individual rights permeates the legal and medical professions. In clinical medicine, an acute care encounter may challenge the caregiver's interpretation of established ethical premises; advanced technology may complicate ethical decision making even further (e.g., end-of-life care planning) as implied by General of the Army Omar Bradley: "The world has achieved brilliance without conscience. Ours is a world of nuclear giants and ethical infants."[1] The combination of advanced technology, the interrelationship of medicine and social activism, and increased medical knowledge and awareness of the civil rights of patients has stimulated interest in medical ethics, and particularly surgical ethics, where physical actions that may constitute battery outside of clinical medicine are part of every discussion between surgeon and patient.[2]

ETHICS AND THE LAW

The legal system defines how disparate members of society can interact and function in a mutually beneficial manner.[3] Acts prohibited by law are clearly unethical medically, but legal doctrine is not immutable, nor is it enforced consistently. An example of such inconsistency is the historical debate regarding assisted suicide. A prominent proponent, Doctor Jack Kevorkian, believed that sane patients have a right to die when the pain of a permanent physical illness outweighed the pleasures of living.[4] He promulgated his views within the State of Michigan in an unsuccessful attempt to change the state law against assisted suicide, but the several suicides he facilitated created discomfort for officials reluctant to stake their political reputations on a criminal prosecution that would be deeply unpopular with the electorate, most of whom believed Kevorkian was providing ethical treatment to his patients (opponents opined that only God can terminate a human

life). Only after Kevorkian defied the law openly by filming an assisted suicide and making the film public was he charged criminally. A sympathetic jury nonetheless found him guilty. After imprisonment for several years, he was paroled after promising not to be involved further in any assisted suicides. Subsequently, the State of Oregon legalized assisted suicide under specific conditions; this process has been upheld by the United States Supreme Court.[5]

The Kevorkian saga is but one of many examples of how conflict between personal medical ethics and legal doctrine can eventually lead to changes in the law. Another example of such conflict is the ongoing debate regarding abortion. Ethical and moral beliefs are widely divergent; should abortions be prohibited under any circumstance, or can they be performed in the first trimester when the mother's life is threatened or when the pregnancy resulted from rape, or is abortion permitted at any time including so-called "partial birth" abortions, whereby the fetus is destroyed prior to delivery and ligation of the umbilical cord?[6] Legal definitions regarding the propriety of abortion at different stages of pregnancy are still being tested in the courts. Individual physicians likely will act according to his or her beliefs, but certainly within the law. Although the law may not prohibit actions that many physicians would consider unethical, illegal activity should be deemed unethical regardless. Recognizing the great diversity of views present in society when human individual rights and expectations tend to outweigh societal constraints, this treatise highlights ethical surgical practice, especially as it relates to acute surgical care.

THE SURGEON AND MEDICAL ETHICS

The foundation for ethical surgical practice begins with familial encounters with parents, siblings, and neighbors. Personal relationships are formed with individuals from different backgrounds during early education, and the individual is introduced to the concept of the *golden rule*, that one should "do unto others as they would do unto you." Ethical development continues during high school and college, and especially during medical school, when exposure to physicians and patients identifies potential conflicts between personal ethics and the needs of patients. Formal teaching of surgical ethics is now incorporated into postgraduate medical education (i.e., residency training).

SURGICAL CURRICULUM IN ETHICS

Miles Little classified ethical issues as they relate to (1) rescue; (2) proximity; (3) ordeal; (4) aftermath; and (5) presence.[7] Little points out that the patient recognizes and is subject to the surgeon's power during the first encounter, especially so under emergency conditions. However, the recognition of surgical power is contingent on a perception of trust that the surgeon will act in the best interest of the patient, including

obtaining appropriate help, to correct the problem (i.e., to *rescue* the patient). The surgeon's obligation is inviolate, requiring all that is legally and ethically possible to do be done. The principle of *proximity* acknowledges that the surgeon will be within the patient's body, thus the patient must trust that his or her body and mind will be treated with respect. This is particularly relevant when the physical problem cannot be corrected and the surgeon distances him- or herself from the patient as part of instinctual self-preservation. The principle of proximity dictates that the surgeon must share in this failure to heal while continuing to support the patient emotionally. The principle of *ordeal* recognizes that surgical remediation is associated with pain, discomfort, and inconvenience; however, the patient trusts that suffering will be minimized by the surgeon's concern for the overall well-being of the patient. The surgeon must strive for optimal patient care by balancing the alleviation of pain and suffering and the avoidance of treatment-related morbidity, especially when the patient requires ongoing treatment. An even greater ethical commitment is required of the surgeon when the emergency is caused by a neoplasm to which the patient will succumb eventually. The fourth principle, *aftermath*, refers to the need for the surgeon to maximize the patient's enjoyment of life to the fullest extent subsequent to the acute encounter. The surgeon must recognize the importance of frequent, regular visits as part of the treatment program. The fifth principle emphasized by Little is *presence*, which refers to the knowledge that the surgeon will always be available to answer questions, alleviate pain, and provide counsel well after the encounter has been completed.[7]

THE UNPLANNED ENCOUNTER

Occasionally, the surgeon will be in close proximity to an emergency event because of happenstance. For example, the surgeon's private life might be disrupted by a nearby restaurant patron who suddenly develops tracheal occlusion, the airplane passenger who develops acute respiratory distress, or a driver on the highway who loses control and crashes. It is easy to be passive and conceal one's surgical skills, but although the surgeon who intervenes on behalf of the endangered citizen enjoys legal protection from "Good Samaritan" laws in all 50 states, there is little statutory requirement for the surgeon to surrender anonymity while acknowledging his or her skills and providing care.[8–10] The only exception to this lack of a statutory mandate comes from the State of Vermont, which identifies that the physician in this setting has a "duty to rescue."[11] The Vermont statute states that

> "*a person who knows that another is exposed to grave physical harm shall, to the extent that the same cannot be rendered without danger or peril to himself or without interference with important duties owed to others, give reasonable assistance to the exposed person unless that assistance or care is being provided by others*."[3,11]

Although the decision to come to a patient's rescue in an unplanned encounter is not mandated in most states, it would certainly be considered proper ethical behavior. This code of ethics should stimulate the surgeon to offer assistance at the scene of a motor vehicle collision, to a pedestrian "found down," and intraoperatively to a fellow surgeon in time of need.

The American College of Surgeons (ACS) has developed a program for teaching ethics to surgical residents.[12,13] This program covers: (1) conflict of interest; (2) problems of litigation; (3) substituted decision making; (4) truth in communication; (5) end-of-life decisions; and (6) confidentiality. The practicing surgeon has to adhere to the tenets of each of the above in practicing in an ethical manner.

ADVANCE DIRECTIVES

The federal Self Determination Act of 1991 allows a citizen to define a preferred level of care that is to be provided at a future time when the said individual is unable to provide consent at the time of the encounter.[2] This act promotes advance directives as a means of controlling one's destiny even when incapacitated. Despite this option, the vast majority of people do not avail themselves of the benefit.[14] Advance directives may be part of a "living will" or may be delegated to an agent who holds the patient's Durable Power of Attorney for Health Care, also called a health care proxy. Technically, a living will addresses the implementation of care to the terminally ill patient. A decision to not provide care even though death would be imminent without care is best made in consultation by two physicians. The health care proxy transfers legal decision-making authority to an agent empowered to act when an individual lacks capacity to make health care decisions. When such documents have not been executed, decision making accrues to the relative of highest standing, usually the spouse. In cases of dispute, an opinion may be sought from the facility's legal counsel. Decisions made by surrogates are more easily supported when informed by the patient's known wishes, but sometimes only a best guess can be made as to what the surrogate believes the patient would want. Sulmasy and Terry[15] reported that judgments made by surrogates often do not represent the patient's best interests, particularly when dealing with terminal illness (i.e., there can be a powerful inclination to do "everything" to the point of futility). This dilemma is compounded when no surrogate decision maker can be identified.[16] The surgeon has the ethical responsibility to act in the best interest of the patient, based upon education and experience.[16] The golden rule that applies is that the surgeon will probably make a proper decision if the decision is to do what would be preferred for his or her own care in the same circumstance.[17] Many such decisions in acute care surgery involve endotracheal intubation and mechanical ventilation, use of catecholamines to support blood pressure, and pain management. When addressing limits to care stipulated by an advance directive or the patient's agent, the delivery of care must be modified (Table 62.1).[17] This is an example of a preventable death and unethical care in the view of the writers, but the case record provided is incomplete with respect to determination of the patient's capacity to make decisions and the involvement of a surrogate, therefore many medical ethicists might disagree. In the authors' view, decisions regarding pain management with opioids must be made in the context of the do not resuscitate (DNR) and do not intubate (DNI) orders. The surgeon is obligated to balance sedation and analgesia in the context of the DNI directive. Ideally, the discussion regarding the limits of care under the DNR order should occur as soon as practicable after admission, and the results made known to all caregivers. For example, it may be decided to adhere strictly to the advance directive (in which case care in the intensive care unit (ICU) may be unjustifiable). Alternatively, some or all aspects of care may be deemed permissible by mutual agreement, or the DNR/DNI orders may be rescinded for a period of time certain (e.g., the periprocedural period or the length of stay in the ICU. Such a discussion is decidedly less than ideal after (or during) a destabilization complication. Absent the discussion, should the patient be intubated until the opioid effects have worn off or been reversed? The authors would opine in the affirmative, after which further discussion with patient and family would determine subsequent care, because most advance directives are designed to prevent futile care or prolonged terminal care, not the short-term management of a reversible complication, but not all medical ethicists would agree.[17,18]

TABLE 62.1

EXAMPLE CASE OF HEALTH CARE LIMITED BY ADVANCE DIRECTIVE

- A 64-year-old male was thrown from an all-terrain vehicle at 15 mph.
- Unconscious for 3 min, helmet dented.
- Upon arrival at the Emergency Department, the patient had slurred speech, was amnestic to events, and complained of left leg pain. Vital signs were normal.
- Imaging studies suggested an old right hemisphere stroke.
- An advance directive specified "Do Not Resuscitate" (DNR), and "Do Not Intubate" (DNI). Morphine sulfate was administered for discomfort.
- Day 2: Increased oral secretions.
- Day 4: Increasing somnolence.
- Day 5: Gastrojejunal tube placed by interventional radiology for enteral feeding. Postprocedure restlessness treated by patient-controlled analgesia infusion of morphine sulfate at a basal rate of 2 mg/h. Respirations became labored but the patient was not intubated owing to the DNI order. The patient died that day.
- Postmortem examination showed a small subarachnoid hemorrhage at the base of the brain and a small tear of the dura mater.
- The peer review committee concluded that the death was nonpreventable due to the DNI restriction in the advance directive.

Providing optimal care in an ethical manner is more complicated when dealing with the incapacitated patient.[18] Legally, one must obtain *informed consent*.[17] The State of New York defines "lack of informed consent" to mean:

"*the failure of a person providing the professional treatment or diagnosis to disclose to the patient such alternatives thereto and the reasonably foreseeable risk and benefits involved as a reasonable medical, dental, or podiatric practitioner under similar conditions would have disclosed, in a manner permitting the patient to make a knowledgeable evaluation.*"[10,19,20]

New York further goes on to mandate that the plaintiff (in litigation regarding lack of infirmed consent):

"*establish that a reasonably prudent person in the patient's position would not have undergone the treatment or diagnosis if (s)he had been fully informed and that the lack of informed consent or diagnosis is a proximate cause of the injury or condition for which recovery is sought.*"

Obtaining informed consent prior to a major elective operation involves a thorough explanation of the anatomy, physiology, pathology, and complications of the operation. Thus, this level of informed consent is a paradigm that is never achieved unless, perhaps, the patient is another surgeon.[3] Therefore, consent is based typically upon less-complete information, because even an experienced nonsurgical physician may not really comprehend all of the potential risks of a complex operation or underlying condition.[3] Thus, the legal requirements focus on important or material risks and benefits of having surgery versus nonoperative management. The patient who is not acutely ill must be engaged seriously in the discussion,

and even then may not comprehend fully. Such comprehension becomes impossible for a patient with hypotension or sepsis and impaired judgment from altered cerebral blood flow and metabolism. For example, consider a middle-aged patient who presents to the emergency department with a perforated duodenal ulcer and peritonitis. Refusal of operative intervention, in this setting, most likely will result in the death of the patient. In the setting of refusal, the surgeon is obligated to assess the patient's capacity for medical decision making by consulting a disinterested medical professional. If the individual is determined to lack capacity, then authority can be transferred to a surrogate or external legal entity,[3,16] but using the court system to appoint a guardian takes time that the situation may not afford. Often the surgeon must document in writing the life-saving nature of the intervention and the inability of the patient to consent, and then proceed with the emergency operation with the knowledge of the facility's legal representative.[3]

The ethics of surrogate consent are less defined if the incapacitated patient is not in a life-or-death situation. Each surgeon has to determine, within legality, the optimal, ethical solution to a dilemma.[3,17] For example, consider the case of a patient with schizophrenia admitted for recurrent acute pancreatitis due to neuroleptic medications. Following partial improvement with nasogastric suction, intravenous fluids, and nutrition support, a pancreatic pseudocyst associated with ductal ectasia was identified, and a lateral pancreaticojejunostomy was recommended. The patient declined operation but his legal guardian gave permission. Should the surgeon operate against the patient's wishes, or demur and instead offer to refer the patient to another surgeon?[13] In this case, the patient was discharged on a liquid diet, but recurrent dietary intolerance necessitated rehospitalization. Operation was recommended again, accepted by the patient, and carried out without complication and with a good result. Had the operation been performed initially against the patient's wishes but with the consent of the guardian, readmission and substantial additional cost would have been saved.

Refusal of consent may be influenced by temporary incapacity due to the emotional state, or alcohol, or other intoxicants. For example, consider the case of a muscular, young adult male, hypotensive and uncommunicative after a stab wound to the groin, bleeding from a presumed femoral artery injury. He responded to resuscitation and control with direct pressure. Now awake, operation was refused; angry and under the influence of cocaine, the patient was eager to exact revenge upon his assailant. The patient was observed until somnolence supervened, at which time the patient was taken to the operating room under emergency administrative consent for uneventful femoral arteriography. Postoperatively, the patient was apologetic and grateful as a result of the surgeon acting in the best interest of the patient.

A more common dilemma occurs when a patient who has capacity refuses care, such as the receipt of blood or blood products.[10] Case law is unequivocal that a patient with capacity has the legal right to refuse care.[20,21] Consequently, the surgeon who acts contrary to the patient's wish has committed battery.[2,3,13] Even more complex is the circumstance where a patient is willing to have surgery that is likely going to be associated with a need for blood transfusion but, the patient refuses to receive blood or blood products for religious reasons.[22,23] In this setting, the surgeon must determine whether the risk:benefit of the operation justifies performance without availability of blood. Surgery under that parameter increases the risk to the patient, which may be mitigated if the surgeon is experienced and believes that the operation can be performed successfully without blood bank support. Candid discussion among surgeon, patient, and family must occur and must be documented in the medical record.[24] When the surgeon is unable to accept these restrictions, referral to another surgeon

SPECIAL TOPICS

must be facilitated.[24] These proscriptions do not apply when the patient is not known and cannot communicate owing to incapacity.[2,25,26] However, discovery of a wallet card prohibiting blood products constitutes valid refusal,[27] and physicians have been found liable for failure to follow such indicia of the patient's wishes (but not for adherence thereto).[27]

Restrictions to treatment do not extend to children whose consents are provided by parents. The surgeon caring for an injured child who needs blood or blood products that have been prohibited by the parents should follow his or her ethical instincts and treat the patient regardless.[21,26] Blood transfusion in this circumstance is correct ethically and protected legally in most states.[21,28] When uncertainty exists in a life-threatening situation, the surgeon is well-advised to administer blood products.[3,17,26]

An advance directive no longer applies when a patient presents after an attempted suicide.[2,3] Emergency surgical intervention is correct legally and fully compliant with ethical standards, and protects the interests of the patient, the caregivers, and the hospital.

THE UNEXPECTED FINDING

A major ethical and legal challenge related to acute care surgery is the unexpected intraoperative finding. Consider the example of an adenocarcinoma of the cecum identified rather than acute appendicitis during appendectomy through a standard low transverse incision. Should the surgeon close, or proceed with a right hemicolectomy? Again, the ethical dilemma in this situation may be resolved according to the Golden Rule.[16,17] If the colon is empty of stool, the patient has normal and stable vital signs, and the hepatic flexure can be mobilized with a modest extension of the incision, proceeding with a definitive right hemicolectomy and primary anastomosis is reasonable. Alternatively, some surgeons will believe that, because colectomy was not consented to they would therefore close, thereby subjecting the patient to subsequent reoperation. This latter approach is also legally correct, but increases the potential for morbidity and mortality. The situation can be mitigated by foresight and common sense. Presuming that a computed tomography scan was performed, identification of a large phlegmon with indistinct features may prompt a request for the patient to consent to "possible bowel resection." Put simply, the best ethical decision is to perform the procedure that provides the best (lowest) risk:benefit for the patient.[17,28]

A different situation arises when a patient is operated upon for an abdominal gunshot wound that is believed to have penetrated the peritoneal cavity near the descending colon. During exploration, the missile tract is found to be retroperitoneal, but the patient has a left-sided colon mass, probably malignant by palpation, with bulk feces within the colon. Should the surgeon close or perform a left hemicolectomy? If resection and primary anastomosis results in a leak causing fatal peritonitis, the assailant might be charged with murder even though the patient died from iatrogenesis. If resection and a colostomy is performed, the patient may be displeased. Even though it is ethically correct for the surgeon to perform the hemicolectomy, the potential for a bad result and the far-reaching consequences for a third party may favor abdominal closure followed by a second operation for cancer.

Definitive care for an unexpected finding is easy to rationalize when the preoperative symptoms are related directly to the unexpected finding, so that lack of definitive care would be detrimental to the patient. For example, a decision may be made to operate on a patient with sudden, severe upper abdominal pain and marked tenderness, even absent any evidence of pneumoperitoneum on imaging studies. At operation, a finding of a ruptured hepatic adenoma with active bleeding

mandates definitive therapy. If the surgeon is not experienced with hepatic resection, a colleague should be called in.

THE DILEMMA OF PAIN MANAGEMENT

The baptism of pain as the "fifth vital sign" has created a new ethical dilemma for the acute care surgeon.[29] Physicians and other caregivers, desirous of providing optimal patient care, have promulgated a detailed system for rating the extent of pain and the caregiver response thereto.[30] The Visual Acuity Scale (VAS) has been adopted most frequently to categorize the severity of pain, rating pain from 1 to 10 and permitting both documentation in electronic medical records[29] and monitoring by "authorities" of physician performance/compliance. However, nowhere in the electronic medical record are there easily retrievable data to identify signs and symptoms of overmedication.

The Joint Commission has mandated that whenever a VAS is five or greater, the patient must be reassessed. Nurses working in a busy hospital area routinely give more narcotic because there is insufficient time to do a full reassessment.[30] This knee-jerk response to a VAS of five or greater is commonplace and possibly detrimental, but may go unchallenged for fear of personal recrimination or threatening the hospital's external credentialing.[29] All surgeons, especially acute care surgeons, recognize that pain management is a high priority, but also that preventable death from overmedication is anathema. The authors assessed the effects of this new pain management paradigm, using before-after methodology, on the incidence of preventable deaths following injury among patients treated in hospitals reviewed by the American College of Surgeons Verification Review Committee.[29] The determination of a preventable death was made locally by existing trauma center peer review performance improvement methodology; individual records were reviewed randomly. Preventable deaths due to overmedication increased by 250% following the identification of pain as the "fifth vital sign." Overmedication occurs by multiple routes of administration, including epidural catheter, patient-controlled analgesia, standing orders for medications regardless of patient status, and supplemental medication based on VAS. Taylor et al. reported that oversedation was most likely to occur within 4 hours of a patient arriving on the surgical floor after transfer from a monitored setting,[31] and identified further that a patient was at greatest risk for oversedation (usually, respiratory depression) during the first postoperative day.[32] The risk of preventable death correlated directly with age and with the use of hydromorphone. The pendulum may have swung too far in the management of perioperative pain; it is time for a scientific reassessment of current policies[31,33] and for acute care surgeons to accept personal responsibility.

THE MEDICAL-INDUSTRIAL COMPLEX

When President Dwight D. Eisenhower addressed the 1960 Republican National Convention, he alerted the citizens about the "Military-Industrial Complex." "Ike" warned that contributions to elected officials, in one form or another, could influence military contracts. His prescient predictions have been realized. The same potential conflict of interest exists in 21st century health care and might be referred to as the "Medical-Industrial Complex." Conflict of interest in the development of clinical practice guidelines has been alleged in two recent mass-market books entitled *The Truth About the*

Drug Companies and *On the Take*.[34,35] Many aspects of health care related to acute care surgery are addressed. Examples that relate to acute care surgery include medications and treatment for venous thromboembolic disease, prophylaxis of "stress gastritis," and hemopoietic agents in patients without chronic kidney disease. Commercially-sponsored symposia, designed ostensibly to educate physicians about a specific disease entity or complication, often have commercial bias.[34,35] The pharmaceutical industry is also involved in continuing medical education (CME). Rohrich et al.[36] estimated that 90% of the $1 billion spent annually on CME is supported by industry, and estimated further that the true cost of industrial promotion of pharmaceuticals may exceed $10 billion annually.[36] Acute care surgeons are presented opportunities to participate as faculty and audience members, and must consider their participation carefully.

The ethical dilemma created by industry-sponsored symposia and product self-promotion is complex.[34,35] A good working relationship between the pharmaceutical industry and physicians is necessary in order to promote excellence in health care; indeed, important, valid clinical trials can sometimes only be funded with industry support.[36] However, certain marketing tactics deserve restriction. Rohrich et al.[36] pointed out that many academic health centers no longer allow pharmaceutical companies to sponsor "journal clubs" or other on-premises meal functions. Notably, when the American Medical Association (AMA) membership proposed severance from the strong pharmaceutical support received by the AMA for their annual meetings and postgraduate courses, the leadership was resistant.[34–36] Interestingly, leadership in this arena of conflict of interest has come from younger physicians. The American Medical Student Association (AMSA) developed guidelines in 2003, updated in 2009, which define how the close relationship between medical schools and the pharmaceutical industry should evolve.[37] The AMSA guidelines address gifts (including meals), consulting relationships, industry-funded speaking relationships, disclosure of all industrial support, free pharmaceutical samples, payment to physicians involved with hospital formularies, and exposure to sales representatives, and funded educational activities including on-site support, travel, and scholarships for trainees. The AMSA encourages university oversight of these activities and willingness to implement sanctions for unethical behavior.

THE TRAINING YEARS

Jones and McCullough warned that the ethical challenge begins in the formative years during surgical residency by saying "one can not go back on their upbringing."[18] Numerous opportunities exist for the resident surgeon to be "led astray" as they relate to the ethical future practice of surgery. Residents often witness informed consent discussions.[16] Should a resident identify that certain surgeons perform procedures that are clearly outside of the permission granted by the patient as a matter of routine, the observation must be brought to the attention of the appropriate departmental officials. Hopefully, when presented such evidence, they will summon the courage to forward the information to appropriate hospital committees to sanction the surgeon as appropriate.[33] For difficult cases with a major intraoperative complication, the operative note must reflect the operation accurately, whether dictated by the attending surgeon or the resident. If not, and the dictation was made by the attending surgeon, the resident is obligated to point out to the surgeon that the dictation is inaccurate or incomplete, and offer to do the re-dictation.[24] If the offer is declined and the surgeon does not amend the dictation himself or herself, the resident again has an ethical responsibility to report this to the chief of surgery.[17] Many senior surgeons recall circumstances, during residency training, when a surgeon who no longer (or never) had the requisite technical skills to operate independently, was protected by a chief of surgery who expected the surgical residents to keep the incompetent surgeon "out of trouble."[38] Hopefully, this form of ghost surgery is no longer practiced. If faced with this practice, the resident needs to inform the program director that he or she can no longer assist that surgeon at surgery.[38]

The operating surgeon must behave ethically when obtaining consent for a complicated procedure (and serve as a role model for trainees),[3,17] explaining to the patient the surgical and nonsurgical options and the risks of a specific operation, not only on the basis of published data but also on the best estimate of his or her personal results for the operation. Adherence to the practice of having the attending surgeon obtain consent will influence the resident to be forthright and honest with his or her patients when out in practice and obtaining operative consent.[17,39]

CONFIDENTIALITY

Confidentiality is both an ethical and a legal issue. Increasing emphasis has been placed on protection of the rights of individual patients to confidentiality of their health information. State laws now define the extent to which a patient's medical records may be disclosed as part of therapy, while avoiding a breach of patient confidentiality. Illinois law cautions that "no member of a hospital's medical staff and no agent or employee of a hospital shall disclose the nature or details of services provided to patients,"[40] but makes numerous exceptions, such as for the patient's information or that of their representative regarding treatment, and for those parties providing treatment to the patient, processing payment for that treatment, instituting peer review or risk management, or defending a claim against the hospital regarding that treatment.[40] The prudent physician would be wise to review his or her own state's confidentiality statute, and should not assume that the Illinois statute is representative of that of other states. In Illinois, there are also mandated disclosures under the Abused and Neglected Child Reporting Act, the Illinois Sexually Transmitted Disease Control Act, or "where otherwise authorized or required by law."[29] At the federal level, the Emergency Medical Treatment and Active Labor Act (EMTALA) mandates, among other things, that when a critically ill or -injured patient is transferred to another center for a higher level of care, the patient's records must also be transferred.[10] Records that are not specifically transferred with the patient, but sent at a later time, should not be transmitted by e-mail, which is not secure. Such information needs to be sent by facsimile or secure package delivery after appropriate permission is obtained from the patient or the designated representative.

Safeguards are enhanced when dealing with public figures, who stimulate interest in the news media, who are often more intent on pursuing the story than protecting the individual's right to privacy.[41] Similar safeguards will likely be extended to other valid review activities. This extends to trauma conference rounds and the trauma peer review performance improvement committee meetings whereby the trauma director and other key members of the team review patient outcomes. Patients will, in the near future, likely be identified only by an identifying number rather than by name. This restriction may possibly interfere in the short term with patient care because identifying patients by name is a long-standing tradition, but confidentiality must be perserved.[3,41] While protecting confidentiality, the acute care surgery team must also respect laws of mandatory reporting, particularly those related to communicable diseases and possible abuse.

Included within the framework is the need to secure all physical evidence, such as might be present following a physical assault or rape, to preserve the "chain of evidence." Likewise, one has to protect the evidence chain as it relates to foreign bodies removed from the injured patient, particularly bullets that are needed for forensic analysis.[41] During this process, the trauma surgeon should be continually reminded that, when in doubt, do what is best for the patient.

PALLIATIVE CARE

The acute care surgeon is often faced with medical challenges that cannot be overcome. Severely injured patients with multiple organ dysfunction syndrome after hemorrhagic shock, patients with severe isolated traumatic brain injury, and patients with overwhelming sepsis are examples where even care of the highest quality may fail ultimately.[42,43] Such patients should be managed by the guidelines on palliative care established by the Institute of Medicine.[44] Many of these guidelines were developed for patients with terminal cancer, but apply equally to the acute care surgical patient. The ethical dilemma may actually begin at the time of the initial encounter. Whereas an 85-year-old patient with localized, perforated appendicitis can usually be restored to health by an appendectomy, the same patient with infarcted small bowel from congestive heart failure and mesenteric ischemia due to a low-flow state may not survive an operation. Likewise, the patient with stage IV ovarian cancer who presents with small bowel obstruction from carcinomatosis is unlikely to benefit from operative intervention. Comfort care was described many years ago by Dame Saunders; it involves four principal elements, namely, the physical dimension, the emotional or psychological component, the social and economic ramifications, and finally the spiritual aspect of pain.[45] The acute care surgeon should be comfortable providing support in all four domains.

The goal of palliative care is the physical and psychological comfort of the patient, rather than prolongation of life, and should not be restricted by typical guidelines regarding pin medication. For example, the administration of opioids to the point of respiratory depression is acceptable if other measures fail. Krizek[46] emphasized the importance of teaching these principles in medical school, during residency, and throughout one's practice, particularly, when dealing with acute emergencies. Dunn pointed out that spiritual barriers to surgeons providing palliative care may be an impediment to providing optimal care in this setting.[47] When such barriers are present, the acute care surgeon should seek consultation with a colleague who is more inclined to do whatever is necessary to make the patient comfortable.

Palliative care does not necessarily mean that operative intervention is proscribed. A gastrostomy to palliate uncorrectable bowel obstruction allows the patient to ingest liquids for pleasure, which are thence to drain freely via the gastrostomy tube, thereby avoiding the discomfort of a nasogastric tube or intractable nausea and vomiting.[48]

Often, family members are in conflict with divergent views about ongoing patient care even though the surgical ICU team recognizes that further care is futile.[45] Usually, the patient lacks the capacity to take a decision at this point on the continuum of care. The ICU team can arrange for consultants in different specialties to speak with family members (i.e., the "family meeting"). If these efforts fail to communicate that ongoing support is not in the best interest of the patient, the ethics committee, pastoral care service, and palliative care team should become involved to achieve reconciliation.

ETHICS CURRICULUM

High ethical standards are promulgated when ethical principles are emphasized throughout one's training, beginning ideally in medical school.[49] The huge debts that accrue from tuition and fees do not justify recommending surgery when nonoperative management yields comparable results.[50] Understanding the ethical dilemmas that the surgeon encounters will help the student determine whether or not surgery is a desirable career. As the surgical resident advances through training, formal conferences should emphasize ethical principles in particular. The ACS categorizes the ethics curriculum into six areas of special interest: conflict of interest; professional obligations; substitute decision making; truth-telling in communications; end-of-life issues; and confidentiality. The Royal College of Physicians and Surgeons of Canada adds: Surgical competence, resource allocation, consent taking, and research. Frequent emphasis of these principles is advantageous throughout one's surgical career. One of the last important ethical decisions that the aging surgeon must make is deciding when to retire, or at least stop operating. Part of this decision relates to what is best for one's patients.[2,49]

MEDICAL PROCEDURES ON THE NEWLY DEAD

Ethical dilemmas may extend after death. Smith, in 1824, proposed that medical procedures and dissection could be performed on unclaimed bodies to enhance knowledge of the living.[51] This concept has expanded over the years so that many program directors report that medical procedures are performed upon the newly dead for teaching purposes, without informing the family.[52] Most common is tracheal intubation, but others include central venous catheter placement, venous cutdown, pericardiocentesis, and thoracotomy.[53] Moore has reviewed this phenomenon in detail.[54] Iserson, a strong proponent of this practice without the need for consent, stated that the need to have experience in the performance of these potentially life-saving (and life-threatening) procedures overrides and supersedes any potential objections from the next of kin.[55] Iserson reasoned that this policy is not disrespectful, but rather conveys respect to the newly dead by attaching a societal value to teaching skills that may save a life in the future. Furthermore, Iserson maintained that there is neither a legal nor a moral need to obtain consent.[55] By contrast, Goldblatt concluded that a proxy consent from the next of kin is necessary both legally and ethically.[56] Goldblatt added that the cadaver is protected according to the dictates of the deceased's Last Will and Testament. That a patient dies intestate must not abrogate the rights of family members to authorize or prohibit educational medical procedures.[57] Considering this controversy, the acute care surgeon would be well advised to obtain valid consent before supervising educational procedures on the newly deceased. Although it is uncomfortable to obtain consent at a time when emotions may be running high, it may be possible to obtain consent for endotracheal intubation, tube thoracostomy, cricothyroidotomy, and central line placement.[58] The legal precedents regarding this practice are not settled. All courts would agree that the newly deceased has lost the right of self-determination. The Georgia Supreme Court ruled that harvesting corneas for transplantation did not violate the rights of the deceased or the family.[59] By contrast, the State of Ohio ruled that protection of the cadaver was a constitutionally protected right, and that the next of kin had some rights regarding the cadaver.[60] A violation of this right could lead to litigation of an allegation of "negligent infliction of emotional distress."

Although it is indisputable that the practice of medical interventions on the newly dead provides valuable training that may save lives in the future, there is also no question that many relatives would be distraught if such procedures were performed without permission. Respect for the remains of the newly dead is strongly built into the social structure from the societies of our Native Americans until the current age.[61,62,63] The acute care surgeon who would be in close proximity to many deaths would be advised to obtain consent from the next of kin before becoming involved in the teaching of technical procedures to the surgical residents.

CHAPTER 63 ■ SCORING SYSTEMS FOR INJURY AND EMERGENCY GENERAL SURGERY

SHAWN NESSEN AND JOHN FILDES

SCORING SYSTEMS FOR INJURY

Introduction

Modern injury severity scoring is an important aspect of managing injured patients because it allows the quantification of an injury and the probability of survival based on the injury scale score. In the field injury, scoring has been used to create field triage systems, and in smaller hospitals, it can be used to aid in the determination of which patients should be transferred to higher levels of care. An important purpose of any scoring system is to allow comparison between similarly injured patients treated at different hospitals and in different trauma systems. Injury scoring controls bias in research by allowing comparison between similarly injured patient populations. The ideal scoring system allows the correlation of increasing injury with mortality, and considers anatomic injury, physiologic derangement, and the comorbid conditions of the patient. The score should be easily calculated and reproducible. Injury scoring systems attempt to predict expected outcomes based on the severity of a given patient's injury. The ability to quantify injury in this way makes accurate scoring systems excellent quality assurance tools.

For the acute care surgeon, extending organ injury severity grading into the realm of nontrauma emergency surgery is appealing and in some cases has been attempted. An example of this is the Hinchey classification of diverticular pericolonic abscesses. Similar to injury scoring, classifying the extent of the pathologic process allows quantification that facilitates quality improvement and research, and guides treatment.

Field Triage Scoring Systems

Triage can be broadly defined as identifying those patients who, if given immediate appropriate medical treatment, will likely survive their wounds. It endeavors to separate those who are minimally or fatally injured from those who will most benefit from timely care.[1] Emergency medical system personnel usually make the first and often most critical triage decisions. For this reason, injury severity scoring systems that accurately and consistently quantify injury for triage purposes are extremely valuable. Field triage systems must categorize patients in such a way as to insure the most severely injured patients are taken to the most capable trauma facilities while ideally preventing such facilities from being overburdened with patients who have inconsequential injuries. The key components of field triage systems include injuries to the central nervous, cardiovascular, and respiratory systems.[2]

The Glasgow Coma Scale

Among the first and most successful of the trauma grading systems was the Glasgow Coma Score (GCS). Developed by Teasdale and Jennett in 1974,[3] this commonly used scale assesses the degree of head injury, and it has predictive value as to outcome. GCS includes three clinical evaluations of eye opening, verbal expression, and motor response. Each component is then assigned a numerical score (Table 63.1). The scale is graded with the best eye opening response receiving a maximum score of 4 points, the best verbal response receiving a maximum score of 5 points and the best motor response receiving a maximum score of 6 points. A lower score indicates worsening neurologic injury, and this allows for quantification of injury to mild, moderate, and severe. This has clinical implications that include indications for intubation, intracranial monitoring, and surgical decompression.[4] The GSC was revised a single time in 1977 increasing the maximum score for motor response from 5 to 6, emphasizing the relative importance of the motor response in the overall evaluation in the patient's neurologic exam.[5] The relative ease of use and reproducibility of the GCS in the context of the overall contribution of neurologic injury to subsequent morbidity and mortality of trauma patients make it an important component of field triage systems.

The Revised Trauma Score

The Revised Trauma Score (RTS) is a revision of the earlier Triage Index[6] and subsequent Trauma score. The Trauma Score was developed by Howard Champion, William Sacco, Wayne Copes and others as both a quantitative injury scale with predictive value and as a simple and reproducible triage tool for EMS personnel for which it gained wide acceptance.[7] The Trauma score assigned point values for respiratory rate (RR), respiratory effort, systolic blood pressure (SBP), capillary refill, and GCS. In revising the trauma score, the authors acknowledge respiratory effort and capillary refill were difficult to assess and some head injury patients were undertriaged. The RTS eliminated capillary refill and respiratory effort components, adopted commonly accepted intervals for GCS, adjusted values for SBP and RR, and validated the score with empirical data (see Table 63.2).

Two configurations of the score were created, one for triage (Triage RTS) and one to predict outcome (RTS).[8] The field component (T-RTS) is strictly additive and can be quickly calculated in the field. The Triage-RTS is used in the prehospital setting and assigns a maximum of 4 points to the respiratory rate, systolic blood pressure, and the GCS. The maximum point value is 12. A T-RTS of ≤ 11 is a strong indicator that a patient should be transferred to a trauma center (Table 63.2).

The second iteration of the RTS is used for predicting outcome and comparing patient data sets. The RTS is defined as

$$RTS = 0.9368 \ GCS + 0.7326 \ SBP + 0.2908 \ RR$$

The RTS has a range from 0 to 7.841, is heavily weighted toward neurologic injury, and correlates well with the

4–5	1
<4	0

Any score ≤11 suggests the patient should be taken to a trauma center.

probability of survival. It is an important component of the trauma injury score methodology, to be discussed later in the text.[8]

Pediatric Trauma Score

The Pediatric Trauma score is similar to the RTS but designed for children. It has six components: weight, airway, systolic blood pressure, central nervous system, open wound, and skeletal injury. Each component is given a score of –1 to 2, and patients with a score <8 should be transferred to a pediatric trauma center.[9]

Center for Disease Control National Guidelines for Field Triage of Injured Patients

In 2009, the Center for Disease Control (CDC) issued Guidelines for the field triage of injured patients. The expert panel based the criteria on physiologic criteria, anatomical criteria, mechanism-of-injury criteria and special considerations to include age <5 or >55, pregnancy, burns, and comorbidities such as diabetes mellitus and coronary artery disease. Patients with a GCS < 14, systolic blood pressure <90 mmHg, or respiratory rate <10 or >29 or <20/min in an infant under 1 year of age are triaged to a trauma center. Similarly, patients with penetrating injuries to the head, neck, torso, and extremities proximal to the knee; flail chest; two or more proximal long bone fractures; crushed, degloved, or mangled extremity; amputation proximal to the wrist or ankle; pelvic fractures; open or depressed skull fractures; or paralysis should be taken to a trauma center. Finally, it is recommended that in patients older than 55, consideration for transport to a trauma center should be undertaken. The CDC's recommendations include all of the elements of an effective injury scoring system to include physiologic, anatomical, and comorbid conditions.[10]

Anatomic Injury Scoring Systems

Abbreviated Injury Scale In 1969, a Joint Committee of the American Medical Association called the Society of Automotive Engineers and the Association for the Advancement of Automotive Medicine began to develop a scale to classify injuries and their severity. The first scale was published in the *Journal of the American Medical Association* in 1971.[11] The AIS has been revised several times by the Association for Advancement of Automotive Medicine, including the most recent 2008 update.

The AIS is not a scoring system. It is rather an anatomically based scale that classifies injuries on a 6-point scale with a score of 1 representing a mild injury and 6 representing an almost always nonsurvivable injury (Table 63.3). The scale is based on consensus opinion and simply describes the organ injury. The AIS does not attempt to predict survivability of injuries, and there is not a linear correlation to the injuries classified and patient outcome. AIS has been revised to have comparability with the Organ Injury Scales of the American Association for the Surgery of Trauma.

The use of the AIS scale can often be confusing. For example, for a given body region, a scale of 4 represents severe injury and a scale of 5 represents critical injury. To know the difference between a severe and critical injury for a given organ requires referencing the AIS manual. As an example, a grade 4 liver injury involves "parenchymal disruption of ≤75% hepatic lobe; or multiple lacerations >3 cm deep; or a 'burst' injury." A grade 5 liver injury involves "parenchymal disruption of >75% of hepatic lobe or >3 *Couinard's* segments within a single lobe or involving retrohepatic vena cava, or central hepatic veins."[12] The documentation of injury grade is sufficiently complicated to require training for coders who document scores.

The Injury Severity Score The injury severity score (ISS) was introduced in 1974 by Susan P. Baker and others. In their landmark paper, the authors pointed out the difficulty of comparing large numbers of patients with very similar injuries and

TABLE 63.3

Unsurvivable	6

instead proposed comparing patients who did not necessarily have similar injuries but instead had similar injury severity. In evaluating the AIS as a scoring system, they found that the AIS was nonlinear as mortality increased disproportionately with increasing severity. Further, the death rates for persons with two injuries of grade 4 and 3 (mortality 24%) did not have comparable mortality to patients with injuries of grade 5 and 2 (mortality 54%). They also recognized that the AIS pertained to individual injuries and state in their paper that most automotive crashes involve multiple injuries.[13]

Deducing that the simplest nonlinear equation is quadratic, the authors then determined to square the AIS grades for the most severe injury in each body region and then add the scores together. When adding the sums of the two highest squared AIS grades, death rates were found to be similar for comparable totals. The sum of the three highest squared AIS grades improved the correlation between the ISS and mortality. Adding the fourth squared AIS did not improve accuracy. The ISS was therefore defined as the "sum of the squares of the highest AIS grade in each of the three most severely injured areas."[13]

The ISS divides the body into six anatomical regions including the head or neck, face, chest, abdomen/pelvis, extremities, and external and then assigns a score to each region based on the AIS scale. The three highest scores are then squared and added together resulting in the ISS. If a patient receives an ISS of 6 in any anatomical region, a score of 75 is assigned, and the patient is presumed to have nonsurvivable injury.

The ISS has been found to correlate well with mortality and revolutionized trauma research. The immediate impact of the ISS was to allow retrospective analysis of treatment quality and effectiveness as well as comparison between similarly injured patients treated at different hospitals and in different trauma systems.[14,15] However, the ISS does have notable limitations.

The ISS only considers one injury in a body region when multiple serious injuries may exist which may result in the ISS underestimating injury in these cases. For example, a patient with a severe liver injury given an ISS score of 25 and a patient with the same liver injury and an inferior vena cava injury with an injury severity score of 16 would be given the same ISS of 25. The ISS is derived from the AIS scale, which was designed to categorize victims of motor vehicle crashes and therefore is primarily a measure of blunt trauma. Recent revisions have added penetrating injury, but the ISS may underestimate penetrating injury severity. The ISS places equal emphasis on injuries in all body regions. Because the score is not weighted, an injury to the head with an ISS score of 25 may have a different mortality compared to an extremity injury with a score of 25. The ISS is only an anatomic score as it does not consider physiologic derangement or

patient comorbidities. The ISS is thought to be ordinal (well ordered) and monotonic (always increasing); however, this is not true. Kilgo and colleagues using 171,149 patients from the National Trauma Data Base demonstrated that the ISS is nonmonotonic, an example being that an ISS of 25 had a mortality of 43% while an ISS of 27 had a mortality of 14%. Further the ISS scale is from 1 to 75, but only 44 values exist, and several different combinations of injury result in the same score with disparate mortalities for the same value.[16]

Despite substantial limitations, the ISS remains the most popular injury scoring system. The ISS is simple to understand and easy to calculate. Scores from 1 to 8 have a mortality of approximately 1% (minor injury), scores from 9 to 14 have a mortality of approximately 2% (moderate injury), scores from 16 to 24 have a mortality of approximately 7% (severe injury), and scores ≥25 have a mortality of >30% (very severe injury) (Fig. 63.1).

New Injury Severity Score Turner Osler, Susan Baker, and William Long introduced the New Injury Severity Score (NISS) in 1997. This score attempted to improve on the original ISS by using the three most severe injuries regardless of anatomical region. This modification eliminated one of the primary criticisms of the ISS, and ability of the NISS to predict mortality was found by the authors to be superior to that of the ISS. In their original paper, the authors reported that approximately 60% of patients had different NISS scores compared to ISS scores with the NISS being higher than the ISS in all cases. The authors reported data from two separate hospitals and using receiver operating characteristics found the ISS to have a 0.869 predictive value in one institution compared to 0.896 using NISS. In the second institution, ISS was found to have 0.896 predictive value compared to 0.907 using NISS. In both cases the improvement was found to be statistically significant.[17] The NISS, however, like ISS is nonmonotonic, nonlinear, and not ordinal, and it has failed to replace ISS as the standard anatomical ISS.[16]

Anatomic Profile Score Wayne S. Copes, Howard R. Champion, and others identified three fundamental problems with the ISS. They felt the ISS underestimates in many cases the severity of injury because it is limited to the single worst injury in three body regions. Second, the ISS has multiple diverse injury combinations that result in similar ISS, but have clearly distinct survival differences, and third and importantly, the ISS gives the same importance or weight to the same AIS score in different body regions. Their example is that a laceration to the brain and stomach give an AIS score of 4, and an ISS of 16 would predict the same outcome.[18]

Their solution was to develop the anatomic profile (AP). The AP adjusts for severity in body regions by creating the modified components mA, mB, and mC. Each modified component includes all injuries in the given body region, and the regions are weighted differently based on the expected outcome in the body region. The mA component includes the head/brain and spinal cord, the mB component includes the thorax and neck injuries, and the mC component consists of all other injuries. AIS scores of 1 and 2 are not included. The score itself is derived by adding the squares of each AIS injury ≥3, adding the scores and then determining the square root of the total. A coefficient is then assigned to each component.

$$APS = 0.3199(mA) + 0.4381(mB) + 0.1406(mC)$$
$$+ 0.7961(maxAIS)$$

Although the authors showed that AP better discriminated survivors from nonsurvivors compared to ISS and was more sensitive than ISS, it has failed to replace the venerable ISS.

CASE FATALITY RATE BY INJURY SEVERITY SCORE
FIGURE 63.1. Case fatality rates by ISS from the 2010 National Trauma Data Base.

Scores Used to Predict Outcome

The TRISS Methodology The TRISS method combines the components of the RTS with the ISS to generate a probability of survival for individual trauma patients. Additionally, TRISS adds a calculation for age and separate coefficients for blunt and penetrating mechanisms. The TRISS method is used to quantify the severity of injury of a patient population, calculates the probability of survival of patients for identification of cases for peer review, and compares the death or survival rates of different populations.[19]

The TRISS methodology is most commonly used to generate a probability of survival for a patient using the following equation:

$$Ps = 1/(1 + e^{-j})$$

$$\text{Where } j = j_0 + j_1(TS) + j_2(ISS) + j_3(A)$$

The b coefficients in the equation were derived using Walker-Duncan regression analysis of thousands of patients from the Major Trauma Outcome Study.[20] A represents age with $A = 1$ for patients age 55 and older and $A = 0$ for patients 54 and younger. Given a 55-year-old male with a GCS of 10, a systolic blood pressure of 88 mmHg, and a respiratory rate of 22/min, the RTS is 6.171. Assuming a blunt head injury with an ISS of 25:

$$j = -1.2470 + 0.9544(6.171) + -0.0768(25) + -1.9052(1)$$

$$j = 0.8174$$

$$Ps = 1/(1 + 2.718282^{-(0.8174)})$$

$$Ps = 1/(1 + 0.4416)$$

$$PS = 0.69$$

This patient, aged 55, with a blunt head injury has a probability of survival of 69%. The same patient with a penetrating injury would have a probability of survival of 70%. A 44-year-old with the same injury scores would have a probability of survival of 92% for a blunt injury and 88% for penetrating injury.

Once survival probabilities of a group of patients have been determined, they can be plotted against an S 50 isobar using the RTS on the vertical axis and ISS on the horizontal axis. Patients are thought to be unexpected deaths if they have a probability of survival of 50% or higher and die. Patients with a survival probability of <50% who survive are unexpected survivors. It has been suggested that patients who are unexpected deaths should undergo peer review. Using statistical analysis, survival probabilities can be used to compare subsets of patients to determine if survivors and deaths fall within expected parameters.[21]

Criticisms of the TRISS methodology are several. The MTOS database from which the coefficients were derived may be quite different than the population being evaluated. Care must be taken to assure a sufficient match among populations. The sensitivity of the S 50 isobar is also questioned. While a patient with a 52% survival probability who dies is categorized as an unexpected death, the patient had a 48% probability of dying. Therefore, care must be exercised when using the TRISS methodology for evaluating isolated patients.

A Severity Characterization of Trauma The AP score is an attempt to replace the ISS with a weighted anatomical scoring system. Champion and colleagues with a severity characterization of trauma (ASCOT) upgrade TRISS using the AP score in place of the ISS. The equation for the ASCOT methodology is similar to TRISS.

$$Ps = 1/(1 + e^{-k})$$

$$\text{Where } k = k_1 + k_2\ G + k_3\ S + k_4\ R + k_5\ A + k_6\ B + k_7\ C + k_8\ Age$$

The k coefficients for ASCOT like TRISS are derived from regression analysis of patients from the Major Trauma

Outcome Study. The constants G, S, and R represent the GCS, systolic blood pressure, and respiratory rate from the RTS, and the constants A, B, and C are obtained from the first three components of the APS score. The age component of ASCOT has five categories with a numeric scale of 0–4 with the assigned value increasing as age increases.[22] ASCOT has not replaced TRISS. It is substantially more complex than TRISS, and the improvements it offers are not dramatic. A subsequent comparison of TRISS versus ASCOT found the two to be essentially equal in their predictive power.[23]

International Classification of Disease Injury Severity Score The International Classification of Disease Injury Severity Score (ICISS) instead of using AIS grades uses survival risk ratios derived from ICD-9 codes. Survival risk ratios (SRR) are derived for each ICD-9 code by determining the number of patients who survive the coded injury and dividing that number by the total number of patients with the injury. Once SRRs have been developed for a group of patients from a database, the ICISS score is determined by the formula

$$ICISS = \left(SRR_{inj\,1}\right)\left(SRR_{inj2}\right)\left(SRR_{inj3}\right)\left(SRR_{inj...last}\right)$$

The ICISS is the product of all available SRRs for a given patient and is bounded by 0 and 1. An ICISS of 0.5 corresponds to a predicted survival of 50%.

Osler and colleagues introduced ICISS in 1996. In their original description, they developed SRRs for ICD-9 codes using 314,402 patients from the North Carolina database. Once the ratios were obtained, they compared ICISS to ISS using 3,142 trauma patients from the University of New Mexico. ICISS was found in their study to outperform ISS for both penetrating and blunt trauma.[24] They also combined RTS and age to ICISS to create a survival probability model, which they then compared to the TRISS methodology. They found the ICISS model outperformed TRISS in determining probability of survival for both penetrating and blunt injury.[22]

The appeal of a scoring system that used ICD-9–based codes is that smaller trauma centers that do not have the resources to calculate AIS and ISS scores can use the universal ICD-9 codes to predict mortality and develop probability of survival models. ICISS is derived empirically and is not determined by consensus. When large databases are used to derive SRRs, the predictive value of a specific injury is powerful. Because all injuries to a particular patient are used to calculate ICISS, the significance of lesser injuries is overestimated. This is mitigated to some degree. Indeed, Osler and his coauthors identified approximately 100 injuries that were associated with most fatalities. Chief among these were head, burn, and thoracic and abdominal vascular injuries.[22] This finding lends credibility to scoring systems that use only the worst injury like MAXAIS which in one study outperformed multi-injury scoring systems.[25]

Trauma scoring systems are useful as they allow the quantification of injury and the probability of survival based on injury scale score. They have been used to create field triage systems and allow comparison of similarly injured patients treated in different hospital and trauma systems. They are also valuable as a screening tool for quality assurance programs. They are not, however, effective for screening individual patients. A patient with a predicted survival of 55% also has 45% mortality. The variables that determine such a patient's outcome are complex and include the patient's age, comorbidities, prehospital care, and the capabilities of the hospital staff and surgeons, to name a few. The closer the probability of survival to the Survival 50 Isobar, the less able any scoring method is to discriminate outcome. For the purpose of quality improvement, scoring systems are best used to evaluate trauma populations and system outcomes.

SCORING SYSTEMS FOR EMERGENCY GENERAL SURGERY

Introduction and Background

Scoring systems for emergency general surgery must describe the severity of each surgical disease in a way that relates to treatment, complications, and outcomes. The accuracy of a scoring system can be evaluated using statistical measures such as sensitivity, specificity, positive predictive value, and the negative predictive value. The scoring systems in trauma describe the anatomic and physiologic parameters present in the patient. Cancer scoring systems describe the primary tumor, the nodal status, and metastasis. These allow for standardization of patients and comparison of treatment and outcomes. The scoring systems for emergency general surgery are not as well developed, making it difficult to construct research studies and reach firm conclusions about many of these conditions.

Emergency general surgical conditions can be broadly classified as obstruction, perforation, ischemia, infection, or bleeding affecting an organ system or specific anatomical site. Examples are found in the respiratory, cardiovascular, gastrointestinal, and genitourinary systems. These conditions include airway obstruction, pneumothorax, vascular thrombus and embolus, small bowel obstruction, cholecystitis, diverticulitis, duodenal ulcer disease, pancreatitis, and urinary retention, to name a few. There is an opportunity to develop scoring systems for many of these conditions (Table 63.4).

Scoring systems focus on three broad areas: the grade of the anatomic lesion, the physiologic response of the patient, and the patient-specific factors. Some anatomic scoring systems have been developed using the radiographic appearance, operative findings, or pathologic examination to grade the lesion. Other scoring systems describe the physiologic response of the patient to their disease. These responses can be clinical measurements such as temperature, white blood cell count, heart rate, respiratory rate, and blood pressure, or they can be physical findings like localized pain and peritonitis. The systemic inflammatory response syndrome (SIRS) score is an example of a physiologic scoring system.[26,27] Still other scoring systems use patient factors such as age, comorbid conditions, and preexisting diseases. The APACHE II score and Apache III score use physiologic data and patient factors together.[28,29] The American Society of Anesthesiologists (ASA) scoring system uses the patient's physical status, from healthy to moribund, followed by an E for emergency surgery. Anatomic, physiologic, and patient factors all affect surgical decision making, treatment, and the prediction of outcome. Combining these into multiple-factor scoring systems represents the best way to categorize patients, their disease processes, and response to therapy.

This chapter describes some of the best-known scoring systems used to describe common clinical problems in emergency general surgery. This section is also meant to highlight the gaps and opportunities for the research and the need to develop new scoring systems.

Acute Cholecystitis

Gallbladder disease is a common surgical condition with several etiologies. They include acute cholecystitis, chronic cholecystitis, acalculous cholecystitis, biliary colic, and biliary dyskinesia, or are associated with ascending cholangitis. It is crucial that a unified definition of acute cholecystitis exist. The diagnostic criteria and severity assessment of acute cholecystitis were discussed and finalized at an international consensus meeting in Tokyo in 2006.[30] The "Tokyo Guidelines" define acute cholecystitis as signs of local inflammation such

Adapted from the AAST Organ Injury Scaling. Scoring systems for emergency general surgery conditions exist for some of the common problems that could be included in this array. There is little uniformity among them as you would find in trauma or cancer scoring systems.

as Murphy's sign, a mass, or localized pain and tenderness in the right upper quadrant combined with signs of systemic inflammation such as fever, elevated white blood cell count, or elevated C-reactive protein concentrations. In patients who are suspected of having acute cholecystitis, the diagnosis can be confirmed with imaging studies. The consensus group classified severity into three groups: mild (grade I), moderate (grade II), and severe (grade III). Grade I was described as mild acute cholecystitis in a patient with no systemic organ dysfunction and disease limited to the gallbladder. Cholecystectomy was viewed as a low-risk procedure in this group. Grade II was described as moderate acute cholecystitis in a patient with no systemic organ dysfunction but with extensive disease in the gallbladder. Cholecystectomy was viewed as a difficult procedure to safely perform in this group. The clinical features differentiating grade I from grade II include disease duration > 72 hours with increased fever, white blood cell count, pain and tenderness, palpable mass, and imaging studies showing substantial inflammatory changes. Grade III was described as severe acute cholecystitis in a patient with systemic organ dysfunction.

The Tokyo criteria provide an international consensus and evidence-based guideline for the definition and severity of acute cholecystitis. This is an important step in the development of similar scoring systems for other emergency surgical conditions of the gallbladder and biliary tree including ascending cholecystitis.

A scoring system for complications following cholecystectomy has been proposed.[31] This prospective nonrandomized study compared laparoscopic to open cholecystectomy. The Tokyo criteria were not used in this study. Complications were divided into four grades. Grade 1 was a deviation from the ideal postoperative course with spontaneous resolution and no increase in the length of stay. Grade 2 was a transient threat to the patient's life that may have required invasive procedures and management. Grade 3 was a persistent threat to the patient's life that required invasive procedures and was accompanied by permanent sequel. Grade 4 was death of the patient. This type of scoring system focuses on patient safety and outcomes. These are essential when evaluating treatment options in specific patient populations.

Pancreatitis

Pancreatitis is one of the best examples of an emergency general surgery condition that has had scoring systems developed and studied. Acute pancreatitis ranges from a mild self-limiting disease to a fatal illness. This unpredictability stimulated the development of objective scoring systems to predict the clinical course, identify patients for clinical trials, and to compare outcomes.[32] The best-known scoring system is the Ranson Score or Ranson Criteria, introduced in 1974.[33] Ranson developed a multiple-factor score that is calculated on admission and at 48 hours after admission. It assigns a value of 1 or 0 if the criteria are present or absent before calculating the total score. Ranson focused on measures that were related to patient factors and the pathophysiologic manifestations of the disease. The admission criteria include age, white blood cell count, serum glucose, serum lactate dehydrogenase, and serum aspartate transaminase. At 48 hours, the criteria include change in

hematocrit, change in blood urea nitrogen, serum calcium, oxygenation, base deficit, and intravenous fluid requirements. These criteria have been widely used, critically evaluated, and modified over time.

The APACHE II score was introduced in 1985 as way to prognostically stratify acutely ill ICU patients.[28] It is a multiple-factor score that assigns a range of values to each criterion before calculating the total score. The criteria include temperature, mean arterial pressure, heart rate, respiratory rate, oxygenation, arterial pH, serum sodium, serum potassium, serum creatinine, hematocrit, white blood cell count, and GCS. While APACHE II was never developed for pancreatitis, it was found to be a more accurate scoring system for the prediction of outcome and attacks of severe pancreatitis than the Ranson Score.[34] It is common to see the two used in combination.

Computed tomography (CT) severity scoring was the next advance.[35] Initial and follow-up contrast-enhanced CT scans were compared to the patient's clinical course and Ranson score. These CT scans provided better prognostic accuracy. In addition, they improved clinical decision making by differentiating the anatomic lesion as pancreatic inflammation, phlegmon, the degree of necrosis, and the presence of abscess or pseudocyst. Enhanced MRI is now considered comparable to enhanced CT scan.

Further refinement of the definition and severity scoring system for severe acute pancreatitis revealed a 29% decrease in early in hospital deaths.[36] The most recent guideline for acute pancreatitis states that "severity assessment is essential for the selection of the proper initial treatment."[37] These show the relationship between scoring systems with high prognostic accuracy as a driver for clinical care and improved outcomes.

Small Bowel Obstruction

The efforts to create a scoring system for small bowel obstruction were led by radiologists. The diagnosis of intestinal obstruction is usually suspected by history and physical exam. Patients with shock, peritonitis, free air, or other compelling findings require emergency surgery. In the ambiguous case, however, diagnostic studies are helpful. The CT scan can identify the level of obstruction in the gastrointestinal tract, if high- or low-grade obstruction is present, and if strangulation or closed loop obstruction is present.[38] The use of intravenous contrast and 1-mm cuts improves the accuracy and can usually distinguish extrinsic lesions, intrinsic lesions, intussusceptions, and intraluminal foreign bodies.[39] Further experience has led to CT scoring systems that predict the need for surgery by correlating specific anatomic CT findings to the need for emergency surgery and the intraoperative findings.[40] Newer predictive models have incorporated physiologic responses and patient factors to this approach.[41]

Diverticulitis

Diverticulitis is easily diagnosed using the patient's history, physical exam, and diagnostic studies. New treatment paradigms have emerged because the anatomic, physiologic, and patient factors can be accurately described.[42] CT scans were prospectively correlated with patient's clinical course to propose a system for classifying the severity of diverticulitis and to guide clinical management.[43] CT findings consistent with mild diverticulitis included localized wall thickening (>5 mm) and inflammation of the pericolic fat. CT findings consistent with severe diverticulitis included wall thickening (>5 mm) and inflammation of the pericolic fat plus the presence of an abscess, extraluminal air, or extraluminal contrast. Patients with findings consistent with severe diverticulitis underwent operative management more frequently. These findings were also associated with recurrences in patients treated without surgery.

The timing of surgery is determined by the anatomic and physiologic severity of the disease and the patient factors.[44] These are described using the findings in the physical exam, CT scans, as well as the data associated with the ASA, APACHE II/III, or SIRS scoring systems.

Peritonitis-based scoring systems have been used to study the decision making and choice of operations for diverticulitis. Some of the best-known examples are the Hinchey classification,[45] the Mannheim peritonitis Index (MPI),[46] and the colorectal physiologic and operative severity score for the enumeration of mortality and morbidity (Cr-POSSUM).[47] The Hinchey classification system defines stage 1 as pericolic or mesenteric abscess, stage 2 as pelvic or retroperitoneal abscess, stage 3 as purulent peritonitis, and stage 4 as feculent peritonitis (Table 63.5). The Hinchey classification is widely used for research and operative decision making.[48] The MPI includes only clinical risk factors that are commonly documented for perioperative patients. The parameters include age, gender, organ failure(s), presence of malignancy, preoperative peritonitis more than 24 hours, presence of diffuse generalized peritonitis, site of primary focus, and the nature of peritoneal exudative fluid. The Cr-POSSUM appeared to be a promising tool for colorectal cancer surgery and must be evaluated for complicated diverticulitis.

Appendicitis

Acute appendicitis is a long-studied emergency general surgery condition in search of a unified scoring system. The Alvarado Score is based on eight predictive factors found to be useful in making the diagnosis of appendicitis.[49] They include localized tenderness in the right lower quadrant, increased white blood cell count, migration of pain from the umbilicus, increased polymorphonuclear neutrophils, increased temperature, nausea and vomiting, anorexia and positive acetone, and direct rebound pain. The Pediatric Appendicitis Score is a similar system that identified eight predictive findings in children.[50] They include cough-induced tenderness in the right lower quadrant, anorexia, increased temperature, nausea and vomiting, tenderness over the right lower quadrant, increased white blood cell count, increased polymorphonuclear neutrophils, and migration of pain from the umbilicus. These scoring systems have been modified by many investigators and used to direct the selection of diagnostic studies, predict the need for surgery, and correlate with the occurrence of complications. These systems focus on the patient's physiologic response to the disease. What

TABLE 63.5

THE HINCHEY CLASSIFICATION FOR INTRAPERITONEAL CONTAMINATION IN DIVERTICULITIS

■ HINCHEY DIVERTICULITIS CLASSIFICATION		
■ INTRAPERITONEAL CONTAMINATION	■ SCORE	■ INITIAL TREATMENT OPTION

Diffuse peritonitis	3	Surgery with/without diversion
Feculent peritonitis	4	Surgery with diversion

these systems achieve in diagnostic accuracy and specificity they lack in ease of use and a simplified stage or grade approach.

Scoring systems that describe the anatomic and pathologic lesion found in the appendix have been proposed by radiologists, surgeons, and pathologists. The most common surgical and pathologic construct is to describe grade 1 as acute appendicitis, grade 2 as gangrenous appendicitis, grade 3 as perforated appendicitis, and grade 4 as a periappendicular abscess.[51] Studies have cautioned about the poor interobserver variation in the grading of appendiceal perforation by surgeons.[52] Improved accuracy has led to an increased use of CT scanning for diagnosing appendicitis. The effort to correlate CT findings with the surgical and pathologic grading has led to as many as six grades where grade 0 is normal, grade 1 is probable appendicitis and progressing to grade 5 which is complicated appendicitis with abscess or inflammatory mass.[53]

What is clear from the preceding discussion is that a unified scoring system is needed. Some large clinical studies have been difficult to interpret because of the absence of such data.[54]

SUMMARY

Scoring systems must accurately describe the anatomic lesion, physiologic responses, and the patient factors that guide treatment and surgical decision making. In addition, they must prognostically stratify outcomes.

SPECIAL TOPICS

CHAPTER 64 ■ PROCEDURES

AMY J. GOLDBERG AND ABHIJIT S. PATHAK

OPEN TRACHEOSTOMY

Indications

1. Obstruction at or above the larynx secondary to
   a. tumor
   b. edema
   c. trauma/fracture
   d. foreign body
   e. burns
   f. severe pharyngeal or neck infection
2. Chronic/long-term respiratory issues
   a. Coma after head injury, neurosurgery
   b. Paralysis such as spinal cord injury
   c. Patients requiring prolonged ventilatory support
3. Anticipated edema/swelling in patients undergoing major operative procedures of the
   a. oropharynx
   b. mandible
   c. larynx

Preoperative Preparation

Chest x-ray and physical examination of the neck to ensure adequate external landmarks and plan for choice of tracheostomy tube size are paramount, in particular tracheostomy tube length and whether a distal extension or proximal extension tracheostomy tube may be needed. Patients with previous tracheostomy may prove to be challenging. Often, trauma patients may have a concomitant cervical spine injury or a cervical collar in place. This is important to know since the patient's neck cannot be extended and the procedure must be performed in the neutral position.

Anesthesia

Many of the patients an acute care surgeon operates on will have an existing endotracheal tube and general anesthesia. In the emergent setting, local anesthesia can be used if the clinical situation allows.

Positioning

The patient is placed in the supine position with both arms tucked to the sides. A roll (we use a tightly rolled blanket) is placed under the shoulders to allow extension of the neck if there is no contraindication (Fig. 64.1). Patients with a cervical collar (cervical spine injury or in whom the cervical spine has not been cleared) require maintenance of the neutral position, and this can be accomplished with immobilization of the patient's head and neck with sandbags on either side of the head with the anterior portion of the collar removed to gain access to the neck.

Operative Preparation

Sterile field is prepared in the usual manner and includes the anterior neck, chin, and upper chest.

Procedure

A vertical incision from just above the cricoid cartilage or transverse incision a fingerbreadth cephalad to the sternal notch is made in the skin and extended 3 cm. The skin and subcutaneous tissues are incised down to expose the strap muscles, and the median raphe of the strap muscles is identified and incised vertically (Fig. 64.2). The strap muscles are then retracted laterally to expose the isthmus of the thyroid gland. We generally divide the isthmus with electrocautery followed by suture ligation. This exposes the underlying airway. The cricoid cartilage is identified and a tracheotomy is performed through the second or third tracheal ring. This is accomplished utilizing a no. 11 or 15 scalpel to excise the anterior portion of the tracheal cartilage. Care must be taken to not extend the incision too deeply to avoid injury to the posterior wall of the trachea and esophagus. Communication between the surgeon and the anesthesiologist or person managing the airway is critical during the actual tracheotomy, withdrawal of the endotracheal tube, and insertion of the tracheostomy tube. Once the anterior portion of the tracheal cartilage is incised, the endotracheal tube is withdrawn under direct vision so the distal tip is just visible through the tracheotomy. The tracheotomy may then be dilated utilizing a tracheal dilator. The tracheostomy tube is then inserted into the trachea, the obturator removed, the balloon inflated, and the inner cannula placed and connected to the anesthesia machine to ensure end-tidal CO_2 and ventilation (Fig. 64.3). The tracheostomy tube is then secured to the skin with 2–0 nylon sutures, and a dressing may be placed under the flange of the tube. The incision usually does not need to be reapproximated.

Postoperative Care

A chest x-ray is obtained postoperatively to ensure adequate placement and to ensure that the pleura had not been violated with development of a subsequent pneumothorax. A duplicate tube should be at the patient's bedside at all times. The inner cannula should be removed and cleaned frequently to prevent buildup of secretions.

BEDSIDE TRACHEOSTOMY

A tracheostomy can be performed at the patient's bedside in the intensive care unit (ICU) via an open technique as stated above or via a semiopen or percutaneous method. The surgeon must ensure that the same equipment, lighting, monitoring, and personnel are present as in the OR. Lighting must be adequate, and electrocautery is necessary. Within the past 10–20 years,

bedside percutaneous tracheostomy has gained popularity. We utilize the Seldinger-based blunt dilation approach (Blue Rhino Percutaneous Tracheostomy Introducer Kit, Cook Critical Care). A number of these kits are available on the market. When initiating a percutaneous tracheostomy program in your institution, patient selection is critical. Exclude patients with coagulopathy, high oxygen requirements, previous tracheostomy, morbid obesity, and unstable cervical spine injuries or an inability to hyperextend the neck.

The proper equipment must be available to ensure a successful procedure and prevent devastating complications. When beginning to utilize the percutaneous method, both percutaneous tracheostomy kit and surgical instruments should be present at the bedside. Again, adequate light is critical, and electrocautery may be beneficial. The appropriate personnel should also be present. The surgeon and his/her assistant perform the procedure; the anesthesiologist or second surgical assistant monitors the airway and performs the bronchoscopy. We recommend routine use of the bronchoscope for percutaneous tracheostomy. A nurse is necessary to assist in any parts of the procedure from monitoring vital signs to the administration of sedation (propofol and narcotic).

The patient is positioned, prepped, and draped as discussed above. The bronchoscope is passed into the endotracheal tube and positioned to adequately visualize the trachea. Local anesthetic may be infiltrated in the subcutaneous tissues prior to making a 1-cm incision over the second and third tracheal ring. Using a hemostat, the tissues are bluntly dissected to adequately palpate the second tracheal ring. Under bronchoscopic guidance, the trachea is entered percutaneously between the second and third rings. Upon entry into the airway, air bubbles are seen in the fluid-filled syringe, and the bronchoscope easily visualizes the needle. Then, in a Seldinger fashion, a wire is passed into the needle, and the needle is withdrawn (Fig. 64.4A). The track is then dilated over the wire, all under bronchoscopic visualization

(Fig. 64.4B,C). The endotracheal tube is then slowly withdrawn to just above the tracheotomy, and the tracheostomy tube is placed in appropriate position (Fig. 64.4D). An end-tidal CO_2 monitor should be used to reconfirm placement.

CRICOTHYROIDOTOMY

Indications

A cricothyroidotomy is performed when an emergent airway is needed with no time to prepare for routine tracheostomy.

Preoperative Preparation

A sterile field should be attempted; however, the emergent nature of the procedure may not allow this.

Anesthesia

Local anesthesia is preferred if possible.

Positioning

Same as for tracheostomy; however, the usual emergent nature of the procedure precludes any elaborate methods for positioning. Remember that a cricothyroidotomy is performed by palpation, not visualization. If you are right-handed, you should be standing on the patient's right. The thyroid cartilage should be held between the thumb and third finger of your right hand and your index finger essentially in the cricothyroid membrane until you have incised the membrane. This technique ensures that landmarks are not lost resulting in an ill-placed incision.

Procedure

A vertical incision similar for tracheostomy is made; however, the incision is extended cranially to the mid-thyroid cartilage. It is important to avoid the anterior jugular veins that are just off the midline. Since the procedure is often performed emergently with minimal instruments and lighting, palpation of landmarks is key. The skin and subcutaneous tissue over the cricothyroid membrane is incised in a vertical fashion. A transverse incision in the cricothyroid membrane is created with a scalpel and the cricothyroidotomy may be dilated with the end of the scalpel blade or a curved hemostat (Fig. 64.5). Dilate transversely, not longitudinally. Longitudinal incision or dilatation may fracture the cricoid cartilage. Either a no. 7 endotracheal tube or no. 7 tracheostomy tube can be used in an adult male; at times a no. 6 may be necessary. A no. 6 or even a no. 5 tube may be required in a small female. Do not attempt to force too large a tube through the cricothyroid membrane as this may also fracture the cricoid cartilage. We prefer placement of an endotracheal tube, which makes subsequent conversion to formal tracheostomy easier. When utilizing an endotracheal tube, care must be taken not to insert the tube too deeply. Usually, insertion to just after disappearance of the balloon is adequate. The endotracheal tube should be properly secured the skin. If a tracheostomy tube is used, it is secured as noted above.

Postoperative Care

If an endotracheal tube is utilized, care must be taken to prevent dislodgement of the airway as well as malpositioning (usually down the right mainstem bronchus). A cricothyroidotomy is usually converted to formal tracheostomy.

DIAGNOSTIC PERITONEAL LAVAGE

Indications

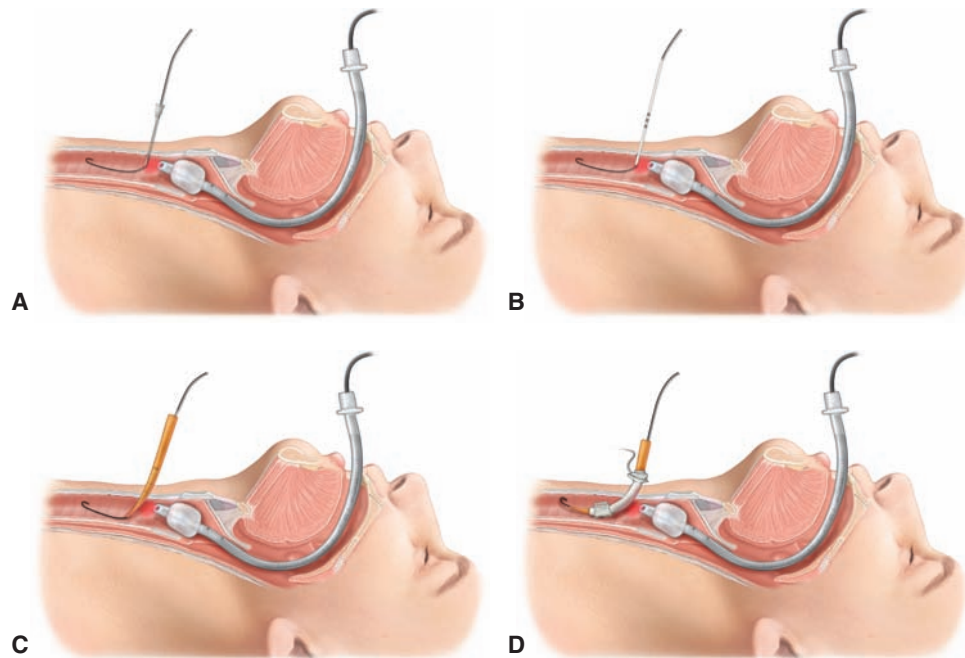
In 1965, Root described the use of diagnostic peritoneal lavage (DPL) for the evaluation of the blunt trauma patient. Much has changed in the past 45 years in the care of trauma patients. Computed tomography (CT) and focused abdominal sonography for trauma (FAST) have dominated the workup of both the blunt and penetrating trauma patient. DPL remains a useful diagnostic tool. Its major disadvantages are that it is invasive and nonspecific. A positive DPL means the patient has hemoperitoneum (generally) with no information about organ injury. Thus, many laparotomies based on positive DPL in the past were nontherapeutic. In the trauma population, DPL is currently reserved for the unstable blunt trauma patient with an equivocal FAST exam. DPL is 98%


FIGURE 64.4. Percutaneous dilatational tracheostomy.

sensitive for intraperitoneal bleeding. This becomes useful when deciding where to proceed from the trauma bay, CT scan/angiography, or the operating room. DPL is also helpful in diagnosis of hollow viscus injury. Many also use DPL in the penetrating trauma patient with a positive local wound exploration.

DPL can also be useful in the ICU. Should the trauma patient become hemodynamically unstable several hours after admission, DPL can be performed to assess bleeding in the peritoneal cavity. Although not commonly considered, DPL can be utilized to evaluate the acute care surgery patient who may be too unstable to be transported to CT scan. A patient with dead bowel will often have a serosanguineous fluid or a positive WBC count.

Preoperative Preparation and Positioning

Prior to starting a DPL, the patient must have a Foley catheter and nasogastric tube placed. This will decrease the likelihood of puncturing these structures while performing the procedure. The patient is placed flat and supine on the trauma bay stretcher and his pulse, blood pressure, and ECG are monitored.

Anesthesia

If the patient's blood pressure permits, a small dose of intravenous narcotic can be administered. Otherwise, the procedure can be performed with local anesthesia, 1% lidocaine with epinephrine.

Operative Preparation

DPL can be performed percutaneously or utilizing the open technique. Whichever is preferred, prior to beginning the procedure, it is critical to have all the appropriate equipment necessary.

Procedure

Unless the patient is pregnant or has a pelvic fracture, the DPL should be performed in the infraumbilical location.

FIGURE 64.5. Cricothyroidotomy.

SPECIAL TOPICS

Figure 64.6 describes the insertion site choices. Prepackaged percutaneous DPL kits are available and should be used for the percutaneous approach. The periumbilical region is prepped and draped. After local anesthesia is infiltrated a very small incision is made in the skin inferior to the umbilicus. The abdominal wall is grasped and the blunt needle is passed through the fascia and peritoneum. This usually feels like two "pops." Saline can be placed in the hub of the needle. If it easily drains, the needle is in the peritoneal cavity. Using the Seldinger technique, the wire then is passed through the needle into the peritoneal cavity. The needle is withdrawn, as the wire remains in place. A dilator is passed over the wire and removed, and lastly, the catheter is passed over the wire, and the wire is removed.

Aspiration of 10 mL of blood or food or bowel contents is positive. If neither is returned, 1 L of warm saline is instilled into the peritoneal cavity. The saline is allowed to mix with the contents of the peritoneal cavity and then drained. Be sure that some fluid remains in the IV bag to allow for adequate drainage from the peritoneum. The fluid is then sent for RBC, WBC, and Gram stain.

A positive DPL is >100,000 red cells per cubic millimeter, 500 white cells per cubic millimeter, or the presence of bacteria on Gram stain.

After the fluid has been removed, the catheter is withdrawn. A small Steri-Strip can be placed over the incision. In a hemodynamically marginal patient, the catheter may be sewn in place and the DPL repeated.

Postoperative Care

Postoperatively, the incision should be inspected daily for the presence of infection.

TUBE THORACOSTOMY

Indications

1. Pneumothorax
2. Hemothorax
3. Hemopneumothorax
4. Pleural effusion
5. Hydrothorax
6. Empyema

Supraumbilical approach

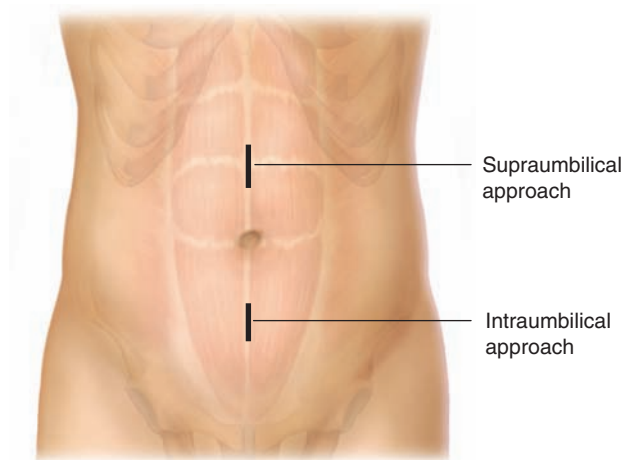
Intraumbilical approach


FIGURE 64.6. DPL insertion choices.

7. Penetrating chest wall injury requiring positive pressure ventilation
8. Air transport of patients who are at risk for pneumothorax

Anesthesia

Systemic analgesia such as intravenous narcotic is used in conscious patients, and sedation can be considered as well. Local anesthesia is utilized at the insertion site.

Positioning

The patient is placed in the supine position, and the ipsilateral upper extremity is abducted, and externally rotated so it is positioned above the patient's head.

Operative Preparation

For adult trauma patients undergoing chest tube placement, we usually utilize a 32–36 French chest tube, which is large enough to adequately drain a hemothorax. Consideration for a smaller caliber tube should be given for drainage of a pneumothorax or pleural effusion. Empyemas will usually require a larger caliber tube for effective drainage. The drainage system for the chest tube should be connected to suction, and the appearance of bubbles in the water chamber indicates that the device is functioning properly. A sterile field is prepared in the usual manner centered on the chest tube insertion site located in the anterior axillary line at nipple level in males and inframammary crease in females. This should correspond to the fourth or fifth intercostal space. After the sterile field is prepped, the distance between the clavicle and the incision site is measured with the chest tube. This estimates how far the tube should be inserted. This is accomplished by noting the marking on the chest tube (i.e., 12 cm from proximal end). The last hole on the chest tube must be placed sufficiently deeply in the patient's thoracic cavity. Remember that you can pull back a chest tube if placed too deeply. You cannot advance a chest tube that is too shallow on CXR as this is now contaminated externally.

Procedure

We perform insertion of a chest tube over the rib at the fifth intercostal space without creation of a subcutaneous tunnel. This is the simplest, most direct method for rapid insertion and decompression of the chest. Local anesthesia is injected in the skin and subcutaneous tissues initially. Next, a no. 10 scalpel is used to create transverse incision directly over the rib measuring approximately 2 cm. This is carried down through the subcutaneous tissues. At this point more local anesthesia is injected into the deeper tissues including the intercostal muscles, periosteum of the rib, and the parietal pleura. Next, a Kelly clamp is used to bluntly dissect the subcutaneous tissue down to the intercostal muscle. Figure 64.7 outlines placement of a chest tube. The tract is palpated with a finger to ensure that the tract extends over the top of the rib. Further blunt dissection by repeated opening and closing of the Kelly clamp along with gentle pressure is continued. Once the intercostal space is palpated, more local anesthetic can be injected into the muscle and parietal pleura. The closed Kelly clamp is then used to puncture the intercostal muscles and parietal pleura, being careful to stay along the superior margin of the rib. This maneuver requires some force and should be controlled so the Kelly clamp does not enter too far into the pleural space and

injure the underlying viscera. The Kelly clamp is then opened while only the tip is in the pleural space, thereby enlarging the dissected tract. A finger is then inserted into the pleural space and rotated to ensure there are no adhesions, and if present, they can be gently broken. If adhesions are present and cannot be broken, then placement under imaging or placement at a different site should be considered if the clinical situation allows. Next the proximal end of the chest tube is grasped with a Kelly clamp such that the clamp is parallel to the tube. This allows the Kelly clamp to introduce the chest tube into the pleural cavity. Another Kelly clamp is used to clamp the distal end of the chest tube if the patient is spontaneously breathing. The Kelly clamp grasped to the proximal end of the chest tube is inserted into the tract and into the pleural cavity and directed posteriorly and superiorly, making sure that all the side holes on the chest tube are within the thoracic cavity. This is accomplished by knowing the predetermined length as noted above. The Kelly clamp is removed while the chest tube is held stationary. Rotating the chest tube 360 degrees ensures that the tube is in proper position and not within the lung parenchyma or fissure or caught in adhesions. The chest tube is then connected to the drainage system and the distal Kelly clamp removed. The chest tube is then secured to the drainage system tubing with tape and to the skin with 0-silk suture. Either a purse string or simple suture can be used, making sure to wrap the suture around the chest tube several times. The insertion site and sutures are sealed with a petrolatum gauze and an occlusive dressing placed. We utilize a mesentery fold of tape securing the chest tube to the lower thoracic wall.

Postoperative Care

A chest x-ray is obtained to ensure adequate positioning of the tube and to ensure resolution of chest pathology.

PERCUTANEOUS GASTROSTOMY TUBE

Indications

1. Enteral access for feeding
   a. Dysphagia
   b. Inability to take PO secondary to
      i. Trauma, cancer, or recent surgery of the gastrointestinal (GI) tract or respiratory tract
      ii. Prolonged ventilation
2. GI tract decompression—usually for patients with abdominal malignancies causing gastric outlet obstruction, small bowel obstruction, or ileus.

Contraindications

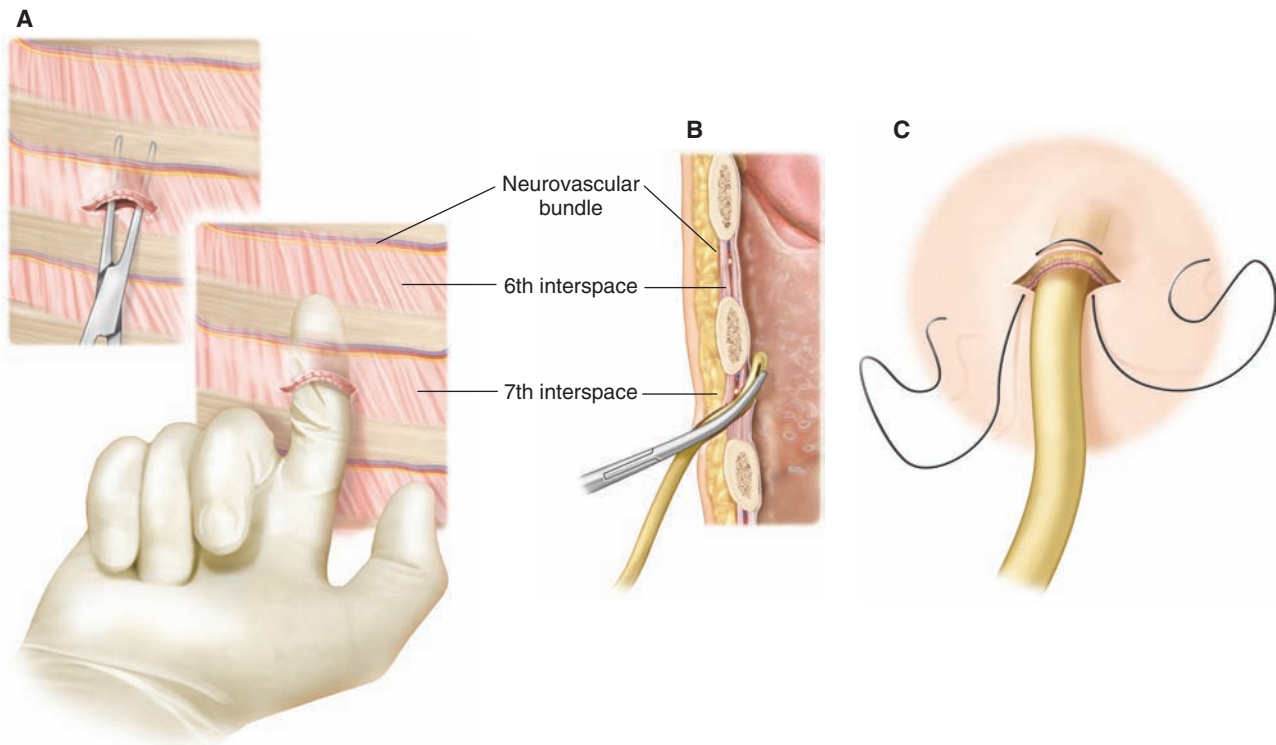
1. Absolute
   a. Coagulopathy or thrombocytopenia
   b. Ascites
   c. Intra-abdominal sepsis
   d. Severe gastroparesis
   e. Abdominal wall infection at site of insertion
2. Relative
   a. Oropharyngeal/esophageal malignancy
   b. Hepatomegaly
   c. Splenomegaly
   d. Gastric varices
   e. Previous abdominal surgery
   f. Ventral hernia
   g. Peritoneal dialysis
   h. History of partial gastrectomy


FIGURE 64.7. Tube thoracostomy insertion.

SPECIAL TOPICS

Anesthesia

The procedure can be performed with moderate to deep sedation with local anesthesia at the site of placement. It can also be performed under general anesthesia, and this is the usual technique in patients undergoing concomitant tracheostomy.

Positioning

The patient is placed in the supine position with the head of the bed elevated to about 30 degrees to prevent aspiration especially if performed with sedation and local anesthesia.

Operative Preparation

The patient should be NPO for at least 8 hours prior to the procedure. Preoperative antibiotics such as a first-generation cephalosporin should be infused prior to skin incision to prevent infection at the insertion site. An alternate antibiotic such as clindamycin to cover gram-positive organisms in penicillin-allergic patients is given. The sterile field should be prepared in the usual manner and should include the upper abdomen/lower chest.

Procedure

The procedure is performed utilizing a two-surgeon team with one surgeon performing the endoscopy and the other surgeon managing the abdominal wall portion of the procedure. An esophagogastroduodenoscopy is performed using the standard technique. When performing a percutaneous endoscopic gastrostomy (PEG) tube in conjunction with a tracheostomy, we find that PEG tube placement performed prior to the tracheostomy is technically easier since the existing endotracheal tube assists in passage of the endoscope. During the endoscopy, the stomach is inspected and any gastric contents suctioned. Any gastric outlet or duodenal obstruction is excluded (if using tube for feeding) as is any evidence of gastritis or ulcer. Next, the stomach is insufflated using the air channel of the endoscope. The OR lights are dimmed, and the abdominal wall is transilluminated using the endoscope light set at maximum intensity (many light sources have a transilluminate setting). The ideal location for placement of the PEG tube is two fingerbreadths below the left costal margin and two fingerbreadths to the left of the midline. Finger pressure is applied at this location over the previously transilluminated region, and the anterior stomach is visualized endoscopically. If transillumination is not achieved but finger pressure is visualized, one pass at insertion of the catheter may be attempted. If both are not achieved, then a decision to aborting the procedure should be taken. As finger pressure is applied and visualized endoscopically, location within the stomach is important since the tube should not be placed too close to the pylorus. The site on the abdominal wall is then anesthetized using lidocaine. Next, the catheter-over-the-needle is then passed through the abdominal wall using a rapid insertion technique to avoid having the stomach fall away form the abdominal wall. The endoscopist visualizes the placement of the needle while continuously insufflating air to ensure gastric distension and apposition of the stomach to the abdominal wall. The endoscope snare is inserted through the endoscope at this time, and the needle is removed, leaving the catheter within the stomach. A looped guidewire is then inserted through the catheter and into the stomach. The endoscopist then snares the guidewire and pulls the entire endoscope with the snare/guidewire out of the mouth. The catheter is then removed by threading it back over the guidewire. At this time, a scalpel is used

to make a horizontal incision measuring 0.5–1 cm in width at the guidewire insertion site on the abdominal wall, being careful not to cut the guidewire. The PEG tube is then secured to the looped end of the guidewire exiting the mouth. This is performed by passing the looped end of the guidewire through the loop of the PEG tube and then passing the PEG tube disk through the guidewire loop and pulling the entire tube through it. The PEG tube is then lubricated, and the person at the abdominal wall then pulls the guidewire so the entire PEG tube goes through the mouth, esophagus, and stomach and exits at the incision site. Meanwhile, the endoscopist reinserts the endoscope and follows the PEG tube as it is placed. The internal disk should be snug against the gastric mucosa without undue tension, and the site is inspected for bleeding. The guidewire is then cut at the tapered end of the PEG tube, and the external flange or bumper is then passed over the external portion of the PEG tube so that it sits on the abdominal wall without tension. The level of the PEG tube at the skin should be noted and recorded in the operative note. The endoscope is then withdrawn after desufflation of the stomach. The external portion of the PEG tube is then cut, and the supplied adapter is secured and the tube placed to gravity drainage or capped. The flange is secured to the skin using 2–0 nylon suture.

Postoperative Care

A drain sponge or split gauze is used as a dressing over the flange. We typically begin tube feeds on POD no. 1. The PEG tube insertion site should be cleaned daily.

FASCIOTOMY

Indications

1. Definitive compartment syndrome
2. High-risk lower extremity vascular injury
   a. Combined arterial and venous injury
   b. Associated bone fracture or massive soft tissue destruction
   c. Prolonged ischemia (>4–6 hours) prior to revascularization
   d. Treatment of major artery or vein injury by ligation

Positioning

The patient is in the supine position with both lower extremities exposed.

Operative Preparation

Circumferential sterile field preparation of the affected lower extremity.

Procedure

The double-incision technique is a safer, more effective, and preferred approach since the overlying skin can prevent decompression despite release of the underlying fascia.

There are four compartments in the lower leg (distal to knee); when performing a fasciotomy, all four compartments must be decompressed.

The anterior and lateral compartments are decompressed through one incision on the lateral aspect of the leg. A 15- to 20-cm incision that is centered over the fibula is created and taken down through the subcutaneous tissues. A flap needs

to be created anteriorly (transversely) to expose the intermuscular septum. A nick in the anterior compartment fascia is performed midway between the septum and the tibia. Metzenbaum scissors are used to perform a longitudinal fasciotomy proximally and distally staying parallel to the septum. The lateral compartment is then released in the same manner by staying posterior to the intermuscular septum, and the longitudinal fasciotomy is carried out proximally, being careful not to extend it beyond the fibular head since the peroneal nerve courses around it. Likewise, the fasciotomy is carried out distally aiming for the lateral malleolus to avoid injury to the peroneal nerve that will run more anteriorly.

The medial incision is made two fingerbreadths posterior to the posterior medial margin of the tibia and is extended 15–20 cm. The subcutaneous tissue is incised and care taken to avoid the saphenous vein. This will expose the superficial posterior compartment fascia, a nick is made, and a longitudinal fasciotomy is carried out proximally and distally with Metzenbaum scissors. To expose the deep posterior compartment, the superficial posterior compartment muscles need to be dissected free of the tibia. This will expose the deep posterior compartment, which can then be released in the same manner. Bleeding is controlled with electrocautery or sutures. The two wounds are then dressed with Xeroform gauze. Alternatively, some surgeons "shoelace" the incision with vessel loops secured to the wound edges with staples and apply gentle progressive traction over several days to facilitate closure.

Postoperative Care

The fasciotomy sites are inspected daily; once the swelling has subsided, primary closure can be undertaken. If swelling continues, a vacuum assist closure device can be used to facilitate closure and promote granulation tissue if skin grafting seems necessary.

INFERIOR VENA CAVA FILTER

Indications

Inferior vena cava (IVC) filters are placed to decrease the risk of pulmonary embolism from a deep vein thrombus originating in the pelvic or lower extremity veins. IVC filters should be placed in patients who have a contraindication to anticoagulation, prophylactically in high-risk patients, and in patients who develop recurrent pulmonary emboli on therapeutic anticoagulation.

Contraindications to anticoagulation can include patients with recent trauma or surgery, recent history of a GI bleed or development of a GI bleed while on anticoagulation, or patients with intracranial bleed. Prophylactic filters may be placed in patients who are at high risk for development of a deep vein thrombosis or pulmonary embolus. In the trauma patient population, this includes patients with severe head injury, spinal cord injuries with neurologic deficits, and significant long bone and pelvic fractures.

Procedure

IVC filters can be placed at the bedside, decreasing any risks from the transport of critically ill patients from the ICUs to the operating room or interventional suite. Patients should have a venous duplex of both common femoral veins to assess patency. Only on rare occasions is an IVC filter placed from the right internal jugular vein. Bedside fluoroscopy or ultrasonography is necessary to ensure patency of the IVC, measure its diameter, and evaluate for a duplicated IVC. The right common femoral vein is accessed via a percutaneous approach, and utilizing the Seldinger approach, the guidewire is passed into the IVC, the sheath is passed over the wire, and the appropriately sized filter is deployed. The filter should be placed below the level of the right renal vein.

Retrievable

Within the last several years, retrievable filters have gained popularity. These filters are ideal for patients who are temporarily at high risk for pulmonary embolism and deep vein thrombosis or those who later become candidates for anticoagulation. The benefit of the retrievable filter is to decrease the complications from filter placement, such as migration and filter or caval thrombosis.
