Preface

Though many of the “usual diseases of childhood” have been eliminated through expanded immunizations, new and more challenging morbidities confront pediatric patients, their families, and their health care providers. Violence, obesity, genomics, and the Internet and their impact on children are ever-present on the front pages of our newspapers and in our offices and clinics. The world is contracting and diseases once isolated by oceans are now only a plane ride away. This fourth edition of *Berkowitz’s Pediatrics: A Primary Care Approach* examines a series of emerging entities that pediatricians are expected to be knowledgeable about and able to address. Because we interface with other disciplines, we must be equipped to understand the principles of their practices and communicate effectively with them. And lastly, our multicultural society includes children from all parts of the world and from all kinds of families, and we need to be prepared to address their needs.

My thanks to all the contributors and to the staff of the American Academy of Pediatrics, especially Diane Lundquist, MS; Kate Larson; Linda Smessaert; Theresa Wiener; and Peg Mulcahy, and my assistant, Mary Magee, for all their help.

Carol D. Berkowitz

Contributors

Sudhir K. Anand, MD

Professor of Clinical Pediatrics, David Geffen School of Medicine at University of California Los Angeles; Chief, Division of Pediatric Nephrology, Harbor-UCLA Medical Center, Torrance, CA

David Atkinson, MD

Associate Professor of Clinical Pediatrics, David Geffen School of Medicine at University of California Los Angeles; Division of Pediatric Cardiology, Harbor-UCLA Medical Center, Torrance, CA

Sarah Atunah-Jay, MD

Academic General Pediatrics Fellow, Division of General Pediatrics, Department of Pediatrics, University of Minnesota, Minneapolis, MN

Justine Bacchetta, MD, PhD

Visiting assistant researcher, Pediatric Nephrology, David Geffen School of Medicine at University of California Los Angeles

Martin Baren, MD†

Attending Physician, Developmental and Behavioral Pediatrics, Children's Hospital of Orange County, Orange County, CA

Andrew J. Barnes, MD, MPH

Assistant Professor of Developmental-Behavioral Pediatrics, Division of Academic General Pediatrics, University of Minnesota, Minneapolis, MN

Lindsay S. Baron, MD

Resident, Department of Radiology, Montefiore Medical Center of The Albert Einstein College of Medicine, Bronx, NY

Maneesh Batra, MD, MPH

Assistant Professor of Pediatrics
University of Washington School of Medicine, Seattle

Andrew K. Battenberg, BS

Medical Student, David Geffen School of Medicine at University of California Los Angeles

Carol D. Berkowitz, MD

Professor of Clinical Pediatrics, David Geffen School of Medicine at University of California Los Angeles; Executive Vice Chair, Department of Pediatrics, Harbor-UCLA Medical Center, Torrance, CA

Primary Care: Introduction

Julie E. Noble, MD

Primary care is defined as the comprehensive health care that patients receive from the same health care provider over a longitudinal period. The term was first used in the 1960s to designate the role of the primary care physician in response to the abundance of subspecialists and lack of generalists among practicing physicians. It is generally accepted that primary care physicians include pediatricians, family physicians, and internists. In 1966 the Millis Committee Report to the American Medical Association on graduate medical education recognized the importance of primary care and recommended a national commitment to educating primary care physicians. Primary care was further defined in 1974 by Charney and Alpert, who separated it into component parts: first contact, longitudinal care, family orientation, and integration of comprehensive care. To understand the depth of primary care, the component parts should be explored.

First contact occurs when a patient arrives for medical care at the office of a primary care physician. The visit includes an intake history, complete physical examination, and an assessment of problems with treatment (if indicated). Of great importance is the establishment of the physician–patient relationship. Physicians become the primary medical resource and counselors to these patients and their families and the first contacts when successive medical problems arise.

Longitudinal care, the second component of primary care, implies continuity of care over time. Physicians assume responsibility for issues concerning both health and illness. In pediatrics, such care involves monitoring growth and development, following school progress, screening for commonly found disorders, making psychosocial assessments, promoting health, and preventing illness with immunization and safety counseling programs.

Family orientation is the third component of primary care. Patients must be viewed in the context of their environment and family. Otherwise, practitioners cannot adequately care for patients. In pediatrics, a child's problems become the family's, and the family's problems become the child's. This has become increasingly apparent with the recognition that problems of poverty, drug use, HIV exposure, teenage pregnancy, and gang involvement directly affect a child's health and quality of life. The psychosocial forces in a particular child's life are intricately interwoven into their health care, and their assessment is an essential component of the primary care of that child.

As pediatric medical problems become more complex, many health and educational resources may be used to supplement care.

Primary care physicians integrate and coordinate these services in the best interest of patients, thus providing **integration of comprehensive care**, the fourth component of primary care. Working with social service agencies, home care providers, educational agencies, and government agencies, physicians can use multiple resources for the benefit of patients. Understanding the resources of the community is an important part of a primary care physician's education.

Medical Home

When patients select a primary care provider, they have identified a medical home. That home incorporates the physical, psychological, and social aspects of individual patients into comprehensive health care services, thus meeting the needs of the whole person. This concept of the medical home was first documented by the American Academy of Pediatrics (AAP) in 1967 in the book *Standards of Child Health Care*, which noted that a medical home should be a central source of all the child's medical records. The idea of a medical home developed into a method of providing comprehensive primary care and was successfully implemented in the 1980s by Dr Calvin Sia in Hawaii. He is considered to be the "father" of the medical home. In policy statements published in 1992 and 2002, the AAP defined the characteristics of a medical home to be "accessible, continuous, comprehensive, family-centered, coordinated, compassionate, and culturally effective." To make that home work for patients, geographic and financial accessibility are key elements. The most important aspect of a home is that it is a place where patients feel "cared for."

Since its implementation in pediatrics in 2004, the medical home model was adopted by the American Academy of Family Practice and American College of Physicians. Its definition was expanded to include use of electronic information services, population-based management of chronic illness, and continuous quality improvement. The concept has been accepted as a form of high-quality health care. Cost and quality benefits have been well documented. Recognizing these benefits, large corporations with providers formed the Patient-Centered Primary Care Collaborative to promote the idea of designated medical homes. As part of that collaborative, the National Committee for Quality Assurance adopted eligibility criteria for a practice to define itself as a medical home. Requirements for the designation include the adoption of health information technology and decision support systems, modification of clinical practice patterns, and ensuring continuity of care. With the advent of health care reform in the United States, as part of the effort to control the rising cost of health care, the federal government has endorsed

the concept of the medical home model. The Academic Pediatric Association has defined the family-centered medical home to delineate the dependency of the child to the family and community in the medical home model.

Role of the Primary Care Pediatrician

As a primary care physician, the role of the pediatrician has not only included the care of acute illnesses and injuries, but also the preventive aspects of well-child care with its focus on immunizations, tracking growth and development, and anticipatory guidance. Now there is a renewed emphasis on the importance of the role of the pediatric primary care provider in assessing the psychosocial aspects of pediatric patients. Termed the *new morbidity* by Robert Haggerty, MD, in the 1970s, recognizing these social issues including family dysfunction; developmental problems, including learning disabilities; and behavioral problems, including emotional disorders, have become a significant part of the role of the provider. In 1993 the AAP stated that pediatricians are obliged to have knowledge of physical and environmental factors and behaviors affecting health, normal variations of behavior and emotional development, risk factors and behaviors affecting physical health, and behavior problems. The focus of the pediatrician should be detection, evaluation, and management, with referrals if needed. Newer morbidities secondary to the increasing complexity of our society were outlined in 2001 by the AAP. These include school problems, mood and anxiety disorders, adolescent suicide and homicide, firearms, school violence, drug and alcohol abuse, HIV, obesity, and the effects of the media on children. Other psychosocial factors such as poverty, homelessness, single-parent families, divorce, working parents, and child care necessitate that pediatricians work with social service agencies to deliver appropriate care to their patients. The role of the primary care physician is continually expanding in an effort to deliver comprehensive care to each patient.

Subspecialist Care

Medical knowledge and technology have made amazing advancements in the past several decades. Total knowledge of all fields is impossible for individual physicians. As a result, the role of the subspecialist physician has developed as an adjunct to that of the primary care physician. New fields of subspecialties, such as child abuse pediatrics, have arisen as a response to the increased knowledge. Primary care physicians should seek subspecialist consultation when the suspected or known disease process is unusual or complicated, when it demands specialized technology, or when they have little experience with the disease. Generally, subspecialists evaluate patients and concentrate on the organ system or disease process in their area of expertise.

Primary care physicians can use a subspecialist for either a consultation or referral. When initiating a consultation, primary care physicians seek advice from the consultant regarding workup or management of the patient. Consulting physicians assess the patients

with a history and physical examination, focusing on their specialty. They then recommend possible additional laboratory tests, offer a diagnosis and treatment plan, and send the patients back to their primary care physicians for coordination of further care.

Use of the subspecialist is termed **secondary care**. For example, an 8-year-old girl with weight loss and persistent abdominal pain has an upper gastrointestinal radiograph series that reveals a duodenal ulcer. She is sent by her primary care physician to a pediatric gastroenterologist for **consultation**, with a request for an endoscopy to allow definitive diagnosis and up-to-date management guidelines. The girl then returns to the primary care physician with recommendations for treatment and further care.

Primary care physicians can also generate a referral to a subspecialist, which differs from a consultation. A **referral** requests that the subspecialist assume complete care of the patient. This transfer of a patient to a tertiary care site establishes a subspecialist as the coordinator of further health care for the patient. For example, a 4-year-old boy with recurrent fevers, hepatosplenomegaly, and blasts on peripheral blood smear is referred to a pediatric oncologist for diagnosis, the latest treatment, and ongoing medical care.

When requesting advice from subspecialists, whether on a consultative or referral basis, primary care physicians should outline specific questions with a probable diagnosis to be addressed by the subspecialist. For example, a consultation requesting evaluation of a child with hematuria is inappropriate. The primary care physician should perform a basic diagnostic evaluation and should make the most likely diagnosis. The child can then be referred appropriately. For example, a child diagnosed with nephritis should be sent to a pediatric nephrologist, whereas a child diagnosed with Wilms tumor should be sent to a pediatric oncologist.

When primary care physicians and subspecialists function cooperatively and offer the 3 levels of care (primary, referral, and consultative), patients receive the highest-quality medical care. In general, care provided by subspecialists is characterized as being more expensive and procedure driven. Laboratory studies are ordered with increased frequency by subspecialists, further inflating the cost of medical care. If patients have no longitudinal health care and see multiple providers, repeat laboratory studies are often ordered. Primary care is believed to deliver more cost-effective, improved medical care. With the spiraling cost of medical care, there continues to be a nationwide movement to produce more primary care physicians. However, it should be remembered that the role of the subspecialist is an essential supplement to the primary care physician when managing complicated disease. A balance between generalists and subspecialists needs to be maintained in the education process.

Laboratory Tests

For most conditions, the diagnosis is revealed by the history and physical examination in more than 95% of cases. Thus good communication skills are a basic tenet of primary care. Patients' complaints

often concern unnecessary laboratory tests, which increase the cost of medical care, and the prescription of unnecessary medications. To lessen these problems, the primary care physician should use laboratory tests and medications discriminately, recognizing their value as well as their potential iatrogenic effects.

In primary care, laboratory tests should be used to help confirm a condition suspected on the basis of the history or physical examination or diagnose a condition that may not be apparent after a thorough history and physical assessment. In pediatrics especially, the value of each test result should be weighed against the inconvenience, discomfort, and possible side effects in children. Tests can also be used as screening tools to prevent disease or to identify a disease early so that treatment can begin and symptoms can be minimized. Laboratory studies can provide a variety of other information, including data to establish a diagnosis, knowledge necessary to select therapy or to monitor a disease, and information about the risk of future disease. Organ function, metabolic activity, and nutritional status can also be assessed, and evidence of neoplastic or infectious disease can be provided. In addition, laboratory studies can be used to identify infectious and therapeutic agents or poisons.

Screening laboratory tests are used when the incidence of an unsuspected condition is high enough in a general population to justify the expense of the test (see Chapter 11). Subclinical conditions, such as anemia, lead poisoning, and hypercholesterolemia, are part of some health maintenance assessments.

Physicians must remember that there is variability in test results and that laboratory error can occur. Laboratory results should always be viewed in the context of the patient. The sensitivity of a test, the ability of the test to detect low levels, and the specificity of a test for the substance being measured must also be considered by the physician when evaluating a test result.

Challenges for the Future

As this edition of *Primary Care Pediatrics* is being written, the initial elements of health care reform are being implemented. As with any political initiative, it remains to be seen whether full reform will continue or whether the reform may be modified. But it is apparent that the role of the primary care physician has increased importance in health care delivery. Two of the basic tenets of primary care, accessibility and an ongoing relationship with the provider (both of which are reported by patients to be very important), are now recognized as essential components of the medical home. The challenge continues to ensure continuity in health care funding to preserve the continuity of the medical home. Payment reform promises to improve reimbursement to primary care practices and rewards high performance. Through accountable care organizations as proposed in health care reform, primary care physicians would be the foundation of the organization whose mission is management of the continuum of care and cost, as well as to ensure quality of care.

Access to same-day care, which is part of the obligation of the medical home, can be difficult in the busy schedule of primary care

providers. It will be a challenge for primary care physicians to reorganize their practices to accommodate same-day visits. Walk-in immediate medical care clinics and retail clinics have arisen. Patients like the convenience, but episodic visits in a variety of settings do not deliver comprehensive care for the patient, and these short visits may not take into account the entirety of the patient's medical history. This creates a challenge for the primary care provider and medical home to develop a system to integrate the information from these encounters into the comprehensive medical record.

With the advent of hospitalists providing inpatient care, primary care physicians may not be included in in-patient management. They then face a challenge in retrieving important information regarding the care of their patients.

Medical care reform incorporates accountability, demonstration of quality of care, and standards of medical practice into the medical home model. These have increased the oversight and bureaucracy of medical care exponentially. This business of medicine with redundant oversight of medical care has put a tremendous burden of administrative activities in the lap of the primary care physician. There is a significant challenge to providers to provide care while answering to administrative structures.

The biggest challenge to pediatric primary care providers continues to be ensuring the future of health care funding to provide access and availability in a medical home of health care to all children. This is a priority for child health policy reform at the national level. At this point there are a multitude of programs, varying in each state, to pay for children's health care. Universal health care for children is being advocated. Without a national plan for financing, children's health care will continue to be variable, leading to disparities in children's health.

Child Advocacy

Grant P. Christman, MD, and Julie E. Noble, MD

CASE STUDY

A 15-year-old male is brought to the emergency department with a gunshot wound to his left leg. He says he was hanging out at the park with his friends when a random car drove by and shots were fired. He denies being in a gang, but his mom suggests otherwise during a private conversation with the emergency physician. His physical examination reveals a gunshot wound to his left lower leg, with intact sensation, movement, and pulses in the left foot, and no other signs of injury. A radiograph shows

a fractured left tibia, and he is admitted for orthopedic surgical treatment.

Questions

1. What does it mean to be a child advocate?
2. Aside from caring for individual patients, what is expected of pediatricians in the community?
3. What is the role of pediatricians in child advocacy?
4. What are the levels of advocacy?
5. How do pediatricians implement advocacy?

An advocate is someone who speaks on behalf of a person or cause. No group in our society has a greater need for advocates than children. Children are ill equipped to face the many threats to their health; they cannot obtain their own health insurance, access available social services, or even take themselves to the doctor when sick. Children also have no voice in our society. They cannot vote, donate money to political campaigns, or speak publicly to advance their interests. The word *advocate* is derived from a Latin root meaning “one who has been called to another’s aid.” From the beginnings of pediatrics as an independent branch of medicine, pediatricians have answered this call to advocate for the health and well-being of children.

The father of American pediatrics, Abraham Jacobi, MD, spent his career in the late 1800s and early 1900s advocating for children through legislation in New York and Washington, DC. He was a great teacher of pediatrics, introducing the discipline into academic medicine, but truly believed that physicians needed to be involved in public policy. Another founder of American pediatrics, Job Lewis Smith, MD, recognized the need for a clean water supply and decent housing to decrease the high infant mortality rate at that time. He worked through public advocacy to improve conditions not only for his patients but for children in general. The American Academy of Pediatrics (AAP) was founded on federal advocacy principles. In June 1921, the Sheppard-Towner Act on maternal and child health legislation was introduced into Congress. It was the first involvement of the federal government on behalf of children and provided federal matching funds to states for services for pregnant women and new mothers. The American Medical Association (AMA), worried that the legislation would lead to socialized medicine, condemned the act, while the AMA Section on Diseases of Children supported the legislation. When the act was up for reauthorization in 1930 and the AMA

still opposed it, the pediatric group left the AMA and founded the AAP. This organization has been advocating for children ever since.

The New Morbidity

Advocacy has become increasingly important because the new morbidities in pediatric medicine are related to community forces. As our society has become more complicated, major health concerns have become even more intertwined with the environments in which children are involved. Child health outcomes improved dramatically in the 1900s with the development of vaccines, antibiotics, and new and improved surgical care to treat the classic morbidities of infectious disease, infant mortality, poor nutrition, epidemics, overcrowding, and chronic disease. But there have emerged new morbidities that are negatively affecting child health outcomes. These morbidities of the 1960s to 1980s, as described by Robert Haggerty, MD, include family dysfunction, learning disabilities, emotional disorders, and educational problems. The face of childhood morbidity continued to evolve in the 1980s to 2000s. Judith Palfrey, MD, documented social disarray; political ennui; the sequelae of high-tech care; and new epidemics of violence, AIDS, cocaine, and homelessness as the new challenges for pediatricians. We have now expanded morbidities in the 2000s to include major health concerns with the increased prevalence of overweight children, increased mental health issues, significant health disparities in cultural groups, and major socioeconomic influences affecting child health.

At the same time, children in America continue to face challenges in obtaining access to quality health care. Over the past several decades, government programs like Medicaid and the Children’s Health Insurance Program have expanded the availability of health care to children of limited financial means. As of 2007 there were still 8.1 million children younger than 18 years with no health

insurance coverage, representing 11% of that population. Among insured children, 23.5% had inadequate coverage as determined by a survey of their parents.

It is clear that these significant issues affecting child health cannot be adequately dealt with on an individual basis, but require advocacy on a community or national scale to improve child health outcomes and life for children.

Community Pediatrics

Community pediatrics has developed as the vehicle to implement advocacy. Robert Haggerty, MD, first originated the concept in 1968 in an article published in the *New England Journal of Medicine*. In his work as department chair of pediatrics at the University of Rochester, NY, he developed an extensive advocacy agenda for the children of the community of Rochester. Subsequently, the AAP published a policy statement from its Committee on Community Health Services titled, “The Pediatrician’s Role in Community Pediatrics.” The policy delineates 5 components of community pediatrics: a *perspective* from the individual patient to all the children in the community; a *recognition* that family, education, society, culture, spirituality, economy, environment, and politics all affect the health of children; a *synthesis* of clinical practice and public health principles directed to providing health care to a child and promoting the health of all children; a *commitment* to collaborate with the community to optimize health care for all children, especially disadvantaged children; and an *integral part* of the role of the pediatrician. All of these components are recommended as a part of pediatric practice, and training in advocacy has been instituted in pediatric training programs. Examples of potential involvement in the community include serving as a board member, developing health agendas, working with an existing organization to design and fund a community service project, and being a source of information for the community on child health issues.

Levels of Advocacy

Every pediatrician functions as a child advocate on a daily basis. With every patient encounter the pediatrician advocates for care in the best interest of the patient. This first level of advocacy includes treating the *individual’s* immediate medical needs, performing screening tests, giving anticipatory guidance, and coordinating referrals as needed. The pediatrician may step beyond direct medical care to advance the welfare of the child, for example by writing letters to help a patient obtain social services, or visiting a patient’s school for an Individualized Education Program meeting. The second level of advocacy is *community* advocacy. Pediatricians are an integral part of the community, and the community directly affects the health of their patients. Thus pediatricians have a responsibility to improve conditions in their community to benefit children. To do this, they must be familiar with the services that are available for children. They can develop relationships with child care centers, schools, community coalitions, city governments, and local organizations to advocate for the best interest of children. On a *state* level, pediatricians

can work to improve health care resources or develop policies to help and protect children. Opportunities for involvement include working on legislation, budgets, regulations, and initiatives or working with the executive branch of local and state government. The next level of advocacy would be the *federal* level, where pediatricians can be involved with their senators and congressmen lobbying for child health issues. Pediatricians may also be involved in testifying before a congressional subcommittee. The final level of advocacy is the *international* level. For example, pediatricians may decide to work with the World Health Organization to improve immunizations for all children worldwide.

Becoming a Child Advocate

To become an effective child advocate, pediatricians must first identify an issue that they want to change or set a goal to improve the lives of children. The more specific the issue or goal, the easier it is to develop a solution. Ideas often come from clinical practice, where repeatedly engaging in individual advocacy efforts on behalf of patients suffering from the same problems suggests the need for a larger solution. The first step is to obtain background information about the problem and to collect objective data that support the need for change, and then to define the nature of the problem and the affected population in clear and precise terms.

Community Projects

The pediatrician may find that the issue would be best addressed through a community advocacy project. In developing such a project, the pediatrician’s relationship with the community is of the utmost importance, and the pediatrician should endeavor to become familiar with the community as a whole. Community exploration, potentially as simple as walking or driving through the community and looking around, can reveal areas of need, such as dilapidated housing or unsafe streets. Equally important is the discovery of the community’s assets, institutions such as churches, schools, and banks, which give the community strength and could provide support and counsel for the project. Pediatricians should view themselves as members of the community, acting from within and in collaboration with the community, rather than as outsiders bringing about change externally.

The next step is to develop an intervention. After the possible solutions are considered, pediatricians need to collaborate with community stakeholders to develop and implement the solution that is the most practical. Having credibility in the community makes the task of collaboration much easier. Everyone is more effective working with others, but collaboration necessitates the ability to compromise and be flexible in implementation plans. Larger projects may require funding, and grants may be sought from advocacy organizations, the government, or even local corporations. Data should be collected during the intervention to monitor the success of the project. If the project is successful in effecting change, its methods may be adopted by child advocates in other communities.

Legislative Advocacy

Though initially daunting for a physician without political expertise, involvement in the legislative process is often the only way to effect a desired change for children's health. A pediatrician might begin by tracking existing bills that affect child health and contacting legislators by letter, e-mail, or phone to offer a position. It is helpful to become familiar with the process by which a bill becomes a law, both at the state and federal levels; the identities of the important players change as a bill progresses through the various subcommittees and committees, and ultimately to a floor vote.

The pediatrician may also arrange to meet with a legislator or staff member at a district or capital office to discuss the position personally. When meeting with a legislator or staff member, remember to inspire both the heart and the mind. State the problem clearly and explain why a new law is the solution. Present well-researched facts that support your position, and stick to layman's terms, avoiding medical jargon whenever possible. Share a story about a patient encountered in practice who has been affected by the problem. This is especially helpful if the patient is a constituent of the legislator (though the patient's identity must of course never be discussed). After the meeting, leave behind a concise 1-page fact sheet summarizing your position and the pertinent background information.

Be prepared to encounter opposition from some legislators, and avoid responding with angry statements that would alienate a legislator. Effective advocacy requires building relationships with legislators over the long term, and a legislator who opposes your position this year may be a potential supporter next year, when the political climate changes, or may be a potential ally on another important issue. There are a number of other potential pitfalls to avoid. Avoid making or agreeing with partisan statements. Do not claim to represent an organization like the AAP or an institution like a university unless you are authorized to do so. Minimize the appearance of self-interest by focusing on how the proposal will benefit children, rather than how it will benefit pediatricians. Avoid guessing if you do not know the answer to a question; offer to do further research and contact the legislator with the requested information.

When seeking to develop a new legislative proposal from scratch, remember that though the factors contributing to child health may be numerous and complex, legislative proposals must by nature be concrete and limited. Don't be afraid to start small, and to work for incremental change. Identify a clear and, if possible, measurable objective, and define the target population. If the proposal requires funding, consider what the funding source will be. Know which government agencies may be involved in implementation or enforcement. Having a legislator as an ally early on in the process is important, as some of the aforementioned issues will be outside the experience of the average pediatrician, and because a bill must be sponsored by a legislator to be considered for passage. Build a coalition of support within the community, involving important stakeholders such as politicians, businessmen, other health care professionals, educators, and parents.

Again, be prepared to meet opposition and identify potential sources of opposition in advance. If opposition from a powerful interest group is anticipated, meet with a representative of that group to state your case. Potential arguments might include ways in which the proposal is really in the group's self-interest, the moral imperative to help children, or that opposing an initiative to benefit children might generate negative publicity. Consider compromising on aspects of the proposal, when to do so might turn an enemy into an ally. When facing intractable opposition from powerful interests, try to bring even stronger allies into your coalition.

Be aware that the process of turning a policy idea into real legislation may be lengthy. A bill may have to be reintroduced repeatedly over several years before achieving passage. Once a bill becomes a law, advocates must continue working to ensure that the bill is reauthorized when applicable and that regulatory processes develop favorably. Physicians who are recognized as experts in child health policy will be called on to testify before committees in Congress or the state legislature on other policy issues affecting children.

Media Advocacy

The media, including newspapers, magazines, radio, television, and the Internet, are extremely influential in our society. News stories about child health and welfare may not always be written from a child-friendly point of view. Pediatricians play an important role in providing the media with better information and a different angle on a story. For instance, a pediatrician reading a newspaper story about a child who exhibited signs of autism shortly after his 1-year-old physical might write a letter to the editor discussing the lack of scientific evidence for a connection between vaccinations and autism. Over time pediatricians can develop relationships with local journalists, who can then turn to them for information when covering child health stories.

A directed media campaign may also be a key element in an advocacy project. At the community level, the media can help spread ideas, notify the public of events, and bring out potential allies and coalition members. When advocating for legislation, pediatricians can use the media to reach legislators directly and, equally important, to reach thousands of the legislators' constituents all at once, who may in turn help pressure their legislators for change. In such situations, it is essential to plan a media strategy ahead of time by determining the most important target audience, selecting the appropriate types of media to approach, crafting a message appropriate to those media, and preparing thoughtfully for encounters with journalists.

Getting Connected

The AAP is a vital resource for pediatricians interested in child advocacy, with its Federal Advocacy Action Network, as well as the various state chapters advocating at the state level. Other national organizations that are available for involvement by pediatricians include Docs For Tots, Children's Defense Fund, and the Child Welfare League of America. Toolkits for advocacy are available through these organizations.

Improving the health of all children through advocacy is considered to be the responsibility of pediatricians and can be a tremendously rewarding part of pediatric practice.

CASE RESOLUTION

In the case scenario, treating this teen for his orthopedic injury is only the first part of thorough pediatric care. His social history and the environment in which he lives are essential information for the pediatrician to obtain to be an advocate for this patient and prevent a second admission for a subsequent and potentially worse injury. A social work evaluation is performed and reveals that he lives in poverty in the inner city and does indeed belong to a gang. The patient and his family are counseled regarding his high-risk behavior, and he is referred to the police department for their Gang Alternative Program. His pediatrician becomes concerned about the high prevalence of gang activity in the community putting many teens at risk of injury. He explores coalitions in the area that recognize similar concerns. To have an effect on decreasing youth gang activity, a solution is identified to establish high-quality after-school programs to involve teens in productive activities. The Boy's and Girl's Club organization is contacted, and they have an interest in establishing a center in this community. The pediatrician volunteers to be on the board and help develop the after-school programs.

Global Child Health

Suzinne Pak-Gorstein, MD, PhD, MPH, and Maneesh Batra, MD, MPH

CASE STUDY

You are watching television when the programming is interrupted by breaking news that a severe earthquake has struck a developing country that you have recently visited. You wonder if and how you could become involved in efforts to help the country respond to the disaster, prevent diseases, and help rebuild its health structure.

Questions

1. What are the global trends in childhood disease and mortality? How does this compare with the United States?
2. What is global health (GH)?
3. What is the role of a pediatrician in GH?
4. What are the key organizations in GH that pediatricians work in?
5. How can pediatricians carry out international work in an ethical and effective manner?

Background

Worldwide, an estimated 7.7 million children younger than 5 years died in 2010, which translates into more than 21,000 children dying each day. This figure actually represents a one-third reduction from the 11.9 million child deaths estimated in 1990. Still, significant disparities in child mortality persist and have become increasingly concentrated in specific regions of the world that bear a disproportionate burden. Africa and Asia combined account for 83% of all child deaths, with one-third of these deaths occurring in south Asia, and half in sub-Saharan Africa. Less than 1% of deaths occur in high-income countries.

Three diseases—pneumonia, diarrhea, and malaria—accounted for 41% of all child deaths worldwide in 2008. Most of these lives could be saved through increased coverage of low-cost prevention and treatment measures, including antibiotics for acute respiratory infections, oral rehydration therapy for diarrhea, immunizations to protect against pneumococcal pneumonia and rotaviral diarrhea, and the use of insecticide-treated mosquito nets and appropriate drugs for malaria.

Undernutrition is an underlying cause of at least a third of all deaths in children younger than 5 years. Reducing both chronic and acute undernutrition will have a substantial impact on reducing child mortality. Furthermore, improved coverage of specific nutritional interventions, such as early and exclusive breastfeeding, are cost-effective and reduce the prevalence of pneumonia and diarrhea.

An estimated 40% of deaths in children younger than 5 occur in the first month of life, and most of these deaths occur at home in the first postnatal week. Hence, improving newborn care is essential to the goal of improving child health. Increased access to basic, inexpensive interventions are needed to reduce neonatal mortality

rates globally, including delivery by skilled birth attendants, hygienic umbilical cord care, and training community health workers to assess and begin early treatment for neonatal infections.

In September 2000 world leaders from 190 nations came together to adopt the United Nations Millennium Declaration, committing to reduce extreme poverty through a series of time-bound targets. The 8 Millennium Development Goals (MDGs) range from halving extreme poverty to providing universal primary education, and reducing child mortality by two-thirds—all by the target date of 2015 (Box 3-1). The MDGs form a blueprint ratified by more than 190 nations and have galvanized unprecedented efforts to meet the needs of the world's poorest people.

Though progress has been made toward achieving MDG 4, the pace has been modest and insufficient to meet the goal of two-thirds

Box 3-1. Millennium Development Goals (MDGs)

The MDGs were developed and signed by all United Nations member countries in September 2000. There are 8 goals with 21 targets and a series of measurable indicators for each target.

Goal 1: Eradicate extreme poverty and hunger.

Goal 2: Achieve universal primary education.

Goal 3: Promote gender equality and empower women.

Goal 4: Reduce the child mortality rate.

Target: Reduce the under-5 mortality rate by two-thirds between 1990 and 2015.

Goal 5: Improve maternal health.

Goal 6: Combat HIV/AIDS, malaria, and other diseases.

Goal 7: Ensure environmental sustainability.

Goal 8: Develop a global partnership for development.

reduction in childhood mortality by 2015. Enormous gaps in child mortality rates exist between high- and low-income countries, with a rate of 2 child deaths per 1,000 live births in Singapore compared with 257 in Afghanistan in 2008.

Large inequities in child health also exist within countries. For example, in Bolivia and Peru the richest fifth have almost universal access to a skilled attendant at birth, compared with only 10% to 15% among the poorest fifth. Women in poor rural households accounted for two-thirds of unattended births.

How does the United States compare to the rest of the world with respect to child mortality rates and health inequities? While the United States has one of the world's highest expenditures on health (\$7,285 per capita in 2007, United Nations Development Programme) it ranks among the poorest among highly developed nations with respect to its under-5 mortality rate (8 deaths per 1,000 live births), which is higher than rates in most of Europe, including countries with far fewer resources, such as Estonia, Croatia, and Hungary. Although the under-5 mortality rate in the United States has improved in recent decades, it is still higher than many other wealthy nations—2.3 times that of Iceland and more than 75% higher than the rate of the Czech Republic, Finland, Italy, Japan, Norway, Slovenia, and Sweden. Great health inequities are also apparent within the United States. Native American children ages 1 to 4 have the highest death rates (49 per 100,000), followed by African American children (46 per 100,000), while non-Hispanic white children have the lowest death rates (28 per 100,000).

It has been projected that policy interventions aimed at country-level inequities would have a major effect on the under-5 mortality rate for the country as a whole, even in low-inequality regions. Worldwide, about 40% of all under-5 deaths could be prevented by bringing rates in the poorest 80% of the population down to those of the richest 20%.

While the Institute of Medicine has defined GH to encompass “health problems, issues, and concerns that transcend national boundaries, and may best be addressed by cooperative actions and solutions,” the World Health Organization has emphasized GH to signify health problems that impact global politics and economies, and arise from disparities in sociopolitical and economic status. Inequalities in health within and between countries arise from inequalities within and between societies. These disparities in social and economic conditions impact children's risk of illness as well as the actions that families take to prevent or treat illness when it occurs. Consequently, the emerging field of GH intersects medical and social science disciplines, such as demographics, economics, epidemiology, political economy, and sociology.

Integrating GH into Pediatrician Careers

The most vulnerable groups in a society are children, and the strongest medical advocate for the health of children is the pediatrician. Consequently, pediatricians have been leaders in addressing global and local health disparities, and their collective voice has been powerful. Global health work varies widely in scope and extent. The

duration of GH activities ranges from singular short-term medical missions to long-term postings in resource-limited settings. Involvement in GH encompasses the direct provision of clinical services, technical assistance for program development, research, education and training of health care workers, and governmental advocacy for policy changes. The goals of GH activities range from forging novel directions in areas of basic sciences and epidemiological, clinical, and operations research, to addressing the needs of the world's poorest communities. Ideally, GH experiences should be transformative, both for the poor communities of the world, as well as for the clinicians who engage in these experiences.

By committing to a single international site—such as a hospital, rural clinic, or community—and by working with a partner based at that site, the pediatrician can engage in a longitudinal supportive relationship that is sustainable and effective. Pediatricians can also make a sustainable impression by empowering in-country partners through training of trainers, such as community health workers, supervisors, and clinicians responsible for health professional trainees.

Pediatricians have also played an important role in responding to humanitarian emergencies in the United States as well as in other countries, such as the aftermath of the Haiti earthquake. In addition, pediatricians with skills in research and evaluation may contribute to GH through clinical research and program evaluations.

Many GH opportunities do not require an overseas trip. While vulnerable populations and inequities to health certainly exist in low-income countries, significant inequities abound in the United States. Among developed countries, those with the highest health status have the lowest levels of health inequality. The United States ranks at the bottom of this list, with one of the poorest health rankings and the highest inequalities in health. Opportunities to carry out *local* GH work are plentiful and include supporting the care and resettlement of local refugee and immigrant families, supporting international adoptees, serving migrant farm workers, and supporting Native American health issues.

The pediatrician may also work locally for GH by advocating for equity of health care at all levels domestically and globally, working in the home office of a US-based GH organization, and providing expertise to support international organizations dedicated to vulnerable children. Finally, pediatricians can make a significant impact in GH by lobbying the US government for more international relief funding, or supporting corporations with ethical international trade practices.

Beyond the Hospitals—Global Public and Community Health, and Advocacy

As a growing number of US medical students and residents seek training opportunities in developing country settings, most of these trips are spent in a foreign hospital on a pediatric ward providing direct clinical care. In addition to observing and managing tropical diseases and more severe forms of commonly encountered pediatric conditions, visiting physicians and students learn and experience common themes in these low-resource settings: underpaid and

under-trained health workers, hospital administration untrained in health management, dilapidated facilities, basic medicine shortage, lack of tools in testing and imaging, and higher mortality rates. Because the needs at such hospitals and clinics are glaring, the clinician instinctively seeks to fill the gaps with what defines quality health care in the United States—more medicines, equipment, clinical staffing (through visiting physicians), and perhaps training. However, the long-term impact of a brief visit, even repeated visits, may be further improved through efforts to prevent disease using public health approaches and focusing on communities.

With further training in areas such as public and community health or health service management, the pediatrician may act as an “agent of change” by undertaking systems-based quality improvement approaches, public health measures, and community-based strategies to have lasting positive impact on child health. Box 3-2 lists some key categories of GH organizations. In collaboration with community groups, the clinician or student can effectively empower community health workers and work within local community-based nongovernmental organizations (NGOs) to contribute to lasting and contextually appropriate change.

“Experiencing” how most of the world lives is a tremendous gift, honor, and burden that accompanies these experiences. Continuing to advocate for the children living in poverty in the world after returning from a short-term medical experience is a fantastic way to enact one’s ongoing responsibility. Additionally, though perhaps less glamorous than traveling overseas, working within the US health care and political system to promote awareness for change has the potential to catalyze lasting and significant improvements in child health. Similarly, through work to empower local refugee communities in the United States or to advocate for more equitable access to health care for vulnerable immigrant children, pediatricians can make a significant and lasting difference in the efforts to close the gap in health disparities.

Ethical Issues in GH

The traditional model for medical experiences for US-based physicians presumes that in the United States we possess the knowledge, skills, and resources to improve the conditions of people living in developing countries. However, most students and physicians who have participated in such an experience report that the greatest benefit from such experiences is for themselves.

Though the desire to improve the conditions of children by providing clinical care is well-intentioned and altruistic, there is potential for both short- and long-term harm. In the short-term, caring for children in such settings with conditions that are unfamiliar to the visiting student or physician and out of the scope of their training can lead to errors in diagnosis and management. For students, often there is less supervision of their clinical work in these settings, which can result in harm to the patient and the student’s growth as a clinician. In the long-term, provision of clinical care by visiting providers can undermine the existing health system infrastructure.

Box 3-2. Global Health (GH) Organizations— Some Examples

International Health or Multilateral Organizations

World Health Organization (WHO)
UNICEF

Bilateral Government Organizations

US Agency for International Development (USAID)
Centers for Disease Control and Prevention (CDC)
The Peace Corps

International Donor Foundations

Bill and Melinda Gates Foundation
Wellcome Trust
Children’s Investment Fund Foundation (CIFF)

US-Based Nongovernmental Organizations (NGOs)

Partners in Health
Global Health Council
Save the Children

International NGOs

Specialized services and/or training—short-term service/training trips (eg, cleft palate repairs)

Emergency relief and rehabilitation

Doctors Without Borders (MSF)
International Committee of Red Cross
CARE International

Consultant Organizations—For-Profit and Not-for-Profit

Family Health International
John Snow International
• GH consultant organizations may take government contracts to provide international support

Faith-Based Organizations

World Vision
Aga Khan Foundation
American Friends Service Committee

Academic Institutions

An increasing number of academic institutions are developing GH programs in partnership with international groups, overseas academic institutions, or ministries of health.

Local and Domestic

GH advocacy organizations
Refugee resettlement agencies
Indian health services

Resources

Global Health Education Consortium (GHEC)
American Academy of Pediatrics Section on International Child Health (AAP-SOICH)
Physicians for Social Responsibility

As the number of US medical students, trainees, and physicians who visit developing countries for short-term training experiences continues to grow, concern for medical tourism and the long-term impact of these training experiences on the under-resourced hosts is rising. Key factors for ensuring effective, sustainable, and ethical international collaborations include forethought, planning, and long-term partnership.

Proper *pre-departure preparation and education* for any overseas medical experience is a critical first step. Proper education entails orientation regarding the country and its sociopolitical context and public health priorities. Knowledge of the key medical problems facing the communities as well as international and local treatment guidelines and strategies to deliver care within the confines of the existing local resources are also important.

Suchdev et al and others have outlined fundamentals for the creation of a meaningful international partnership with a community. The first step is the development of a *mission* or an identified shared purpose with the partners prior to visiting a new international site. Also, it is critical to establish a *collaboration* with a local agency, such as an NGO, governmental agency, or other local organization to promote sustainability and to enhance the effectiveness of the care delivered. Another important component for long-term impact and partnership is to ensure that the *education* of the community members, other physicians, and trainees is a part of the mission and that appropriate educational experiences are structured into the trip and planning. Closely related to this is the appreciation of the reciprocal nature of any education: The visiting physician is in a position to be learning just as much if not more than the local providers about working in the local setting.

A fourth fundamental for meaningful partnerships involves ensuring that *service* is truly being provided to the community by *learning about the health priorities* of the community from the NGO or other local agency. Also, it is important to encourage *teamwork* by working with appropriate supervision, including physicians from the host country. Effective international collaboration also requires

sensitivity to the *costs and burden* that a visitor will have on the host. Finally, assurance of the partnership effectiveness requires building an *evaluation* process early on that incorporates the perspectives of all the players, including local officials, health professionals, and community members. This would include assessment of whether the educational objectives are being met for all stakeholders, including the host site.

CASE RESOLUTION

You learn about a US-based NGO with a long history of partnership and work in the earthquake-stricken country. You research that NGO further and find that it is a reputable group with long-term interests in the country. You speak to friends who have recently visited the country and learn more about what skills and resources are needed. You make arrangements to join a team of experienced health workers from the NGO by taking time from work and garnering support from your family to manage with your absence. You undergo an in-depth orientation of the site, the people, the sociopolitical situation, team roles, and expected activities through a series of discussions with all participants.

Talking With Children

Geeta Grover, MD

CASE STUDY

The moment you walk into the examination room, the 2-year-old girl begins to cry and scream uncontrollably. She clings to her mother and turns her face away. The mother appears embarrassed and states that her daughter reacts to all physicians this way. After reassuring the mother that you have received such welcomes before, you sit down at a comfortable distance from the girl and her mother. You smile at the girl and compliment her on her dress, but she does not seem to be interested in interacting with you at this point. You begin your interview with the mother and try not to look at the girl. Out of the corner of your eye, you see that her crying is easing a bit and that she is looking at you very carefully. Without moving from your chair, you hand her your stethoscope with

a clip-on toy teddy bear attached to it. She accepts it hesitantly and begins to examine it as you and the mother continue talking.

Questions

1. How does children's age influence their understanding of health and illness?
2. Should physicians speak directly with children about their illnesses?
3. At what age can children begin to communicate with physicians about their illnesses?
4. How can positioning and placement of children in the examination room affect the overall tone and quality of the visit?

Effective doctor–patient communication, which is difficult enough when patients are adults, becomes even more challenging when patients are children. In pediatrics, interviewing involves balancing the needs of both parents and children. Whereas parents may be more focused on issues pertaining to disease, treatment, or aspects of parenting, children look to physicians with different needs and concerns, depending on their age. To have a meaningful and satisfying exchange with children, pediatricians must take into account children's age, intelligence, and developmental maturity because all of these factors affect their concepts of health and illness. As children grow and develop, their understanding of health and illness increases.

Developmental Approach to Communicating With Children

An appreciation of the cognitive stages of development helps pediatricians develop a healthy relationship with their patients by allowing them to communicate with the children in an age-appropriate manner. Piaget defined 4 stages of cognitive development, which occur in the same sequence but not at the same rate in all children (Table 4-1). Children in the sensorimotor stage (birth–2 years of age) experience the world and act through sensations and motor acts. They are developing the concepts of object permanence, causality, and spatial relationships. Children in the preoperational stage (2–6 years) understand reality only from their own viewpoint. As egocentric thinkers, they are unable to separate internal from external reality, and fantasy play is important. School-aged children (6–11 years)

Table 4-1. Piaget's Stages of Cognitive Development

Age ^a	Stage	Characteristics
Birth–2 y	Sensorimotor	Experiences world through sensations and motor acts
2–6 y	Preoperational	Egocentric thinking; imitation and fantasy play
6–11 y	Concrete operational	Mental processes only as they relate to real objects
>11 y	Formal operations	Capacity for abstract thought

^aApproximate ages.

are capable of concrete operational thinking. These children can reason through problems that relate to real objects. Older children (>11 years) have the capacity for abstract thought, which defines the stage of formal operations.

An appreciation of how children's cognitive development affects their understanding of illness and pain aids physicians in developing therapeutic relationships. Bibace and colleagues have outlined a developmental approach to children's understanding of illness: Children's explanations of illness are classified into 6 categories consistent with Piaget's cognitive developmental stages. Children 2 to 6 years of age view illness as caused by external factors near the body (phenomenism and contagion). Young children engage in so-called magical thinking; proximity alone provides the link between cause and illness. Children 7 to 10 years of age should be able to

differentiate between self and nonself. At this stage they begin to understand that although illness may be caused by some factor outside the body, illness itself is located inside the body (contamination and internalization). Children older than 11 years understand physiological and psychophysiological explanations for illness (Table 4-2).

A similar developmental sequence applies to children's understanding of pain. Gaffney and Dunne have outlined a developmental approach to this understanding. Younger children may attribute pain to punishment for some transgression or wrongdoing on their part. They may not understand the relationship between pain and illness (eg, "Pain is something in my tummy"). Children with concrete operational thought can appreciate that pain and illness are related, but they may have no clear understanding of the causation of pain (eg, "Pain is a feeling you get when you are sick"). Older children and adolescents begin to understand the complex physical and psychological components of pain. For example, they realize that although the bone in the arm is broken, pain is ultimately felt in the head (eg, "Pain goes up some nerves from the broken bone in my arm to my head").

Guidelines for Doctor–Child Communication

A developmental framework that takes into account children's language skills and causal reasoning abilities is essential in providing appropriate health care to children. Successful communication with children depends not only on spoken words but also nonverbal cues and the environment itself. A pleasant, child-friendly environment with bright colors, wall decorations, and toys helps make children feel more comfortable. Health care practitioners should be sincere, because children are extremely sensitive to nonverbal cues. Pediatricians should take a few minutes to enjoy children; this not only gives children a chance to evaluate their physicians, but also allows clinicians to begin assessing areas of development. A general principle of the pediatric examination is to begin with the least invasive portions of the examination (eg, heart, lungs, abdomen) and save the most invasive for last (eg, oropharynx, ears). Pediatricians should maintain their self-control in difficult situations. If they approach their limit, they should step outside for a few minutes or ask someone for assistance. Overall guidelines for communicating with children are provided in Box 4-1. Age-specific guidelines follow.

Birth to 6 Months

Examination of children of this age is usually pleasant. Although verbal interaction is limited, it is important to play with children, hold them, and talk to them. By watching physicians interact with their children, new parents have an opportunity to learn how to behave with their infants. Infants have not yet developed a fear of strangers and can usually be easily examined either in parents' arms or on the examination table.

7 Months to 3 Years

This is perhaps the most challenging age group with regard to developing rapport and performing examinations. After entering

Table 4-2. Children's Concepts of Illness^a

Age	Concept of Illness	Example
	Preoperational	How do people get colds?
2–6 y	Phenomenism	"From the sun."
	Contagion	"When someone else gets near them."
	Concrete Operational	How do people get colds?
7–10 y	Contamination	"You're outside without a hat and you start sneezing. Your head would get cold—the cold would touch it—and then it would go all over your body."
	Internalization	"In winter, people breathe in too much air into their nose and it blocks up the nose."
	Formal Operations	How do people get colds?
>11 y	Physiological/ Psychophysiological	"They come from viruses, I guess."
		How do people get a heart attack? "It can come from being all nerve-racked. You worry too much, and the tension can affect your heart."

Box 4-1. Physician–Child Communication

Dos	Don'ts
Provide a pleasant environment.	Limit the child's participation.
Pay attention to nonverbal cues.	Threaten the child.
Be sincere and honest.	Compare the child to others.
Enjoy the child.	Get into power struggles.
Speak age appropriately.	
Get down to the child's eye level.	
Examine from least to most invasive.	
Respect the child's privacy.	
Maintain self-control.	
Have a sense of humor.	

the examination room, pediatricians should take a few moments to converse or play with children. Such actions help put children at ease and allow them to get to know their doctors. Children who are 1 to 2 years of age will probably busy themselves, exploring the room during the history taking. By acknowledging them periodically, physicians build rapport that will help later during the examination. Two- to 3-year-old children are usually very apprehensive of the examination. Physicians should get down to children's eye level when speaking to them. Reassurances such as, "You're not going to get any shots today," can help alleviate their fears. Because stranger anxiety has developed, physicians should try to do as much of the examination as possible with children in parents' laps. Distractions such as stethoscope toys, flashing penlights, or keys may be helpful.

3 to 6 Years

Children's expressive capabilities are growing at tremendous rates during this period. Children can usually be engaged in conversation. They should be given repeated opportunities for participation, but they should not feel pressured to take part. Children may doubt physicians' true intentions and will probably only speak once their comfort level has been achieved. Children should be involved; they can be asked simple questions regarding their illness (eg, "Where does it hurt?"). In addition, children should be given some control during the examination (eg, "Should I look in your mouth next or your ears?"), and they should be allowed to handle physicians' equipment. Knowing what to expect next and having some control over the examination can help to decrease fear and increase cooperation.

7 to 11 Years

Examination of children in this age group can be rewarding. Physicians should make a point to speak directly with children and not just with parents concerning the chief complaint and history. Children can usually provide a good history regarding their illness, although their concept of time may be misleading. For example, a "long, long time" may mean hours, days, or months, and parents need to clarify this. Children should be asked about school, friends, and favorite activities. Answers to such questions give physicians an idea of children's social and emotional well-being, which may be affecting their physical health. Physicians sometimes overlook children's need for privacy at this age. Drapes should be used appropriately during the examination, and physicians should be sensitive to the presence of other children or adults in the room.

Physicians should begin to involve older children in the management of their illness. Children's understanding of their illness and its management should be assessed (eg, children with asthma could be asked, "What is this inhaler for? When are you going to use it? Show me how."). Children should be given an opportunity to express their fears and anxieties, and these concerns should be discussed (eg, "Asthma can be scary, especially when you can't catch your breath. Have you ever felt like that? Tell me about it."). Children should be involved in the management of their illness, which allows them to develop a sense of responsibility for their own health and medical care. Active participation in their health care visits leads to greater visit satisfaction, knowledge, and competence of prescribed medical therapies.

Older Than 12 Years

Communication with adolescents is discussed in detail in Chapter 6.

Barriers to Effective Communication With Children

The manner in which adults speak to children is influenced by what they think children can understand. Clinicians tend to overestimate the understanding capabilities of younger children and underestimate those of older children. Lack of appreciation for the cognitive sophistication of children may lead to frustration for all involved.

Younger children are presented with information they may not be able to comprehend, and older children may feel frustrated because they are being spoken to in a childlike manner.

Overestimating children's receptivity to medical information can be particularly problematic in the case of children with chronic illness. It is easy to assume that children with chronic medical conditions or those with more hospitalizations would have more sophisticated understanding regarding illness causation. Although these children may seem more savvy and knowledgeable regarding medical procedures, there is little research to support the assumption that they have more sophisticated understanding of illness causation than would be expected based on their age or developmental level, nor that they are better able to understand and retain medical information than their peers without chronic medical concerns.

Another potential barrier in communicating with children is limiting their participation. Physicians tend to elicit information from children but exclude them from diagnostic and management information. Older children want to know about their illness and are capable of learning about management.

All physicians have been frustrated or pushed to the limit at one time or another when working with children. In such situations, practitioners should remember that children are probably not trying to irritate physicians on purpose. Crying or lack of cooperation generally stems from fear or a sense of lack of control over the situation. Pediatricians should avoid taking part in a battle over power or control with children. Threatening remarks (eg, "If you're not good, I'll have to give you a shot.") or comparisons between children (eg, "Your brother is younger than you, and he didn't cry.") not only are ineffective but may make the situation worse. A clear perspective, empathy, and a sense of humor are much more useful.

CASE RESOLUTION

In the case presented in the opening scenario, you learn from the mother that her daughter has been in good health. The mother has brought in the child for a routine health maintenance visit. You assess that her development is normal and that her immunizations are up to date. As you and the mother talk, the child appears more relaxed and less frightened. She begins to respond to your questions and cooperate with the examination, but she chooses to remain on her mother's lap. Praising a child who is cooperative helps reinforce preferred behavior.

Talking With Parents

Geeta Grover, MD

CASE STUDY

An 8-month-old boy with a 1-week history of cough and runny nose and a 2-day history of vomiting, diarrhea, and fever, with a temperature of 101°F (38.3°C) is evaluated in the emergency department (ED). The mother is very concerned because her son's appetite has decreased and he has been waking up several times at night for the last 2 days.

A nurse interrupts and says that paramedics are bringing a 5-year-old trauma victim to the ED. The appearance of the 8-month-old child is quickly assessed; he seems active and alert. Bilateral otitis media is diagnosed. Before leaving the examination room the physician says to the mother, "Your son has a viral syndrome and infection in his ears. I am going to prescribe an antibiotic that you can begin giving him today. Give him Tylenol as needed for the fever. Don't worry about his vomiting and diarrhea; just make sure that he drinks plenty of liquids and

don't give him milk or milk products for a few days. Bring him back here or to his regular doctor if his fever persists, he doesn't eat, he has too much vomiting or diarrhea, he looks lethargic, or if he isn't better in 2 days."

Questions

1. How much information can most parents handle? Did this mother receive more information than she can be reasonably expected to remember?
2. How do you assess parental concerns? Did the physician address the mother's worries sufficiently?
3. How do you know whether a parent has understood all the information? Was this mother given a chance to clarify any questions she had?
4. What are some barriers to effective doctor–patient communication?
5. How does the setting itself influence communication?

Communication is the foundation of the therapeutic relationship between clinicians, patients, and their families. Effective communication in the pediatric setting involves the exchange of information between physicians, parents, and children. In addition, observing the interaction between parents and children gives physicians an opportunity to assess parenting skills and the dynamics of the parent–child relationship. The communication needs of both parents and children are quite different; this makes the exchange of information challenging. Parental concerns should be addressed in a sensitive, empathetic, and nonjudgmental manner. A nonthreatening, pleasant demeanor and age-appropriate language help facilitate communication with children (see Chapter 4).

Pediatrics encompasses not only the traditional medical model of diagnosis and treatment of disease but also maintenance of the health and well-being of children through longitudinal care and the establishment of ongoing relationships between physicians and families. Personal relationships between physicians and families create an atmosphere in which information can be exchanged openly. The pediatrician's role in such relationships is to not only diagnose and treat, but also to listen, advise, guide, and teach.

The doctor–patient relationship is truly a privilege. Patients entrust physicians with their innermost thoughts and feelings, allow them to touch private parts of their bodies, and then trust them to perform invasive procedures or administer medications. Mutual respect is essential for the development of a healthy relationship

between physicians, parents, and children. Through practice and continued awareness of interpersonal abilities, physicians can develop good communication skills. All physicians eventually develop their own personal interviewing and examination style. What seems awkward and difficult at first soon becomes routine and even enjoyable as physicians become more comfortable with patients.

Parental Concerns

Parents' preconceived ideas and concerns regarding their children's illnesses can greatly influence the exchange of information between physicians and patients. At health maintenance or well-child visits, it is important for pediatricians to address the nonmedical and psychosocial concerns of parents, such as their children's development, nutrition, and growth. Often these questions stem from discussions with other parents or information received through the media. Although such concerns may seem trivial to pediatricians, they may be extremely important to parents. In addition to addressing the needs of the child, the health maintenance visit also gives the pediatrician an opportunity to assess and address parental needs. Parental depression, substance abuse, family violence, or marital discord can all have profound effects on children's health and development. When evaluating children brought in for illness, it is important to ask parents what concerns them the most. Parental fears may be much different than medical concerns. Failure to give parents the

opportunity to ask questions or to address these concerns in a sensitive manner may lead to dissatisfaction and poor communication.

The Pediatric Interview

Pediatric interviews are conducted in a variety of settings for many different reasons. The first interaction between the physician and parents may be during the prenatal interview before the birth of the child, in the hospital following the delivery, or in the doctor's office during the well-baby visit. Later, the physician may see children in the office for regular health maintenance visits or in the office, ED, or hospital for an acute illness.

The specific clinical situation dictates the information that needs to be gathered and the appropriate interviewing techniques. During the prenatal visit, physicians should discuss common concerns and anxieties about the new baby with prospective parents. In addition, parents have an opportunity to interview physicians and evaluate their offices and staff.

In the emergency setting, physicians must elicit pertinent information needed to make decisions regarding management within a short period. Absence of long-term relationships can make communication in the ED particularly challenging. Focused, closed-ended questions should be used primarily. The periodic health maintenance visit is at the opposite end of this spectrum. Here the use of broad, open-ended questions is more appropriate; closed-ended questions should be used as needed for clarification.

Communication Guidelines

Overall principles, applicable regardless of the setting, include interacting with the child and family in a professional yet sensitive and nonjudgmental manner. Common courtesies, such as knocking before entering the room, dressing and behaving in a professional manner, introducing oneself, and addressing parents and children by their preferred names, are always appreciated and welcomed. Taking a few moments to socialize with families develops a more personal relationship that may allow more open conversation about sensitive and emotional issues.

Family-centered care is an approach to health care in which the practitioner realizes the vital role that families play in ensuring the health and well-being of children. Family-centered care practitioners convey respect for parents' insight into and understanding of their children's behavior and needs and actively seek out their observations and incorporate their family preferences into the care plan as much as possible. Benefits of family-centered care include a stronger alliance between the practitioner and the family; increased patient, family, and professional satisfaction; and decreased health care costs.

The medical visit may be divided into 3 parts: the interview, the physical examination, and the concluding remarks. Examples of doctor–parent and doctor–child communications for each of these components are given in Table 5-1.

The Interview

The goal of the interview is to ascertain the chief complaint and determine the appropriate medical history. The interview usually begins with open-ended questions to give parents and children an opportunity to discuss their concerns and outline their agenda for the visit. Not uncommonly, the real reason for the visit may not be disclosed until the family believes the physician is trustworthy and honest. Once the issues have been laid out, closed-ended questions can be used to clarify and further define the information presented. It often becomes necessary to guide the interview, especially when parents have several broad issues on their agenda for that visit and time does not permit their discussion.

Physicians should gently acknowledge parental concerns and define time limitations. These actions allow physicians to focus on the most salient issues of that visit. Physicians should limit their use of medical jargon (scientific terms) and be aware of nonverbal communication. Practitioners should empathize with parents; this makes them feel that their situation is truly understood even if physicians can do very little to help them. Pauses and silent periods should be used, especially when discussing emotionally difficult issues, to convey to parents and children that their physician cares enough to listen. Physicians should not underrate their own knowledge, but at the same time they should recognize their limitations and use consultants appropriately. Finally, physicians' understanding of the chief complaint and history should be summarized so parents have an opportunity to clarify points of disagreement.

Today there are increasing demands for primary care practitioners to address not only the physical but also the psychosocial health needs of their patients. Patient-centered care is a comprehensive approach to medical care that encourages communication between physicians, patients, and their families. Clinicians address the immediate pressing medical concerns in the context of each patient's unique environmental circumstances and underlying psychosocial concerns, both of which may directly or indirectly affect health-related outcomes. Empathy, unconditional positive regard, and genuineness are essential clinician characteristics in this collaborative approach. Motivational interviewing (MI) is one such patient-centered, collaborative, and directive interaction style that offers an effective means of addressing these developmental, behavioral, and social concerns within the context of a primary care setting. Motivational interviewing addresses the ambivalence and discrepancies between a person's current values and behaviors and their future goals. In contrast to more traditional medical approaches that rely primarily on authority and education, MI is a collaborative approach that relies on elicitation of the patient's ideas regarding change. Motivational interviewing practitioners understand that trying to move beyond a patient's readiness to change is likely to increase their resistance to treatment (eg, lecturing to an adolescent who is not yet ready to quit smoking about the dangers of smoking is unlikely to be effective and may even produce more resistance). Motivational interviewing requires that the practitioner

Table 5-1. Communication Guidelines and Techniques

<i>Techniques</i>	<i>Examples</i>
The Interview	
Open-ended questions	"How is Susie?"
Closed-ended questions	"Does she have a cough?"
Repetition of important phrases	"She has had a high fever for four days now?"
Clarification	"What do you mean by 'Susie was acting funny'?"
Pauses and silent periods	
Limit medical jargon	"Susie has an ear infection." vs "Susie has otitis media."
Guide the interview	"Right now I am most interested in hearing about the symptoms of this illness."
Be aware of nonverbal communication	Use eye contact and phrases such as "I see."
Acknowledge parental concerns	"Worrying about hearing loss is understandable."
Empathize	"A fever of 104°F can be very frightening."
Remember common courtesies	Knock before entering.
Recognize personal limitations	"I am not an expert in this area. I would like to consult with a colleague."
Summarize	"So she has had fever for four days but the rash and cough began one week ago?"
The Physical Examination	
Show consideration for the child	"It's OK to be afraid."
Inform	"That took me some time, but her heart sounds normal."
Explain procedures	"You may feel a little uncomfortable during the rectal examination."
Avoid exclamations	"Wow! I have never seen anything like this."
Concluding Remarks	
Provide closure	"Our time is over today. May we discuss this at the next visit?"
Minimize discharge instructions	
Be specific	"I am going to treat her with amoxicillin." vs "I'll prescribe an antibiotic."
Praise	"You're doing a great job."
Confirm parental understanding	"Please repeat for me Susie's diagnosis and treatment instructions so I'm sure I've been clear in explaining them to you."

follow 4 principles (Table 5-2). Operationally, open-ended questions (eg, "How do you feel about smoking?"), affirmations (eg, "You are tired of having to monitor your blood sugar every day and stick to your diet."), and reflective listening (eg, "You are worried about your daughter's behavior and are concerned that if it persists, she may be expelled from school.") are important tools of MI. In addition, MI practitioners ask permission before giving advice (eg, "Would it be OK if I shared some information with you?"), or the practitioner may state the facts but let the parent interpret the information (eg, "What does this mean to you?"). Motivational interviewing is not only effective with adults, but research with adolescents has shown MI to be an effective tool to increase self-efficacy to enact change (eg, adolescent smoking cessation).

The Physical Examination

Parents keenly observe physicians' interactions with their children during the examination. It is an important time for physicians to

Table 5-2. Principles of Motivational Interviewing^a

<i>Principle</i>	<i>Example</i>
Express empathy.	Use reflective listening.
Develop discrepancy between patient's current behavior and his treatment goal.	Patient, not practitioner, presents arguments for change.
Roll with the patient's resistance.	Avoid arguing for change.
Support the patient's self-efficacy.	Patient's own belief in the possibility of change is an important motivator.

^aAdapted from Miller WR, Rollnick S. *Motivational Interviewing: Preparing People for Change*. 2nd ed. New York, NY: Guilford Press; 2002.

build a therapeutic relationship with children (see Chapter 4). The transition between the history and physical examination can be made by briefly telling children and parents what to expect during the examination. Practitioners should show consideration for children's fears. Clinicians often find it helpful to speak with families at

periodic intervals during the examination regarding their observations. Prolonged periods of silence as the doctor listens or palpates may be anxiety provoking for families. Physicians should be sure to explain any procedures that either they or their staff are going to perform at a level that is appropriate for both parents and children. In addition, physicians should try to avoid exclamations or comments to themselves during the examination (eg, “Wow, that’s some murmur!”), which may be alarming to families.

Concluding Remarks

This portion of the visit, which is all too easy to rush through, is extremely important. Closure can be provided by either summarizing the diagnosis or outlining plans for the following visit. Parents should be asked to participate by acknowledging closure and helping to develop a management plan. It is important to assess parental readiness for knowledge (especially in emotionally difficult situations) and keep family resources and limitations in mind. Discharge instructions should be minimized; physicians should be specific; and the number of diagnoses, medications, and “as needed” instructions (indications for seeking medical advice such as “return as needed for high fever”) should be limited. When complicated discharge instructions are given, additional physician time may be required to ensure parental understanding. Praising parents on their care of their children can boost their self-esteem and confidence and may minimize calls and questions. Parental understanding should be confirmed; parents should be asked to repeat the diagnosis and treatment plan. Simply asking parents if they have understood is not enough, because parents often say “yes” out of respect for the physician’s time or embarrassment that they have not understood what has been said. For example, the physician could say, “I want to be sure that I’ve spoken clearly enough. Please repeat for me [child’s name] diagnosis and treatment instructions.”

Barriers to Effective Communication

Barriers to effective communication may be divided into systems barriers and interpersonal barriers (Table 5-3). The primary systems barriers are the setting itself and lack of continuity of care. Because of access problems within the health care system (ie, lack of health insurance coverage), many children receive only episodic

Barriers	Examples
Systems	
Lack of continuity of care	Episodic care that is primarily illness driven
The setting itself	Emergency departments and acute care clinics
Interpersonal	
Physician time constraints	Appearing impatient or preoccupied
Frequent interruptions	Beeper goes off or asked to come to the phone
Cultural insensitivity	Suggesting treatments that are not acceptable within the family’s belief systems

care from different physicians in acute care clinics or EDs. Without the benefit of long-term relationships, doctor–patient communication may suffer.

Interpersonal barriers include physician time constraints, frequent interruptions, and cultural insensitivity. Frequent interruptions or apparent impatience on the part of physicians conveys to parents and children that either they do not care or they are too busy for them. Language differences may pose a significant barrier depending on the region in which physicians practice. Ideally, physicians themselves should be able to speak with parents and children. If translators must be used, children should not play this role, if possible, because this places them in an awkward situation. Parents of other patients should not be used because this violates patients’ privacy. Physicians should be sensitive to cultural differences (eg, gender issues, views on illness, folk remedies, and beliefs). Suggesting treatments that are not culturally acceptable or are contrary to folk wisdom simply decreases compliance with prescribed treatment plans. For example, many Eastern cultures believe in the concept of “hot” and “cold” foods and illnesses. Suggesting to a mother that she feed primarily “hot” foods to a child she believes to have an illness that is also “hot” may not be acceptable to her. Such information is rarely volunteered and must be elicited through sensitive patient interviewing.

Effective communication is not only essential for accurate diagnosis, but also correlates with improved patient recall of instructions and adherence to prescribed courses of treatment. Poor communication can have negative consequences for both the patient (eg, compromised care) and for the practitioner (eg, medicolegal consequences).

CASE RESOLUTION

The doctor–patient interaction presented in the case history lacks several of the points discussed here. The physician did not acknowledge parental concerns or make sure that the mother had understood the diagnosis and treatment plan. The mother was presented with more information than she could have reasonably been asked to remember. This interaction could have been improved (1) if the physician conveyed to the mother that her concerns were appreciated and (2) then reassured her that her child was going to be all right. Furthermore, the physician could have told the mother the name and dosage schedule of the antibiotic to be prescribed and limited the number of “as needed” instructions.

Talking With Adolescents

Monica Sifuentes, MD

CASE STUDY

This is a first-time visit for a 15-year-old girl who is accompanied by her mother. The mother is concerned because her daughter's grades have been dropping since beginning high school, and she appears fatigued and irritable. The mother reports no new activities or recent changes in the home situation and no new stressors in the family. Both parents are employed, the girl has the same friends she has always had, and her siblings currently are doing well academically. The girl is healthy and has never been hospitalized. After the mother leaves the room, the girl is interviewed alone.

Questions

1. When interviewing adolescents, what is the significance of identifying their stage of development?
2. What are important areas to cover in the adolescent interview?
3. What issues of confidentiality and competence need to be discussed with adolescents before conducting the interview?
4. When should information be disclosed to others, despite issues of confidentiality?

Adolescence is a time of unique change. Unlike other periods in life when individuals have at least some knowledge or experience to guide them, adolescence can be characterized by feelings of physical awkwardness, emotional turmoil, and social isolation. In addition, the teenage years are dreaded by most parents, who often feel ill equipped to handle the wide range of children's responses. So instead of "taking the bull by the horns," parents choose the route of quiet observation. They fully intend to "be there" for their children but wait to be approached. Hence, many adolescents do not have the guidance or advice of parents during the teenage years and prefer to spend their time alone or in the company of friends or acquaintances. Fortunately, most adolescents pass through this period uneventfully. In fact, many individuals go through this period gladly, finally being permitted to drive a car or go out on a date.

Physicians must use a different approach when interviewing adolescents because information comes directly from the teenager, rather than the parents. Unlike an interview with a younger pediatric patient, the adolescent interview should focus on several psychosocial issues that may be uncomfortable to discuss with the parent present. Each teenager should therefore be interviewed alone. The goal of the interview is to discover any problems that might interfere with a relatively smooth passage through adolescence.

Stages of Adolescence

Adolescents are stereotypically labeled as difficult, complex, time-consuming patients with complicated problems or complaints that lead to uninteresting diagnoses. In addition, they are often accompanied by overbearing, demanding parents, or sometimes no parents at all.

The quality and quantity of information obtained during the medical and psychosocial interview can be greatly enhanced by taking developmental milestones into consideration. Adolescence can be divided into 3 developmental stages: early, middle, and late (Table 6-1). For example, interest in discussing long-term educational goals varies depending on the age of the adolescent. Most 18-year-olds are prepared to discuss college plans, specific vocational interests, and employment opportunities. In contrast, 12-year-olds are still anchored in the concreteness of early adolescence and often are ill prepared to discuss plans for higher education. Current school experiences are much more important to this age group and should therefore be the focus of discussion. Peer pressure is most prominent during middle adolescence; therefore, 14-year-olds with friends who smoke cigarettes and drink beer probably use the same illicit substances.

Table 6-1. Developmental Milestones During Adolescence^a

	<i>Early Adolescence (11–13 y)</i>	<i>Middle Adolescence (14–16 y)</i>	<i>Late Adolescence (17–21 y)</i>
Thought processes	Concrete	± Abstract	Abstract
Parental supervision	+	±	–
Risk-taking behavior	+	±	–
Peer pressure	±	++	+

^aModified from March CA, Jay MS. Adolescents in the emergency department: an overview. *Adolesc Med State Art Rev.* 1993;4:1.

Knowledge of these developmental differences allows the interviewer to more effectively explain instructions and diagnoses to teenagers. For example, 19-year-olds can better understand the effects of untreated or recurrent chlamydia cervicitis on long-term fertility than 13-year-olds. This is not to say that physicians should not discuss these possible consequences with a sexually active 13-year-old with chlamydia, but they should use more concrete wording and repeat the information at future visits. Age guidelines are not rigid, however, and each interview should be individually tailored to the particular adolescent and the circumstances surrounding the visit.

Issues of Confidentiality and Competence

A discussion regarding **confidentiality is essential** and can be approached in 2 ways. Each method has distinct advantages as well as disadvantages. Interviewers should use the approach that they find most comfortable; this allows conversation to flow more naturally.

The first approach involves informing adolescents at the beginning of the interview that most issues discussed are held in strict confidence and will not be repeated to anyone. Exceptions are suicidal or homicidal behavior and a history of or ongoing sexual or physical abuse. In any of these instances, other professionals are told of the disclosed information, and parents ultimately are informed of the disclosure. The advantages to this approach are that discussion of these “logistics” at the beginning of the interview is less awkward, making the ground rules clear from the start. This contributes to an atmosphere of trust and honesty. The disadvantage is possible inhibition by adolescents who are unsure about disclosing particular incidents (eg, those concerning sexual abuse); some teenagers are now almost certain not to share this information for fear of involving other professionals or family members. Interviewers should be nonjudgmental, reassuring, and empathetic to reduce the possibility of such an occurrence.

The second, less popular approach to the discussion of confidentiality involves informing adolescents at the end of the interview or when and if one of the exceptions to maintaining confidentiality arises. Proponents of this approach argue that adolescents tend to respond more honestly to questions when they do not believe physicians will inform others, including their parents or legal guardians. Physicians have a legal responsibility, however, to report sexual and physical abuse; in cases of suicidal or homicidal behavior, it is in the patient’s best interest to inform other professionals of this disclosure. The disadvantage to this method is that these issues often arise at very emotional times during the interview, and it is difficult to interrupt the patient to discuss mandated reporting. If physicians wait until the end of the interview to inform adolescents about mandated reporting, however, patients may leave the office feeling deceived and probably will not return for future visits. For this reason, most health care providers prefer to inform adolescents at the onset of the interview about confidentiality with the hope that it contributes to the development of a trusting relationship.

An assessment of the adolescent’s ability to make health-related decisions is another important aspect of the interview. **Competence** is the ability to understand the significance of information and assess the alternatives and consequences sufficiently to then identify a preference. Various factors besides age must be considered, such as level of maturity, intelligence, degree of independence, and presence of any chronic illness. This last factor is included because adolescents with chronic conditions may have already participated in decisions regarding their health care. Regardless, it can be difficult to assess competence from just one visit. It may not even be necessary to make an assessment emergently, except in certain cases such as with unplanned pregnancy.

Although it is imperative to interview adolescents alone, every attempt should be made to involve parents in all health-related decisions. Although specific state laws allow physicians to treat minors in emergent situations and in cases of suspected sexually transmitted infections (STIs) without parents’ consent, physicians should urge adolescents to inform their parents of any problems disclosed during the interview. The ultimate decision, however, rests with the adolescent. Physicians can assist adolescents to discuss delicate issues with their parents by role-playing with the teenager or by sitting in on the conversation between the adolescent and the parent.

Psychosocial Review of Systems

A major part of the adolescent interview involves taking an adequate psychosocial history, which can be completed in 20 to 30 minutes in most cases. The approach, known by the acronym **HEADSSS** (*home environment, employment and education, activities, diet, drugs, sexual activity/sexuality, suicide/depression, safety*), allows interviewers to evaluate the critical areas in adolescents’ lives that may contribute to a less than optimal environment for normal growth and development (Questions Box). Questions about sexuality must be asked in a nondirected, nonjudgmental fashion, giving adolescents time to respond. This information is useful to assess risks for conditions such as STIs, including HIV. In addition, an inquiry about both sexual and physical abuse is indicated during this part of the interview.

Since many adolescents now have access to the internet 24/7 via their cellular telephone or home computer, it is important to discuss “screen time” with them and their parents. In addition to reviewing the amount of time actually spent on the computer each day, the health care provider also should inquire about texting, sexting, and whether the patient is a victim of cyberbullying.

Issues That Need Immediate Attention

Many issues discussed during the psychosocial interview can be a source of anxiety for adolescents. Certain problems must be taken more seriously than others, and may demand immediate attention. Suicidal ideation, with or without a previous attempt, definitely requires a more in-depth analysis of the gravity of the problem. Physicians should make sure that adolescents feel they can make

Questions

Talking With Adolescents: HEADSSS^a

H: Home environment

- With whom does the adolescent live?
- Have there been any recent changes in the living situation?
- How are things between parents?
- Are the parents employed?
- How does the adolescent get along with the parent and siblings?

E: Employment and education

- Is the adolescent currently in school?
- What are his or her favorite subjects?
- How is the adolescent performing academically?
- Has the adolescent ever been truant or expelled from school?
- Are the adolescent's friends attending school?
- Is the adolescent currently employed? How many hours does he or she work each week?
- What are the adolescent's future education/employment goals?

A: Activities

- What does the adolescent do in his or her spare time?
- How much time is spent on the computer and cell phone?
- What does the adolescent do for fun? Is the adolescent ever bored?
- With whom does the adolescent spend most of his or her time?

D: Diet

- What is a typical meal for the adolescent?
- Does the adolescent have any food restrictions?
- What does the adolescent think about his or her current weight and shape?
- Is there a recent history of weight loss?

D: Drugs

- Is the adolescent currently using, or has he or she ever used, tobacco?
- Is the adolescent currently using, or has he or she ever used, any illicit drugs? What about steroids? Alcohol?
- Does the adolescent ever feel pressured by friends to use drugs or alcohol?

S: Sexual activity/sexuality

- What is the adolescent's sexual orientation?
- Is the adolescent sexually active?
- If so, what was the age of the adolescent's sexual debut?
- How many sexual partners has the adolescent had in his or her lifetime?
- Does the adolescent have a history of sexually transmitted infections?
- Does the adolescent (or the partner) use condoms?
- Does the adolescent (or the partner) use other methods of contraception?
- Does the adolescent have a history of sexual or physical abuse?

S: Suicide/depression

- Is the adolescent bored all the time? Ever sad or tearful? Tired and unmotivated?
- Has the adolescent ever felt that life is not worth living or ever thought of or tried to hurt himself or herself? More importantly, does the adolescent have a suicide plan or access to a firearm?

S: Safety

- Does the adolescent use a seat belt and bicycle helmet?
- Does the adolescent participate in high-risk situations, such as riding in the car with someone who has been drinking?
- Does the adolescent feel safe at home? At school? In his or her neighborhood?
- Is there a firearm in the adolescent's home? If so, what does the adolescent know about firearm safety?

For more detailed information, see the Goldenring entries under Selected References

^a Reprinted with permission from Goldenring JM, Rosen DS. Getting into adolescent heads: an essential update. *Contemp Pediatr.* 2004;21:64. Copyright © Advanstar Communications.

verbal contact and call someone if they feel like hurting themselves. Mental health professionals should be involved in the clinical assessment of these situations. Other issues that require immediate attention include possible danger to others, possible or confirmed unplanned pregnancy, and sexual or physical abuse.

Concluding the Interview

The adolescent interview should be conducted at a time when the adolescent is relatively healthy and the interviewer has set aside ample time for a thorough, uninterrupted discussion. However, all topics need not be addressed during the initial interview if time does not permit. Issues that are not covered at this visit can be addressed at the next one. The number of appointments needed to work through or solve a particular problem is unlimited.

At the end of each visit, the interview should be summarized; any difficult topics should be mentioned, and the issue of confidentiality should be reviewed. Adolescents should then be asked to identify

a person whom they can trust or confide in should any problems arise before the next visit. In some instances, this issue may already have been discussed during the interview. Adolescents also should be given the opportunity to express any other concerns not covered in the interview and ask additional questions.

Physicians should clearly point out to the adolescent any significant risk factors or risk-taking behaviors that have been identified during the interview and assess the teenager's readiness to change this behavior. For those adolescents who are not engaging in high-risk behaviors, physicians should acknowledge that things seem to be going well, praise them with positive feedback, and review their individual strengths and accomplishments that have been discussed. Available resources, such as teen hotlines and popular Web sites, should be given to the adolescent prior to inviting the parent or guardian back into the examination room. General concerns should then be reviewed with the parent while maintaining the adolescent's confidentiality. The follow-up visit should be arranged at that time.

CASE RESOLUTION

The adolescent in the case history initially should be informed about confidentiality and the specific exceptions to maintaining it. Nonthreatening topics, such as home life, school, and outside activities, should be explored first, followed by questions regarding sexuality, sexual activity, and illicit drug use. Suicidal behavior or depression and safety issues should also be reviewed with the teenager alone. In addition, computer and cell phone use should be evaluated. High-risk behaviors and their consequences should be discussed with the adolescent at the end of the interview, and a plan for future visits should be arranged.

Telephone Management

Iris Wagman Borowsky, MD, PhD

CASE STUDY

The mother of an otherwise healthy 10-month-old girl calls and tells you that her daughter has a fever. The girl's rectal temperature has been 103°F to 104°F (39.4°C–40.0°C) for the past 2 days. Although she is cranky with the fever, she plays normally after receiving acetaminophen. The girl is eating well and has no runny nose, cough, vomiting, diarrhea, or rash.

Questions

1. How do telephone and face-to-face encounters between physicians and patients differ?
2. What are some general guidelines for effective doctor–patient communication over the telephone?
3. What historical information is necessary for appropriate telephone management?
4. What points are important to cover in-home treatment advice?

Parents frequently call their pediatricians seeking medical advice about their children. It is estimated that pediatricians spend more than 25% of their total practice time engaged in telephone medicine. Telephone medicine serves 2 purposes: (1) it provides a service and (2) it controls costs and overcrowding by reducing unnecessary visits to the office and emergency department (ED). Most calls concern upper respiratory symptoms, fever, rash, trauma, or gastrointestinal complaints—the same problems most commonly seen in the office. In addition to acute illness care, triage, and advice, telephone care services provided by pediatricians include chronic disease management, care coordination, patient education, counseling, test result interpretation, illness follow-up, adherence checks, and medication adjustments.

Telephone management of illnesses differs in that it requires pediatricians to give advice based on history alone and precludes the opportunity to see the child, much less do a careful physical examination. For example, a practitioner in the ED who does not know the patient or family may choose to see the child if questions about the child's general health or the feasibility of continued contact with the family arise. On the other hand, a primary care physician who knows the patient and family and can follow the child's progress by telephone may advise home management for a child with a similar history. Pediatric practice settings, whether in an ED or primary care office, should have an organized approach to telephone care. In addition to physicians, nurse practitioners, and physician assistants, telephone care systems may include trained and supervised nurses and nonmedical office staff using protocols.

Telephone Communication Skills

Parents commonly call their pediatricians because they are worried about their child. The friendly voice of a health care worker who is ready to lend an ear goes a long way toward reassuring an anxious

parent. Calls should begin with a “verbal handshake.” Staff should identify themselves and the place where the call is received and offer to help. They should learn the caller's name, his or her relationship to the child, and the child's name and gender; these names, as well as the child's gender, should be used in the conversation, thereby creating a more personal atmosphere.

Telephone calls for medical advice are often received in busy environments, such as EDs or clinics, where patients are waiting to be seen. It is easy to be abrupt under these circumstances and not give complete attention to callers. If calls are not emergencies, practitioners can take the caller's telephone number and return the call as soon as possible. If callers do not feel that their concerns have been fully acknowledged, they are likely to feel dissatisfied, even if they are given sound advice. Furthermore, research on doctor–patient relationships suggests that lack of friendliness or warmth in the doctor–patient relationship and patient dissatisfaction are associated with noncompliance with medical advice. Studies show that the length of a patient visit does not correlate with patient satisfaction. Telephone encounters do not necessarily have to be lengthy; the average length of a call is reported to be 3 to 5 minutes, depending on the setting. Calls must be pleasant, however, and they must address callers' concerns. Open-ended questions such as “Tell me about your child's illness” or “Are there any other symptoms?” are useful at the beginning of a call because they give callers an opportunity to explain the situation without interruptions.

Establishing rapport over the telephone is more difficult than in person because the practitioner is limited to verbal communication. In face-to-face encounters, physicians can use words as well as means of nonverbal communication, such as facial expressions, eye contact, gesturing, and touch, to convey warmth and empathy. Practitioners should use various aspects of **verbal communication** to convey sincere interest in callers' concerns, and they should pay

attention to these verbal cues in callers. Many components of verbal communication (in addition to words themselves), including vocal expression, pace, articulation, tone, volume, and pauses, affect telephone interactions. Health care professionals should speak clearly and use vocabulary that callers understand; **medical jargon should be avoided**. A friendly yet respectful tone and a calm, professional manner should be maintained.

Careful listening is crucial to obtaining the information necessary to make medical decisions over the telephone. One of the major goals of health care professionals is to recognize and respond to callers' main concerns and expectations. This can be difficult because most callers do not specifically tell their major concerns to their physicians. Researchers have found the following questions useful in the identification of parents' chief concerns: "What worries you the most about [use child's name] illness?" and "Why does that worry you?"

For callers who ramble, health care professionals may need to focus the conversation. Asking the question "What can I do to help?" should clarify the reason for the call. If information needs to be verified, practitioners can summarize what they have heard and ask if they have understood correctly.

Angry callers may elicit defensive or confrontational behavior from health care professionals. Responding to anger with arguments, however, is time-consuming, stressful, and pointless. Practitioners should be warm and understanding so that callers who want to discuss their feelings are comfortable. Acknowledging anger may encourage open discussion and problem-solving (eg, "You sound upset. Is there anything I can do to help?"). Empathizing with callers (eg, "I don't blame you for being upset." "That must have been very frustrating.") may also help.

Practitioners can build confidence in callers by complimenting them on the way they have handled things so far (eg, "You did the right thing by giving [child's name] Tylenol and a lukewarm sponge bath for the fever. That is exactly what I would have done." or "I'm glad that you called about this."). They may even be able to offer reassurance to parents who are not managing their child's illness correctly by commenting that many parents try the same treatment. A different treatment approach can then be suggested.

Before the end of the conversation, callers can be given an opportunity to ask questions and encouraged to call again if additional problems occur.

Telephone History Taking

How much history should be obtained over the telephone? Enough information should be gathered to make an appropriate decision. Questions should be directed at **determining whether an emergency exists** and **making a diagnosis**. For example, if the mother of a 20-day-old girl reports that her daughter has a temperature of 102°F (38.9°C), the infant must be seen immediately. If diarrhea is the chief complaint, some additional information would be helpful before giving advice (eg, "How many bowel movements did the girl have in the last 24 hours? Is there any blood in the diarrhea? Does she have a fever? Is she drinking less than usual? Is there any decrease

in urine output?"). An older child with the same chief complaint of fever may be safely managed at home, depending on the answers to other questions about additional symptoms.

Pediatricians typically follow an organized approach to history taking for acute care visits that includes the chief complaint, history of present illness, pertinent review of systems, medical history, and family and social history. A similarly **organized framework** should be used to obtain a history over the telephone (Questions Box). Specific questions should then be asked to clarify the child's condition and obtain all the information necessary to make a good decision. A child's medical history may affect a practitioner's management of the current problem. For example, knowing that a child who has been exposed to chickenpox has asthma and is receiving steroids or has leukemia is crucial in providing the appropriate telephone advice. Practitioners can refer to several texts on pediatric telephone decision-making (see Selected References). These books outline protocols for common chief complaints to serve as guides for history taking and management over the telephone. The most efficient way to provide such medical advice is to obtain critical information that affects decisions about diagnosis and management instead of asking all possible questions. For example, with a child who is vomiting or has diarrhea, the state of hydration is critical; with a cough, the occurrence of breathing difficulty; and with head trauma, loss of consciousness. Methods of teaching telephone management skills include role-playing, listening to mock calls by "simulated" parents, and reviewing tapes of actual calls.

Because most childhood illnesses are mild and self-limited, evaluation of the safety of medical advice obtained over the telephone requires large samples to detect poor outcomes associated with mismanagement. Research has described a "wellness bias" in which practitioners, who primarily see patients with mild, self-limited illnesses, may downplay the severity of reported symptoms and choose the most benign diagnostic possibility. This bias may be more pronounced in a telephone encounter, where the physician cannot see the child. One study reported telephone encounters in which physicians seemed to make a decision early in the conversation and then "shut out" additional information that should have led to the consideration of more serious diagnoses. The safest approach is to always have a high index of suspicion for a serious condition. Questions can then be asked to confirm or dispel those suspicions.

Questions

Telephone Management

- How old is the child?
- What is the child's chief problem? What are the child's symptoms?
- How long has the child had these symptoms?
- How is the child acting?
- Does the child have any chronic illnesses?
- Is the child taking any medications?
- What is the caller most worried about?

Telephone Advice

Pediatricians should formulate an **assessment and management plan** based on the child's history. If the situation is an emergency, this should be explained to the caller, and appropriate follow-up plans should be made (ie, sending an ambulance for life-threatening conditions such as respiratory depression or uncontrollable bleeding, advising the caller to bring the child by car to the ED or physician's office within a specified amount of time for potentially dangerous complaints, such as right lower quadrant pain or possible fracture). If the call is not an emergency, then health care professionals must decide if and when the child should be seen by a physician and the appropriate home treatment.

Research shows that parents need and expect to receive an explanation of their child's illness. Practitioners should clearly state what the child's illness seems to be, what probably caused it, and what the parents can expect (eg, length of time that the child is likely to be sick, additional symptoms that may appear).

Before giving any treatment advice, health care professionals should ask callers the following questions: "What have you done so far?" "Have you given the child any medications?" and "How is this treatment working?" If the therapy seems appropriate, callers should be complimented and encouraged to continue the treatment. The regimen should be modified as indicated. Instructions for home treatment should be clear and as easy to implement as possible. If the instructions are complicated or lengthy, callers may want to write them down. When prescribing medication, ask if the child has any known drug allergies, and give the dose, frequency of administration, and information about possible side effects. Practitioners should verify that the caller can follow the telephone advice (eg, a parent has a thermometer and knows how to use it). If pediatricians plan to check up on children by telephone, they should confirm that callers (or relatives or neighbors) have a telephone and record the number.

Practitioners should confirm that callers understand the information and instructions and agree with the plan. Asking questions such as "What questions do you have?" encourages callers to raise uncertainties and ask for needed clarification. Most importantly, if the decision is to manage at home, callers should always receive specific instructions about when to call back. Caregivers should call if the child's symptoms change, persist, worsen, or cause anxiety. Also, symptoms specific to the child's condition should be followed (eg, child has fever for more than 2 days, irritability, decreased urination). Parents who seem unduly anxious or uncomfortable with home treatment should be given the opportunity to have their child seen by a physician.

Documentation

All calls for medical advice should be documented in a telephone log book or the child's medical record, for both medical reasons (eg, better follow-up, improved continuity of care) and legal purposes. The form used for documentation should include the date and time of the call; the name, identity, and telephone number of the caller; the name and age of the child; the chief complaint; other symptoms; possible diagnoses; advice given; and the name of the person who took the call.

CASE RESOLUTION

In the case history at the beginning of this chapter, the pediatrician learns several facts that lead to the recommendation that the child be seen that day (the next day if the call is made at night). These facts include the child's age, the height and duration of the fever, and lack of any symptoms of localized infection.

Informatics

Alan Tomines, MD

CASE STUDY

You are a physician in a small pediatric practice. Your hospital is planning to acquire an electronic medical record, which will be made available within the hospital and to the offices of its affiliated practices. The hospital chief of staff asks you to sit on the hospital's informatics committee to participate in the vendor selection process and to assist with the implementation of the selected system. You have previously used the hospital's computer to check patients' laboratory results, and your practice uses computers for billing and scheduling. However, you don't consider yourself a technology expert and express your trepidation to the chief of staff, who asks you to speak with the head of the informatics committee.

Questions

1. What is informatics?
2. What are the important informatics concepts to understand?
3. What are the important drivers of health care information technology?
4. What are the challenges to implementing successful health information systems?
5. What are the special pediatric considerations in health information systems?

To make the best possible clinical decisions, physicians must have information about their patients' health that is current, accurate, complete, and reliable. This information should be available wherever and whenever it is needed. Where possible, the physician should be presented with information that will encourage an evidence-based approach to decision-making, and the decisions made should be communicated to other health care providers in a manner that is clear and error-free. The physician should also be able to receive feedback on the quality of care provided. Health care information technology (HIT) holds the promise of increasing access to patient health information, improving patient safety, reporting and measuring desired health outcomes, and making health care more efficient; at the same time, it holds the promise of decreasing health care expenditures. However, the implementation of HIT is not without challenges.

Basic Concepts

Although the terms *data*, *information*, and *knowledge* are sometimes used interchangeably, these concepts are distinct. Data are mere observations or facts (eg, hemoglobin equal to 9 g/dL). Information is data placed in meaningful context (eg, hemoglobin equal to 9 g/dL in a breastfed 3-month-old infant). Knowledge is the understanding of information, including an assessment of its completeness (eg, hemoglobin equal to 9 g/dL in a breastfed 3-month-old infant may represent a physiological nadir, but may also represent blood loss, increased destruction of red blood cells, or decreased production of red blood cells). Any structured collection of data may be referred to as a *database*.

Information technology refers to any hardware or software that support the acquisition, storage, retrieval, transformation, interpretation, and dissemination of data and information. An *information system* is the sum of the people and work processes that are supported by information technology. Depending on the degree to which technology is applied, the processes of an information system may be automated, manual, or a combination of both.

What Is Informatics?

Medical informatics is the science that deals with the appropriate application of information technology to health care work processes. To apply information technology appropriately, specialists in informatics (referred to as *informaticians* or *informaticists*) focus first on improving the quality of data and the efficiency of workflow in the patient care setting; it is in this optimized environment that technology may be applied most effectively. Medical informatics places great emphasis on non-technological considerations that can influence the successful implementation of health information systems, including information science, cognitive psychology, project management, organizational and change management, health care policy, and ethics.

As a field, medical informatics can itself be subdivided into specific clinical domains, such as nursing, pharmacy, veterinary medicine, dentistry, and imaging. *Biomedical informatics* is a term of broader scope that encompasses medical informatics, bioinformatics (having the primary domain of genomics and bioengineering), and public health informatics. Outside of the United States, *health informatics* is the term more frequently used to convey the same breadth.

Electronic Health Information Systems

Although all electronic health information systems ultimately deal with managing some aspect of patient care, they are divided here into 4 coarse groupings: electronic records of patient care, administrative systems, ancillary clinical systems, and telemedicine. Box 8-1 lists several common abbreviations used in electronic health information systems.

Electronic Records of Patient Care

An electronic medical record (EMR) represents the clinical documentation and legal record of care provided to a patient by a health care provider or organization. An EMR can usually create and store traditional clinical documentation, such as progress notes and consultations. However, a full-fledged EMR represents more than an “electronic version” of the traditional paper-based record. Important components of an EMR include a clinical data repository (CDR), a clinical decision support system (CDSS), and computerized provider order entry (CPOE). A CDR is a real-time database containing all of the clinically relevant patient data in an institution. A CDSS is a special computer program that applies medical knowledge to clinical data to produce patient-specific recommendations, such as differential diagnoses or clinical recommendations. A CPOE is a special computer program that allows providers to write electronic orders that are directed to the appropriate clinical staff or ancillary department. A CPOE can decrease errors due to illegible handwriting, decrease delays in the receipt and execution of orders, allow for orders to be entered away from the care setting, and (in conjunction with a CDSS) provide for error checking (such as appropriate weight-based dosing, drug–drug interactions, or drug–allergy interactions).

An EMR generally operates within the functional boundary of a hospital or practice. However, information about a patient’s health is not limited to traditional care settings. A personal health record (PHR) is a summary of an individual’s health history, usually self-maintained, that contains information collected from encounters with different providers, medicolegal documents (such as living wills or advance directives), and other health information that may be relevant to the patients (such as regimens for nontraditional remedies or the results of home testing for blood pressure). The concept of a PHR is not new: Patients with multiple medical problems have long maintained paper-based PHRs out of necessity—to have at least one reliable and portable source containing a complete medical history. The electronic PHR is an evolving entity, ranging from scanned paper documents stored on CD-ROM or other removable media to Web-based applications that interface with EMRs and capture data from medical devices. The PHR is not considered a legal record of care.

The electronic health record (EHR) represents the next stage in the evolution of the EMR. An EHR will have all of the desired functionality of a full-fledged EMR, but will capture data from multiple different EMRs to provide the entire longitudinal history of the patient. In addition, the EHR will support functionality related to research and public health, such as identification of patient-appropriate clinical

Box 8-1. Abbreviations Used in Informatics

ARRA	American Recovery and Reinvestment Act of 2009
CDR	clinical data repository
CDSS	clinical decision support system
CPOE	computerized provider order entry
EHR	electronic health record
EMR	electronic medical record
eRx	electronic prescribing
HIE	health information exchange
HIPAA	Health Insurance Portability and Accountability Act
HIS	hospital information system
HIT	health care information technology
HITECH	Health Information Technology for Economic and Clinical Health Act
IIS	immunization information system or registry
P4P	pay-for-performance
PACS	picture archiving and communication system
PHI	protected health information
PHR	personal health record
RIS	radiology information system

trials, mandatory reporting of notifiable disease, and provision of clinical data (stripped of patient-identifying information) to support clinical and public health research.

A health information exchange (HIE) is an enabling technology that acts as a hub for the secure exchange of data between EMRs. An EMR that is connected to an HIE has the ability to exchange health information with other EMRs that are connected to that HIE, precluding physicians and hospitals from having to establish an interface between their EMR and every other EMR where a patient might have data. While an HIE generally serves a specific geographic region, the interconnection of HIEs provides the capability for an EMR in one region to share data with an EMR in another region, reducing the barriers to accessing a patient’s entire longitudinal history of care.

Administrative Systems

A hospital information system (HIS) encompasses all of the clinical and nonclinical information systems of an institution. An HIS may be a single integrated information system or it may represent multiple information systems that are connected with specially designed interfaces. Hospitals and large practices often have separate information systems to manage individual administrative functions, such as appointment scheduling, insurance eligibility, and billing and reimbursement. A practice management system is an information system designed to manage administrative tasks and is considered to be appropriate for small- and medium-sized practices.

Ancillary Clinical Systems

Information systems that support clinical ancillary services focus on a limited set of tasks and data. A laboratory information system manages the entry and reporting of laboratory results, often capturing electronic data directly from laboratory analyzers. A pharmacy information system manages patients' prescription information, checks appropriate dosing and drug interactions, and tracks medical insurance; a related concept is e-prescribing (electronic prescribing or eRx), which uses technology to write and transmit prescriptions electronically to a pharmacy information system. A picture archiving and communication system (PACS) manages the storage and distribution of patients' electronic medical images; a radiology information system incorporates the functionality of a PACS and also manages radiology service activities, such as reporting, scheduling, and billing. An immunization information system (IIS or immunization registry) is used to document and track patient vaccinations. An IIS can send reminder or recall notices, as appropriate, to physicians and parents when vaccinations are due or delinquent. Because these systems are usually maintained regionally by public health entities, they also collect reports on adverse vaccine events and provide summaries of regional vaccination prevalence. These systems are usually able to exchange data with capable EMRs.

Telemedicine

Telemedicine is not an information system, but a related concept of interest in informatics. Telemedicine is the use of information and communication technologies to deliver health care over a distance, often to support patient care in rural or underserved areas. There are many specialties within telemedicine, roughly corresponding to distinct medical specialties, such as teleradiology (the transmission of radiologic images electronically for interpretation) and telesurgery (the use of video and robotic technology to perform surgery). The use of e-mail and Web sites to communicate with patients is also a form of telemedicine.

Drivers

The key health care drivers for the adoption of HIT are the improvement of patient safety, the measurement of health care outcomes, the increased efficiency of workflow in the patient care setting, and the reduction of health care expenditures.

Patient safety, through the reduction of preventable errors, is the primary driver of information technology adoption in many health care organizations. In its report *To Err Is Human*, the Institute of Medicine (IOM) estimated that up to 98,000 US deaths annually are attributable to medical errors. Most errors were noted to be preventable and caused by systems and processes that increase, or fail to prevent, human errors. Computerized provider order entry is an example of information technology that has the potential to improve patient safety—by alerting the physician to errors before an order is submitted.

Changes in the health care marketplace are driving the measurement of health care outcomes. Pay-for-performance (relating reimbursement to measures of the quality of care provided) and “medical report cards” that permit comparison of health care plans and providers are examples of market drivers. Information technology is critical to collecting and analyzing data to calculate these measures. In addition, a CDSS may improve health care outcomes through guideline adherence by reminding physicians and patients about necessary care services that may have been overlooked.

Improvements in efficiency are another driver in the adoption of information technology. The automation of highly repetitive, data-intensive activities, such as billing or scheduling, is an example of where efficiency can be improved. However, introduction of information technology into a clinical setting without thorough consideration of workflow may actually decrease efficiency.

Health care spending is approaching 20% of the gross domestic product of the United States and is increasing at a rate nearly twice that of inflation. Information technology is considered to be a potential source of cost savings by reducing duplication of diagnostic studies and decreasing the time spent on administrative tasks. In addition, in the IOM report *Crossing the Quality Chasm*, the use of e-mail was touted as a method for meeting the needs of patients more quickly and at lower cost than a traditional visit.

Challenges

Despite the significant health care drivers for adopting HIT, there are a number of challenges that prevent the easy implementation of systems.

The ease with which information systems can exchange electronic patient data should not belie the care that must be taken to protect that data. Protected health information (PHI) is any information about a patient (such as name or medical record number) that may be used to identify a patient. Privacy is the patient's right to keep this information a secret. Confidentiality is the assurance made by health care providers that private information will not be revealed. Security involves the policies and technologies that support the assurance of confidentiality. The Health Insurance Portability and Accountability Act defines the measures that must be taken to ensure that PHI is secure and made available only to authorized individuals or organizations. Appropriate concerns exist about breaches of patient privacy when data are stored electronically. Although health information systems often employ sophisticated technical barriers to protect patient data, it is often the case that data breaches are the result of people failing to adhere to policy safeguards. Educating providers and other users of patient data is critical to guaranteeing patient confidentiality.

The cost of implementing health information systems can be prohibitive for health care delivery organizations, particularly small practices. To address this barrier, the Health Information Technology for Economic and Clinical Health (HITECH) Act was included in the American Recovery and Reinvestment Act of 2009. The HITECH Act authorizes Medicare and Medicaid incentives to be provided

to clinicians and hospitals that adopt EHRs and demonstrate their *meaningful use* by meeting specific objectives toward improved health care delivery and outcomes. These objectives include using EHRs for fundamental activities, such as recording patient demographics and vital signs; maintaining active problem, medication, and allergy lists; providing patients with summaries of outpatient visits and inpatient discharge instructions; electronic prescribing and ordering; and providing drug–drug and drug–allergy checks. The objectives also include more esoteric or complex functions, such as providing data to public health agencies for disease surveillance, providing data to immunization registries or immunization information systems, generating lists of patients with specific conditions for quality improvement and research, identifying and providing patient-specific education resources, and providing summary of care records and medication reconciliation across health care settings. To assure physicians and hospitals that they are adopting EHRs that allow them to meet meaningful use regulations, the US Department of Health and Human Services has developed a process and criteria for certifying EHRs.

Change management is an important element to consider when implementing an information system. Introduction of technology inevitably results in changes in the workflow of physicians and nurses and may lead to repurposing of administrative staff. Resistance to change should be anticipated; strategies to mitigate resistance should be employed, including involvement of health care professionals in the selection and deployment of HIT.

Human–computer interaction is the study of the interactions between people and information technology. It is important for users to perceive that the technology is useful (supports the work being done) and that the technology is usable (readily learned, efficient, and helps them to avoid and correct errors).

Effects of technology on the patient–physician interaction must also be considered. Constraints on time or location of computers may compel some providers to do electronic documentation during their visits. Physicians should be sensitive to patients who feel that technology is intrusive; where appropriate, physicians should acknowledge the intrusion, and identify potential benefits to the patient (including efficiency of access to information and more efficient communication of prescriptions to pharmacies or orders to ancillary services).

Pediatric Considerations

Although pediatric patients represent approximately one-quarter of the US population, pediatric features are often underdeveloped in electronic health information systems. When considering these systems for pediatric settings, particular attention should be focused on the highly specific data, task, and policy needs of pediatric practice.

The presence of functionality to support clinical tasks that are generally, if not uniquely, pediatric should always be examined. Immunization management, including the ability to assess a patient's

status or to exchange data with an immunization information system, is highly desirable. Weight-based dosing and the tracking of growth parameters are other functions that are often overlooked. Age-specific documentation and educational materials can be well-managed electronically.

The data and terminology of an information system should suit the highly specific needs of pediatric practice. Units of measure should reflect the requisite data precision. For example, the age of a patient in hours (rather than years, months, or even days) and weight in grams is critical to appropriate care in the neonatal period. Laboratory values should be accompanied by age-appropriate normal ranges. Patient identification must account for the frequent changes in names and numerical identifiers that may occur in infancy or during change of custody. Pediatric terminology, such as developmental milestones, type of cry, or characterization of stool, are often overlooked in information systems designed for adults.

Pediatric policy issues should also be reflected in the design of an information system. Authorization for the child (or the child's parents, guardians, or other legal authority) to view all, none, or parts of a child's medical record should be enforced electronically as it would be for the paper medical record. Likewise, secondary use of patient data for public health, research, or commercial purposes should be allowed or restricted as appropriate.

At this time, there is no electronic medical home for the care of children. The electronic history of care may be distributed across EMRs, immunization information systems, school health information systems, and specialty registries for rare conditions, trauma, or foster care. With the emergence of health information exchanges as a conduit for data exchange, it may be possible to create a virtual medical home. It is important that pediatricians work toward reducing the legislative, technological, and cultural barriers to linking child health information systems without compromising the security or confidentiality of protected health information.

Pediatricians should be actively involved in the acquisition and development of information technology to ensure that child-specific data and policy needs are addressed. Pediatricians should also be involved in national policy initiatives to ensure that health information systems are certified for pediatric use and integrated to support care that is child-centered.

CASE RESOLUTION

In the case history at the beginning of this chapter, the pediatrician speaks with the head of the informatics committee. The pediatrician learns that she has been asked to participate because of her understanding of physician workflow in the office setting and to advocate for the highly specific data needs and policies associated with the pediatric population. Her expertise will help to identify issues that, if addressed, may contribute to successful acceptance of the information system by pediatricians and other physicians.

Counseling Families About Internet Use

Alan Tomines, MD

CASE STUDY

A 16-year-old girl is accompanied by her mother for a routine visit. The girl is doing well in school, is active in team sports, and has a small circle of friends that are well-known to her mother. The mother describes no new problems at home, nor any changes in behavior, except that she is concerned that her daughter “spends too much time on the computer.”

Questions

1. What is the Internet?
2. What are the commonly used Internet services?
3. What are the benefits and risks of the Internet?
4. What strategies may be used to make the Internet safer to use?
5. What signs may indicate that an adolescent is engaging in risky behaviors on the Internet?

The Internet is a worldwide system of interconnected computer networks. At its inception, it was the exclusive domain of the military and academia; today, the Internet is a public gateway to electronic information, communication, and commercial services. The Internet has profoundly changed the way that we learn, work, play, and interact with others. Its influence is so pervasive that it has become an integral part of the education and socialization of children, making it a subject of interest for parents, providers, and researchers. Physicians can provide pragmatic counsel to families that focuses on the benefits and risks of the Internet, strategies for safer use, and the assessment of online behavior in adolescents. Physicians should also be prepared to discuss health information that families find on the Internet.

A Brief History of the Internet

The Internet began in the 1960s as ARPANET (Advanced Research Projects Agency Network), a US Department of Defense project to share government-funded, university-based computer resources across a reliable communications network. Through the 1970s, ARPANET found acceptance with academics and researchers as a conduit for scientific information exchange, due in large part to **e-mail** (electronic mail), a technology for sending and receiving messages.

Recognizing the potential of the ARPANET, the National Science Foundation (NSF) began a separate effort to connect the computer science departments at non-ARPANET universities; initially dubbed CSNET (Computer Science Network) and later renamed NSFNET, this new network further expanded electronic information exchange. In 1990 the ARPANET was retired, with many of its networks being

absorbed into NSFNET. The resulting network, renamed the *Internet*, extended its reach into the business sector and to international researchers but remained relatively inaccessible to the general public.

During the early 1990s, the European Organization for Nuclear Research (CERN) developed protocols to facilitate the sharing of physics research data over the Internet. These protocols allowed computer files, on different computers and having different formats (such as text and images), to be shared as single documents that could be viewed using a special computer program (browser). This system of linked documents was collectively dubbed the *World Wide Web* (WWW, or simply the Web), with collections of documents referred to as *Web pages* or *Web sites*. In 1993 CERN made their work freely available, leading to the rapid proliferation of commercial and individual Web sites.

Internet Services and Concepts

Today the most commonly used Internet services are e-mail and the Web. A person actively using an Internet service is said to be **online**. Use of the Web is sometimes referred to as *surfing the Web* or *surfing the Net*, and is facilitated by **search engines** (programs that use keywords or topics to find related documents, images, Web sites, or other services on the Internet) such as Yahoo! and Google. Internet services may be accessed by a wide range of computing devices, from personal or laptop computers to smartphones (mobile phones that provide access to Internet services). No matter what technology is used, access is usually provided by an **Internet service provider** or ISP (a company that has an Internet connection that it shares with consumers on a subscription basis).

Due to their popularity in the pediatric age group, there are a few specialized Internet services of which physicians should take special note. Web logs (or **blogs**) are Web-based journals. Like a traditional paper-based diary, a blog can be used to express activities, thoughts, or feelings. Blogs may be public (available for anyone to read) or private (having restricted access); the owner of a blog may allow readers to add comments to the blog. **Social networking** Web sites, such as Facebook, Twitter, and MySpace, are similar in content to blogs, with the added dimension that users are encouraged to create a network of online friends by establishing links to other users' Web pages. Blogs and social networking Web sites are examples of **asynchronous** services (where communication between users does not have to take place in real time) whose content may be moderated by the owner of the service to ensure that content is appropriate. In contrast, **chat rooms** are Internet venues that permit the real-time exchange of text messages between multiple simultaneous participants. **Instant messaging** is similar to a chat room, although it is generally limited to one-on-one exchanges of real-time messages. Although sometimes referred to as *text messaging*, instant messaging is a more inclusive term that better reflects the immediacy of interaction and expansion of content to include images and multimedia (such as streaming audio and video files). Instant messaging is a popular premium service with mobile phone subscriptions, making it possible to have an online presence at all times without a computer. Adolescents have shown an increasing preference for instant messaging—estimated to be used by one-third of all teens.

Internet Benefits and Access

Physicians should be able to identify the benefits of Internet use. The Internet provides access to a wealth of educational resources and cultural experiences through the use of text, images, and multimedia. Access to these resources allows children to exercise their reading, writing, information-seeking, and technology skills. The Internet also provides the opportunity to exchange messages frequently with family and friends. In addition, children with common interests, or even common medical conditions, can use e-mail, chat, blogs, or social networking to communicate, commiserate, and encourage.

Physicians may also take a role in reducing disparities to Internet access. Internet use and access is correlated with socioeconomic status. While nearly 90% of adolescents in the United States are regularly online, millions do not have access. Pediatricians may help families gain access to the Internet by identifying institutions that provide safe online environments, such as libraries, community centers, and schools. In addition, patient-centered Internet-based health interventions are increasingly being studied as a supplement to traditional health care delivery; addressing disparities to Internet access may increase opportunities for these interventions, particularly in underserved communities.

Physicians should also be aware that children with disabilities may have a difficult time using the Internet without **assistive technology** (hardware or software designed to improve the accessibility of computers). Visually impaired or blind children may be aided

by the use of special software, including screen magnifiers, Braille embossers, or screen readers (software that uses a computer-generated voice to read e-mail and Web pages); however, it is important to note that many Web sites are not developed to be compatible with screen readers. Hearing-impaired or deaf children may be aided by ensuring that their computers are set to provide visual cues rather than audio prompts; this functionality is usually built into the operating system of a computer. Children with mobility or dexterity challenges may find it difficult to use a traditional keyboard and mouse; alternative keyboards, manual pointing devices, and computer touch screens should be investigated. Pointing devices that employ sound or infrared beams, as well as software that responds to the spoken word, may be viable alternatives where manual control is not possible.

Internet Threats

While the Internet has many benefits, being online does entail some risks. To understand these risks, it is helpful to understand many of the Internet's neutral properties. The Internet is interactive: Unlike traditional media, such as newspapers, radio, and television, the Internet user may have real-time interactions with a person or a sophisticated computer program. The Internet has few restrictions: Anyone can put almost anything on the Internet, without regard to credibility or appropriateness. The Internet is public and permanent: Although information on a Web site may be removed, it is possible for anyone that visits a Web site to make an electronic copy of what is there, and many Web sites are archived historically (www.archive.org) and remain publicly retrievable long after they seem to be gone. The Internet is anonymous: People are not necessarily who they represent themselves to be. These Internet properties do not encourage, but do enable, the most common threats, which include strangers/predators, interpersonal victimization, and pornography, among others (including gaming, gambling, and shopping).

Internet predators are the greatest concern of parents. More than one-half of children online have shared personal information about themselves (including name, address, or phone number) with a stranger. Nearly one-third of children online have "friends" that they have never met in person. Approximately three-fifths of online adolescents have received an instant message or e-mail from a stranger.

Online interpersonal victimization is the receipt of unwanted harassment or sexual attention over the Internet. One-fifth of children have reported being victimized, and a high risk factor was talking about sex with someone online. Cyberbullying is a specific type of online interpersonal victimization involving repetitive contact with electronic messages or images that are harmful or threatening. Cyberbullying may be as prevalent online as "traditional" bullying, with nearly one-fifth of middle school-aged children reporting that they had been cyberbullied at least once in the last couple of months and more than 10% reporting that they had cyberbullied others at least once in the last couple of months.

While children may be individually targeted by strangers or cyberbullies, they may passively encounter undesired Internet

content. More than 40% of children reported having been exposed to pornography online, and nearly two-thirds of them described this exposure as unwanted. In adolescents between the ages 15 to 17, more than 70% reported accidentally being exposed to online pornography. A high risk factor for exposure to pornography was the downloading of images.

Sexting is the exchange of sexually explicit text, images, or multimedia, generally via instant messaging. Sexting sits at the convergence of pornography and cyberbullying, with the added danger that some adolescents may not perceive sexting as harmful or threatening. In some jurisdictions, minors that have participated in sexting have been charged with possessing child pornography.

Strategies for Safer Internet Use

The American Academy of Pediatrics (AAP) has provided age-specific guidance for a safer Internet experience: For children through age 14, parents should be actively involved with all online activities, establish rules for safe online behavior, and use Internet safety tools; by age 15, parents may permit Internet access without restriction, but should continue to reinforce rules.

Parents may be actively involved by educating themselves about the Internet and their children's Internet access, sharing time with their children online, and advocating for a safer Internet environment. Some parents may not be technically savvy and may require basic instruction on Internet technology. Classes may be available through libraries, community centers, the local Parent-Teacher Association, or online primers such as "Teach Parents Tech" (www.teachparentstech.org). Parental education on Internet safety can begin with Web-based resources, such as the Federal Trade Commission's OnGuard Online (www.onguardonline.gov), NetSmartz Workshop (www.netsmartz.org), iKeepSafe.org (www.ikeepsafe.org), and INOBTR (www.INOBTR.org). Parents should be aware of other venues where their children may access the Internet, such as schools, libraries, and friends' homes, and they should find out what Internet safety policies and technologies have been instituted in these environments.

By sharing time online, parents can promote and model responsible Internet behaviors. Parents should talk about what they see together on the Internet, and encourage children to share what they have experienced when online alone, whether good or bad. Placing the computer in a public location in the home will encourage the idea that the Internet is a shared experience; however, parents should be aware that laptops and mobile telephones allow covert Internet access. Children should be provided with a separate account to access the Internet, which their parents can also access. Having a separate account will allow parents to directly restrict the software and content that children can access and periodically review Web sites visited and e-mails. Parents should understand that some children may be savvy enough to erase their Web browsing history; absence of a Web browsing history may be a cause for suspicion. Parents should regularly monitor mobile telephone activity for instant messaging activity.

Parents should act as advocates for their children's Internet experience. When a child encounters inappropriate Internet content, or messages that are hurtful or distressing, parents should alert their ISP, as well as the owner of the Web site where the content or messages were discovered. Parents should also contact the appropriate legal authorities and the National Center for Missing and Exploited Children (www.missingkids.com). Commercial Web sites that collect personal information from children younger than 13 are required to follow the Children's Online Privacy Protection Act of 1998, which is enforced by the Federal Trade Commission. According to this law, Internet Web site operators must post their policy indicating what personal information is collected, how that information will be used, and if that information will be shared with a third party. Parents must consent to the collection and use of personal information, and may revoke this consent at any time.

Parents should set and enforce house rules for Internet use. Children should not communicate with nor plan to meet strangers known only to them through the Internet, nor should they respond to unsolicited messages, or any other messages that make them feel uncomfortable. Children should not share personal information or pictures with others on the Internet, nor should they download files from the Internet. Children should be encouraged to be good citizens, including not doing anything that may be hurtful to others or plagiarizing information that they find freely on the Internet. For older children, safety pledges can be used as formal agreements of acceptable use. Time limits should be set and strictly enforced. The AAP recommends not more than 2 hours of total screen time (computer and television) for children older than 2 years. Any activities that are not allowed should be specifically identified.

Even with house rules in place, physicians should recommend the use of Internet safety tools to protect against inappropriate use and external threats. Although not directly targeted at children, parents should be aware of software to protect against malware. Malware generally includes viruses and worms (software programs that can corrupt the information saved on a computer), spyware (software that tracks Internet activity and sends this information to another person), and pop-ups (a new browser window that may contain marketing or other undesired content). Viruses and worms are generally downloaded as attachments in e-mail, whereas spyware and pop-ups are introduced by surfing the Web. Parents should also protect against spam (unsolicited e-mail), which may contain undesired content or solicitations.

Filters are special computer programs that allow acceptable Internet content to be presented and block content deemed to be inappropriate. Filtering may use one or more of the following methods: "black lists" of Web sites that are specifically blocked, "white lists" of Web sites that are specifically permitted, the blocking of specific words or terms, and the maturing technology of blocking suspicious image content. Filters are neither perfectly specific nor perfectly sensitive and may require parental adjustment to achieve an acceptable level of filtering. Parents may contact their ISP to enable filtering of content before it enters the home (server-side filtering). If

server-side filtering is too restrictive for some members in the household, or not restrictive enough for others, parents may acquire filtering software that is installed directly on computers in the home (**client-side filtering**). Client-side filters work with standard Web browsers, although special child-oriented Web browsers may be acquired that have client-side filtering built in.

Monitoring software automates parental tracking of Internet usage by creating a reviewable record of Web sites and images viewed, messages sent and received, and even individual keystrokes entered. The potential benefits of monitoring software should be weighed against the invasiveness to the privacy of the child. Monitoring software often includes time-limiting software, which can be set to allow Internet access only during certain hours of the day and can be set to disable access to the Internet after a specified amount of time has elapsed.

Adolescents on the Internet

As with other aspects of their lives, adolescents should feel that they can discuss what they see on the Internet with their parents without imperiling their access to the Internet. Most adolescents have access to the Internet from home, and nearly all have access to the Internet at school or at a friend's house. Parents should be aware that adolescents who have restrictive Internet rules at home are more likely to attempt Internet access outside the home, where their activity may be more difficult to monitor.

Adolescents may engage in risky online behaviors, including communicating with and planning to meet in person strangers met online. From a review of past cases, the Federal Bureau of Investigation has identified specific behaviors that may indicate a child is engaging in risky online behaviors, including spending several hours online, especially at night; having pornographic images on the computer; turning the monitor off, or quickly changing the screen when a parent enters the room; and using unrecognized usernames or accounts. Other non-Internet behaviors that should arouse suspicion include phone calls from unknown adults, outgoing calls to unrecognized phone numbers, gifts or packages received, or unexplained credit card activity.

The physician should consider addressing online activities in the adolescent psychosocial review of systems. Asking adolescents about online activities may unveil risky online behaviors or provide an opportunity to discuss concerns about their health and well-being. Nearly one-third of adolescents have searched the Internet for health information, most often related to sex and sexually transmitted infections, nutrition, and exercise and fitness. Additionally, adolescent girls also search for information on physical abuse, sexual abuse, and dating violence. Online activities worthy of inquiry include health topics searched for on the Internet; maintenance of a social networking (such as a Facebook or MySpace) page; sharing

personal information on the Internet; communicating with strangers; meeting people known only via the Internet; and engaging in, or being a victim of, cyberbullying or sexting. Adolescents should also be reminded that the Internet is not private, and that colleges and employers may discover information about the adolescent on what seem to be "private" social networking pages.

Health Information on the Internet

Patients regard physicians as the preferred and most trusted source for health information; however, patients do seek out health information on the Internet prior to, or sometimes in lieu of, consulting with their physician. It is important to remind families that health information on the Internet may be outdated, incomplete, incorrect, intentionally misleading, or easily misinterpreted. When patients have questions about information that they find on the Internet, physicians should take care not to disregard the information outright. Inquiries should be viewed as opportunities to address points of concern. Most often, patients simply want their physician's opinion of the information, as opposed to a specific treatment.

Providing patients with Web sites that provide reliable information can improve the quality of information seen and reduce the overwhelming quantity of information that parents must sort through. Physicians may help support patients by identifying evidence-based health information resources on the Internet, such as the AAP (www.aap.org), the National Library of Medicine's MEDLINEplus (www.medlineplus.gov), the Centers for Disease Control and Prevention (www.cdc.gov), and the US Department of Health and Human Services' Healthfinder (www.healthfinder.gov). Specialists should be prepared to identify online information sources and support groups, particularly for rare, chronic, or debilitating conditions. Physicians should caution families caring for children with special medical conditions about the characteristics of less reliable online resources or support groups, which may include novel or alternative treatment regimens, advice to stop treatment, or charging of fees for participation or treatment.

CASE RESOLUTION

In the case history at the beginning of this chapter, the pediatrician finds out that the girl uses the computer for 1 to 2 hours every afternoon to complete her homework assignments and is on the Internet for 2 to 3 hours every evening surfing the Web and checking her Facebook page. The pediatrician advises the girl that, for safety reasons, personal information should never be shared over the Internet, adding that colleges and employers often research prospective candidates using the Internet. With the mother and daughter, the pediatrician discusses the option to have a parent-child contract that clearly establishes the rules for acceptable Internet use in and out of the home, including appropriate time limits. The pediatrician also directs the mother to Internet-based resources for safeguarding the home environment, and to a workshop for new Internet users at the local library.

Cultural Considerations and Competence in Pediatrics

W. Suzanne Eidson-Ton, MD, MS; Hendry Ton, MD, MS; Blanca Solis, MD; and Jesse Joad, MD, MS

CASE STUDY

You are seeing A.J., a 12-year-old Mexican American boy, for a well-child visit. His mother speaks Spanish and “a little” English, is single, and works full time in motel custodial services. After school and during summers, A.J. is cared for by his older brother (17 years old) and his maternal grandmother, who lives a block away. His weight and body mass index (BMI) are well above the 95th percentile for his age. When discussing his diet, you learn that his mother buys packaged foods that he can make for himself when she is away. She is concerned that he will not eat if she does not buy the processed, high-fat foods that he likes. Further, these types of foods are more readily available than healthier options at the local market where she shops. A.J. sometimes eats at his grandmother’s place, but

she is elderly and not cooking much anymore. When discussing physical activity, he states that he wants to play soccer. His mother is concerned about this, however, because he often complains of headaches and stomachaches when it is time for practice, and she does not want to buy the equipment if he will quit after a few weeks, as has happened in the past.

Questions

1. What is meant by culture?
2. What is meant by cultural competence?
3. What constitutes health care disparities?
4. What are some of the social determinants that impact the health of a population?

Culture

Culture is defined as a set of meanings, norms, beliefs, and values shared by a group of people. It is dynamic and evolves over time and with each generation. Culture encompasses a body of learned behaviors and perspectives that serves as a template to shape and orient future behaviors and perspectives from generation to generation and as novel situations emerge. As relates to health, culture shapes how and what symptoms are expressed and influences the meaning that one attributes to symptoms, including one’s beliefs about the cause, the impact, and the potential remedies. Culture is considered to be broad, encompassing not only race/ethnicity, but also sexual orientation, gender roles, gender identity, socioeconomic status, nationality, and other group affiliations. The interaction between the culture of the patient and family and that of the provider is often significant, and can lead to bias in assessment and treatment. These biases, in turn, can contribute to health and health care disparities.

Health Disparities

Health disparities are defined as differences in health outcomes across different groups. Health care disparities, as defined by the Institute of Medicine in the document *Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care* are “racial or ethnic differences in the quality of health care that are not due to access-related factors

or clinical needs, preferences, and appropriateness of intervention.” Both health disparities and health care disparities exist within the United States and particularly affect minority populations. While health disparities may be due to many social determinants of health, such as class, access to safe neighborhoods and healthy food, as well as access to health care, health care disparities are directly related to what happens to certain patients in the health care system once they have accessed care.

Latino children in the United States face significant health and health care disparities. In particular, as alluded to in the case study, the highest prevalence of overweight children in the United States is in the Latino population. Latino children also have a lower fitness level and watch more television than white children in the United States. The reasons behind these disparities are complex and multifactorial. Latino children also face disparities in the health care they receive. For example, the duration of their routine well-child visits is shorter and they are less likely to receive counseling at these visits compared with white children.

In addition to the lack of access to quality health care, there are many social, political, and cultural elements that contribute to the health care disparities observed in certain ethnic groups. Individual providers may have limited impact on the economic, environmental, and political issues that contribute to poor outcomes. It is nevertheless important to understand these issues and how they may

contribute to their patients' health outcomes. For example, lack of access to quality, low-cost foods in one's neighborhood, lack of transportation, advertising practices that target low-income communities, and lack of access to safe playgrounds are examples of social determinants that contribute to obesity. It is also essential to understand the influence of culture on patients' health beliefs, health behavior, and health status.

Finally, acculturation is likely to have an impact on health, health beliefs, and health behaviors as well. Second-generation Latino adolescents are twice as likely as first-generation ones to be obese or overweight. Acculturation across generations in Latinos has been associated with decreased fruit and vegetable consumption, increased soda consumption, and decreased physical activity. However, acculturation is a complex variable in relationship to pediatric obesity. Mexican American mothers who were less acculturated had children with higher BMIs in one study.

Cultural Competence

Providers who strive for cultural competence try to minimize their bias and seek to incorporate cultural assets into their work with patients. Cross and colleagues also describe cultural competence as a continuum. While this continuum was used to characterize organizations, it is also relevant for health care providers (Box 10-1). At the most negative pole, *cultural destructiveness* is comprised of attitudes and practices that are meant to be harmful to cultures and individuals within the particular culture. Clinicians at this level may overtly discriminate against individuals based on their culture (ie, intentionally making homophobic, racist, or sexist remarks to colleagues). Clinicians who have *cultural incapacity* do not overtly discriminate, but lack the ability and willingness to recognize and intervene when discrimination happens. As a result, they ultimately reinforce culturally oppressive behaviors and policies. In the *cultural blindness* phase, culture is believed to make no difference and that all people are the same. This viewpoint ignores cultural strengths, encourages assimilation, and often leads to blaming the victims of racial injustices for their problems. Clinicians at this stage may have difficulty believing in the validity of health disparities, despite the enormous body of evidence supporting this. While they strive to give quality care to everyone, they fail to recognize the culture-specific experiences that impact their patient's health (such as poverty or violence based on race, sexual orientation, or gender), and they miss opportunities to incorporate culturally relevant strengths into the treatment (ie, collaboration with traditional healers, extended family, and/or

faith-based organizations). *Cultural pre-competence* is characterized by a willingness to deliver quality services and a commitment to civil rights but a lack of knowledge and experience to implement culturally relevant services. Clinicians here often struggle with knowledge that disparities exist, and that they perhaps continue to contribute to them. Yet they are at a loss as to what to do about it. A provider at the stage of *cultural competence*, in contrast, seeks to expand his or her cultural knowledge and resources often in consultation with culturally diverse communities. They also continuously self-assess and adapt traditional service models to enhance care for culturally diverse patients. Finally, a provider with *cultural proficiency* holds cultural diversity in highest esteem and continuously advocates for increased cultural competence throughout the system of care. It is important to recognize that providers move back and forth along this continuum dynamically, influenced by their own experiences. For example, a provider who identifies with being in the culturally competent phase when working with Latino patients may find themselves having cultural incapacity when working with gay or lesbian patients.

Communication

As proposed in the opening case study, communication between the physician, the patient, and the parent may pose unique challenges when dealing with language and cultural differences. Effective communication results in improved patient–doctor relationship, treatment adherence, and health outcomes. Poor communication may have negative consequences. Patients with limited English proficiency (LEP) in particular have greater barriers to health care, poorer quality of health, and poorer health status. In a Joint Commission on Accreditation of Health Care Organizations study involving 6 hospitals, researchers found that patients with LEP were at greater risk for iatrogenic harm. In contrast, use of interpreters is associated with greater follow-up with preventive and primary care services. Ideally, one would have a trained medical interpreter in order to communicate with the patient and their parents. It would be inappropriate for a patient to communicate for his parents, although this happens often in clinical practice. It is clearly a difficult position for a child or teen to interpret health information to his parent. There is no guarantee that the patient understands what the physician is communicating, nor that he is interpreting correctly. It also disturbs the appropriate power balance between parent and child. Strategies to incorporate when using interpreters are noted in Box 10-2.

Unconscious Bias

In addition to ensuring effective communication, it is important to address the unconscious biases that one may have as the provider. While few health care providers intentionally discriminate based on culture, studies suggest that physicians are likely to have unconscious biases that can significantly affect their care of patients. Providers can take steps to decrease unconscious bias. It is essential to first acknowledge that bias really does exist, in the health care system

Box 10-1. Continuum of Cultural Competence

- Cultural destructiveness
- Cultural incapacity
- Cultural blindness
- Cultural pre-competence
- Cultural competence
- Cultural proficiency

Box 10-2. Strategies When Using Interpreters in Medical Settings

1. Meet with the interpreter briefly prior to the interview to discuss overall goals for the interview and ground rules (ie, use word for word interpretation).
2. Use nonverbal behaviors, such as eye contact, nodding, or facial expressions, to let the patient know that the provider understands what is being communicated.
3. Speak directly to the patient and address the patient in the first person.
4. Use short, simple statements and stick to one topic at a time.
5. Avoid medical jargon and ambiguous statements.
6. Meet briefly with the interpreter after the interview to confirm pertinent information, ask about cultural information, and discuss feedback.
7. Remember that the interpreters are not medical professionals. Therefore, regard information volunteered by interpreters as reliable as collateral information provided by other non-health professionals.

and within the lived experience of patients as well as providers. It is good practice for health care providers to explore Harvard's Project Implicit Web site (<https://implicit.harvard.edu/implicit/>) and take the online tests designed to detect bias across various cultural dimensions, including race, gender, and sexual orientation. Most people who take these tests realize rather quickly that they carry biases that they had no idea existed within themselves. For many, acknowledging one's own biases may be the most difficult step. The next step is to work toward replacing one's biases with positive and realistic associations about other groups. For example, seeking out dialogue and companionship with people culturally different from oneself can help to reshape one's negative assumptions with more positive associations. Finally, it is important to be mindful of the potential influence of unconscious bias on medical decision-making, whether treating a patient of similar background to the provider or a patient of a very different background. While it is essential to consider the cultural context, it is also important to keep in mind that each patient is a unique individual. In situations where bias may be present, providers should speak less and listen more, striving to avoid assumptions.

Eliciting the Patient's Perspectives

A patient's and provider's understanding of the health issue is an important part of the overall clinical collaboration. Typically, the patient's history is obtained with limited consideration to the patient's beliefs about the health problem. Difficulties may arise if the patient and/or their family members disagree with the physician's explanations of the illness. Openly disagreeing with a physician's assessment and treatment recommendations is considered disrespectful in many cultures. The patient and their family may instead acknowledge the physician's status by expressing agreement but maintain their own ideas about how to address the issue. The mother in our case study, for example, may report her intention to follow through with his physician's recommendations to change to a healthier diet, but may in fact continue with the ready-made foods because she feels there are

difficulties getting healthier foods given her long work hours and the availability of healthy food in her neighborhood. The provider may characterize the obesity as a primarily biological problem, whereas A.J.'s mother might see it as primarily a problem of access and time.

Further, our patient's mother may not see his overweight status as a problem at all. The relationship of pediatric obesity to cultural ideals and norms around food, eating, and parenting is complex. There is some evidence in ethnographic studies that, in some Latino cultures, feeding children, and especially giving "treats," is a way of showing love. Parents who have children who are "healthy eaters" may not want to limit their children's enjoyment of food. In addition, body size ideals vary across communities, and there is some evidence that in some Latino as well as other communities (Pacific Islanders, some Asian communities), children meeting criteria for being overweight are considered more attractive and healthier than thinner children, who may be considered frail. Further, poverty and the experience of food scarcity can further exacerbate overeating when food is more accessible. Finally, particularly when other friends or family members offer food to children, it may be considered socially unacceptable for the parent to refuse or criticize the type of food being offered. Understanding these types of cultural norms can be helpful in treating individual patients. However, it is important to remember that particular individuals and families have their own cultural norms, which may or may not be consistent with others in their ethnic group.

Conflicts in health beliefs between the provider and patient/family may result in treatment non-adherence and drop out. It is important that the physician and patient/family both discuss their respective health perspectives. The more that the provider understands the patient/family's health beliefs, the more effective he or she will be at addressing differences and building on common ground. Likewise, patients/families may feel a greater level of comfort with the provider's recommendations if their questions and concerns about the provider's perspectives are addressed. Questions can help a provider further understand their patient's health beliefs and facilitate discussions about health issues identified by the provider (Box 10-3).

Box 10-3. Questions to Help Facilitate Discussion About Provider-Identified Issues

1. About which problem are you most concerned?
2. What do you think about my concerns (the provider's identified problems, eg, obesity)?
3. What do you think has caused the problem?
4. What are your concerns about this problem? How does it affect you?
5. What treatments do you think might work for it?
6. What are your goals for treatment?
7. What is your understanding of the treatment offered? What are your concerns about it? What are the barriers for completing or carrying out the treatment?

Decision-making

It is also important to understand how a patient or their family makes medical decisions. Many providers look to the child's parents as the primary decision-makers. This process may be culturally influenced. Parents from strongly collectivistic cultures, in which the needs and priorities of the group supersede those of the individual, may wish to have others, such as family members, spiritual leaders, or clan leaders, be involved in health care decision-making. Failure on the part of the provider to allow the inclusion of these people in decision-making may result in the parents feeling forced into a decision, precipitate conflict within the family, and lead to the family or community blaming the parents if a bad outcome occurs. Again, dialoguing may promote better understanding about health care decisions (Box 10-4).

Box 10-4. Questions to Facilitate Decision-making

1. How do you usually make decisions about health care?
2. Do you involve anyone else in that process? Who, and what are their roles?
3. Who usually makes the final decision?
4. How comfortable are you with using that process to make decisions about your current situation?

CASE STUDY, continued

At a follow-up visit for A.J., you ask to speak with him alone. During your HEADSSS assessment, you learn that he is attracted to boys, but has not shared this with anyone. He is certain that his brothers will not approve and his mother will be heartbroken. He is sometimes teased at school because he is "not tough enough," and he fears some of the bigger bullies might try to jump him if he hangs around after school to participate in any of the after-school sports activities.

At this visit, it is extremely important to remain nonjudgmental and supportive of this patient's early sexual identity development. See Chapter 41 and Chapter 137 for suggestions in addressing the sexual identity and bullying issues presented here. The Fenway Learning Module is another resource on caring for lesbian, gay, bisexual, and transgendered (LGBT) youth (http://www.fenwayhealth.org/site/PageServer?pagename=FCHC_ins_fenway_EducPro_modules).

There are several other factors to consider with respect to health disparities in this case. In the National Longitudinal Study of Adolescent Health, in which 20,000 adolescents were surveyed in 1995, Latino male and female adolescents were more likely to report same-sex romantic attraction than their white and Asian peers. In addition, both male and female Latino adolescents are more likely than their peers to experience violence. Therefore, both the issues of sexual minorities and that of bullying are important to consider in addressing adolescent health disparities in culturally diverse communities in the United States. It is also important to understand A.J.'s sexual orientation in the context of his family and ethnic community. While there are certainly challenges for LGBT youth in Latino families, such as anti-gay sentiments in some faith traditions, there are also strengths for LGBT individuals with strong cultural identities.

For example, urban young Latino men who have sex with men were less likely to engage in risky sexual behavior if they were connected to their ethnic community. These are some examples of the complicated intersection of sexual identity and ethnic identity in cultural issues in pediatrics.

CASE RESOLUTION

You are supportive of your patient in his early sexual identity development, explore safe adults in A.J.'s life with whom he can explore his feelings and concerns, and identify LGBT community resources. You also discuss A.J.'s and his mother's perspectives around food, his weight, and his activity level, using a medical-trained interpreter for his mother. You identify some of this family's strengths: A.J.'s mother's desire to help him be healthier; A.J.'s relationship with his grandmother, who cooks healthy traditional foods; and A.J.'s supportive relationship with his older brother. After discussion, the patient decides that he would like to learn to cook from his grandmother and will commit to cooking dinner for a family meal once a week, which delights his mother. His brother has also agreed to take him to soccer practice and games for a neighborhood soccer team. The patient likes this idea as he feels safe from bullies around his brother, and he feels that soccer will help him be stronger and more confident. You arrange for a follow-up visit in several months to check in with A.J. and his mother regarding their progress and to brainstorm about further interventions.

Principles of Pediatric Therapeutics

Elizabeth A. Edgerton, MD, MPH

CASE STUDY

An 18-month-old girl who has had a cough, runny nose, and fever for 2 days is brought to your clinic for evaluation. The previous night she awoke from sleep crying and pulling at her ear. The patient has no other symptoms. Her mother states she has had previous ear infections, the most recent occurred 2 months ago. The last time she took amoxicillin she broke out in hives. Otherwise the patient has no significant medical history.

On physical examination, the patient is febrile to 102°F (38.9°C) and has yellow rhinorrhea. The ear examination reveals a red, bulging, nonmobile tympanic membrane in one ear, while the other ear appears normal. The remainder of the examination is benign.

Questions

1. What are the current practice guidelines for antibiotic treatment of otitis media? How does treatment change with the age and symptoms of the patient?
2. How does the previous reaction to a medication influence the antibiotic choice?
3. How do factors such as child care, work, and family plans affect the choice of medication?
4. What role do over-the-counter medications have in the management of the patient's symptoms?
5. What resources are available to obtain information on therapeutic effectiveness, costs, side effects, and drug–drug interactions?

The use of prescription and over-the-counter (OTC) medications is common in pediatrics. The Slone Survey, a random digit–dial survey of medication use, found that families with children reported more than 55% of children younger than 12 years had taken some medication preparation within the last 7 days. Of those taking a medication, 22% were taking at least one prescription medication. Many OTC medications contain multiple active ingredients, raising the concern about their safety profile for children, considering that the use of OTC medications is reported as being so prevalent. Furthermore, it is estimated that only one-third of drugs used to treat pediatric patients have adequately been studied in the populations in which they are being used and have appropriate labeling information. This does not mean that the other two-thirds of medications are unsafe for children but that their use in children is extrapolated from adult studies.

Differences in pharmacokinetics among infants, children, and adolescents can produce significant differences in drug efficacy and toxicity. Body composition, the rate of drug binding, and metabolism change with development. The consequences of not fully studying the clinical effectiveness and safety profile of therapeutics can lead to potentially harmful outcomes. Significant medical tragedies in the past include the use of sulfonamides in the newborn period leading to kernicterus, chloramphenicol causing gray syndrome, and in utero exposure to thalidomide leading to birth deformities. Recently, the US Food and Drug Administration (FDA) removed

OTC cough and cold preparations for infants and toddlers due to safety concerns. Poison control centers managed 750,000 calls due to cold and cough medications, and the FDA is investigating the deaths of 123 children associated with these types of medications. Factors believed to contribute to the harm associated with OTC cough and cold medications included inappropriate dosing by caregivers, use of more than one product, and use of adult product formulations.

Since 1962 the FDA has required drugs to be proven safe and effective before they can be marketed. The FDA can only regulate the safety, effectiveness, and labeling of medication and is not authorized to regulate a physician's use of a medication. When data are not sufficient for a specific population or age group, it will be specified in the product labeling that use in that population has not been established. Using a medication for a condition or specific population not specified by the product insert is referred to as **off-label prescribing**. Depending on the practice setting, off-label prescription rates range from 11% to 80%, with the highest rates among younger patients and hospitalized settings. Pediatricians rely on the published literature, adult studies, and knowledge of pediatric physiology and pharmacokinetics for prescribing. While off-label prescribing is not illegal, it does put children at greater risk of unexpected adverse reactions as well as lack of optimal treatments. Through the Best Pharmaceuticals for Children Act in 2002 (Public Law 107-109) and again in 2007 (Public Law 10-85) and the enactment of

the Pediatric Research Equity Act (Public Law 108-155), the FDA has been mandated by Congress to increase the level of pediatric research prior to approval and during the post-marketing phases. Even with increased regulation, implementation of pediatric clinical trials faces critical issues, such as the ethics of parental consent, multiple age groups to be tested, and the unknown long-term effects in a developing child. The pediatric population lacks the autonomy to fully give consent and understand the implications of studies, thus the American Academy of Pediatrics Committee on Drugs and Committee on Pediatric Research developed guidelines to address the special issues of drug research among children.

Principles of Therapeutics

A drug or therapeutic can be defined as any substance that is ingested, absorbed, or injected that alters the body's function. This includes OTC medications, homeopathic substances, illicit substances, and prescription drugs. Each drug has a different safety profile and level of regulation depending on its category. The most regulated and standardized drugs are those requiring a prescription. Homeopathic substances often lack any standardization, safety testing, and regulation, and illicit drugs such as heroin or cocaine receive no quality testing. Choosing the most appropriate therapeutic is a complex process involving a number of factors: patient characteristics, disease epidemiology, safety profile, patient compliance, and cost-effectiveness (Box 11-1).

Box 11-1. Factors in Choosing the Appropriate Therapeutic

Patient Characteristics	Patient Compliance
Age	Taste
Medical history	Purpose of treatment
Allergies	Storage
Use of other medications	Side effects
Diagnosis	Cost-effectiveness
Epidemiology	Drug availability
Age-specific factors	Formulary restrictions
Safety Profile	
Therapeutic index	
Black box warning	

Patient Characteristics

The organs of infants and children are growing and maturing, which can affect how a medication is absorbed, distributed, and excreted. Neonates have immature liver and kidney function compared with older children and adults. For example, similar microgram per kilogram doses of fentanyl can result in a 2- to 3-fold higher plasma concentration in the neonate compared with an adult. Knowledge of the age of the patient is critical to account for developmental pharmacokinetic differences for age-appropriate as well as weight-based dosing.

The choice of an appropriate therapeutic is influenced by a patient **medical history**. Depending on the type of clinical conditions or surgeries a patient has, the absorption, metabolism, or clinical effectiveness of the therapeutic may be altered. Children with short bowel syndrome can potentially have difficulty absorbing oral medications depending on which portion of the bowel was removed. Children with mental retardation who are given central nervous system-altering medications can be difficult to monitor for changes in mental status seen with systemic infection. In addition, children with glucose-6-phosphate dehydrogenase deficiency can suffer from drug-induced hemolytic anemia when given certain drugs such as sulfonamides. Malnourished children are at a greater risk for drug toxicity because low serum albumin levels decrease the amount of bound drug and result in increased levels of unbound drug in circulation. While not an exhaustive list of medical conditions that can alter medication delivery, these demonstrate the need to consider underlying medical conditions in choosing the most appropriate therapeutic.

Before prescribing any medication, physicians need to ask patients and their families about any previous reactions to drugs and obtain detailed information about the symptoms and class of medications involved in these reactions. **Drug allergies** are those reactions that have an immunologic basis. Of the 4 types of immune mechanisms associated with drug allergies, immunoglobulin E-mediated reactions are of greatest concern because they can result in anaphylaxis, a life-threatening condition. **Adverse reactions** can be idiosyncratic or non-immune-mediated. A **side effect** is an expected but undesirable consequence of taking the medication. Families often attribute any symptom the patient suffered while taking the medication to a drug allergy. It is therefore important to know which side effects are associated with a medication to determine whether an allergy is present. Any medication that has been associated with an allergic reaction (eg, skin eruptions, swelling, urticaria, or respiratory difficulty) should not be used again without consulting a specialist.

Finally, knowing what other medications a patient is taking can affect the choice of therapeutic. The mechanism of metabolism of one drug can affect the metabolism of another. Drug metabolism is divided into 2 types: phase I reactions include oxidation, reduction, and hydrolysis; phase II reactions involve adding subgroups to a drug. Other drugs can affect reactions during either phase. For example, the enzyme activity of the P-450 system involved in oxidation can be induced or inhibited depending on the other medications being taken, resulting in an altered rate of metabolism. Common drugs used in pediatrics that inhibit the P-450 system include cimetidine and erythromycin, while phenobarbital and phenytoin induce the system. Drug interactions are not a contraindication to the use of a therapeutic, but the dose and serum levels may need to be closely monitored. Referencing the package insert, the *Physicians' Desk Reference (PDR)*, or a pharmacist can aid in determining potential drug-to-drug interactions. Handheld devices that provide formulary information often have drug compatibility functions that allow a provider to enter a patient's medication list and screen for potential drug interactions.

Diagnosis

Choosing the appropriate medication depends on understanding the condition being treated as well as the epidemiology of the disease for a specific age group. Etiologies of pneumonia for an infant, child, and adolescent can be completely different, thus requiring a different type of antibiotic. Even when a potential organism is identified, the profile of the medication needs to be reviewed. For a patient with group A streptococcal pharyngitis, a gram-positive organism, penicillin G, penicillin V, erythromycin, or a first-generation cephalosporin is an acceptable choice. Although tetracycline and sulfonamides can be effective in treating patients with gram-positive infections, tetracycline is contraindicated in young children, and sulfonamides do not eradicate group A streptococcal infection. Treatment duration can also vary depending on the age of the patient. An adult with a simple urinary tract infection may receive only a 1- to 3-day course of treatment, while a child may receive 7 to 10 days of treatment because of the high recurrence of infection that has been observed with a shorter duration of treatment.

Safety Profile

The safety profile of a medication is the balance between its benefits and its potential risks. The risks can be dependent on the duration of treatment, dose, or interactions with other medications. Using the **therapeutic index** is one way to quantify the risk associated with a specific dose. The therapeutic index is the difference between the dose that provides a desired effect and the dose that provides an undesired effect. For example, a medication with a wide therapeutic index is one in which a desired effect is achieved with a dose much lower than that required to produce a toxic effect. In general, a medication with a wide therapeutic index, such as ibuprofen, is considered safer than a medication with a narrow therapeutic index. The higher the morbidity and mortality associated with a condition the smaller the accepted therapeutic index can be. Food–drug interactions and drug–drug interactions are other risks that can be anticipated. These are best delineated in pharmacologic references. There are also risks that are independent of the dose of the therapeutic called idiosyncratic effects. These are unexpected and usually unavoidable risks associated with the medication.

In the United States, a **black box warning**, also known as a **black label warning**, is a type of warning that appears on prescription drugs that may cause serious adverse effects. Named for the black border that usually surrounds the text of the warning, it means that medical studies indicate that the drug carries a significant risk of serious or even life-threatening adverse effects. The FDA can require a pharmaceutical company to place a black box warning on the labeling of a prescription drug or in literature describing it. It is the strongest warning that the FDA requires. Psychotropic medications, selective serotonin reuptake inhibitor antidepressants, stimulants for attention-deficit/hyperactivity disorder, and the long-acting β -agonist salmeterol are a few of the medications that have a black box warning for use in the pediatric population. A complete

list of medications with black box warnings can be found at www.fda.gov. This warning does not preclude the use of the medication, but requires the physician and family to evaluate the risks and benefits of its use.

Patient Adherence

Patient adherence is dependent on the convenience of administering and taking the medication, the patient's and caregiver's comprehension of the medication's purpose, and any potential discomfort caused by side effects. Because children are dependent on their caregivers to administer medications, it is crucial that caregivers know why the drug has been prescribed, how it should be dispensed, and why it must be given for a specific length of time. For a child with tinea capitis, a fungal infection of the scalp and hair follicles, parents may think that a topical antifungal is sufficient to treat the infection. Explaining the difference between a fungal skin infection (tinea corporis) versus the fungal scalp infection can facilitate adherence with the treatment. To eliminate the fungal infection in the hair follicles, a systemic medication is needed. Furthermore, because of the slow growing cycle of both the fungus and the hair, patients need to take the medicine for up to 6 weeks. To ensure accurate dosing, a staff member should demonstrate how to dispense the medication and then ask the parent to repeat the process. Such a simple intervention can make an important difference in obtaining adherence and influence the effectiveness of the therapeutic.

The taste and texture of a medication are also important considerations in pediatrics. Children may not be able to understand the importance of taking a medication and refuse to take it because they don't like the taste. Physicians should be familiar with the taste and consistency of medication and be prepared to find alternatives. Prednisone is a commonly used medication for the treatment of acute asthma. It comes in both a pill and suspension form. For children requiring a suspension, a vast difference exists in taste depending on the preparation prescribed. Children are known to vomit the less palatable version. Knowing in advance what is acceptable to children may prevent complications with noncompliance.

Cost-effectiveness

Cost-effectiveness is defined as the best outcome per unit cost. The outcome is the treatment of a condition or alleviation of a symptom; the cost includes the price of the medication and the time spent by the physician and family. For instance, a specific medication may cost less but be less effective, so that in the long run it costs more to the patient in return visits to the doctor. Many physicians practice in settings where the pharmacy has a set inventory or formulary of medications, limiting the selection of medications for each condition. Thus the physician's choice of a cost-effective drug might depend on which are available in the formulary. From the patient perspective, many families may have limited or no health insurance coverage and may have to incur the total cost of a medication. The cost of an antibiotic for a course of otitis media can differ by 10-fold depending on the medication prescribed. Thus an appropriate drug

of choice is influenced by the out-of-pocket cost to the family. The perceived cost-effectiveness of a therapeutic is different for each situation and depends on the external factors affecting the physician and the family.

Drug Dosing

Most medications used in the adult population are based on a standard dose for an individual regardless of age or body size. In pediatrics, a patient's size and metabolism vary with age such that dosing is usually based on weight or body surface area. When drug dosing is determined by weight, it represents a proportion of the adult dose; when a child reaches a weight of 40 to 50 kg, the dosing is often changed to a standard adult dose. With the increasing prevalence of obesity of children, many school-aged children weigh more than 50 kg, thus it is important to know the maximum daily adult dose of a medication because calculating milligrams per kilogram doses can easily exceed this amount. For drugs with narrow therapeutic indexes, such as immunosuppressive medications, body surface area is used to determine appropriate dosing.

Once a drug is identified, the appropriate dosing schedule must be determined. Dosing guidelines can be presented as a total dose per 24 hours or an amount per dose. Usually a range is given per unit weight, and then the physician must determine the amount of medication based on the concentration of therapeutic agent. An example for dosing acetaminophen for a 1-year-old child is given in Box 11-2.

Medication Errors and Adverse Drug Events

Increasing data demonstrate that a significant number of errors can occur in the delivery of medications. Pediatric patients are at greater risk because most of the dosing needs to be calculated based on weight or surface area, and pharmacists may need to prepare solutions or suspensions rather than use manufacturer-produced pills. These medication errors can lead to potential or actual adverse drug events. It is estimated that 5 medication errors occur per 100 dispensed medications, of which 0.21 per 100 go on to non-preventable adverse drug events. More than half of these errors occur during the prescribing stage, the phase where the medication dose is calculated. Referencing a pediatric drug manual and consulting a pharmacist can be used as steps to reduce medication errors.

The American Recovery and Reinvestment Act of 2009 provides additional momentum toward widespread electronic health records, which include e-prescribing. Patient safety initiatives demonstrate that computerized systems can decrease medication errors. Specifically, systems that use computerized physician orders or e-prescribing can reduce medication errors by having alerts for inappropriate dosing, improved legibility, warnings for drug interactions, and just-in-time information on the most appropriate drug choice.

Box 11-2. Dosing

A 1-year-old is suffering from a fever and the family wants to know how much acetaminophen to give her. She weighs 11.2 kg. The recommended dose of acetaminophen is 10 to 15 mg/kg every 4 to 6 hours. Acetaminophen drops are sold in a concentration of 80 mg/0.8 mL or as a suspension with the concentration of 160 mg/5 mL.

1. Determine the amount of medication needed by multiplying the weight of the child by the recommended dose.

$$11.2 \text{ kg} \times 10 \text{ mg/kg} = 112 \text{ mg acetaminophen}$$

2. Determine the volume of medication based on the concentration of acetaminophen to be used. Either the dropper or the suspension can be used.

Dosing volume =

(amount of medication) ÷ (concentration of medication)

Dropper

$$\begin{aligned} \text{Dosing volume} &= 112 \text{ mg} \div 80 \text{ mg}/0.8 \text{ mL} \\ &= (112 \times 0.8)/80 \\ &= 1.12 \text{ mL} \end{aligned}$$

(This can be rounded to 1.2 mL because the lower range of 10 mg/kg was used to calculate the dose.)

Suspension

$$\begin{aligned} \text{Dosing volume} &= 112 \text{ mg} \div 160 \text{ mg}/5 \text{ mL} \\ &= (112 \times 5)/160 \\ &= 3.5 \text{ mL} \end{aligned}$$

The family can be instructed to give their daughter either 1.2 mL using the drops or 3.5 mL of the suspension of acetaminophen orally every 4 to 6 hours as needed for fever.

Therapeutic References

Various resources provide information on drug uses, dosing, side effects, and costs. The *PDR* is a comprehensive listing of FDA-approved prescription and commonly used OTC drugs that provides a description of the drug, pharmacology, indications and contraindications, adverse reactions, drug interactions, and manufacturer name. The *Medical Letter* is a periodical that reviews drugs, citing current research on risks and benefits as well as cost comparisons of newly released drugs with those already approved for similar indications. Pocket manuals that are specific to pediatrics include the *Pediatric Dosage Handbook* and *Harriet Lane Handbook*. *Epocrates* is another therapeutic formulary specifically designed for handheld devices that also provides pediatric-specific dosing and side effects. Due to the lack of standardization between the various resources, caution still needs to be used by the clinician when prescribing medications.

CASE RESOLUTION

After obtaining the history and performing a physical examination, the pediatrician determines that the patient has acute otitis media. Depending on the age of the child and the severity of symptoms, the American Academy of Pediatrics clinical practice guideline* suggests a stratified approach to therapeutics. For children younger than 2 years, pediatricians can treat with antibiotics if the diagnosis is certain or observe the patient without antibiotics if the patient is otherwise healthy. In this case the pediatrician discusses the options with the family and, because of the severity of pain and previous ear infections, chooses to treat the infection. The antibiotic of choice for treatment of otitis media is amoxicillin at a dose of 80 to 90 mg/kg/d. The mother stated that her daughter had hives with amoxicillin, a type I hypersensitivity. Other antibiotic choices would include azithromycin 10 mg/kg on day 1 followed by 5 mg/kg for the remaining 4 days or clindamycin at 30 to 40 mg/kg/d. The treatment of pain is essential with otitis media. The patient can take oral acetaminophen or ibuprofen or use otic benzocaine drops.

The mother raises concern about her daughter's cough and runny nose and would like to use an OTC cough medication. The FDA does not recommend use of cough preparations in this age group. Educating the mother about conservative therapies, including nasal suctioning, humidification, and nasal saline, to treat her respiratory symptoms is more appropriate.

If the patient were not allergic to amoxicillin, it would have been the drug of choice. It is inexpensive, has a narrow microbiological spectrum, and is palatable. Amoxicillin does require refrigeration, which would be of concern if the family were traveling. While this case illustrates several obvious constraints, it is important to emphasize that choosing the appropriate medication is dependent on both the intrinsic needs of the patient and the extrinsic factors that can affect adherence and ultimately the effectiveness of treatment.

Pediatric Pain and Symptom Management

Rick Goldstein, MD

CASE STUDY

You are caring for a 5-year-old girl with stage 4 neuroblastoma who is at home receiving palliative care. Her tumor is refractory. She receives oral chemotherapy and transfusions as an outpatient to offset the bone marrow depletion caused by her tumor. Pain from her metastases is becoming increasingly problematic, most especially in her chest wall and right femur. Her spine is also involved but she does not experience weakness. Though fatigued, she derives great pleasure from attending school and being surrounded by friends and family members, playing as she is able. She hates the hospital and her parents have chosen to avoid it, intending to keep her comfortable at

home until she dies. Her pediatrician has remained closely involved throughout her illness and would like to help with the management of her symptoms.

Questions

1. What is the approach to pain management in children?
2. How does one assess the level of pain in children?
3. What is meant by adjuvant therapy?
4. What is the role of distraction in pain management?
5. What are non-pain symptoms that can cause distress?
6. What is the management of non-pain symptoms?

When children are ill or injured they experience distressing physical symptoms. This is particularly true when the illness or injuries are chronic or serious. The optimal management of such symptoms is fundamental to minimizing their suffering and optimizing their quality of life. A child experiencing poorly controlled pain will withdraw and be unable to engage in the activities that make life, however limited, meaningful. Pain can not only diminish a child's physical well-being, but also impact her psychological, social, and spiritual health. Similarly, a child troubled by nausea will experience distress from the symptom while also losing the simple pleasure of eating and other satisfying comforts. Symptom management is especially important in improving the lives of medically fragile children.

Studies of dying children have noted that distressing symptoms are often untreated. Wolfe et al, in landmark research investigating the symptoms and suffering of children dying from cancer, found that most of the children experienced fatigue, pain, dyspnea, anorexia, nausea and vomiting, and constipation in the last month of their life (Figure 12-1). Similar findings are noted in other children. Neurologically impaired children are particularly difficult to assess because their verbal skills are limited and their responses to pain may be atypical. Research on parents has found that the greatest parental concerns are about symptoms that cannot be satisfactorily controlled. Symptom management of seriously ill children has been improved significantly since these early studies. As more children

with chronic and serious illnesses are cared for, and sometimes die at home, their management will increasingly involve their primary care pediatrician.

This chapter will review the basic medical approaches to pain and symptom management in children, particularly those with serious diseases. In addition to pain, approaches to nausea, anorexia, fatigue, and secretions will be presented. The focus will be on the medical management issues a primary care pediatrician should be able to manage in the community setting. When the primary care pediatrician is insufficiently familiar with such treatment, consultation with pain or palliative care specialists is appropriate.

Pain

Pain is an integrated biophysical and “existential” construct. It involves complex mechanisms of nociception modulated by biochemical factors, plasticity, genetic and familial factors, and one's past experience with painful events. Children experience pain in unique ways and quickly develop learned behaviors related to it. As such, there is not a linear association between the objective degree of injury and the experience of pain. More accurately, physical, psychological, interpersonal, and existential factors all contribute in important ways to the experience of pain. A comprehensive approach to pain will address all of these elements.

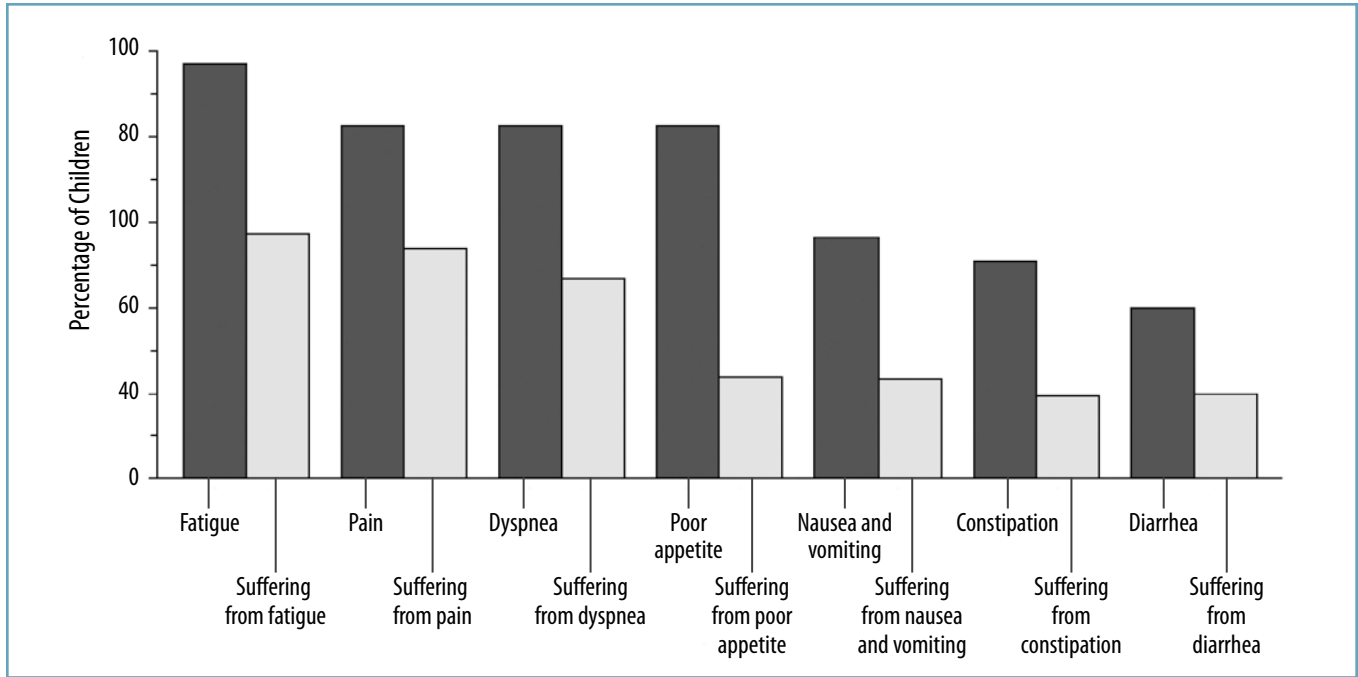

Figure 12-1. The presence and degree of suffering from specific symptoms in the last month of life. (From Wolfe J, Grier HE, Klar N, et al. Symptoms and suffering at the end of life. *N Engl J Med.* 2000; 342:326–333. Reprinted with permission.)

Assessment

Pain is often divided into 2 basic types: nociceptive and neuropathic. An understanding of their presentations can help differentiate the source of pain in children. Nociceptive pain is the activation of peripheral nerve receptors by noxious stimuli causing tissue damage, and its intensity is generally related to the location and the amount of damage. Somatic pain refers to nociceptive pain from musculoskeletal, bony, or superficial sources (skin, mucosa). Deep somatic pain tends to be localized and concentrated, and described as stabbing, aching, or throbbing. Bone pain is deep and aching. Superficial somatic pain is sharper and can be burning or pricking. The source of nociceptive pain can also be visceral. Visceral pain is usually poorly localizable; can be described as cramping, gnawing, or pressure; and may follow daily patterns of varying intensity.

Neuropathic pain is due to injury or dysfunction of the central nervous system (CNS) or peripheral nerves. It can be described as burning, tingling, shooting, or scalding. Its presence points to neuropathies, CNS insult, or evolving damage to the nervous system. Understanding whether the source of pain is somatic, visceral, or neuropathic helps guide treatment choices.

Pain has been referred to as the “fifth vital sign” and should be a part of the medical evaluation of every child. Pain is phenomenological and, thus, while its existence is “real” and “objective,” it can only be experienced by the affected person. Though it is not a completely subjective experience, it can only be truly articulated by the person in pain and, fundamentally, the patient’s report of the presence or severity of pain is the key to the assessment. In children, and especially children with developmental issues, objective assessment tools may be useful to identify the presence of pain and quantify its

severity. In most patients these scales are also helpful in understanding the symptom of pain over time.

Pain scales assess the intensity of pain. Analog pain scales (Figure 12-2), generally scoring intensity on a scale of 1 to 10, have some reliability when used in the same patient over time. Younger children may have difficulty with the concept of quantity or the meaning of greater intensity. An important modification of the analog scale for children with impaired communication skills or cognition is an individualized numeric rating scale, where parents’ observations of their child’s facial expression, body movements, activity and interaction, cry, and consolability as they experience worsening pain are used to label the points of the scale.

For young children older than 3 years, the Wong-Baker Faces Pain Scale (Figure 12-3) is often used. After showing the child the faces, they are instructed that Face 0 is happy because he has no pain but Face 5 is sad because he has a lot of pain. The child is then asked to choose the face that best describes how he is feeling. More comprehensive pain assessment tools are available that also assess function and mood, but these scales are used most widely. In addition, the perspective of parents and others familiar with the child is crucial to any assessment of a child’s pain.

Obviously, the child in pain must be relieved of it. However, it is advantageous to make a strong effort to understand the source of the pain and treat conditions amenable to non-pain medication. For example, chest pain may be due to candidal esophagitis or abdominal pain to constipation. Thinking clearly about the source of pain and not simply providing analgesic agents in a reflexive manner has the benefits of preserving alertness, sparing side effects, and sustaining the least impaired quality of life. It also can permanently eliminate the pain by eliminating the underlying condition responsible for it.

the least invasive route necessary to ensure control of a child's pain. Generally, this can be achieved with oral medications, though intravenous (IV) or subcutaneous medications may be required at times. Intramuscular medications are to be avoided because they are painful and erratically absorbed. "With the child" means that regular assessment of the child, the many aspects of their pain, and their response to treatment must be ongoing.

Children with mild or moderate pain, or those who have not been on any analgesic medication, are managed with acetaminophen and ibuprofen or intravenously with ketorolac (Step 1). Adjuvants may be added if appropriate (see below). Acetaminophen can be given orally or rectally. An IV form of acetaminophen is currently being introduced into the US market. Compounded ibuprofen can be given rectally, though its efficacy is still under study. The topical application of these agents in ketoprofen cream or aspirin cream may also be of benefit. All nonsteroidal anti-inflammatory drugs (NSAIDs) have ceiling doses and gastrointestinal toxicities. Except for acetaminophen all affect platelet function.

Adjuvants are non-analgesic medications that are helpful in the management of a child's pain. For example, a medically fragile child's anxiety may potentiate their pain and distress even at Step 1. A benzodiazepine may be helpful in such cases. A lidocaine patch can help with some somatic pain. Certain forms of mild to moderate pain (ie, neuropathic pain) may be adequately addressed with gabapentin or pregabalin and can spare opioids either in part or completely.

Step 2 addresses children with moderate to severe pain and involves the addition of opioids to the treatment plan (Table 12-1). It recommends "weak opioids," which is controversial since codeine is the agent generally intended. There is a growing body of literature to suggest removing codeine from consideration. Research has

shown that codeine may be a weaker analgesic than a standard dose of many NSAIDs and it has a ceiling effect. Its oral bioavailability is widely unpredictable at 15% to 80%. Most importantly, codeine is a prodrug, which must be metabolized by the liver into morphine. This is problematic because it is estimated that 35% of children do not metabolize codeine in the anticipated way, leading to great uncertainties in a calculated effect. As an alternative, tramadol has been shown to be effective and safe in children, though it should not be used in children with seizures. Often, Step 2 involves the use of oral oxycodone with a non-opioid analgesic.

When pain persists or worsens, Step 3 advocates for a strong opioid. Hydromorphone, morphine, or oxycodone is a typical initial choice. Doses are escalated until pain is controlled, using the least invasive form of administration necessary. This step may involve the addition of controlled-release preparations of opioid or methadone, while using shorter-acting agents for breakthrough pain. To calculate the prn dose for breakthrough pain, a rule of thumb is that the prn dose is 10% to 15% of the 24-hour total opioid dose or its equivalent, given every 1 to 2 hours.

An in-depth discussion of methadone and fentanyl exceeds the scope of this chapter, but it is worth making several points about them. Neither have active metabolites, making them important options for patients with renal failure where accumulated metabolites from other opioid agents can cause myoclonus, confusion, or hyperalgesia. Fentanyl, a potent analgesic, is available in a transdermal patch, which is an important non-IV, non-oral option for children having difficulty swallowing. They must have adequate body fat, because the drug is deposited across the rate-limiting membrane into fat reservoirs and is absorbed from that reservoir into the child's bloodstream. Methadone has some distinct analgesic advantages. It

Table 12-1. Dosing of Selected Step 2 and 3 Analgesic Medications

<i>Drug Name</i>	<i>Initial Oral Dosing</i>	<i>Initial IV Dosing</i>	<i>Preparations</i>	<i>Comments</i>
Tramadol	(<50 kg): 1–2 mg/kg PO q 3–6 hours (>50 kg): 50–100 mg PO q 3–6 hours	Not available in US	50- or 100-mg tablets, can be compounded into suspension	Maximum dose of 8 mg/kg/day or if >50 kg 400 mg/day May be administered PO or PR
Oxycodone	0.1–0.2 mg/kg q 4–6 hours	NA	1-mg/mL and 20-mg/mL solutions; 5-, 10-, 15-, 20-, or 30-mg tablets	Available in controlled-release tablets (OxyContin) May be administered PO, sublingual, or PR
Morphine	0.15–0.3 mg/kg q 4 hours	50–100 µg/kg q 2–4 hours Continuous infusion 10–30 µg/kg/hour	2-mg/mL, 4-mg/mL and 20-mg/mL solution 10-, 15-, 30-mg tablets 5-, 10-, 20-, 30-mg suppository	May be administered PO, IV, sublingual, or PR Available in controlled-release tablets (MSContin)
Hydromorphone	60 µg/kg q 3–4 hours	15–20 µg/kg q 4 hours Continuous infusion 5 µg/kg/hour	1-mg/mL oral solution 2-, 4-, 8-mg tablets, 3-mg suppository	May be administered PO, IV, sublingual, or PR Controlled-release tablets not available in US

Abbreviations: IV, intravenous; PO, orally; PR, far point of accommodation; q, every.

is inexpensive, its half-life allows for more convenient twice-a-day or 3-times-a-day dosing, and it is especially helpful in treating neuropathic pain. It is complicated to dose, however, and its long and variable half-life make it a more complicated choice for those not familiar with its use.

The management of moderate and severe pain over time can lead to the development of difficult unintended effects, including sedation, nausea and vomiting, pruritus, or urinary retention. At high doses or when metabolites accumulate, patients may develop delirium, myoclonus, or hyperesthesia. Opioid rotation can be very helpful in these situations. This method involves converting one form of opioid to an equivalently analgesic dose of another. Doses can be calculated using equianalgesic dosing charts (Table 12-2). A critical concept in the conversion is allowing for incomplete cross tolerance.

Rotation of the opioid agent (ie, using a different opioid) holds the promise of maintaining analgesia with lesser amounts of the newly introduced drug and eliminating side effects. Tolerance is the term used to describe the need over time for greater amounts of a specific opioid to achieve the desired analgesic effect. While there is no ceiling dose for opioids, with higher doses there may be an accompanying increase in adverse effects (ie, the emergence of the intolerable side effects noted above, the accumulation of toxic metabolites, or high costs due to the required amounts of the drug). Because of differences in receptor binding between opioids, the cross tolerance from one opioid to another is not complete. An equianalgesic dose of another opioid will require less of the medication and achieve a more favorable balance between analgesia and side effects.

The reduction in equianalgesic dosing for cross tolerance is between 25% and 50%, usually about one-third. In cases of poorly controlled pain, a lesser reduction is appropriate. The steps in a

rotation are (1) calculating the daily dose of current opioid in oral morphine equivalents, (2) determining the equianalgesic dose of the agent to be introduced, (3) reducing the calculated amount by one-third to allow for cross tolerance, and (4) dividing the total daily dose into the units of bolus dosing or continuous infusion.

For example, a child is receiving 120 mg oxycodone and 80 mg total prn morphine orally each day. He vacillates between barely adequate pain control and over-sedation. He is no longer able to walk. The decision is made to rotate his opioid to IV hydromorphone. A dosage of 120 mg oxycodone is equivalent to 180 mg oral morphine (oxycodone is 1.5 times more potent than oral morphine) and, when added to the 80 mg oral morphine being used prn, the equivalent daily dose of oral morphine is 260 mg. Parenteral hydromorphone is 20 times as potent as oral morphine, so the equianalgesic amount of parenteral hydromorphone is 13 mg. Reducing by one-third for cross tolerance but rounding up given the barely adequate pain control, the total daily equianalgesic dose of parenteral hydromorphone is 9 mg. That can be divided by 24 to determine the hourly infusion rate of a continuous IV infusion (375 µg/hour) or divided by 6 to determine the bolus dose to be given every 4 hours (1.5 mg). Finally, to determine a prn dose, 10% to 15% of the daily hydromorphone dose is 1 mg, offered every 1 to 2 hours.

Physicians lacking experience in pain management often worry about the difficulty of addressing uncontrolled pain. In addition to feeling distress about their patients' discomfort, physicians are concerned that an escalation in medication will make the child apneic and unnecessarily hasten death. Because expert and effective management is a critical skill in the care of seriously ill children, especially those facing the end of life, the primary care physician may choose to consult with palliative care or pain treatment specialists to

Table 12-2. Opioid Equivalency^a

<i>Drug</i>	<i>Oral/Rectal Route</i>	<i>Parenteral Route</i>	<i>Conversion Ratio to Oral Morphine</i>	<i>Equianalgesic Dose of Oral Morphine</i>
Morphine sulfate	30 mg of oral morphine	10 mg of parenteral morphine	Parenteral morphine is 3 times as potent as oral morphine.	30 mg
Oxycodone	20 mg of oral oxycodone	NA	Oral oxycodone is roughly 1.5 times more potent than oral morphine.	30 mg
Hydrocodone	20 mg of oral hydrocodone	NA	Oral hydrocodone is roughly 1.5 times more potent than oral morphine.	30 mg
Hydromorphone	7 mg of oral hydromorphone	1.5 mg of parenteral hydromorphone	Oral hydromorphone is about 4–7 times as potent as oral morphine. Parenteral hydromorphone is 20 times as potent as oral morphine.	30 mg
Fentanyl	NA	15 µg/hour	Transdermal fentanyl is approximately 80 times as potent as morphine (This is based on studies converting from morphine to fentanyl. Currently, there are no empirical studies converting fentanyl to morphine.)	30 mg

^aAdapted from http://endoflife.stanford.edu/M11_pain_control/equivalency_table.html. © End of Life Curriculum Project, a joint project of the US Veterans Administration and SUMMIT, Stanford University Medical School. Used with permission.

ensure that the child's needs are adequately addressed. Alternatively, hospice medical directors can provide palliative care consultations if hospital-based teams are not available.

The risk of respiratory depression while using an accepted escalation rationale is actually quite small. Patients may fall asleep when their pain is "captured," but this is generally due to exhaustion related to the pain. Even in mild to moderate pain, patients do not notice a change in dose increases when they are less than 25% above baseline. In cases of moderate to severe pain, a dose escalation of 50% to 100% is appropriate. Research has shown that pain relief can be achieved quickly with a rapid medication escalation under close supervision. The recommended approach is to provide doses every 10 minutes, increasing by 50% every third dose, until the symptom is relieved. For instance, using the previous example, 1 mg hydromorphone would be given, then repeated 10 minutes later, then followed 10 minutes later by 1.5 mg hydromorphone, then repeated 10 minutes later, etc, until the pain is adequately controlled. The pain is generally "captured" within 30 to 40 minutes.

The management of neuropathic pain presents a considerable challenge. The source of neuropathic pain is the insult or dysfunction of the central, peripheral, or autonomic nervous system. Pediatric patients may experience this pain due to degenerative CNS processes or injury, as well as treatment-related injuries to the nervous system from drug toxicities, radiation therapy, or surgery. Infection may also cause neuralgia. Children describe neuropathic pain as jolts of burning, stabbing, or shooting. It also causes allodynia, dysesthesia, and hyperalgesia. The results of various approaches to the treatment of neuropathic pain are mixed, and a multimodal approach, including an emphasis on physical therapy and more than one therapeutic agent, is recommended. Adjuvant medications are offered as a first line in children, with gabapentin beginning at 10 mg/kg/day divided 3 times a day and titrating upward to doses as high as 60 mg/kg/day. Strong opioids may be included in an appropriate regimen. Tricyclic antidepressants tend to be used less for children in the management of neuropathic pain due to concerns of arrhythmia risk.

Dystonia and neuroirritability, while not properly neuropathic pain, present similar challenges in children with neurodegenerative conditions. Generalized dystonia is a condition in which there are sustained, erratic, painful muscle contractions that cause twisting and repetitive movements or abnormal postures. Neuroirritability is a term used to describe the difficulty in settling and persistent crying seen in some cognitively impaired children with metabolic and neurodegenerative conditions. These symptoms are distressing and often occur in children whose impairments make an assessment of their experience difficult. Benzodiazepines, typically diazepam, are the first line for dystonia (Table 12-3). Trihexyphenidyl is also commonly considered, as is valproate, baclofen, carbamazepine, or tetra-benazine. In severe, intractable cases, the implantation of deep brain stimulators is being increasingly considered, although the empiric basis for that decision is most unclear. Anticonvulsants are the mainstay in the treatment of neuroirritability. Phenobarbital is often the first medication tried. The treatment of these conditions is generally determined in consultation with a child neurologist.

Management of Non-Pain Symptoms (Table 12-3)

Dyspnea

There are many similarities between the treatment of severe dyspnea and severe pain. Dyspnea is caused by increased work of breathing, hypoxia, and hypercapnia, and the driving desire of the brain to relieve them. Experientially, it may cause a feeling similar to being under water too long and needing to surface. Like pain, it has a physical basis but the distress is potentiated by psychological, interpersonal, and existential aspects. After oxygen, opioids are the treatment of choice and they are dosed at one-third of the dose for pain treatment. While this is another situation where inexperienced physicians are typically worried about worsening the patient's condition by causing respiratory depression, there is strong evidence for its effectiveness in alleviating dyspnea. Due to the anxious state dyspnea often causes and the fact that anxiety worsens dyspnea, an appropriate dose of a benzodiazepine is also helpful, although never as the principal medication. Simple environmental measures, such as the breeze from an electric fan on the patient's face, also cause relief.

Nausea and Vomiting

Nausea and vomiting are common symptoms in children with complex illnesses or facing the end of life, and a significant source of distress and discomfort. They can have different etiologies, principally gastrointestinal, CNS, or treatment-related. Children with neurologic impairments can suffer from retching, and many of their medications have nausea among their side effects. Children are especially vulnerable to anticipatory nausea, a conditioned behavioral response in anticipation of a medication or procedure that has caused nausea and vomiting in the past. Anorexia can be a symptom of low-grade nausea. An approach to nausea and vomiting based on an understanding of the cause of the symptom exacerbation and understanding the symptom mechanism can prove valuable. A careful history and physical examination, with special attention to medications and procedures, is crucial.

While a patient's presentation may be complex, there are 4 pathways to nausea and vomiting. The vomiting center, which lies in the brain stem, receives input from the chemoreceptor trigger zone (CTZ), the cerebral cortex, peripheral pathways in the gastrointestinal tract, and the vestibular system. The CTZ responds to toxins (and medications) in blood and spinal fluid; the cerebral cortex responds to sensory input, anxiety, meningeal irritation, and elevated intracranial pressure; peripheral pathways are stimulated by mechanical stretch in obstruction and by mucosal injury; and the vestibular system is affected by motion and labyrinth disorders. Each pathway involves different neuroreceptors for mechanism-based therapy to target.

The CTZ can be suppressed by the blockage of dopamine type 2 receptors with haloperidol, prochlorperazine, chlorpromazine, or metoclopramide. Peripheral pathways can be addressed by identifying the underlying cause and with the blockage of 5HT₃ receptors by

Table 12-3. Medications Used for Common Symptoms in Pediatric Palliative Care^a

Symptom	Medication	Starting Dose	Comments
Dystonia	Diazepam	0.5 mg/kg/dose IV/PO q 6 hours prn; initial dose for children <5 years is 5 mg/dose, for children ≥5 years dose is 10 mg/dose	May be irritating if given by peripheral IV
	Trihexyphenidyl	0.1 mg/kg/day PO	Would initiate in consultation with child neurologist; not for children <3 years; 2 mg/5 mL liquid available
	Phenobarbital	3 mg/kg/d PO	Helpful with neuroirritability; many liquid concentrations
	Baclofen	5 mg PO tid, increase by 5 mg/dose prn	Helpful with neuropathic pain and spasticity; abrupt withdrawal may result in hallucinations and seizures; not for children <10 years
Nausea	Metoclopramide	0.1–0.2 mg/kg/dose q 6 hours, up to 10 mg/dose (prokinetic and mild nausea dosing) For chemotherapy-associated nausea 0.5–1 mg/kg q 6 hours prn PO/IV/SC, give with diphenhydramine	Helpful when dysmotility an issue; may cause extrapyramidal reactions, particularly in children following IV administration of high doses; contraindicated in complete bowel obstruction or pheochromocytoma
	Ondansetron	0.15 mg/kg/dose q 8 hours to max of 8 mg/dose Some institutions also use daily dosing for chemotherapy	Significant experience in pediatrics; good empiric therapy for nausea in palliative care population; higher doses used with chemotherapy; oral dissolving tablet contains phenylalanine
	Lorazepam	0.025 mg/kg up to 2 mg IV/PO q 6 hours	May be given sublingually; particularly helpful with anticipatory nausea; avoid use in neonates
	Scopolamine patch	1.5 mg patch, change q 72 hours	Good for motion-induced nausea/vomiting; handling patch and contacting eye may cause anisocoria and blurry vision; may fold patches but do not cut them
	Prochlorperazine	0.4 mg/kg/day PO/PR divided q 8 hours	Available in suppositories and 1 mg/mL syrup; not for children <2 years
Anorexia	Megestrol acetate	10 mg/kg/day in 1–4 divided doses, up to 15 mg/kg/day or 800 mg/day.	For children >10 years; acute adrenal insufficiency may occur with abrupt withdrawal after long-term use; use with caution in patients with diabetes mellitus or history of thromboembolism; may cause photosensitivity
	Cyproheptadine	0.25–0.5 mg/kg/d PO divided q 6 hours	
Respiratory secretions	Glycopyrrolate	0.04–0.1 mg/kg po q 4–8 hours	Excessive drying of secretions can cause mucus plugging of airways; anticholinergic side effects possible
	Scopolamine patch	1.5-mg patch, change q 72 hours	Excessive drying of secretions can cause mucus plugging of airways; handling patch and contacting eye may cause anisocoria and blurry vision; may fold patches but do not cut them
	Atropine 1% ophthalmic drops	One drop sublingual, titrate to effect	
Fatigue	Methylphenidate	Norms not established Begin with a fraction of a 0.3 mg/kg/day	Daytrana patch can be helpful

Abbreviations: IV, intravenous; PO, orally; PR, far point of accommodation; prn, as needed; q, every; SC, subcutaneous; tid, 3 times a day.

^aModified from Wolfe J, Ullrich C. Pain and symptom control in pediatrics. In: Walsh et al, eds. *Palliative Medicine*. Philadelphia, PA: Saunders Elsevier; 2008, with permission.

ondansetron. The cortex can be addressed with anxiolytics; attention to sensory stimuli (smells, tastes); and, in cases of elevated intracranial pressure, high-dose steroids. Dronabinol may also be helpful. The vestibular system is managed by blocking muscarinic acetylcholine and histamine receptors with scopolamine, hyoscyamine, and diphenhydramine. (Promethazine is useful in adults but is to be avoided because of its implication in sudden death in some children.)

The causes of nausea and vomiting are often not pure but involve multiple pathways. For instance, opioid-induced nausea and vomiting may be due to constipation or gastroparesis, stimulation of the CTZ, or sensitization of the labyrinth. Choices must be made about how to approach the possible causes in a step-wise manner. The literature suggests that mechanism-based therapy is more effective, employs a systematic approach that identifies all possible

contributors, and encourages the treatment of underlying causes. It uses medication in a targeted manner, lessening the risk of untoward effects and oversedation. Finally, it is worth remembering that the risk of extrapyramidal side effects is greater in children, and when using high doses of metoclopramide or the phenothiazines, premedication with diphenhydramine is recommended.

Anorexia

Anorexia is an anticipated symptom at the end of life. Some parents have great difficulty with this symptom and can feel overwhelmed by the loss of a concrete expression of their nurturing. They want their child to eat to be better able to fight their illness. Food preparation and feeding them is something concrete they can do for their child. Dying children want to please their parents as much as healthy ones, maybe more so. It is important to acknowledge the feelings behind the desire of parents for their child to eat. Small portions of the child's favorite foods or new favorites he asks for may be comforting to all.

There are times earlier in an illness when it may be appropriate to improve appetite. Cyproheptadine has a long history of safe use in children and has been shown to be helpful in some cases. Megestrol acetate has been shown effective in increasing weight, but not muscle mass, and may be considered in children older than 10 years. Cannabinoids, while stimulating appetite, have not been demonstrated to increase weight. Steroids, while likely to improve appetite, often come at an unacceptable cost of irritability and immunosuppression.

One other consideration related to feeding is whether children are starving when they no longer have the desire to eat. Research comparing the “anorexia-cachexia syndrome” with starvation shows 2 very different metabolic states. Differences in energy expenditure, protein synthesis and proteolysis, glucose metabolism, and hormonal levels reinforce the view that anorexia-cachexia is a hypermetabolic state, while starvation in healthy individuals is an effort by the body to conserve itself. An understanding of this difference enables physicians to explain to parents how the disease is robbing the child's energy and that it is not the fault of their efforts or the lack of food. In fact, research on adults dying of advanced cancer found that even the patients who ate the most lost weight.

Respiratory Secretions

Respiratory secretions are a common symptom in seriously ill children. Children with neuromuscular diseases and neurologic impairment can have problems managing secretions. The presence of a tracheostomy can further complicate matters. The use of suction and cough assist machines is important, particularly in the setting of acute respiratory illnesses that cause increased secretions. In children

at this stage of illness, drying agents (eg, glycopyrrolate, atropine, scopolamine, or hyoscamine) are sometimes helpful, but they may increase the risk of acute obstruction by thickening secretions and causing mucus plugging.

Terminal secretions (the “death rattle”) are understandably very distressing to parents. The child does not typically notice them. They are not relieved by suctioning, but sometimes respond to repositioning. Drying agents are usually prescribed in this setting. There is not much advantage to switching between agents if the effect is not substantial, though more than one agent should be tried. Glycopyrrolate stands alone among these agents as the only one that does not cross the blood–brain barrier and thus is the least likely to cause CNS effects.

Fatigue

Fatigue is a highly prevalent symptom at the end of life. In one study of children with terminal cancer, 96% were found to have experienced fatigue in their last month. This symptom is especially disheartening because fatigued children may have the desire to do things that provide a quality of life, but not be up to the task. Fatigue may be due to illness, treatments, stress, isolation, poor sleep hygiene and circadian disorientation, mood, or the lack of pleasure or activity. The sedative effects of some medications certainly contribute. Sleep, exercise, nutrition, anemia treatment, increased interactions, and activity all have been shown to have a beneficial effect in decreasing fatigue. Medical therapy with methylphenidate or modafinil may be helpful, dosed at lower amounts than typically prescribed for attention-deficit/hyperactivity disorder.

CASE RESOLUTION

The patient lived for 4 more months, was never again admitted to the hospital and, until her last days, remained engaged and as playful as her fatigue allowed. Her primary care pediatrician teamed with the pediatric palliative care team at the closest children's hospital, and was assisted with many of the symptom management decisions. In her last days, she was on methadone, morphine boluses, lorazepam, citalopram, gabapentin, ondansetron, Miralax, senna, and prn methylphenidate. Her pediatrician made home visits and remained available for evolving symptoms. She was in the child's home at the time of her death, ensuring comfort, declaring the death, and affirming the value of her life.

Complementary and Alternative Medicine in Pediatric Primary Care

Miriam T. Stewart, BA, and Erica Sibinga, MD, MHS

CASE STUDY

A 14-year-old girl is brought to your office to follow up on her migraine headaches. She has no other significant medical history, but has experienced intermittent migraine headaches over the past few years. The headaches occur approximately weekly in the evenings, do not wake her from sleep, and improve with ibuprofen 400 mg, as had been previously prescribed at your office. At this visit, the girl states that she wishes she didn't have to take medicine for her headaches. Her mother reports that a family friend has suggested acupuncture or herbs for the headaches and asks whether there are other "complementary and alternative medicine" (CAM) approaches that they could try.

Questions

1. What are CAM therapies?
2. How does a provider explore if there are any CAM approaches that are appropriate for the treatment of chronic or recurrent conditions such as headaches in a child or adolescent?
3. What is the best way to determine if a family is using CAM?
4. What is the best way to communicate with a family about CAM therapies?
5. What is the best way to monitor the safety of CAM approaches?

Complementary and Alternative Medicine

Complementary and alternative medicine (CAM) refers to a wide variety of therapies that are not typically part of "conventional" medical approaches. Conventional medicine (also called allopathic or Western medicine) is the general approach of medical doctors (MDs), doctors of osteopathy (DOs), and the allied health professionals. The specific therapies thought of as CAM versus allopathic may change over time, as CAM practices may be incorporated into allopathic medicine.

Complementary and alternative medicine therapies may be used in a number of different ways. When CAM therapies are used in addition to allopathic care, they are termed "complementary"; this is by far the most common way CAM therapies are used. "Alternative" medicine refers to therapies used instead of allopathic care. A small but growing number of practitioners are using both allopathic and non-allopathic approaches, a practice referred to as "integrative medicine."

Epidemiology

The use of CAM has risen steadily over the past several decades and now comprises a significant subset of health-related visits and expenditures. In 2007 more than one-third (38.3%) of American adults surveyed reported having used some form of CAM in the previous 12 months. As of 1997 the number of visits to CAM providers exceeded those to primary care physicians, and out-of-pocket expenditures for CAM, estimated at \$33.9 billion per year. These statistics demonstrate the importance of physician awareness of CAM and support the routine inclusion of questions about CAM in the medical history.

A growing body of evidence reveals that the pediatric population is also using CAM. A large-scale survey of caregivers found that 1 in 9 children use CAM (11.8%). Higher prevalence, up to 60%, has been found in certain populations, such as children with cancer, epilepsy, sickle cell disease, and other chronic diseases. Adolescents are more likely to use CAM than younger children, and CAM is more often used in the Western United States than in other regions of the country. Other factors associated with CAM use in children include

parental education beyond high school; higher household income; coverage by private health insurance; use of prescription medications; and number of health conditions, doctor visits, or school days missed for illness in the past year. Non-Hispanic whites are more likely to use CAM than Hispanics or blacks, though the strength of this association diminishes when data are adjusted for confounding factors. When worry about cost delays or prevents the receipt of conventional medical care, children are more likely to use CAM. The strongest predictor of CAM use in children is CAM use by a parent; children whose parents use CAM are 5 times more likely to use CAM. When discussing CAM with families who are using it for their children, pediatricians need to be aware that parents may also be using CAM.

Motivations for Using CAM

Complementary and alternative medicine can be used for health maintenance, for symptomatic relief, as an adjunct to curative conventional medical care, for relief from side effects of conventional medical care, or in place of conventional medical care. Families choose to use CAM for many reasons. Word of mouth and belief in the efficacy of the treatment can be strong motivators. Some parents express a desire for more options and feel a sense of empowerment in their parental role as a result of CAM use. Complementary and alternative medicine may also be more congruous with a family's values, philosophies about health, and understanding of the basis of disease. Parents may fear the side effects of conventional medicines or be dissatisfied with the care their child receives in conventional medical settings. Families may seek the additional personal attention afforded by CAM providers. For some families, CAM offers additional hope when conventional medical care fails. Underlying all these motivations is the desire for the child's health and well-being and the quest for safe and effective treatments for disease. Physicians and families can find common ground in this most basic of motivations, which can inform conversations about both CAM and conventional medical care.

CAM Categories

Complementary and alternative medicine therapies can be thought of as falling into one of 5 categories: whole medical systems, mind-body therapies, biomechanical therapies, bioenergetic therapies, and biochemical therapies (Table 13-1). Besides whole medical systems, these categories are chosen to reflect purported similarities in underlying mechanism of effect. A particular therapy may be used as part of a whole medical system approach or on its own. For example, acupuncture may be part of an individualized, comprehensive traditional Chinese medicine (TCM) treatment approach, also consisting of herbs and lifestyle recommendations. Or a standardized acupuncture treatment may be used without evaluation and treatment by a TCM provider, in which case it can be thought of as a bioenergetic therapy. Additionally, a particular therapy may belong to more than one category, for example herbal preparations may have both a biochemical and a placebo (mind-body) effect.

Whole Medical Systems

Whole medical systems, including allopathic medicine, are whole-system approaches to treatment, consisting of an underlying theory of healing, standardized training, and diagnostic and treatment approaches reflective of the underlying theory. For instance, TCM is based on the theory that illness and symptoms result from yin-yang energy imbalances. These energy imbalances are diagnosed through history and physical examination and treated by altering the energy balance using acupuncture (or other mechanical or thermal stimuli), herbs, and lifestyle changes (diet, sleep, physical activity).

Mind-Body Therapies

These therapies are intended to enhance the mind's ability to benefit health. A number of mind-body therapies are integrated into allopathic treatment, such as psychotherapy, group therapy, imagery, and biofeedback. Others are still considered CAM, such as meditation and hypnotherapy.

Biomechanical

Biomechanical therapies aim to improve health through physical manipulation of the body. This may involve working with muscles, as with massage, or spinal alignment, as with chiropractic and osteopathic approaches. Massage therapies range from relatively light muscle work to deep tissue massage, as well as physical therapy to work with muscles and joints. Spinal manipulation therapies are used commonly in the United States and are most often practiced by chiropractors or DOs.

Bioenergetic

Bioenergetic therapies are directed at improving health through altering the body's energy as it runs through, on, or around the body. As allopathic training does not include the concept of energy in this way, bioenergetic therapies tend to draw skepticism from allopaths. With increasing scientific evidence for its beneficial effects, acupuncture is purported to affect the body's vital energy (*qi*) as it courses through energy channels, called meridians. In 1997 a National Institutes of Health (NIH) consensus panel declared the evidence sufficient for integration of acupuncture into a number of allopathic treatments, including the treatment of chemotherapy-associated nausea and emesis, anesthesia-associated nausea and emesis, and pain syndromes. Homeopathic remedies are theoretically bioenergetic therapies, as the "ingredients" are successively diluted beyond the point of significant molecular presence; therefore, it is the resulting change in the energy of the diluents (sometimes called the "memory of the molecule") that is responsible for the therapeutic effect. Additionally, a number of therapies aim to affect energy at or near the surface of the body, including therapeutic touch and Reiki, which involve a trained practitioner identifying the energy imbalance and directing his or her own energy to improve the patient's energy balance and promote healing.

Table 13-1. Selected Examples of Complementary and Alternative Medicine Therapies by Category^a

Modality	Description: At a Glance	Licensure and Regulation
Traditional Chinese medicine (TCM)	<ul style="list-style-type: none"> • Originated in China more than 5,000 years ago; rooted in the Taoist philosophy. • Views the human body and mind as an integrated whole in which tissues, organs, and parts function interdependently. • Yin-yang theory—the concept of 2 opposing but interdependent forces that shape the world—is a core principle. Health and disease relate to balance between yin and yang in the body. • Treatments to restore balance include herbs, massage, acupuncture (see page 72), diet, and exercises such as tai chi (see page 72) and qi gong. 	<ul style="list-style-type: none"> • Most states license acupuncture, but vary in their inclusion of other TCM treatments in licensure. • Acupuncture and TCM schools are accredited by the federally recognized Accreditation Commission of Acupuncture and Oriental Medicine.
Ayurveda	<ul style="list-style-type: none"> • Originated in India several thousand years ago and is still used by 80% of the population either exclusively or in combination with Western medicine. • Health and disease are thought to relate to a person's constitution (<i>prakriti</i>), which is composed of a unique combination of the 3 life forces (<i>doshas</i>). Imbalances between the <i>doshas</i> can lead to disease. • Treatments are tailored to the individual's unique constitution and are aimed at eliminating impurities, reducing symptoms, increasing resistance to disease, reducing worry, and increasing harmony in the patient's life. • Treatments include herbs, vitamins and minerals, massage, yoga (see page 70), enemas, and specialized diet and lifestyle recommendations. 	<ul style="list-style-type: none"> • Ayurvedic medicine is not accredited in the United States, though several states have accredited ayurvedic schools. • In India, ayurvedic medicine can be studied at the bachelor's and doctorate level.
Naturopathy	<ul style="list-style-type: none"> • Developed in Germany and the United States in the late 19th—early 20th centuries. • Central belief is that nature has healing power and practitioners view their role as supporting the body's inherent ability to restore health. • Naturopathic practitioners strive to use the most natural and the least invasive approach to restore and maintain health. • Treatment modalities used by naturopaths include nutrition, vitamins and minerals, herbal medicines, homeopathy (see page 72), therapeutic massage and joint manipulation, hydrotherapy, exercise, and lifestyle counseling. 	<ul style="list-style-type: none"> • Naturopathic physicians (ND or NMD degrees) complete a 4-year graduate-level program at a naturopathic medical school accredited by the Council on Naturopathic Medical Education, which is recognized by the US Department of Education. States vary in their licensing of naturopathic physicians and the scope of naturopathic practice, including the ability to prescribe drugs, perform minor surgery, and assist in childbirth. • The American Association of Naturopathic Physicians (www.naturopathic.org) is the national professional society of naturopathic physicians.
Native American healing	<ul style="list-style-type: none"> • Broad term that encompasses the healing traditions of hundreds of indigenous tribes. Has been practiced in North America for more than 40,000 years. • Can combine religion, spirituality, herbal medicine, shamanic healers, purification activities, and symbolic rituals in the treatment of medical and emotional problems. Treatments may be individual or may involve the entire community. • Treatment is often a slow process that is spread over days and weeks. There is a strong belief in the therapeutic value of the relationship with the healer. 	<ul style="list-style-type: none"> • There is no government oversight of education or licensure for Native American healers.

Table 13-1. Selected Examples of Complementary and Alternative Medicine Therapies by Category^a, continued

	Modality	Description: At a Glance	Licensure and Regulation
Mind–Body Therapies	Meditation/ mindfulness	<ul style="list-style-type: none"> • There are many types of meditation, most of which originated in ancient religious and spiritual traditions. Some of these include mindfulness meditation, transcendental meditation, and Zen Buddhist meditation. • In meditation, a person learns to focus attention. Some forms of meditation instruct the practitioner to become mindful of thoughts, feelings, and sensations and to observe them in a nonjudgmental way. • Meditation is believed to result in a state of greater calmness, physical relaxation, and psychological balance, and can change how a person relates to the flow of emotions and thoughts. • Meditation has been studied in a variety of populations and is used for general wellness and for various health problems, including anxiety, pain, depression, stress, insomnia, and physical or emotional symptoms that may be associated with chronic illnesses such as AIDS and cancer. 	<ul style="list-style-type: none"> • There is a broad diversity of meditation practices, each of which may have its own training programs and certification policies. • There is no national or state-based accreditation for meditation practitioner education or licensing. However, meditation programs may be eligible for continuing education credits toward licensing for health professionals. • The University of Massachusetts Center for Mindfulness in Medicine, Health Care, and Society (www.umassmed.edu/cfm) is the oldest and largest mindfulness program associated with an academic institution and is a source for training and research on mindfulness and mind–body medicine.
	Hypnotherapy	<ul style="list-style-type: none"> • Hypnotherapists use exercises that bring about deep relaxation and an altered state of consciousness, also known as a trance. • Through hypnosis, people learn how to master their own states of awareness. By doing so they can affect their own bodily functions and psychological responses. • Hypnotherapy has been studied for a number of conditions, including state anxiety (eg, before medical procedures or surgeries), headaches, smoking cessation, pain control, hot flashes in breast cancer survivors, and irritable bowel syndrome. It is also used in managing pain during childbirth. 	<ul style="list-style-type: none"> • Most hypnotherapists are licensed medical doctors, registered nurses, social workers, or family counselors who have received additional training in hypnotherapy. Several national bodies provide training certificates. • The American Society of Clinical Hypnosis (www.asch.net) is the largest organization of health professionals using clinical hypnosis and provides hypnotherapy training.
	Biofeedback	<ul style="list-style-type: none"> • Technique that trains people to improve their health by controlling certain bodily processes that normally happen involuntarily, including heart rate, blood pressure, muscle tension, and skin temperature. • Biofeedback practice involves attaching the patient to electrodes (or other monitoring device) that monitor the desired process (eg, muscle tension, skin temperature). The therapist leads the patient in exercises designed to assist them in controlling the desired variable, while the electrodes provide real-time feedback on the patient’s success. • Biofeedback is used in a variety of conditions, including high blood pressure, headaches, chronic pain, and urinary incontinence. 	<ul style="list-style-type: none"> • The Biofeedback Certification International Alliance (BCIA) certifies individuals who have met their educational and training standards, which include didactic training, supervision hours, patient sessions, and case presentations. • Pelvic floor muscle dysfunction is a subspecialty within biofeedback that provides specialized training. Only licensed health care providers may apply for certification in this specialty.
	Yoga	<ul style="list-style-type: none"> • Yoga practice was developed in ancient India, with fully developed practice appearing around 500 BC. There are numerous branches or paths of yoga. • Derived from the Sanskrit word meaning “union,” yoga strives to connect the body, breath, and mind with the goal of energizing and balancing the whole person. • Yoga practice can be individual or class-based and consists of physical postures (<i>asanas</i>), breathing exercises, and meditation. • Yoga is used for maintaining health and has also been studied in a wide variety of conditions, including anxiety, arthritis, asthma, cancer, back pain, diabetes, heart disease, pregnancy (when modified for pregnancy), and chronic headaches. 	<ul style="list-style-type: none"> • There is no government oversight of yoga training or practice. • There are numerous organizations and training programs in the United States and worldwide that offer training. • The Yoga Alliance is the most widely recognized educational and professional organization for yoga in the United States. It accredits yoga training programs based on a minimum training standard. Teachers who complete Yoga Alliance accredited training are eligible to register as Registered Yoga Teachers (RYT).

Table 13-1. Selected Examples of Complementary and Alternative Medicine Therapies by Category^a, continued

	Table 13-1. Selected Examples of Complementary and Alternative Medicine Therapies by Category ^a , continued		
	<i>Modality</i>	<i>Description: At a Glance</i>	<i>Licensure and Regulation</i>
Biomechanical	Chiropractic	<ul style="list-style-type: none"> Developed in the United States at the end of the 19th century. Based on the notion that the relationship between the body's structure—most notably the alignment of the spine—and its coordination by the nervous system affects health. People most often seek chiropractic care for musculoskeletal complaints (back, neck, and shoulder pain), headaches, and extremity problems. Hands-on spinal adjustment and manipulation is a core treatment in chiropractic care, but treatment can also include heat and ice; electrical stimulation; exercise; and counseling about diet, exercise, and lifestyle. 	<ul style="list-style-type: none"> Chiropractic practitioners must meet the licensing and continuing education requirements of the states where they practice. All states require chiropractors to complete a Doctor of Chiropractic degree at an accredited college. The American Chiropractic Association (www.acatoday.org) is the largest professional organization representing chiropractic doctors.
	Osteopathy	<ul style="list-style-type: none"> Developed in the United States at the end of the 19th century. Core principle is that disease and illness begin with structural problems in the spine and resulting abnormalities in the function of the nervous system. Doctors of osteopathy receive conventional medical training, but are also trained in osteopathic manipulation techniques and craniosacral therapy, both of which involve hands-on manipulation of bones and tissues. People seek care from osteopathic doctors both for conventional medical care and specifically for musculoskeletal conditions. 	<ul style="list-style-type: none"> Doctors of osteopathy (DOs) complete a 4-year training program in conventional medicine and osteopathy and also complete medical residencies in their specialty of choice. DOs are recognized for full practice rights in all 50 states once they are licensed. The American Osteopathic Association (www.osteopathic.org) is the primary professional organization and accreditation agency for osteopathy in the United States.
	Massage therapy	<ul style="list-style-type: none"> Massage therapy has been in use for thousands of years in diverse cultures, including China, Japan, India, Egypt, and Europe. The term "massage therapy" encompasses more than 100 distinct techniques, but the core practice is manipulation of the muscles and soft tissues of the body using the hands and fingers. People use massage for general wellness, as well as in a wide range of conditions including sports injuries, stress, pain, musculoskeletal complaints, anxiety, and depression. 	<ul style="list-style-type: none"> Most states have laws regulating massage therapy and typically require a minimum number of training hours and passage of a national exam. Massage training can be accredited by state boards or by an independent agency. The National Certification Board for Therapeutic Massage and Bodywork certifies massage practitioners who pass a national examination. The American Massage Therapy Association (www.amtamassage.org) is the nation's largest professional organization for massage practitioners.
	The Feldenkrais Method	<ul style="list-style-type: none"> A method of somatic education that uses gentle movement and directed attention to movement patterns in order to expand movement options and improve functioning. Treatment can be carried out via verbal guidance in a class setting or with hands-on gentle manipulation. People use Feldenkrais to maintain well-being and enhance performance in performing arts and athletics, as well as in the treatment of a variety of conditions including multiple sclerosis, stroke, cerebral palsy, and repetitive stress injuries. 	<ul style="list-style-type: none"> Feldenkrais practitioners must complete 700–800 hours of training over 3–4 years in order to apply for certification. Certification and training is governed by the Feldenkrais Guild of North America (www.feldenkrais.com). There is no government oversight of training or licensure.
	Alexander Technique	<ul style="list-style-type: none"> Educational method whose emphasis is on changing faulty postural habits in order to improve mobility and performance. Treatment has 2 components: table work (hands-on manipulation) and guided activity, in which the practitioner observes the person in action and gives verbal, visual, and physical cues to help the person perform the activity with greater ease. People use the Alexander Technique for improved performance in performing arts and sports as well as in the treatment of musculoskeletal problems, repetitive stress injuries, and chronic pain. 	<ul style="list-style-type: none"> In order to be certified by the American Society for the Alexander Technique (www.amsatonline.com), practitioners must complete 1,600 hours of training over 3 years. There is no government oversight of training or licensure.

Table 13-1. Selected Examples of Complementary and Alternative Medicine Therapies by Category^a, continued

	Modality	Description: At a Glance	Licensure and Regulation
Bioenergetic	Acupuncture	<ul style="list-style-type: none"> Acupuncture is a modality of TCM (see page 69). The earliest recorded use of acupuncture dates from 200 BCE. The core principle of acupuncture is the belief that a particular type of life force or energy (<i>qi</i>) circulates through the energy pathways (meridians) in the body. <i>Qi</i> maintains the dynamic balance of yin and yang. An imbalance of <i>qi</i> can cause symptoms and disease. Acupuncture treatment involves stimulation of specific points along the meridians using pressure (acupressure), thermal energy (moxibustion), or very fine acupuncture needles. Acupuncture has been studied in a variety of conditions, including chronic pain, post-surgical recovery, chemotherapy-related nausea, musculoskeletal problems, headaches, addiction, asthma, and menstrual problems. 	<ul style="list-style-type: none"> Most states require a license to practice acupuncture, though licensing and education standards vary from state to state. Licensure confers the title of LAc. In 1997 the National Institutes of Health recognized acupuncture as a mainstream medicine healing option with a statement documenting the procedure's safety and efficacy for treating a range of health conditions. The American Academy of Medical Acupuncture (http://www.medicalacupuncture.org/) maintains a database of licensed physicians who are also trained to perform acupuncture.
	Tai chi	<ul style="list-style-type: none"> Originated in ancient China as a component of TCM. Rooted in the principles of yin-yang balance and the balanced flow of a vital life force or energy (<i>qi</i>). There are many different styles, but all involve slow, deliberate movements that flow into each other. Meditation, deep breathing, and maintenance of good posture during continuous movement are foci of the practice. People use tai chi to improve overall fitness, balance, coordination, and agility. It is also used for chronic pain, gout, heart disease, high blood pressure, arthritis, osteoporosis, diabetes, headaches, and sleep disorders. 	<ul style="list-style-type: none"> No licensing or government accreditation exists for the training or practice of tai chi. There are a variety of organizations that offer training programs and certification for tai chi.
	Reiki	<ul style="list-style-type: none"> Developed in Japan in the early 20th century. Based on the idea that there is a universal energy that supports the body's innate healing abilities. Practitioners seek to access this energy, allowing it to flow to the body and facilitate healing. During treatment, the practitioner's hands are placed lightly on or just above the client's body, palms down, using a series of 12–15 hand positions to promote the flow of energy. Each position is held for 2–5 minutes. People use Reiki for relaxation, stress reduction, symptom relief, and general well-being. It can also be used to help promote peace at the end of life. 	<ul style="list-style-type: none"> No licensing or government accreditation exists for the training or practice of Reiki. Multiple organizations offer training programs and certifications.
	Homeopathic remedies	<ul style="list-style-type: none"> Developed by a German physician at the end of the 18th century. Based on 2 core principles: (1) the principle of similars ("like cures like") states that a disease can be cured by a substance that produces similar symptoms in a healthy person and (2) the principle of dilutions ("law of minimum dose") states that the lower the dose of the medication, the greater its effectiveness. Homeopathic remedies are so dilute that few or no molecules of the healing substance remain in the diluent. It is believed that the substance has left its imprint, which stimulates the body to heal itself. Homeopathic remedies are derived from natural substances that come from plants, minerals, or animals. 	<ul style="list-style-type: none"> Homeopathic remedies are prepared according to the guidelines of the <i>Homeopathic Pharmacopeia of the United States</i>, which was written into federal law in 1938. The US Food and Drug Administration requires that homeopathic remedies meet legal standards for strength, purity, and packaging, but since they contain little or no active ingredient, they do not have to undergo the same safety and efficacy testing as other over-the-counter medications. If a homeopathic remedy claims to cure a serious disease such as cancer, it needs to be sold by prescription.

Table 13-1. Selected Examples of Complementary and Alternative Medicine Therapies by Category^a, continued

	<i>Modality</i>	<i>Description: At a Glance</i>	<i>Licensure and Regulation</i>
<i>Bioenergetic</i>	Therapeutic touch	<ul style="list-style-type: none"> Developed in the 1970s in the United States. Based on the belief that problems in the patient's energy field that cause illness and pain can be identified and rebalanced by a healer. The technique consists of using the hands to release harmful energy and direct healthy energy for healing purposes. During a session, the hands are held 2–6 inches away from the body and there is no direct physical contact between practitioner and patient. 	<ul style="list-style-type: none"> No licensing or government accreditation exists for the training or practice of therapeutic touch. Multiple organizations offer training programs, including some hospitals. Many therapeutic touch practitioners are nurses or other licensed health professionals.
	Herbal medicine	<ul style="list-style-type: none"> Herbal medicine refers to using a plant's seeds, berries, roots, leaves, bark, or flowers for medicinal purposes. Plants have been used for medicinal purposes since long before recorded history in a wide range of human cultures. According to the World Health Organization, 80% of the world's population relies on herbal medicines for some part of their primary care. Nearly one-third of Americans use herbs. The most commonly used herbal supplements in the United States include echinacea, St John's wort, ginkgo, garlic, saw palmetto, ginseng, golden seal, chamomile, feverfew, ginger, valerian, evening primrose, and milk thistle. Herbal remedies are used in conventional medicine as well as in a variety of complementary and alternative medicine practices, including naturopathy, TCM, ayurveda, and Native American healing. Many people also use herbal remedies on their own, without the advice of a health practitioner. 	<ul style="list-style-type: none"> In the United States, herbal supplements are classified as dietary supplements and thus can be sold without being tested to prove they are safe and effective. They must be made according to good manufacturing practices. In the United States, no organization regulates the manufacture or certifies the labeling of herbal preparations.
<i>Biochemical</i>	Dietary supplements	<ul style="list-style-type: none"> Dietary supplements contain one or more dietary ingredients, including vitamins, minerals, herbs, or amino acids, or their constituents. Herbal medicines are considered a subset of dietary supplements in the United States. Some dietary supplements have been proven to prevent or treat disease (eg, folic acid in the prevention of neural tube defects, and calcium and vitamin D in the prevention of osteoporosis), while other claims about dietary supplements are unproven. The most commonly used dietary supplements are fish oil, echinacea, flaxseed, ginseng, multivitamins, vitamins E and C, calcium, and B-complex vitamins. 	<ul style="list-style-type: none"> In the United States, dietary supplements can be sold without being tested to prove they are safe and effective. They must be made according to good manufacturing practices. In the United States, no organization regulates the manufacture or certifies the labeling of dietary supplements.

^aInformation in this table is adapted from the Health Topics pages at the National Center for Complementary and Alternative Medicine Web site (<http://nccam.nih.gov/health/atoz.htm>), the University of Maryland Alternative Medicine Index (www.umm.edu/altmed), and The American Cancer Society's Complementary and Alternative Medicine Index (<http://www.cancer.org/Treatment/TreatmentsandSideEffects/ComplementaryandAlternativeMedicine/index>).

Biochemical

These therapies are intended to improve health through their biochemical effects. Conceptually related to the biochemical mechanism of effect of allopathic medications, herbal remedies and dietary supplements have a few important differences. First, herbal remedies are by nature complex mixtures of chemicals, so their effects are likely due to multiple biochemical reactions. Second, there is currently no federal regulation or oversight of the production of herbs or supplements in the United States, as there is with pharmaceuticals, so quality control is extremely variable. Third, safety concerns are not addressed before they are available commercially to consumers, as with pharmaceuticals, but only after products are on the market and adverse events are reported to the US Food and Drug Administration (FDA). Because of the lack of oversight of both production and pre-market safety, it is important for practitioners to research not only the evidence for an herb's effect and potential adverse effects, but also the particular formulation's production and quality control.

Approaching CAM Use From an Allopathic Perspective

As with any treatment option, the safety (risks) and efficacy (benefits) of a CAM modality must form the basis for therapeutic decision-making about its use. Table 13-2 can be a helpful guide in directing physician responses to a particular CAM therapy.

Table 13-2. Guide to Complementary and Alternative Medicine Treatment Recommendations			
		Is the therapy effective?	
		Yes	No
Is the therapy safe?	Yes	Recommend	Tolerate
	No	Monitor closely or discourage	Discourage
If there is insufficient evidence to assess safety or efficacy <ul style="list-style-type: none"> Establish a plan with the family for monitoring response to treatment. Discourage if adverse reactions develop. Tolerate if no adverse reactions develop. 			

Assessing Efficacy

Data on the efficacy of CAM treatments are increasingly available as CAM becomes a greater focus of research effort and funding in the United States and worldwide. When searching the medical literature for CAM evidence, international and foreign-language articles can be useful, as certain CAM modalities may have been studied in greater depth or over a longer period in other countries. As with any research data, it is important to consider study design, outcome measures, sources of bias, methods of data analysis, and applicability of results for a given indication, patient, or patient population. With herbal remedies and supplements, it is also important to acknowledge that

formulations differ, so efficacy as reported in a clinical trial may be altered if a different formulation is used.

Assessing Safety

The huge diversity of CAM makes it difficult to discuss safety in general terms. Each CAM modality has its own unique risk profile. However, awareness of broad categories of risk can help physicians prevent bad outcomes.

- *Delay of allopathic care:* In studies of CAM risks in the pediatric population, the risk associated with the highest morbidity and mortality is delay of allopathic care. This delay can come about for a number of reasons, including a family's perception that care from a CAM provider obviates the need for allopathic care, a family's inability to afford allopathic care, or a family's belief that allopathic care will be harmful. It may be helpful to contract with families that they will seek allopathic care prior to or in conjunction with CAM care for a new symptom or acute illness to rule out disease processes that require allopathic treatment.
- *Drug–drug interactions:* Certain supplements and herbal remedies may interfere with or alter the effects of conventional medicines. Particular attention has been given to substances that are inhibitors or inducers of hepatic drug metabolism by the cytochrome P-450 enzyme, with St John's wort (used for depression) and grapefruit juice being the most well-known examples. See Resources at the end of this chapter for online resources for checking drug–drug interactions with herbal remedies and supplements.
- *Adverse reactions:* Allergic reactions, side effects, and idiosyncratic reactions are possible with CAM therapies as well as conventional therapies. Close follow-up is helpful in monitoring response to therapy.

Regulation and Licensure

Licensure and accreditation for CAM providers varies from state to state. Chiropractic care, massage therapy, acupuncture, naturopathy, and homeopathy have licensing bodies in some states. In states where licensing exists for a CAM modality, it is incumbent on the physician to ensure that any referrals are made to licensed practitioners. None of these licenses authorizes the practitioner to practice medicine. Other CAM modalities may have a national organization that supervises training and certifies practitioners. Though these are not subject to government oversight, there still may be value in preferentially seeking out providers who are approved by their national organization, as these providers have had to meet a standard established by their colleagues.

Regulation of herbal remedies and supplements is the subject of ongoing scrutiny and debate. Currently, the FDA does not regulate production or marketing of these products, so it is often difficult to verify their composition, safety, or efficacy unless they have been independently studied. The burden of researching products and manufacturers falls to the consumer.

Communication About CAM Use

Most caregivers of children who use CAM do not disclose this use to their pediatrician despite the fact that most report a desire to discuss it. The high rate of nondisclosure is alarming, as it places patients at risk for drug–drug interactions with conventional medications, robs physicians of the opportunity to monitor for adverse reactions, and interferes with the development of trust in the doctor–patient relationship. Reasons cited by patients and caregivers for nondisclosure include

- Negative experiences with past disclosures to physicians
- Fear of disapproval or judgment on the part of physicians
- Belief that physicians do not need to know
- Lack of time with physician
- The physician does not ask

Many of these barriers can be improved by the health care provider.

Physicians may be reticent to discuss CAM, as evidenced by the fact that CAM discussions are patient-initiated in most cases. Physicians may worry about legal liability if there is a bad outcome. They may fear conflict with families over use of CAM. They may be afraid to reveal their lack of knowledge about CAM and may worry that this lack of knowledge will threaten a family's trust in their abilities. They may feel pressured by time constraints and overwhelmed by the need to acquire new knowledge. There is often a disconnect between the meaning that patients and families attribute to CAM use—more options and a greater sense of empowerment—and the meaning that physicians may attribute to it—irrationality given lack of evidence and the threat of interference with conventional medical care. This disconnect can influence both patients and physicians to avoid the subject of CAM.

Communication Tips

- Make questions about CAM use a routine part of the medical encounter.
- Pose questions about CAM use in an open and nonjudgmental way.
 - Suggested opening: “In order for me to take the best possible care of your child, it is helpful for me to know about all the ways your family manages health and illness. Are there any treatments, medications, herbs, or supplements that your child uses that we have not talked about yet? Does your child see any other providers for health-related care or treatments?”
- Explore details of CAM use. Ask families not only what CAM modalities they are using, but also why they chose the treatment, how it works, whether they have noticed a difference, and if there have been any downsides to the treatment.
- Validate the family's desire for health and well-being for their child.
- Do not be afraid to acknowledge the limits of your knowledge. If asked to provide a recommendation about an unfamiliar CAM modality, offer to do further research and revisit the question at a follow-up visit.

- Seek out information about CAM, including literature on safety or efficacy.
- Involve families in the thinking process regarding risks versus benefits of a CAM intervention or modality. Provide evidence-based advice when possible. If there is little or no evidence to support or discourage use of a CAM modality, share this information with families.
- Make a plan with families to monitor the child's response to treatment, including measurable outcomes (eg, symptom relief, increased quality of life) and any adverse effects.
- Encourage families to share information about CAM use on an ongoing basis, even if they choose to continue a treatment about which you have raised concerns.
- Document CAM-related discussions in the medical record.

Effective communication about CAM use is a wonderful opportunity to improve rapport and better understand a patient and his or her family. Communication can be a powerful tool for ensuring safety and reducing harm, as well as for broadening physician knowledge and building trust with families. Even if they do not initiate or recommend a CAM treatment, pediatricians can play an important role by monitoring a child's response to the treatment over time and engaging the family in a discussion about risks and benefits if adverse reactions arise. Discussion about CAM may also bring about a greater understanding of families' explanatory models of illness as well as their expectations of health care providers and their beliefs about conventional medicines. Deeper insight into a family's health beliefs and values can facilitate more successful patient–physician partnership and better patient care.

CASE RESOLUTION

Explaining that this is not your area of expertise, you ask the family to return in 1 week to discuss this further. After consulting the National Center for Complementary and Alternative Medicine Web site and a brief review of the medical literature, you find that there are data on efficacy and safety of CAM therapies for migraine headache prevention, including acupuncture and self-hypnosis. At the follow-up visit, you discuss these options with the family. The girl is interested in both modalities but decides to try acupuncture first. You offer her support for this choice and ask that she keep close track of her headaches and return in 1 month to let you know how she's doing with the acupuncture treatments and her headaches.

Resources

National Center for Complementary and Alternative Medicine (NCCAM) at NIH

<http://nccam.nih.gov/>

NCCAM is the federal government's lead agency for scientific research on CAM. The Web site provides information about CAM modalities for both providers and patients, results of clinical trials supported by NCCAM, lists of ongoing trials, and information about training and funding opportunities in the field of CAM.

University of Maryland Medical Alternative Medicine Index

<http://www.umm.edu/altmed/>

Provides information on CAM therapies, which is searchable both by modality name and by symptom/disease. Also provides information on drug–drug interactions and side effects of herbal remedies.

Georgia Health Sciences University Robert E. Greenblatt, MD Library

Complementary and Alternative Medicine Resources

<http://www.lib.mcg.edu/resources/links/cam.php>

A list of helpful links to governmental, university-based, and nonprofit sources for information on research, training, policy, regulation, and integration of CAM.

CAM on PubMed

<http://nccam.nih.gov/research/camonpubmed/>

NCCAM provides a link to a PubMed search box that is limited to the CAM subset of PubMed.

Cochrane Reviews

<http://www2.cochrane.org/reviews/en/subtopics/22.html>

Link to more than 700 Cochrane Reviews on CAM interventions. The Cochrane Collaboration is an independent, international network of leaders in the health care field who are committed to helping health care providers make evidence-based decisions. Subgroups devoted to specific topic areas produce systematic reviews of available evidence for health-related interventions. The CAM-related subgroup is coordinated through the University of Maryland Center for Integrative Medicine.

Longwood Herbal Task Force

<http://www.longwoodherbal.org/>

Detailed, evidence-based monographs on individual herbal remedies including a review of available evidence, contraindications/cautions, and safety information. Administered by a group of faculty from the Boston Children's Hospital, the Massachusetts College of Pharmacy and Health Sciences, and the Dana Farber Cancer Institute.

The Natural Standard

<http://naturalstandard.com/>

Subscription-based site that includes evidence-based information on CAM modalities as well as online tools to check for drug–drug interactions.

Consumer Lab

<http://www.consumerlab.com/>

A for-profit organization that carries out independent testing of dietary supplements and herbal remedies, both by request of manufacturers and for the benefit of the public. In either case, samples for testing are not obtained directly from the manufacturer, but from the consumer marketplace. The use of the “CL seal of approval” image that appears on vitamin bottles can be purchased by manufacturers once their product has been tested by Consumer Lab.

Principles of Pediatric Surgery

Steven L. Lee, MD

CASE STUDY

A 4-month-old male infant is evaluated by his pediatrician for swelling in the groin and diagnosed with a right inguinal hernia. The parents are told that their child will be referred to a pediatric surgeon. The parents are concerned about surgery in so young an infant and ask their pediatrician multiple questions. Is he big enough to have surgery? Will he be able to eat before the surgery? Will he be in pain? Will he need to have blood drawn? Will he need to be hospitalized? Will he be put to sleep for the procedure?

Questions

1. What are the typical questions parents ask if their child is undergoing surgery?
2. What is the role of the primary care provider in advising patients/parents about surgical procedures?
3. What is the role of the operating surgeon in advising patients/parents about the surgery?
4. What are general guidelines for feeding infants and children prior to surgery?
5. What are the risks of general anesthesia in infants and children?
6. How long is the hospitalization following surgery?
7. What should parents do before meeting with the surgeon?
8. How do you prepare children who are about to undergo surgery?
9. What laboratory studies are needed prior to surgery?

No matter what the age of the patient, the prospect of surgery is generally anxiety-provoking for both the patient and the patient's parents. As with any stressful patient encounter, communication is the key to educating, calming, and reassuring both patients and their parents. This is particularly true when patients are being referred even initially for surgical consultation. Pediatricians can make a significant impact by providing basic information to parents regarding surgical care. It is also important for primary care physicians and surgeons to communicate with each other in order to provide the highest level of care.

Preoperative Care

Initial Consultation

The first task of the primary care provider is to initiate a referral to the pediatric or general surgeon. The initial surgical visit will be to confirm the diagnosis and discuss surgical and nonsurgical options for treatment. Typically, no surgical procedures are performed during this consultation. This point must be clarified as many children and parents mistakenly think that surgery will occur at the time of the first encounter and are therefore unduly anxious. Some parents will even schedule time off unnecessarily, expecting to have to care for their postoperative child. They become disappointed and even angry when the surgery is not performed. Sometimes the diagnosis of the primary care provider is incorrect, and the surgeon can reassure the parents about the correct diagnosis obviating the need for any surgery.

A significant amount of information is given to parents and children during the surgical consultation. The diagnosis is confirmed and a decision is made whether the patient will require an operation. The operation is described in detail to the parents and to the patient when age-appropriate to do so. In addition, a thorough review of the risks of the operation is performed. The surgeon also gives a time estimate on how long the procedure will take. There is also a general discussion on the expected recovery, such as whether the procedure will be as an outpatient versus as an inpatient, where hospitalization occurs, how long the child will miss school, and whether there are any activity restrictions.

To avoid confusion, parents are encouraged to make a list of questions prior to this first encounter and make sure each question is answered. Parents should also write down the answers to refer to them at a later time. Once parents agree to proceed with surgery, the surgeon starts the process and paperwork. Often, this will be the only visit required before the date of the operation. However, some hospitals require patients to be seen by the surgeon within 30 days of a procedure, thus a return visit may be required if the date of surgery is beyond the time frame. Also, some centers require patients to have a preoperative evaluation with the anesthesia team prior to surgery.

Anesthetic Preparation in Infants and Children

Anesthesia is extremely safe in infants and children. The risk of a poor outcome from general anesthesia is less than 1%. In most

institutions, pediatric anesthesiologists provide the anesthetic care for infants and young children. If pediatric anesthesiologists are not available, the anesthetic care for infants and children is often limited to a set of experienced general anesthesiologists.

There are many types of anesthetics that can be used, including moderate sedation (“conscious sedation”), regional anesthesia, and general anesthesia. Typically, the type of anesthesia will be determined by both the surgeon and anesthesiologist; however, the anesthesiologist makes the final decision. Although the least amount of anesthesia is desired, all patients must be treated as if they may need to undergo general anesthesia in case moderate sedation or regional anesthetic is inadequate.

To minimize the risk of aspiration with general anesthesia, the stomach must be empty of food and liquids. Although each hospital has its own policies, Box 14-1 lists frequently recommended guidelines for the time interval between meals and the surgery. In general, most infants and children will have to miss one meal prior to surgery. Often this meal can be replaced with clear liquids.

Laboratory Studies

Laboratory studies should be performed if indicated by the patient’s underlying comorbidities or current disease process. Blood products may be needed during or after surgery if there is blood loss. If blood loss is anticipated, the parents or other family members will be given the option of directly donating blood prior to the procedure. However, directly donating blood takes time (days to weeks depending on the specific blood bank) and may not be an option for urgent and emergency operations. In addition, the cost of directly donating blood is often the responsibility of the patient.

Patients Requiring Urgent/Emergency Surgery

Patients with acute conditions will often present to their pediatrician or primary care provider. Common conditions include abdominal pain consistent with appendicitis, abscess requiring drainage, incarcerated hernia, or vomiting due to pyloric stenosis. Such patients will need to be directed to the emergency department (ED) for further management, and the pediatric surgeon should be notified. Any time a patient is sent to the ED, it is essential to remind the parents to keep the patient NPO, that is, not to give them anything to eat or drink. If parents feed patients en route to the ED, this will delay treatment due to anesthetic concerns. The NPO guidelines (Box 14-1) will still be enforced even in urgent conditions; only in life-threatening emergencies will the NPO guidelines typically be disregarded. In most acute situations, patients are often dehydrated, either from vomiting, poor oral intake, or third space fluid losses. Thus, prior to surgery, it is essential that patients are adequately resuscitated. Standard intravenous (IV) fluid resuscitation of 20 mL/kg of lactated Ringer’s solution or normal saline should be administered followed by continuous administration of maintenance (or higher) fluids. Appropriate antibiotics should also be administered as indicated. Patients with acute appendicitis should be started on single, double, or triple agent broad spectrum antibiotics depending on their symptoms and the

preference of the surgical team. Patients with abscesses should be administered antibiotics with excellent gram-positive coverage, with special attention to methicillin-resistant *Staphylococcus aureus*, given its high prevalence. Pain medication should also be given as needed, even if the surgeon has not evaluated the patient. It is rare that a true surgical condition will be masked by an appropriate dose of pain medication. Finally, basic laboratory studies, such as a complete blood cell count and electrolyte panel, should be obtained.

Perioperative Care

The final operating room schedule for elective cases is made the day before. Thus the specific time of an elective procedure is not known until 1 day prior to surgery. Often the surgeon can give parents an estimated start time. Families will be called the day before surgery to confirm the time of the procedure and when and where to arrive. Often, patients are asked to arrive 1.5 to 2 hours before the scheduled start time. This extra time is to ensure patient safety by completing all of the necessary steps before the actual operation.

In general, patients are put under anesthesia in the operating room. For infants and young children, an IV line is placed after the patient is asleep. To minimize anxiety, preanesthetic sedation is administered orally before proceeding to the operating room. Once in the operating room, patients are often administered an inhalational anesthetic, followed by placement of the IV line, and then intubation. Some institutions allow parents to accompany their child to the operating room and see the child put to sleep with the inhalational anesthetic.

Once the operation is complete, patients are brought to the recovery room. Parents typically are allowed in the recovery room until the time of discharge. Criteria for discharge from the recovery room are listed in Box 14-2. For children who have undergone surgery as outpatients, careful written instructions are provided to the parents along with follow-up appointments and telephone numbers in case problems should arise. Children who are inpatients are discharged

Box 14-2. Criteria for Discharge After Outpatient Surgery

Stable and appropriate-for-age vital signs
 Age-appropriate ambulation
 Ability to tolerate oral fluids
 No bleeding
 No respiratory distress
 No pain that cannot be controlled by oral medication
 Age-appropriate alertness

from the recovery room to the pediatric inpatient service, along with appropriate orders for the nursing personnel.

There continues to be controversy over the postoperative management of former premature infants following general anesthesia. Ex-premature infants are at higher risk of postoperative apnea. Reasonable recommendations for typical outpatient operations include overnight admission with apnea monitoring for ex-premature infants who are less than or equal to 50 weeks' postconception. However, each institution has its own specific policy and the exact age for required admission varies. The decision for admission is also based on the patient's current health and comorbidities and should be made by the surgeon, anesthesia team, primary care physician, and the patient's parents. Table 14-1 lists the most common elective and urgent/emergency operations and the anticipated postoperative hospitalization stays.

Postoperative Care

Parents will often call their pediatrician with questions postoperatively, thus the pediatrician should be knowledgeable about routine postoperative care. Most children recover from anesthesia and surgery faster than adults. Unless otherwise specified, such as following an appendectomy for perforated appendicitis, a normal diet can be resumed as soon as the patient desires. If patients are not tolerating a normal diet, a bland diet and plenty of fluids are recommended. Furthermore, patients should resume taking all of their preoperative medications the evening after surgery or the next morning.

Nearly all surgical wounds are closed with absorbable sutures and covered with steristrips. Additional dressings can be removed in 1 to 2 days or as needed. Again, unless otherwise specified, most wounds can get wet (shower or quick bath) 48 hours after surgery. Dressings, except for steristrips, should be removed prior to bathing. Wounds do not need to be covered, unless they are open or there is drainage.

The surgeon will provide details regarding activity limitations and returning to school. Often heavy physical activity, such as physical education in school or with organized sports, should be avoided until the surgeon sees the patient following discharge. While heavy physical activity is to be avoided after surgery, patients should be encouraged to walk as well as to cough and to deep breathe many times a day. Patients can return to school when they are feeling up to it and have no more than minimal pain.

Table 14-1. Common Elective and Urgent/Emergency Operations and the Anticipated Postoperative Hospitalization

<i>Procedure</i>	<i>Length of Hospitalization</i>
Elective	
Inguinal hernia repair	Outpatient
Umbilical hernia repair	Outpatient
Cyst excision	Outpatient
Central venous catheter insertion/removal	Outpatient
Orchidopexy	Outpatient
Laparoscopic cholecystectomy	Outpatient
Lymph node biopsy	Outpatient
Ostomy takedown	3–4 days
Lung resection	3–4 days
Imperforate anus repair	3–4 days
Pectus excavatum repair (Nuss procedure)	4–5 days
Urgent/Emergency	
Laparoscopic or open appendectomy for non-perforated appendicitis	1–2 days
Laparoscopic or open appendectomy for perforated appendicitis	5–7 days
Pyloromyotomy	1 day
Intussusception reduction	1 day
Bowel resection	5–7 days
Bowel obstruction	5–7 days
Tumor resection (Wilms or neuroblastoma)	7 days
Choledochal cyst or portoenterostomy	5–7 days
Pull through for Hirschsprung disease	5–7 days

Main reasons to contact the surgeon after the operation are for fever greater than 101.5°F (38.6°C), worsening or persistent pain, persistent emesis, and any wound drainage or redness. Additional instructions specific to the operation are also provided.

CASE RESOLUTION

In this case, the pediatrician reassured the parents that she has referred many patients to this surgeon. The parents were assisted by the pediatrician in crafting their questions for the surgeon. The surgeon subsequently confirmed the diagnosis of an inguinal hernia and recommended surgery. All of the details were provided and the parents had their questions answered. The patient was scheduled for outpatient surgery and everything went smoothly. Postoperatively, there were no concerns and the patient saw both the surgeon and pediatrician in follow-up.

Image Gently™:

Approach to Pediatric Imaging

Jane S. Kim, MD; Lindsay S. Baron, MD; and Benjamin H. Taragin, MD

CASE STUDY 1

A 15-year-old boy comes to your office complaining of 1 week of back pain after exertion. He reports no significant recent trauma. He does play varsity basketball, but has not had any recent falls during games. He is otherwise healthy with no significant medical history.

The pain does not prevent him from playing sports or from going to school. He has no history of prior episodes of back pain. He says the pain is relieved by nonsteroidal anti-inflammatory drugs (NSAIDs). On physical examination, he has left-sided paraspinal focal tenderness in the L3–L4 region. He has limited range of motion twisting to that side.

CASE STUDY 2

A 10-year-old girl is brought to your office with runny nose, congestion, cough, and headache. You saw this patient 4 months ago as well as 6 weeks ago, when she had similar complaints. Her mother reports full compliance with the antibiotic regimen you prescribed, but states that her daughter's symptoms have never fully resolved. On physical examination, the child is afebrile

with purulent nasal discharge. There is tenderness to palpation over the cheeks and forehead.

Questions

1. What, if any, is the appropriate imaging for each patient?
2. How does one decide the appropriate imaging studies to obtain on a patient?
3. What is the ALARA principle?
4. What information is available for counseling patients regarding the risks of diagnostic radiation?
5. Where can one find appropriate imaging recommendations for pediatric patients?
6. Does the history influence the choice of imaging studies?
 - a. What imaging would be appropriate for the patient in Case Study 1 if there was recent significant trauma?
 - b. What imaging would be appropriate for the patient in Case Study 2 if her symptoms were new and started last week?

Overuse of medical imaging is a growing problem in the United States that has both financial and medical repercussions. The primary care provider must often decide what, if any, is the proper imaging for patients with common complaints. In many situations, clinical assessment and physical examination are adequate for diagnosis. In some instances, however, imaging provides vital information that cannot be adequately obtained from other sources. Often, patients and their families insist on diagnostic imaging and can be under the impression that the more technologically advanced the evaluation, the better the care.

Currently approximately 370 million studies that use diagnostic radiation are performed yearly in the United States (Figure 15-1). The most dramatic increase has been in the use of computed tomography (CT) scans. In 1982 there were 1 million CT scans performed in the United States. In 2006 there were 67 million CT scans performed, and of this number it is estimated that 4 to 7 million of these were performed in children. In response to this, many concerned health care professionals and radiologists gathered to create the national

Image Gently™ campaign, focusing on minimizing the use of diagnostic radiation and using appropriate pediatric imaging for children in the United States.

Basic Concepts

Diagnostic radiology examinations that use ionizing radiation include plain radiography, fluoroscopy, CT, and nuclear medicine. Ionizing radiation causes damage to DNA molecules and may lead to cell death or a mutation. The induction of cancer takes several years, and the effects are hereditary (may be passed down to the next generation).

One of the most common ways to measure radiation dose is by the effective dose (unit: Sieverts), which takes into account all of the exposed tissues and each organ's relative radiosensitivity. Certain organs are more radiosensitive than others and, in particular, children are at an increased risk for breast cancer, thyroid cancer, and leukemia. It is important to note that children are more

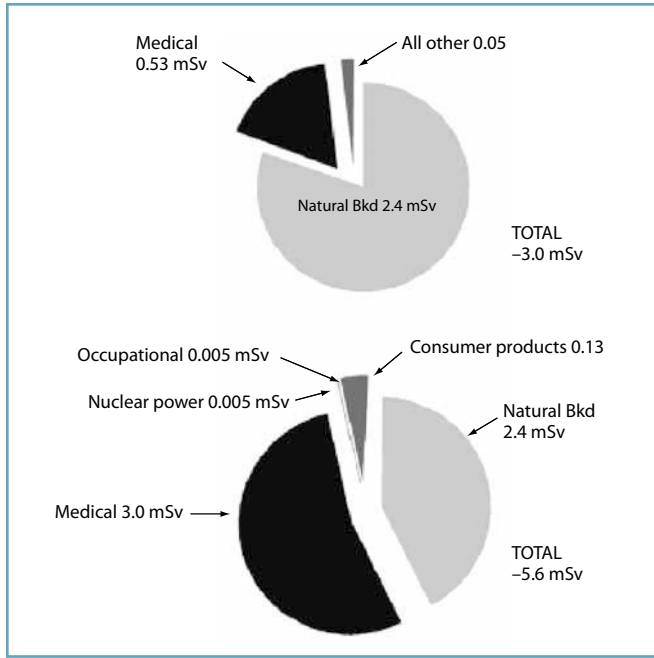

Figure 15-1. US annual per-capita effective radiation dose from various sources. Left: Chart for 1980. Right: Chart for 2006. BKD, background. (From Mettler FA, Bhargavan M, Faulkner K, et al. Radiologic and nuclear medicine studies in the United States and worldwide: frequency, radiation dose, and comparison with other radiation sources—1950–2007. *Radiology*. 2009;253[2]:520–531, with permission.)

radiosensitive than adults, secondary to their growth of rapidly proliferating cells. The effective dose also provides a way to compare radiation dose across different imaging modalities. For example, a single CT scan imparts an effective dose that is equivalent to 100 to 250 chest radiographs in children (Table 15-1).

ALARA Principle (As Low As Reasonably Achievable)

Over the last 10 years, there has been increasing attention and research into the radiation imparted to patients from diagnostic imaging. Much of this concern stems from data derived from the atomic bomb survivors of World War II. Based on the distance of survivors from ground zero, the radiation dose to each individual was calculated. More than 50,000 of these patients were followed for more than 50 years. The data showed an increased cancer risk for many of the survivors. Based on this observation, a mathematical model was created, indicating that the risk of cancer proceeds in a linear fashion without threshold (Figure 15-2). Therefore, even a small amount of radiation increases the risk of cancer. Current estimates vary regarding diagnostic radiation and cancer. Based on research by multiple radiation biologists, the American College of Radiology estimates that for adults, one fatal cancer will be induced for every 1,000 CT scans performed. That risk is increased in children, with one fatal cancer occurring for 500 to 1,000 CT scans performed. This is superimposed on the national cancer incidence of 42%.

Table 15-1. Average Effective Dose in Millisieverts of Different Imaging Studies

Diagnostic Procedure	Typical Effective Dose (mSv) ^a	Number of Chest X-rays (PA film) for Equivalent Effective Dose ^b	Time for Equivalent Effective Dose From Natural Background Radiation ^c
Chest x-ray	0.02	1	2.4 d
Skull x-ray	0.1	5	12 d
Lumbar spine	1.5	75	182 d
IV urogram	3	150	1.0 y
Upper GI examination	6	300	2.0 y
Barium enema	8	400	2.7 y
CT of head	2	100	243 d
CT of abdomen	8	400	2.7 y

Abbreviations: CT, computed tomography; GI, gastrointestinal; IV, intravenous; PA, posteroanterior.

^aAverage effective dose in millisieverts (mSv) as compiled by Mettler FA Jr, Huda W, Yoshizumi TT, Hahesh M. Effective doses in radiology and diagnostic nuclear medicine: a catalog. *Radiol*. 2008; 248:254–253.

^bBased on the assumption of an average “effective dose” from chest x-ray (PA film) of 0.02 mSv.

^cBased on the assumption of an average effective dose from the natural background radiation of 3 mSv per year in the United States.

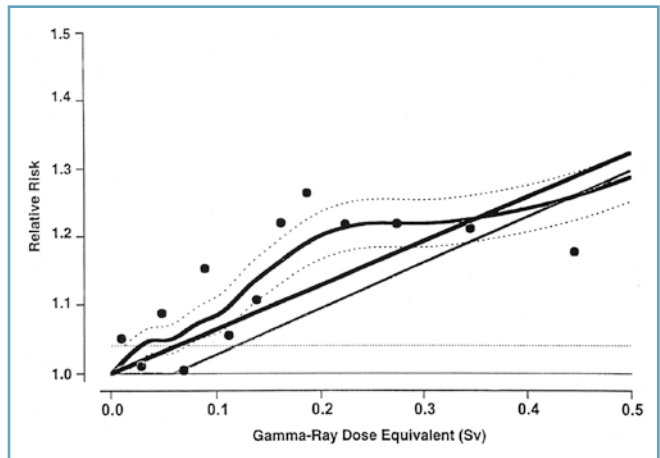

Figure 15-2. Relative risk of contracting cancer in atomic bomb survivors. (Reprinted with permission from Pierce DA, Preston DL: Radiation-related cancer risks at low doses among atomic bomb survivors. *Radiat Res*. 2000; 154:178-186.)

On the basis of this research, the *Image Gently™* campaign was founded, which stresses a multifaceted approach intended to minimize radiation exposure to children. The campaign has brought together 60 medical and professional organizations representing more than 700,000 imaging specialists from the fields of pediatrics, radiology, physics, and radiology technology. The ALARA principle is based on the notion that any amount of radiation exposure, no matter how small, can increase the chance of negative biological

Case Study 2: Symptom Duration and Response to Treatment

Imaging should be obtained in cases of chronic sinusitis that do not respond to treatment and persist without resolution for months. Computed tomography of the sinuses is useful in evaluation of the soft tissues, extent of disease, and any potential intracranial complications. Computed tomography also provides important anatomical detail in the event of the need for surgical intervention. Plain radiography has limited utility in evaluation of sinusitis due to the lack of soft tissue and anatomical detail and low sensitivity. This is particularly true in very young children whose sinuses are not yet well aerated. Imaging is not appropriate in the setting of acute sinusitis. See Resources at the end of the chapter for a link to the ACR Appropriateness Criteria for child sinusitis.

CASE RESOLUTION

Case Study 2

The physician should order a CT of the sinuses as the patient has signs and symptoms of chronic sinusitis despite treatment. If the patient was presenting for the first time with signs and symptoms of sinusitis, medical treatment would be indicated. If the patient does not respond to medical management, imaging should be considered.

Pediatric Genomic Medicine

Derek Wong, MD

CASE STUDY

A 4-year-old male with moderate global developmental delay is brought to his pediatrician's office for evaluation. The patient has an unremarkable family history and a normal physical examination. Previous evaluation included a normal karyotype and fragile X DNA test. The patient's parents would like to know if there is anything else that can be done to determine the etiology of the delay. In addition, his mother has recently read about companies that offer multiple genetic tests to consumers, and wonders if these tests will be useful as well.

Questions

1. How is microarray technology useful in pediatric practice?
2. How will next-generation sequencing technology impact future practice?
3. What are the limitations of these new technologies?
4. What is direct-to-consumer genetic testing?

As a result of the Human Genome Project (HGP), the first essentially complete human sequence was published in 2003. Very rapid progress in DNA sequencing technology has decreased the cost of sequencing an individual from \$750 billion in the HGP to less than \$20,000 per person in 2010. Currently microarray analysis has resulted in dramatically increased yields for patients with developmental delay, autism, and multiple congenital anomalies. Genetic panels for a variety of conditions, such as familial cardiomyopathy and X-linked mental retardation, offer testing for 20 to 100 genes at the same price as sequencing 2 to 4 genes cost a few years ago. Several companies offer direct-to-consumer genetic testing, designed to provide information without physician input. Pharmacogenomics, which promises individualized drug therapy based on genomic data, is moving from specialized disease therapeutics to common diseases. The promise of a \$1,000 genome has been hailed as the beginning of a new era of personalized medicine, in which each patient will have a tailor-made set of interventions to optimize his or her health. As with most breakthrough technologies, these advances will be balanced by significant limitations.

Epidemiology—Human Genome Anatomy

Human cells have 2 haploid genomes, each containing 3 billion base pairs with an estimated 20,000 to 25,000 protein encoding genes, plus a variable number of copies of the mitochondrial genome. On average, 2 humans share 99.9% of their DNA. There are at least 10 million single nucleotide polymorphisms (SNPs), which are single base changes that are present in a substantial percentage of the population (>1%). A small percentage of SNPs fall within the coding or regulatory regions of genes, and directly influence gene function. The remaining SNPs have no known effect on protein production,

but may be inherited in recognizable patterns (haplotypes) with other SNPs.

Recently it has become evident that most human genetic variation is not due to SNPs. Instead, copy number variants (CNVs), in which DNA segments containing up to several million base pairs are duplicated or deleted, account for a substantial portion of variation between individuals. Although studies have found that 12% of the genome is subject to CNV (Redon), the impact of this variation on an individual's phenotype is unknown.

Although most autosomal recessive disorders are rare, most humans are carriers of several disease alleles. In a recent study, there was an average of 2.8 recessive mutations per person in 448 genes involved in severe autosomal recessive conditions.

Pathophysiology—The Genotype/Phenotype Correlation and Environment

There are numerous examples of genetic background affecting the presentation of rare genetic disorders. Although most patients with untreated classic phenylketonuria develop mental retardation, some patients with high blood levels have normal IQ on a regular diet. Patients with thalassemia are affected by the alpha to beta globin gene ratio. Therefore, β -thalassemia "carriers" with one mutation may become symptomatic if they have duplicated alpha chains. Understanding susceptibility to common genetic disorders will require an understanding of a complex network of interacting genes.

Genomic data provide information about only one predisposing factor to a disease state. Many diseases are caused by a combination of genetic susceptibility and environmental forces. The first examples of this interaction that were discovered were monogenic conditions such as complement deficiency, which predisposed

patients to bacterial meningitis, or cancer susceptibility genes that caused extreme radiation sensitivity. However, the gene–environment connection is known to be much deeper, with certain environmental conditions causing methylation of the genetic code, silencing multiple genes without changing DNA sequence. These epigenetic changes may persist across generations, causing mothers exposed to wartime famine to produce children who are born to conserve energy. If these children are fed a typical American diet, they are prone to obesity and diabetes. Fetal cells that persist in maternal circulation (fetal microchimerism) may play a role in both tumor prevention and susceptibility to autoimmune disease. Finally, our bodies contain more bacteria than human cells. The interaction of the bacterial genomes and human genomes plays an important role in some disease states.

Clinical Presentation/History and Physical

A thorough history and physical examination will continue to be a critical component of patient assessment in the genomic age of medicine. Large databases will need to be created in order to correlate human genotypes to corresponding phenotypes, which are defined by the patient's clinical presentation. Even when genetic and epigenetic sequencing is commonplace, the only way to measure the impact of the disease on the individual is by clinical assessment.

Laboratory Testing

New genetic laboratory techniques have had a dramatic impact on common pediatric conditions such as developmental delay and autism. Microarray testing uses closely spaced DNA probes to detect chromosomal deletions or duplications at 10 to 10,000 times the resolution of a standard karyotype. The diagnostic yield for developmental delay and multiple congenital anomalies has increased from 3% to 4% to 15% to 20% using this technology. For example, patients with autism with normal karyotypes may have microdeletions or microduplications of 16p11.2. The limitations of this technology are that it cannot detect balanced translocations or most chromosomal mosaic patients.

Next-generation sequencing is a phrase used to describe new methods that allow parallel sequencing of billions of base pairs at relatively low cost. Whole exome sequencing concentrates on the 1.5% of the genome that is the protein coding region, and is predicted to become available on a clinical basis during the next several years. A recent trial of this technology identified genetic causes in 6 out of 10 patients with unexplained mental retardation who had negative testing for fragile X, and normal karyotype and microarray analysis. Shortly after whole exome sequencing becomes established, whole genome sequencing is expected to become available, allowing discovery of variation in regulatory elements located outside the coding regions.

Next-generation sequencing technology has significant drawbacks that must be overcome prior to general use. An error rate of 0.001% is acceptable for a single test, but impractical if billions of base pairs are tested at the same time. Resequencing each region

tens or hundreds of times will eliminate most errors. However, some genes, particularly those with high guanine-cytosine content, are not well sequenced with current high-volume technologies. Thus whole exome sequencing may miss 5% or more of the genome.

A patient's next-generation sequencing results may have millions of differences from reference sequences. Until huge databases of genomes from millions of patients are available, bioinformatics algorithms must be used to sift through the data and determine which changes are potentially relevant. Parental testing is often essential for these studies and may not be available. In general, results may be divided into 3 categories: known mutations, SNPs or other alterations that do not cause disease, and variants of unknown significance. The last category may contain tens or hundreds of altered genes, and matching potential mutations to a given phenotype is very difficult. Technology will drive down the price of sequencing over time, but the cost of bioinformatics will dominate the price of these new technologies as the amount of data increases.

Direct-to-Consumer Genetic Testing

Several companies market genetic tests that report disease risk by analyzing multiple SNPs along with common disease mutations. The companies argue that consumers have the right to know their genetic information, and some offer genetic counseling services. However, the tests may lack sensitivity and specificity, because the analysis is based on limited genetic markers without family history or phenotypic information. Many consumers (and their physicians) are ill-equipped to understand the nature of the results, and patients of non-Caucasian ethnicity may have many indeterminate results. In 2010 the US Food and Drug Administration decided to develop regulations regarding the sale of direct-to-consumer genetic tests.

Treatment—Pharmacogenomics

Individualized pharmacologic treatment is one of the ultimate goals of the HGP. Although pharmacogenomics is in its infancy, several tests are available that reduce the risk of an adverse drug reaction. Patients with variant thiopurine methyltransferase alleles may have severe toxicity to drugs, such as azathioprine and 6-mercaptopurine, that are used in multiple disorders. Children with a 1555A>G mutation in the mitochondrial genome are susceptible to aminoglycoside-induced hearing loss, even after the first dose. Pharmacogenomics for common diseases such as asthma is currently under investigation and may allow a more rational choice of multi-drug regimens.

Future Developments

Despite huge potential, the impact of the HGP has yet to be felt in most areas of medicine, including pediatrics. However, during the next decade, genomics will revolutionize the diagnosis of Mendelian disease. The impact of the HGP on common diseases and therapy is less obvious. It is unclear whether consumers will use genomic information to alter their lifestyles, whether the information comes from their physicians or direct-to-consumer testing. In addition,

whole exome and whole genome sequencing create a variety of ethical issues. If a patient presents with heart disease, and testing shows an increased risk for Alzheimer disease, should this information be disclosed to the patient? It is certain that pediatricians will need to familiarize themselves with genomic medicine, because the number of tests will overwhelm the available medical genetics specialists and genetics counselors.

CASE RESOLUTION

The patient's microarray testing shows a small microdeletion in chromosome 6. Parental testing indicates that the microdeletion is present in the patient's father, who has had normal development. Further testing includes a "developmental delay" panel, which shows a potential missense mutation in *CASK*, a gene on the X chromosome that may cause developmental delay. This alteration is not found in the patient's mother, implying that it is most likely deleterious. The parents receive genetic counseling about future pregnancies.

Principles of Quality Improvement: Improving Health Care for Pediatric Patients

Bonnie R. Rachman, MD

CASE STUDY

During a routine staff meeting at your group pediatric practice, it was noted that many of the patients followed by your practice are behind in their immunizations. The reasons for this are unclear since you and your colleagues are strong proponents of the timely administration of preventive immunizations. You want to develop a mechanism to determine what factors are leading to a delay in vaccine administration.

Questions

1. What is quality improvement?
2. How does assessing the delivery of recommended health maintenance relate to quality?
3. How is the prevention of medical errors related to quality improvement?
4. What is the difference between harm and error?
5. What factors are associated with medical errors?
6. What is meant by organizational culture?

History

The origin of medical quality improvement lies not in medicine but in industry and dates back to the 1920s. Dr Walter A. Shewhart was an American physicist, engineer, and statistician. In 1924 Dr Shewhart presented a memo where he showed a schematic control chart. The diagram and text set forth all the essential principles and considerations involved in quality control. Dr Shewhart pointed out the importance of reducing variation in a manufacturing process and noted that continual process adjustment in reaction to nonconformance actually increased variation and degraded quality. He went on to develop **data presentation rules**, which continue to be important today: (1) data have no meaning apart from their context and (2) data contain both signal and noise. To be able to extract information, one must separate the signal from the noise within the data.

In the 1950s Dr Shewhart's colleague, W. Edwards Deming, working in Japan taught top management how to improve design and, subsequently, service, product quality, testing, and sales. Deming applying Shewhart's concepts, described the Plan-Do-Study-Act (PDSA) cycle as an approach to quality improvement. He opined,

“The key is to practice continual improvement and think of manufacturing as a system, not as bits and pieces.”

In the 1970s Avedis Donabedian, a physician, proposed a model for assessing health care quality by describing 7 pillars of quality: efficacy, efficiency, optimality, acceptability, legitimacy, equity, and cost (Box 17-1). He posited, “Structure is the environment in which health care is provided, process is the method by which health care is provided, and outcome is the result of the care provided.” He emphasized the importance of measurement and evaluation of health care quality, ensuring completeness and accuracy of medical records, observer bias, patient satisfaction, and cultural preferences for health care.

In 1991 Drs Paul Batalden and Don Berwick helped form the Institute for Healthcare Improvement (IHI), which has led to the

Box 17-1. 7 Pillars of Quality

Efficacy	Legitimacy
Efficiency	Equity
Optimability	Cost
Acceptability	

application of quality improvement science to health care in the United States and internationally. The IHI promotes the adoption of measurement and feedback to improve the quality of health care.

Historically, efforts for improving quality focused on “quality assurance.” The goal was to minimize “defects” as measured by audits. Now the emphasis is on “quality improvement,” which focuses on moving the entire performance curve toward a greater level of performance by adopting best practices instead of simply focusing on low performers. Ongoing measurement is vital to sustaining any improvement. The process of quality improvement requires careful planning, thorough documentation, consistent analysis, and open-mindedness to results.

Introduction

Quality Improvement in Pediatrics

Pediatrics is a specialty that emphasizes health maintenance and disease prevention. Studies have shown that recommended targets are not being consistently realized. Mangione-Smith and colleagues reported that children received only 46.5% of recommended care for preventive services, acute illness management, and ongoing care of chronic conditions. Shaughnessy and Nickel reported that 21% of outpatient prescriptions in a family medicine practice had at least one error. Other investigators found that medication samples were dispensed with inadequate documentation. In a pediatric emergency department in Canada, 100 prescribing errors and 39 medication administration errors occurred per 1,000 patients. In a sample of new prescriptions for 22 common medications in outpatient pediatric clinics, approximately 15% were dispensed with potential dosing errors.

The Learning from Errors in Ambulatory Pediatrics (LEAP) study aimed to learn the scope, range, potential causes, and possible solutions to medical errors in pediatric ambulatory care. The study found that among 14 pediatric practice sites, there were 147 medical errors reported during the 4-month study period. The largest group of errors was related to medical treatment (37%). Of the medical treatment errors, 85% were medication errors. There were also errors associated with patient identification (22%); preventive care, including immunizations (15%); diagnostic testing (13%); and patient communication (8%).

There are many examples of errors in the inpatient arena as well. A study looking at inpatient medication errors found that among 1,000 children in 12 independent children’s hospitals, 1 in 15 children was exposed to wrong medications, side effects, or drug interactions. Takata and Currier reported a rate of 11.1 adverse events per 100 pediatric inpatients; 22% of these errors were deemed preventable. In a 2005 Joint Commission on Accreditation of Healthcare Organizations report, the root cause of more than 70% of 2,400 sentinel events was communication failure between providers or between family and providers. In those events, 75% of patients died due to this type of failure.

Kurtin and Stucky describe 5 barriers or challenges to high-quality care in both the pediatric and adult arenas (Table 17-1). The first is widespread unnecessary variation in care.

In order to prevent medical error, one needs to understand how, when, and where it occurs; to look at the system that allowed the error to happen; and to keep the system open and blame-free (Box 17-2).

The factors associated with risk of error are not the individuals who work in the system but rather the system in which the individuals work. To decrease the risk of error, the language of patient safety must be understood, and a deeper understanding of the principles of systems analysis work models and other problem solutions must be developed.

Definitions

In order to understand quality improvement and improve patient safety, one must be familiar with the terminology. The National Patient Safety Foundation defines *patient safety* as the avoidance, prevention, and amelioration of adverse outcomes or injuries stemming

Table 17-1. Barriers to High-Quality Care

<i>Barrier</i>	<i>Explanation</i>
Unnecessary variation in care	Diagnostic or therapeutic interventions performed at the discretion of the ordering physician and not required by the patient’s condition
Gap between knowledge and practice	May be many years; time it takes a proven new practice to go from medical literature to routine clinical care
Failure of physicians to understand and work in the hospital’s complex systems of care	Challenges to accessing information/data/personnel/materials to facilitate patient care
Need to improve patient safety	No consistent mechanism in place
Slow adoption and routine use of practices that can improve clinical outcomes and patient safety	Use of clinical pathways may mitigate

Box 17-2. Factors Associated With Errors

Communication failures
Frequent distractions and interruptions
Inadequate supervision
Drug ordering issues
Limited access to patient information
Noisy work environment
Lack of 24-hour pediatric pharmacy
Emergency situations

from the processes of health care. The Institute of Medicine (IOM) defines *patient safety* as freedom from accidental injury.

An *adverse event* is defined as injury caused by medical management rather than by the underlying condition. Some are not preventable. One example of a non-preventable adverse event is the person who receives the appropriate antibiotic at the appropriate time and an appropriate dose who has an allergic reaction to the medication. This differs from *medical error*, which is the failure of a planned action to be completed as intended (error in execution) or the use of a wrong plan to achieve an aim (error of planning). *Outcomes* summarize the effectiveness of care, including adverse events.

James Reason, who did extensive work on organization models of accidents, further delineates the terminology. A *slip* is an error in execution; the observable action deviates from what was planned. A *lapse* is an error in execution due to a memory failure. A *mistake* is a knowledge-based failure; the plan is carried out correctly but the planned action was wrong for the situation. An *active error* (sharp end error) typically occurs in a patient care area by a front-line provider; the effects may be felt immediately. A *latent error* (blunt error) is due to system-based problem and may relate to poor design, incorrect installation, look-alike packaging, sound-alike names, faulty maintenance, or bad management decisions. These are more difficult to identify and hard to recognize. Health care workers frequently develop “work-arounds” to bypass the problem. This often leads to the belief that the “work-around” is normal.

A *system* is a set of interdependent human and nonhuman elements interacting to achieve a common aim. In a hospital, it may be a unit or a department. *Processes* are how care is delivered. (Are policies routinely followed? Are evidence-based medicine guidelines implemented? Does the transfer of patients occur in an organized manner?) *Work models* provide a conceptual framework for investigating events and processes so all contributing factors are evaluated. Plan-Do-Study-Act is an example of a conceptual framework. The premise of all work models is that an organized, systematic approach to event investigation results in reliable data that may be used to develop a new *system*.

Continuous quality improvement (CQI) is the continued process of reviewing and improving the processes and procedures associated with providing goods or services. It may evaluate structure, process, or outcome either as independent components of the CQI process or all simultaneously, because considerable overlap exists between the components and quality of care.

When evaluating the quality of health by comparing outcomes, it is important to understand the concept of *risk adjustment*. *Risk adjustment* allows statistical adjustment of patient differences, such as severity of illness, to make comparisons of outcomes clinically meaningful. This enables the translation of statistically significant tests into clinically meaningful results.

Errors and How They Occur

The pervasiveness of the medical error problem is enormous. In 1999 the IOM published *To Err is Human*. This report stated that medical error accounted for approximately 44,000 to 98,000 deaths annually

in US hospitals. This is more deaths than from AIDS, motor vehicle crashes, or breast cancer. The types of events included adverse drug events, improper transfusions, surgical injuries, wrong site surgeries, suicides, and mistaken patient identity. Most errors occurred in intensive care units, operating rooms, and emergency departments. The annual total cost was estimated to be between \$17 billion to \$29 billion. The cost of additional care was \$8 billion. This figure does not account for lost income and productivity. The IOM made many recommendations in this report, including a balanced approach between regulatory and market-based initiatives as well as the establishment of a national focus to create leadership, research, tools, and protocols to enhance the knowledge base about safety. It recommended raising performance standards and expectations for improvements in safety through the actions of oversight organizations, professional groups, and group purchasers of health care. An additional recommendation was to implement safety systems in health care organizations to ensure safe practices at the delivery level. In 2001 the IOM published the follow-up report, “Crossing the Quality Chasm.” Safety was deemed the key dimension of quality. Only a systems approach would work; trying harder was inadequate. A stepwise correction of problems in the system is the key to success. The culture of blame must be overcome: Human error was to be expected. Table 17-2 lists types of errors and their definitions.

Medical errors are not usually a single event or done by a single person. Normally there are numerous safe points and double-checks built into the process, but each layer of safety has gaps or “holes.” When these “holes” line up, the error reaches the patient. Standardized approaches can reduce variability and improve system efficiency. The goal is to make the holes as small as possible or even make them disappear. There are many factors associated with medical error, including human factors triggered by interruptions, fatigue, time pressures, anger, anxiety, fear, and boredom. Mistakes can result from a wrong plan of action. Mistakes involve misinterpretation of a problem, lack of knowledge, and habitual patterns of thought. A violation is the purposeful rule violation whether reasoned or reckless. The factors associated with risk are not the individuals who work in the system but rather the system in which the individuals work.

Table 17-2 Types of Errors in Health Care

<i>Error</i>	<i>Definition</i>
Diagnosis error	Error of delay in diagnosis; failure to employ indicated tests, the use of outmoded tests or therapy, or the failure to act on results of monitoring or tests
Treatment error	Error in the performance of an operation, procedure, or test; an avoidable delay in treatment or responding to an abnormal test or inappropriate/not indicated care
Medication error	Most frequent type of error; includes an error in the dose or method of using a drug
Prevention error	Failure to provide prophylactic treatment or inadequate monitoring or follow-up of treatment

Harm Versus Error

Our ultimate goal is to reduce patient harm. Early quality improvement efforts targeted the elimination of error. It had been believed that reducing error would decrease harm. This is not true; most medical errors never harm patients and may be clinically insignificant. One example would be the acetaminophen dose that is given 1 hour late. Why do we differentiate? Focusing on harm puts the microscope on the system not the individual.

Quality Improvement and Organizational Culture

“This is the way we do things around here.”

Patients expect to receive quality health care without experiencing preventable harm. The IOM has defined quality in health care as “the degree to which health care services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.” One of the things that influence quality in health care is organizational culture.

Many pediatricians are never taught about organizational culture. It is the invisible powerful dictator of how things are done in the organization. It is a latent and often unconscious set of forces that determine both our individual and collective behavior, ways of perceiving, thought patterns, and values. Hospitals have their own cultures. Subcultures also exist among physicians and nurses as well as within departments, such as critical care. It may be challenging to understand all of the hospital’s different subcultures.

Promoting change is rarely easy. Some people may adapt and change appropriately while others resist and become dysfunctional. In order to make changes, there must be an environment where teamwork can grow. “Group think” must be avoided. “Group think” is a term coined by Yale psychologist Irving Janis. It is “a way of thinking that people may adopt when they are members of a cohesive or homogeneous group; in particular, a group whose members seek unanimity of thought to the point that they cannot consider alternative ideas.” It can prevent critical thinking and debate. Without disagreement, creativity can be lost. Negative effects of “group think” include an illusion of invulnerability, insulated leaders who may be protected from contradictory evidence, and members who accept confirming data and reject data that fails to fit their views. Alternatives are not considered and individuals with conflicting views are discounted or demonized. Talented leaders welcome diversity of thoughts and ideas. Leaders must empower team members to have open discussions and offer ideas.

Communication is a key component of organizational culture. Communication involves 2 parts: message and meaning. Message is stated; meaning is interpreted and may be different between people. Strategies to improve communication are legion. Included in these strategies are methods for remaining calm in high workload, stressful situations. Other strategies include more verbalization, verbalizations that relate to problem-solving, speaking in first person plural, and coordinating tasks to the right person’s experience level. Good communication encourages input from team members.

Offering positive feedback builds confidence, reduces stress, and clarifies ambiguities. Team evaluations provide input on how well team members are communicating with each other and the progression toward achieving team goals. Benchmarking against a similar team may provide valuable information. An outside consultant may be used to observe the team and provide feedback. Internally, the use of informal, regular meetings to discuss the team’s progress and provide debriefing sessions to discuss the team process may be constructive in moving the team forward toward their goals and ensuring effective communication. Team conflict is experienced by all teams at one time or another. It happens when people come together to resolve a problem, discuss care improvement, or discuss changing processes to improve care. It needs to be managed effectively so issues at hand can be resolved while still providing the best quality patient care.

Teamwork has been defined by numerous organizations. The IOM in 2003 used this definition: “All healthcare professionals should be educated to deliver patient-centered care as members of an interdisciplinary team, emphasizing evidence-based practice, quality improvement approaches, and informatics.” The IOM defines a multidisciplinary team as one in which members cooperate, communicate, and integrate care to ensure that patient care is continuous and reliable.

Measuring Quality

Ideally, measurements should evolve from the IOM quality aims: timeliness, efficiency, effectiveness, safety, equity and patient-centeredness (Box 17-3). Improvement measures may not be sufficiently valid and reliable for public dissemination yet may still be useful for benchmarking, to identify best practice, or as part of quality improvement initiatives.

Adult measures may not be appropriate for pediatrics. Pediatrics is unique due to heterogeneity, including age, size, diagnoses, and treatment modalities including medication dosing.

Measures must be reliable. The definition of reliability is the ability of the measure to perform similarly under stated conditions over time. In health care, reliability is often used interchangeably with the concept of precision. Precision is the ability of a measurement process to reproduce its own outcome. To achieve precision, a reliable system requires clear and concise definitions of the data fields to be collected. An effective approach is to train data collectors. There must also be a robust method for data coding and entry. Reliability needs to be intermittently assessed within and between observers over time to ensure consistency.

Measures must also be valid. A measure is valid if it adequately represents the attribute of interest. Internal validity is the soundness of the developed indicator. External validity is the ability of the indicator to be applied to a broader population.

Box 17-3. Institute of Medicine Quality Aims

Timeliness	Safety
Efficiency	Equity
Effectiveness	Patient-centeredness

Measures must be feasible and usable. Feasibility is the actual ability to gather the measures. For a measure to be usable, the intended audience must be able to understand the findings and use them in an appropriate fashion. It is usable if it is able to uncover meaningful differences between groups.

Three types of measures are essential to quality improvement.

1. Outcomes measures: Address how the health care services provided to patients affect their health, functional status, and/or satisfaction.
2. Process measures: Address the health care services provided to patients.
3. Balancing measures: Evaluate unintended consequences or the stability of the system being changed in the project.

A balanced set of measures for a quality improvement effort should include at least one outcome, one process, and one balancing measure.

Error Metrics

How does one measure harm?

How does one measure safety?

Measuring harm is often done with occurrence reports. This identifies 2% to 8% of all adverse events in an inpatient setting. It may be done with retrospective, concurrent, or trigger-based chart review. There are no standardized methods for reporting, investigating, or disseminating information related to preventable adverse events. In the past, the qualitative concept of patient safety has been translated in quantitative metrics. Three frameworks that have been used include measuring error, measuring patient injuries, and measuring risk.

Error-based patient safety metrics are premised on the idea that the goal of medicine is to successfully implement the correct plan of care. It is an attractive measure of assessing safety because many errors occur and are somewhat easy to find. There are many problems with error metrics as very few measures of error represent the true rate.

$$\text{Error rate} = (\text{identified errors}) / (\text{potential opportunities for that error to occur})$$

The numerator (identified errors) may be hard to obtain, since with reported events one only knows the errors reported not the actual number of occurrences. Therefore, it is nothing more than a rate of reporting.

Some other modalities proposed to get the true numerator include chart review. The difficulty with chart review includes the number of steps in the process: error occurs, each error is recognized by a provider, the error is documented by a provider, the chart is reviewed, the reviewer recognizes the event during the chart review, and the error is attributed correctly. Ethnographic study, the direct observation of people, has the same pitfalls.

Other confounders include hindsight bias. For problems to be effectively rectified, the correct understanding and attribution of events that created the error must occur. The retrospective analysis

of error creates the potential for incorrect or simplistic identification of causes for events. “Subsystem” failures are difficult to identify as a contributing cause to an adverse event. The incorrect or inadequate attribution of causality creates the potential for misguided actions to “solve” the wrong problem.

Focusing solely on active errors leaves the latent failures and the whole system more vulnerable to adverse events. Identifying errors is important, but solely focusing on errors may lead to the “blame game.” Trends may be a barometer for the organization’s culture as it relates to patient safety. Identified errors provide learning opportunities, preventing harm to other patients.

Injury-based patient safety metrics focus on unintended outcomes, such as catheter-related bloodstream infections, ventilator-associated pneumonia, in-hospital cardiac arrest, and deaths. Improvement efforts are more likely to focus on system vulnerabilities with a high potential for adverse events.

Risk-based patient safety metrics are a measurement of hazards or risks. Using a systems view, errors and injuries are the result of hazards or risks within the system of care. The focus is on hazardous conditions that increase the likelihood of downstream errors. Efforts are centered on 3 core areas: (1) systematic risk identification, (2) risk assessment, and (3) risk reduction/elimination. It is proactive and it saves counting errors and injuries (makes it less important). The elimination of risk includes the substitution of less risky alternatives, the development of administrative controls, and individual protection. It incorporates information gathered from the frontline bedside provider. The focus on risk reduction may decrease the need to quantify error rates or injury prevalence. This requires a shift in thinking from counting errors and injuries to proactively identifying risk. The intent is to identify systems-level problems that may be amenable to quality improvement efforts.

Patient Safety/Error Prevention

The Institute for Safe Medication Practices has developed a rank order of error reduction strategies. They range from most effective (forcing functions and constraints) to least effective (education/information). In between are strategies such as (in order from most effective to least effective) automation and computerization, standardization and protocols, checklists and double-check systems, and rules and policies.

Education and information dissemination are important and helpful; they increase awareness. However, lectures are quickly forgotten and signs are often ignored. It is the least effective means to prevent the occurrence of error. Rules and policies are required by several agencies. They are a good resource but not an effective means of preventing a specific event.

Checklists and double-check systems are very effective when they are a routine part of practice but they are not foolproof. The best example of a double-check system is the surgical sponge and instrument counts done at the end of a surgical case. Checklists are also being used for other procedures like central line placement. Standardization minimizes the risk of error, and protocols bring a

standard approach to a clinical issue. They are designed to eliminate variation from practitioner to practitioner and patient to patient. Weak points may still exist and be prone to error. Automation and computerization are 2 of the best means to prevent medical error from occurring. They are only as safe and good as the person entering the data. Forcing functions and constraints is the best way to prevent error through safeguards. In this manner, systems and products are engineered to be safer from the ground up.

Plan-Do-Study-Act cycles are one way of developing and implementing change leading to improved patient safety and quality of care. Plan-Do-Study-Act cycles force small-scale, stepwise thinking; allow for making predictions; force thoughtful deliberation on the increased knowledge; and subsequently facilitate change. The use of small-scale change can cause rapid adaptation and implementation of change in various health care settings.

Conclusions

The key elements to a system change are (1) the will to do whatever it takes to make a change to a system, (2) the ideas on which to base the design of the new system, and (3) the execution of the changes to the system. Change is difficult, but sustaining change is even more complex. Hardwiring sustainability into a new system is imperative. The “old way” has to be more difficult or inconvenient to perform. In health care, spreading improvements depends on key individuals; one critical success factor for spread is the role of leadership. Leaders must inspire and communicate a shared vision; model the way; challenge the current process; no longer accept the status quo; and enable others with resources, training, and time. The successes must be celebrated.

CASE RESOLUTION

During your staff meeting, you decide to use a PDSA cycle to examine the practice's vaccine administration practice, identify barriers to timely vaccine administration, and develop a plan to ensure that vaccines are administered in a timely fashion.

Plan: The charts of all patients seen for routine care in the past 3 months are pulled. The charts are audited using a premade check sheet to identify vaccines given, vaccines missed, and barriers to administration. After analyzing the data, it becomes clear that many opportunities for immunization were missed due to inability to get parental consent. This seemed to coincide with a television program that discussed increasing rates of autism associated with vaccination.

Do: At your next routine staff meeting, you present the data to your colleagues. You recommend rebutting the television show with a fact sheet and a discussion with the parents that is done by the physician. Your colleagues agree to implement this change since it is low cost and easy to put into practice.

Study: Three months after implementation, you re-collect data and find there are fewer missed opportunities for immunization and your program has had some success. Some parents are still resistant to immunizing their children for fear of autism.

Act: You present the follow-up data to your colleagues and they agree to implement the current strategy. The data will be reexamined in 3 months to see if the program continues to be effective.

Neonatal Examination and Nursery Visit

Julie E. Noble, MD

CASE STUDY

You are performing a newborn examination on a 16-hour-old infant who was born at 39 weeks' gestation to a 28-year-old healthy primigravida via normal spontaneous vaginal delivery. There were no complications at delivery and Apgar scores were 8 at 1 minute and 9 at 5 minutes. The infant weighed 7 lb, 1 oz (3,200 g) and was 19.7 inches (50 cm) long at birth with a head circumference of 34 cm. The mother received prenatal care beginning at 10 weeks' gestation; had no prenatal problems, including infections; and used no drugs, alcohol, or tobacco during the pregnancy. Her blood type is O positive. She is negative for hepatitis B surface antigen, HIV, and group B streptococcus and nonreactive for syphilis. The father is also healthy.

On physical examination, the infant is average size for gestational age with a length and head circumference in the 50th percentile. Aside from small bilateral subconjunctival hemorrhages, the rest of the physical examination is entirely normal.

Questions

1. What parts of the maternal history are important to review before performing the infant's physical examination?
2. What further history is important for a complete newborn assessment?
3. What aspects of the physical examination of newborns are essential to explain to parents?
4. What physical findings mandate a more extensive workup prior to discharge?
5. What is the routine hospital course for a normal newborn?
6. What are important points to cover with parents at the time of discharge for a normal term newborn?
7. What laboratory studies, if any, should be performed prior to discharge?

The newborn physical examination is an important first encounter with the pediatrician, the infant, the mother, and infant's father, if available, all establishing relationships with each other. The key purpose of this examination is to assess the status of the infant and detect any underlying medical problems. Relaying this information to the parents is essential and answers the question foremost in a parent's mind: "Is the baby normal?" By performing a physical examination in the parents' presence during the infant's first 24 hours of life, pediatricians can play a major role in allaying parental anxiety. More than 90% of newborns are normal, but the pediatrician's role includes identifying medical problems or high-risk conditions in the newborn examination and the history. Evaluation and treatment, if necessary, can be initiated before discharge from the nursery.

Pediatric Prenatal Visit

Ideally, the pediatrician has spoken with the parents at a prenatal visit before meeting them in the hospital. The prenatal meeting provides an opportunity for the parents to interview the physician, as well as the rest of the office staff, regarding general policies and procedures for well-child appointments, sick visits, and contacting the

physician after hours. It also is a time to discuss what will take place at the hospital and explain the role of allied health care professionals (eg, lactation specialists) in the overall care of the mother and newborn. For pediatricians and other health care practitioners, the prenatal visit is a time to gather vital medical information regarding the current pregnancy, identifying any high-risk conditions, and to inquire about any problems with previous deliveries. The pediatrician should also review any pertinent family history. In addition, the pediatrician needs to note specific needs of the parents, which may include cultural rituals or ceremonies surrounding the birth of an infant, such as circumcision. Whether the infant is born at a birthing center or in the more traditional hospital setting, arrangements should be made to accommodate the wishes of the family. The prenatal visit also allows physicians to assess any psychosocial issues that may negatively influence initial maternal-infant bonding, such as maternal drug use, no paternal involvement, the absence of a supportive social network, or lack of housing. All of these issues will necessitate social service intervention. The social environment that will surround the infant at home will have a great impact on his future.

This appointment is the ideal time to emphasize the importance of breastfeeding and educate the mother to its many benefits. Anticipatory guidance issues, including positioning the infant on his back to sleep, safe bedding, and child passenger safety, can also be discussed.

Neonatal Nursery Visit

At the time of birth, the infant will receive a screening examination and risk assessment by the nursery personnel when he is stable after any needed resuscitation. If there are no noted abnormalities, the pediatrician is notified of the birth, and the recommendation from the *Guidelines for Perinatal Care* notes that he should evaluate the infant within 24 hours. Meanwhile, in the delivery room, the infant is dried and placed skin to skin on the mother's chest, with a blanket placed over both the mother and infant, to facilitate bonding and early breastfeeding.

If there are perinatal or delivery complications, such as maternal fever, meconium aspiration, asphyxia, prematurity, obvious infant malformations, or distress, the infant should be supported as necessary and kept on a radiant warmer for assessment. The physician should promptly be notified to perform the newborn physical, evaluating the abnormality and initiating treatment.

Evaluation

Perinatal History

The perinatal history is the beginning of the infant's medical history and is very significant to the newborn evaluation. To obtain all of the pertinent history, it may be necessary to review the maternal medical record. Results of maternal laboratory tests, such as blood type; rapid plasma reagin status; purified protein derivative; HIV and hepatitis B status; and chlamydial, gonococcal, and group B streptococcus cultures, should be noted (Questions Box). The pediatrician should also obtain triple screen, prenatal ultrasound, and amniocentesis results if performed. Delivery room events and Apgar scores should also be reviewed before performing the physical examination of the neonate. This review helps the physician focus the examination on findings suggested by the previous medical history. The occurrence of any unusual circumstances surrounding the delivery should be explained to the parents at the time of the examination. They may not have understood the need for a vacuum-assisted delivery or emergent cesarean section. It is important to be prepared to discuss the medical implications of such events.

Physical Examination

Every attempt should be made to perform the neonatal physical examination at the mother's bedside. This gives the physician the opportunity to meet with parents and gives parents a chance to have all of their initial questions answered immediately. In certain circumstances, such as when the infant is premature or when the mother is being treated for a medical complication, an initial bedside

Questions

Neonatal Examination

- Did the mother receive prenatal care? If so, since what month of gestation?
- Were all prenatal studies normal?
- Does either parent have a history of sexually transmitted infections, such as syphilis, gonorrhea, or herpes?
- Does either parent have a history of alcohol, tobacco, or illicit drug use?
- Did the mother take any prescribed or over-the-counter medications routinely during pregnancy?
- Did the mother have any complications, such as bleeding or decreased fetal movement, during pregnancy?
- Were there any indications of a complicated delivery?
- Is there a family history of congenital anomalies or diseases?
- Is the mother planning to breastfeed?
- Does the neonate have any siblings? If so, what are their ages?
- Is anyone available to help with the new baby or siblings?

examination may be impossible to perform. In any event, the physician or other health care provider should speak to parents about the results once the examination has been completed.

The neonatal examination should be performed with the infant completely unclothed and the infant's body temperature maintained. The infant should be assessed for evidence of birth trauma and congenital malformations, and an assessment of normal physiology of organ systems should be done. The infant's birth weight, length, and head circumference should be plotted; physicians should keep in mind that these measurements are often made in the delivery room and may be subject to error. The diagnosis of small for gestational age (weight less than 10th percentile) or large for gestational age (weight greater than 90th percentile) can predispose the infant to several medical problems. Temperature, respiratory rate, and heart rate should be reviewed via the nursery record. Feeding, voiding, and stooling patterns are also available in the nursery record.

The infant evaluation should include an expanded Ballard score, which includes parameters for neuromuscular and physical maturity to accurately estimate gestational age. A late preterm or near term infant, from 35 to 38 weeks' gestation, frequently does not have the physiological maturity to feed vigorously and maintain body weight or heat. These infants are at high risk for readmission for treatment of jaundice, dehydration, and hypoglycemia. They should be followed very closely.

The infant's overall appearance should be noted, particularly for the presence of any dysmorphic features. Physicians should determine whether the infant looks normal or has any abnormal facial features, such as low-set ears and widely spaced eyes (see Chapter 69).

Skin

The presence and location of any rashes or birthmarks should be carefully described and pointed out to the parents. The particular location of the lesion as well as the pathology of the epidermal lesion may aid in its specific diagnosis. Skin lesions from birth trauma must be documented and treated as necessary. Bruising should be differentiated from the benign mongolian spots from dermal hyperpigmentation. Skin color should also be noted: Cyanosis may be indicative of congenital heart disease, the presence of jaundice suggests hyperbilirubinemia, or plethora may be a sign of polycythemia.

Head

Head size and shape, including the size of the fontanelles and the position of the sutures, should be evaluated. The head may be significantly molded into a cone deformity secondary to pelvic pressure at the time of delivery. This resolves within days after birth, and with its resolution there may be a significant change in the head circumference. A cephalohematoma, which is a subperiosteal bleed that does not cross the suture line, appears as a unilateral or bilateral discrete lump on the side of the head. This finding may predispose the infant to hyperbilirubinemia, and resolution may take up to 2 months. A cephalohematoma should be differentiated from a caput succedaneum, which is scalp edema that crosses the midline, and may be ballotable. Edema usually resolves rapidly. Skull fractures may occur with birth trauma and may present as a step-off or crepitus on palpation of the skull. All head findings may be a source of concern to parents.

Eyes

The eyes should be evaluated for subconjunctival hemorrhages, colobomas, extraocular movements, and the presence of red reflexes. If it is not possible to elicit a red reflex, an ophthalmologic evaluation is essential. Its absence suggests conditions such as congenital cataracts or retinoblastomas.

Ears

The placement, size, and shape of the ear pinnae should be noted as well, along with any preauricular or postauricular pits or appendages. The presence of a significant auricular abnormality may correlate with hearing loss or suggest a genetic syndrome.

Nose

The nose should be checked carefully for patency of both nares. This can be easily accomplished by occluding airflow from one nare and observing airflow from the other. Choanal atresia is an important condition to rule out because infants are obligate nose breathers until 3 months of age, and choanal atresia may lead to respiratory distress. A nasal fracture can also occur during the delivery process. This presents as an asymmetrical nose. If the physician presses on the nasal tip and the nares are symmetrical, then the diagnosis is a deformity that will resolve. If the nose falls to one side, there is a probable nasal septum fracture that should be evaluated by an otolaryngologist.

Mouth

The oropharynx should be examined closely for any defects in the hard or soft palate. A bifid uvula may indicate a submucosal defect of the soft palate that may be difficult to appreciate without palpation (see Chapter 70). Common normal findings in the oropharynx, including Epstein pearls located at the midline on the hard palate and epithelial cysts along the gum line, should also be noted. Loose natal teeth should be removed to prevent the possibility of aspiration (see Chapter 71). The tongue should be evaluated for macroglossia or a tight lingual frenulum, which may interfere with effective breastfeeding.

Chest

The neck should be palpated for sternocleidomastoid hematomas and the clavicles for fractures, which are more common in infants who are large for gestational age (LGA) or a delivery complicated by shoulder dystocia. The chest should be inspected for respiratory effort and lungs auscultated to ensure normal breath sounds throughout. The quality of the infant's cry should be assessed. Laryngeal webs or a paralyzed vocal cord may present in the newborn. Chest wall deformities, such as pectus excavatum, should be noted. If an absent rib is suspected, a radiograph is needed. The presence of breast buds is normal, but supernumerary nipples are minor malformations, although no treatment is indicated. Widely spaced nipples are a common minor malformation in patients with Turner syndrome.

Heart

The heart should be auscultated to ensure that it is in the proper position on the left side of the chest. Cardiac murmurs should be appreciated and documented. The presence of a murmur does not always indicate complex congenital heart disease. In the first 24 hours, a murmur may be a closing ductus, and newborns can also have functional murmurs. Peripheral pulmonic stenosis is a common benign heart murmur in the newborn that is characterized by transmission to the back. Every murmur should be evaluated on an individual basis. If assessment is indicated, 4 extremity blood pressures, a pulse oximetry reading, an electrocardiogram (ECG), and a chest radiograph should be obtained. If there are abnormal findings or the murmur is associated with cyanosis, tachypnea, poor feeding, or congenital anomalies there is high suspicion of a pathologic cause. A consult from specialists in pediatric cardiology should be sought and an echocardiogram obtained.

Abdomen

The abdomen is easiest to palpate prior to feeds. It should be assessed for any masses or organomegaly (eg, polycystic kidneys, hepatosplenomegaly, adrenal hemorrhage) that warrant further investigation. Bimanual palpation may be helpful to identify masses. The umbilicus should be examined to identify 3 vessels as well as the quality of the cord. A small, atretic cord can explain a low weight in the infant. Erythema and swelling of the skin around the cord may indicate oomphalitis, a serious infection.

Genitalia

In female neonates, the labia majora may be swollen, but the urethra and vaginal opening should be visualized to ensure patency. It is not uncommon to see hymenal tags. Clitoral size should be noted. Parents should be told that a physiological vaginal discharge and the presence later of a pink or blood-tinged discharge are a normal neonatal response to maternal estrogen withdrawal. In male infants, the penis should be examined for size and length. The foreskin should be retracted sufficiently to reveal the location of the urethral meatus to assess for hypospadias. A testicular examination can rule out hydroceles, inguinal hernias, and cryptorchidism.

Skeleton

The infant skeleton should be assessed for evidence of a skeletal dysplasia. All long bones should be examined for a potential fracture secondary to birth trauma. The infant hip examination is important to detect developmental dysplasia of the hip, seen more commonly after a breech position in utero. The Ortolani test is performed to detect a dislocated hip. The “clunk” felt when performing the examination is the relocation of the femoral head of the affected hip in the joint capsule. In contrast, a “click” may indicate normal perinatal ligament laxity. The Barlow test detects an unstable dislocatable hip. If either test is positive, it is diagnostic for a dislocated or dislocatable hip and warrants an orthopedic consultation. Treatment with a Pavlik harness is initiated until confirmatory testing by an ultrasound is reliable at 6 weeks of age. The spine should be palpated completely to the sacrum. Sacral defects, deep sacral pits, or sacral tufts of hair warrant an investigation for such conditions as spina bifida occulta. Fingers and toes should be counted and assessed for syndactyly. The feet may be turned inward, outward, or up and should be gently moved to a normal position to ensure flexibility. Deformities secondary to intrauterine pressure are common. Clubfoot or equinovarus deformations should receive orthopedic evaluation.

Neurologic Examination

An infant's resting position should be assessed to evaluate tone. All extremities should be flexed. The infant then can be held prone under the shoulder girdle for further evaluation of tone, and extremities should continue flexed. Infants should be observed for motor activity, moving arms and legs symmetrically. Response to sensory stimulation and deep tendon reflexes should be elicited. Facial movements should be closely observed for symmetry. Primitive reflexes, such as suck, rooting, grasp, stepping and, especially, Moro, are an important part of the newborn neurologic examination. The behavior of the infant can also yield information regarding an intact neurologic system. He should respond to sound, fixate on a face, and be capable of attempts at self-consolation.

Normal findings of the nursery physical examination are summarized in Box 18-1. Significant findings that must be addressed immediately when noted at the initial nursery examination include evidence of hydrocephalus, a ductal-dependent cardiac lesion, a diaphragmatic hernia, an abdominal mass, or a possible chromosomal abnormality such as trisomy 13 or trisomy 18, which can all

Box 18-1. Common Benign Physical Findings in Newborns

Skin

Milia, erythema toxicum, salmon patch, nevus flammeus, hemangiomas, mongolian spots, lanugo (body hair)

Head

Cephalohematoma, caput succedaneum

Face

Swollen overall appearance, minor malformations

Eyes

Swollen eyelids, subconjunctival hemorrhages

Ears

Preauricular appendages/pits, folded pinnae

Nose

Flattened nose, milia over bridge

Mouth and Throat

Epstein pearls, epithelial pearls, natal teeth, shortened frenulum

Chest

Supernumerary nipples, breast buds, galactorrhoea, pectus excavatum or carinatum

Genitalia

Females: swollen labia, hymenal tags, vaginal discharge
Males: hydrocele, undescended testicle (palpated in inguinal canal)

Hips

Click

Extremities

Feet turned up, in, or out, but malleable

Neurologic Examination

Primitive reflexes: Moro, grasp, rooting, stepping

be life-threatening. The physical conditions associated with trisomy 21 are rarely life-threatening, although suspicion of the diagnosis does warrant a genetics consultation and evaluation for cardiac and abdominal anomalies (see Chapter 37).

Laboratory Tests

Few laboratory tests are needed for the normal newborn. The only test that all US newborns receive is the state mandated newborn screening test prior to discharge from the nursery (see Chapter 20). Heel stick blood usually is evaluated for inheritable conditions, such as phenylketonuria, galactosemia, hypothyroidism, hemoglobinopathies, cystic fibrosis, congenital adrenal hyperplasia, and a panel assessing inborn errors of metabolism. The newborn screen varies by state and depends on the prevalence of a particular disease in a given region (see Chapter 20), but there is a federal effort to standardize testing. In all states, hearing screening is also part of the mandated newborn screening. Screening methods may be by automated auditory brain stem response, otoacoustic emission testing, or conventional auditory brain stem response.

Other laboratory tests that are often performed in a newborn include a serum glucose in infants at high risk for hypoglycemia (which includes infants who are small for gestational age or LGA, infants of diabetic mothers, and infants who are symptomatic). A hematocrit is necessary in jaundiced, pale, or ruddy-appearing newborns and in twins. In cases of ABO or Rh incompatibility, a serum bilirubin and a Coombs test are important to obtain. Screening for hyperbilirubinemia to prevent kernicterus is recommended for all newborns, but recent evaluations of this testing have not demonstrated efficacy. Bilirubin screening can be done easily by a transcutaneous reading followed by a serum level if the transcutaneous reading is elevated (see Chapter 113).

Imaging Studies

Routine radiographs are not indicated in neonates whose examination is normal and should be ordered only if indicated by the examination. Some minor malformations, such as pectus excavatum, do not need radiographs. Vertebral radiographs or ultrasound of the lumbosacral spine is appropriate in the neonate with a deep sacral pit or sacral tuft of hair for the diagnosis of spina bifida occulta. Clavicular radiographs are indicated if swelling or pain is located in the clavicular area or if an asymmetrical Moro reflex is elicited. A chest radiograph and ECG are warranted for a significant murmur. If multiple anomalies are found, a renal ultrasound looking for malformations of the kidneys should be performed. More extensive studies are indicated if an emergent physical finding is discovered.

Management

After stabilization in the delivery room, the infant should be thoroughly dried and given to the mother for breastfeeding and bonding. If mother and baby are healthy, the infant should stay with the mother, receiving an initial bath when the temperature is stable. The administration of intramuscular vitamin K to prevent hemorrhagic disease of the newborn and the application of ophthalmic ointment or silver nitrate in the newborn's eyes to prevent gonorrhoeal infection is universal. Hepatitis B vaccine is recommended for all infants at birth regardless of mother's serology. Every hospital should encourage rooming-in of the infant with the mother. The infant should feed within 2 hours of birth and continue to feed every 2 to 3 hours to prevent hypoglycemia. The preferred method is breastfeeding, and the mother should receive sufficient postpartum support to ensure success (see Chapter 24). Vital signs should be monitored every 30 minutes until stable during the transition to extrauterine life, then every 4 hours. Daily weights as well as strict documentation of voiding and stooling are necessary to monitor the infant for adequacy of intake and for dehydration. Umbilical cord care remains an area of controversy, and it appears that leaving the cord to dry is a sufficient treatment.

If desired, the circumcision is usually performed on the day of discharge (see Chapter 22). Local anesthesia is now universally recommended for the procedure. Following the procedure, the parents are instructed to leave the gauze or Plastibell in place. It will fall off

spontaneously. Petroleum ointment may also be placed on the corona of the penis to prevent its sticking to the diaper. The physician should be notified if excessive bleeding or oozing occurs (eg, soaking of the diaper with blood) after discharge from the nursery.

Discharge Planning and Counseling

In most cases, mother and infant should be discharged home together. The general hospital stay is 48 hours for a vaginal delivery and 96 hours for a cesarean delivery. The physician should examine the infant again within 24 hours of discharge to identify problems that might have developed as well as counsel the mother. Again this examination is best performed at bedside. The infant's physical findings and hospital course should be reviewed with the mother and father. If studies other than routine neonatal screening were performed, the parents should also be informed of the results.

Discharge is the best time to review anticipatory guidance issues. Topics that should be covered at the bedside include feeding patterns and what to expect, sleeping and elimination patterns in the newborn, umbilical cord care, bathing the newborn, and safety issues such as car safety seats and sleeping position. Guidelines regarding symptoms of illness and when to call the office or emergency department should also be addressed. These include a rectal fever of 100.4°F (38.0°C) or greater, respiratory distress, irritability, lethargy, decreased feeding, and evidence of dehydration. If parents have any concerns about their infant, they should be encouraged to call the physician's office. A follow-up visit should be arranged at day 3 to 5 of life for any breastfeeding infant, to give breastfeeding support as well as to assess the infant for evidence of jaundice or dehydration. An early follow-up appointment may also be indicated in an infant with social risk factors and near term infants who are at higher risk for complications. If the infant is delivered by cesarean section or is formula feeding, a follow-up visit at 1 to 3 weeks after discharge is appropriate.

Early newborn discharge is an option if desired by the mother. There are published recommendations from the American Academy of Pediatrics for guidance regarding discharge at younger than 48 hours of age. Generally the history, including social risk factors, physical, and hospital course, should all be low risk and the infant should have been observed for at least 12 hours. If the newborn is stable and sent home at less than 48 hours, a mandatory follow-up appointment should be scheduled in 2 days.

CASE RESOLUTION

In the case presented at the beginning of the chapter, the parents should be told that the weight, length, and head circumference are all normal. The examination is reviewed at bedside and the subconjunctival hemorrhages should be shown to the parents and their benign self-limited nature explained. The infant's blood type from cord blood should be obtained since the mother is O⁺. Routine neonatal screening, feeding, sleeping, elimination, bathing, and safety should be reviewed. Prior to discharge, the infant should receive the hepatitis B vaccine and newborn screening tests. A follow-up appointment should be made in 48 hours after discharge to follow breastfeeding progress.

Peripartum Depression: The Role of the Pediatrician

Carol D. Berkowitz, MD

CASE STUDY

You are evaluating a 3-week-old infant who is the product of a 39-week gestation to a 30-year-old gravida I para I mother who has been breastfeeding the infant. The birth weight was 3,650 g, and the baby now weighs 3,380 g. The mother expresses concern about her ability to breastfeed. She also admits to being exhausted and feeling detached from the baby and overwhelmed by being a mom, something she had looked forward to since she was a little girl. She has difficulty concentrating and has no appetite. She asks you if it is normal to feel this way.

Questions

1. What are the signs and symptoms of peripartum depression?
2. What are the risks to infants of mothers who experience peripartum depression and other mood disorders?
3. What is the role of the pediatrician in assessing mothers for peripartum depression?
4. What screening instruments are available to assist in assessing mothers for peripartum depression?
5. What resources are available to offer to mothers who may be experiencing peripartum mood disorders?

Peripartum depression is the term used to encompass a cadre of mental health problems that mothers may experience either during pregnancy or following the birth of a baby. Despite public disclosures and open discussions by celebrities such as Brook Shields and Gwyneth Paltrow, the condition is under-recognized, and many mothers go undiagnosed and untreated. The pediatrician is in an ideal position to assess a mother for the presence of these symptoms following the birth of a baby since the pediatrician usually sees the mother–infant dyad prior to the obstetrical postpartum visit at 6 weeks following the baby’s birth. The recommended time points for screening for postpartum depression coincide with well-baby checks: 2 weeks, 2 months, and 6 months. In addition, women are likely to follow up with their child’s physician appointments more than their own. While fatigue is a common complaint of new mothers as well as new fathers, other symptoms, particularly those of impaired functioning and diminished ability to care for the infant, may suggest a more significant disturbance.

Epidemiology

The incidence of peripartum depression varies with the population studied, with the estimated range being from 5% to 25%. Between 14% and 23% of pregnant women experience depressive symptoms while pregnant, and approximately 13% of women take an antidepressant at some time during their pregnancy. The prevalence is felt to be much higher at 40% to 60% in certain groups, including

low income women, certain ethnic minorities (including Latina and African American), pregnant and parenting teenagers, mothers of multiple births, and women who served in the military in Iraq and Afghanistan. The World Health Organization notes that depression is the fourth leading cause of disease burden in the world. In spite of the high prevalence across all groups, fewer than 50% of cases of maternal depression are identified.

Often there is reluctance on the part of obstetricians or psychiatrists to treat pregnant women with antidepressants because of concerns about the potential effects of the medications on the developing fetus. These effects include fetal malformations, cardiac defects, pulmonary hypertension, and reduced birth weight. However, untreated depression and anxiety in pregnancy also increase the risk of preterm delivery, low birth weight, and infants’ own ability to regulate emotions and stress. The American College of Obstetricians and Gynecologists and the American Psychiatric Association have issued joint guidelines on the management of pregnant women with depression, which discuss the indications for psychotherapy as well as psychopharmacology in the pregnant woman. Pediatricians are usually not involved in this part of the decision-making process but should be knowledgeable about the possible complications that the infant may experience following birth from either exposure to antidepressants or to untreated maternal mental illness. Approximately 6% to 10% of fathers experience peripartum depression, with the highest rates seen between 3 and 6 months following the birth of the baby. Paternal rates of depression are higher when there is maternal

depression, and the impact on the infant is greater than if the father is not affected. Depressed fathers have a higher rate of substance abuse.

There is a wide range of symptomatology that can be categorized under peripartum mood disorders (Box 19-1). **Baby blues** or **maternity blues** is used to describe the very common experience of new mothers, said to affect 50% to 80% of postpartum women in the first few days after delivery. There is no *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition Text Revision (DSM-IV-TR)* categorization of “baby blues.” Generally symptoms improve over 1 to 2 weeks, and functioning is not impaired, though “baby blues” may herald later depression. Mothers experience sadness, crying, mood swings, anxiety, and worrying.

A diagnosis of **postpartum depression** meets the criteria of depression according to *DSM-IV*, which include a depressed mood, diminished pleasure (anhedonia), changes in appetite and sleep, psychomotor agitation or retardation, fatigue, feelings of worthlessness or inappropriate guilt, decreased ability to concentrate, and recurrent thoughts of death or suicide. Suicide is the leading cause of death in mothers during the first year postpartum. Technically, symptoms of depression must begin within 4 weeks of delivery and may persist

Box 19-1. Peripartum Mood Disorders Symptomatology

“Baby Blues”

- Sadness
- Crying
- Mood swings
- Anxiety
- Worrying
- First few days after delivery
- Resolves in 1–2 weeks

Postpartum Depression

- Meets *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* criteria for depression
- Depressed mood
- Diminished pleasure
- Change in appetite
- Change in sleep
- Fatigue
- Feelings of worthlessness or guilt
- Inability to concentrate
- Recurrent thoughts of death or suicide

Postpartum Psychosis

- Severe impairment
- Paranoia
- Mood shifts
- Hallucinations
- Delusions
- Suicidal/homicidal ideation
- Usually requires hospitalization

for 1 year, though the onset is often insidious and doesn’t come to attention until much later than a month postpartum.

Postpartum psychosis is less frequent, occurring in 1 to 3 per 1,000 deliveries also within the first 4 weeks after delivery. There is severe impairment, with paranoia, mood shifts, hallucinations, delusions, and suicidal and homicidal ideation. Sometimes there is a history of a preexisting bipolar disorder. Affected mothers require hospitalization, in part because the infanticide rate is 4% to 5%.

It is estimated that 400,000 infants are born to mothers who are depressed. These infants are at risk for a host of adverse physical and developmental consequences.

Pathophysiology

The precise pathophysiology of maternal depression has not been elucidated, but sleep deprivation related to the demands of caring for a new infant and hormonal changes are felt to be contributing factors. While there are rapid decreases in the levels of estrogen, progesterone, and cortisol, the changes noted in mothers who experience peripartum depression do not differ from women who do not experience peripartum depression. Perhaps more significantly, there are a number of risk factors that have been associated with its development. These include prior history of depression in general, but especially during a previous pregnancy; mood disorders, including premenstrual dysphoric disorder; substance abuse; alcohol dependence; low socioeconomic status; lack of social support or community network; unintended or unwanted pregnancy; or a family history of depression. Other social/familial factors include marital discord, divorce, and violence.

Evaluation

Mother

Screening for peripartum mood disorders is felt to be within the scope of the pediatric practice. Studies have shown that mothers are comfortable being queried by pediatricians about how they are doing. Some pediatricians express concern about the appropriate strategies for screening and what to do if they determine that a mother has symptoms of depression.

It is important to couch any depression screening in language that makes a new mother feel comfortable and not judged in any way. Postpartum Support International has developed the “Universal Message” to share with depressed new mothers: (1) You are not crazy; (2) you are not alone; and (3) with the right help, you will get better.

There are several instruments that help screen for postpartum depression. A simple tool, called the Parent Health Questionnaire-2, consists of 2 questions. The questionnaire begins with a background statement related to depression as a common and treatable condition that often goes unrecognized. There follows justification citing the recommendation of the US Preventive Services Task Force that all adults be checked for depression. The questions then are as follows: Over the past 2 weeks, you have felt down, depressed, or hopeless (true or false). Over the past 2 weeks, you have felt little interest or

pleasure doing things (true or false). If true, have you felt this way for (several days, more than half the days, or nearly every day)? If either of these questions is positive, a more extensive assessment is indicated to make the diagnosis of depression.

A second instrument is the Edinburgh Postnatal Depression Scale (EPDS). A sample question from the scale is given in Box 19-2. The scale was developed in 1987 and consists of 10 questions completed by the mother. The mother is asked to check the response that comes the closest to how she has been feeling in the previous 7 days, with there being 4 choices ranging from “often” to “never.” All items must be completed, and the mother must respond by herself, without the assistance of another unless she has limited English skills. The maximum score is 30. A score greater than 10 indicates risk for depression. A positive response to question 10, which asks about suicidality by itself, is considered a positive screen. The instrument is available in more than 40 languages.

Infants and Children

Infants and children may experience a number of problems as a consequence of maternal depression. These children may develop disorders of attachment, particularly insecure attachment, and they are at risk for the subsequent development of conduct or other behavior disorders. Language development may be adversely affected since depressed mothers speak fewer words and have fewer social interactions with their children. Maternal depression has also been associated with the decision not to breastfeed or the early cessation of breastfeeding. Classic environmental failure to thrive can be related to maternal depression and reduced mother–infant interactions. The effects of maternal depression can be detected in 2-month-old infants who regard depressed mothers less frequently, have poorer state regulation, interact with objects less frequently, and have lower levels of overall activity than infants of nondepressed mothers. Long-term effects of maternal depression on child development have been demonstrated in the magnetic resonance imaging of the brain of such children and increased cortisol level at the time of school entry. Children are characterized as anxious, wary, and withdrawn. Social skills are noted to be poor. Early diagnosis and intervention may prevent the development of these problems.

Management

The major role of the pediatrician is to assist in the early identification of mothers who are experiencing peripartum depression and to make the appropriate referral for more definitive management. Support for this recommendation comes from a number of sources, including the 1999 and 2000 Report of the Surgeon General, *Bright Futures*, the American Academy of Pediatrics (AAP) Medical Home Initiative, and AAP policy statement on family-centered care. Practices that include the presence of social workers or mental health specialists can avail themselves of these individuals to assess, counsel, and refer these mothers as appropriate. The mother may be referred back to her obstetrician for a visit prior to the 6-week checkup. Alternatively, mothers may be referred to local mental health specialists when such resources are known and available.

Box 19-2. Sample Question From Edinburgh Postnatal Depression Scale^a

As you are pregnant, or have recently had a baby, we would like to know how you are feeling. Please check the answer that comes closest to how you have felt IN THE PAST 7 DAYS, not just how you feel today.

Here is an example, already completed.

I have felt happy:

- Yes, all of the time
- Yes, most of the time
- No, not very often
- No, not at all

This would mean: “I have felt happy most of the time” during the past week. The other questions should be completed this way.

^aModified with permission from Cox JL, Holden JM, Sagovsky R. Detection of postnatal depression: development of the 10-item Edinburgh Postnatal Depression Scale. *Br J Psychiatry*. 1987;150:782–786.

There are a number of Internet sites that are very helpful in providing information about community resources. Postpartum Support International (www.postpartum.net and 800/944-4PPD) provides geographically specific information. The site can be accessed even while the mother is in the pediatrician’s office. To get the needed information, one goes to the site, clicks on get help, clicks on the map for one’s specific location, clicks on e-mail for region, and one will get a reply within 24 hours. It is also important to have an “emergency protocol” in place, such as calling 911 or a psychiatric emergency team, should the woman endorse suicidality while in the pediatrician’s office. Having such resources and protocols in place can go a long way toward reducing pediatricians’ anxiety about screening for depression and suicidality.

Some perinatal programs offer home visitation or the use of dou-las (women who support other women through labor, delivery, and after the birth of an infant in a nonmedical capacity), which assist mothers-to-be as well as recent mothers with the demands of birth and parenting. Such programs may offer a preventive and early intervention approach to peripartum depression by offering help and emotional support to the new mother.

When older children have been affected by maternal depression, there are other treatment modalities that focus on both the mother and the child to help address attachment disorders. Research on these dyadic interventions has demonstrated they are associated with decreased psychiatric symptoms and significant improvement in functioning of both the mother and the child. Both internalizing and externalizing child behaviors are reduced when maternal depression is addressed. Some programs include parent–child interactive therapy and parent–child psychotherapy. A program called Circle of Security involves video-based intervention that focuses on strengthening caretaker giving.

Prognosis

The prognosis for peripartum depression and its effects on infants and children is contingent on early recognition and appropriate intervention. Promoting screening is critical to ensuring a positive outcome. Unfortunately, pediatricians still face barriers, which include the need to screen for a number of other conditions (eg, parental smoking, interpersonal violence), insufficient time, inadequate training, lack of appropriate resources, and lack of reimbursement. A number of models have demonstrated that screening for peripartum depression can be successfully undertaken in a pediatric practice. The Assuring Better Child Health and Development Project has been implemented in 28 states and involves the AAP chapters in those states. Pediatricians in Illinois can be paid through Medicaid if they administer the EPDS. *Bright Futures*, the health maintenance guidelines developed by the AAP and Health Resources and Services Administration, endorse assessing parental social and emotional

CASE RESOLUTION

While many of this mother's symptoms are common, her self-assessment that she is unable to function suggests that she is experiencing postpartum depression rather than "baby blues." You ask her if it is all right to contact her obstetrician to see if she could be seen sooner. She agrees. When you reach her obstetrician, she schedules the mom to come in the following morning. The obstetrician tells you she has a therapist in her office who will be able to meet with the mother at that time.

well-being. Incorporating questioning into the well-child visits at 1-, 2-, 4-, and 6-month visits is recommended and can be billed for using the *Current Procedural Terminology* code 99420. Additional information about individual state initiatives can be found at www.abcdresources.org and www.nashp.org (National Academy for State Health Policy).

Newborn Screening

Derek Wong, MD

CASE STUDY

A 1-week-old male infant is brought to his pediatrician's office for a positive newborn screening test for congenital adrenal hyperplasia. The baby was a product of a 38-week gestation and was born by normal spontaneous vaginal delivery to a 30-year-old gravida II para II woman with an unremarkable pregnancy. Birth weight was 3,300 g, and the baby is feeding and acting appropriately. Family history is unremarkable, and the physical examination is normal.

Questions

1. What are the proposed benefits of newborn screening?
2. Which newborn screening tests are most commonly performed?
3. How are the results of newborn screening tests reported to physicians?
4. How should a patient with an abnormal newborn screening result be managed?
5. What are the most common causes of false-positive and false-negative results?
6. What are the ethical issues and future challenges surrounding newborn screening?

Newborn screening programs are designed to identify infants at risk for catastrophic outcomes from treatable illnesses. During the past 40 years, technological advances such as tandem mass spectrometry have made it possible to test for more than 50 metabolic disorders from a single blood spot. New techniques in molecular biology allow for rapid diagnostic testing of conditions such as cystic fibrosis.

From the inception of newborn screening in the 1960s until 2005, each state chose a different set of conditions for their newborn screening programs based on disease prevalence, cost, availability of treatment, and false-positive rate. Recently, the American Academy of Pediatrics (AAP) and other agencies produced a series of articles that outlined a strategy to move toward a uniform national newborn screening panel. In 2005 an expert panel from the American College of Medical Genetics recommended 29 core disorders for which newborn screening was most effective (Table 20-1), as well as 25 secondary disorders that are in the differential diagnosis of a core disorder. In 2010, severe combined immune deficiency (SCID) was added to the list of core disorders. By the end of 2010, all states offered testing for the 29 original core disorders, although screening for secondary disorders and SCID was variable. Most infants born in Europe, Japan, and Australia undergo similar screening, and other nations are actively exploring similar technologies.

Primary care physicians have 3 crucial roles in the newborn screening process. First, they provide education to parents about the newborn screening process. Second, they ensure that specimens are drawn under proper circumstances and that the results are promptly followed up. Finally, they provide medical follow-up and referral in

positive cases. Providers need to have contact information for state newborn screening programs and local pediatric subspecialists. The following Web sites link to contact information for these groups:

1. State newborn screening programs—<http://genes-r-us.uthscsa.edu/>
2. Geneticists, metabolic and clinical—The Society for Inherited Metabolic Disorders (www.simd.org) and The American College of Medical Genetics (www.acmg.net)
3. Pediatric endocrinologists—The Lawson Wilkins Pediatric Endocrine Society (www.lwpes.org)
4. Pediatric hematologists—The American Society of Pediatric Hematology/Oncology (www.aspho.org)
5. Pediatric pulmonologists—The Cystic Fibrosis Foundation (www.cff.org) (under “Care Center Network”)

Epidemiology

More than 4 million infants are screened each year in the United States. The National Newborn Screening 2006 Incidence Report shows that as a result of newborn screening, 1 in 3,200 newborns were diagnosed with a metabolic disorder, 1 in 2,200 were diagnosed with congenital hypothyroidism, 1 in 2,200 were diagnosed with sickle cell disease or a related hemoglobinopathy, and 1 in 29,000 infants were diagnosed with congenital adrenal hyperplasia. Several disorders are more common in particular ethnic groups: Cystic fibrosis has an incidence of 1 in 2,500 in whites, and sickle cell disease has an incidence of 1 in 400 in African Americans.

Table 20-1. Core Newborn Screening Disorders^a

Disorder	Possible Signs and Symptoms in Neonates ^b
Organic Acid Disorders	
Glutaric aciduria type I Biotinidase deficiency Multiple carboxylase deficiency HMG-CoA lyase deficiency Cobalamin A,B deficiency Isovaleric aciduria Methylmalonic acidemia Propionic acidemia 3-methylcrotonyl-CoA carboxylase deficiency	Macrocephaly Vomiting, lethargy, tachypnea Seizures, coma, anion gap acidosis Hyperammonemia Anemia, neutropenia, thrombocytopenia
β-ketothiolase deficiency	Asymptomatic ^c
Fatty Acid Oxidation Disorders	
Medium-chain acyl-CoA dehydrogenase deficiency	Lethargy, coma, sudden death, hypoketotic hypoglycemia Reye-like syndrome
Very long-chain acyl-CoA dehydrogenase deficiency Long-chain L-3-OH acyl-CoA dehydrogenase deficiency Trifunctional protein deficiency	Lethargy, coma, sudden death, hypoketotic hypoglycemia Cardiomyopathy, arrhythmias Cholestasis, Reye-like syndrome
Carnitine uptake defect	Asymptomatic ^c
Amino Acid Disorders	
Maple syrup urine disease Citrullinemia Argininosuccinic aciduria	Poor feeding, vomiting, lethargy, seizures, coma, maple syrup odor Hyperammonemia, vomiting, seizures, lethargy, coma
Tyrosinemia type I	Hepatomegaly, increased PT/PTT, liver failure, boiled cabbage odor
Homocystinuria	Asymptomatic ^c
Phenylketonuria	Asymptomatic
Hemoglobinopathies	
Sickle cell disease (Hb SS) Sickle β-thalassemia Hemoglobin C sickle cell disease	Dactylitis Asymptomatic ^c
Other	
Congenital hypothyroidism	Umbilical hernia, enlarged fontanelle, macroglossia, jaundice
Congenital adrenal hypertrophy	Virilization in females; salt wasting crisis
Galactosemia	Cataracts, jaundice, poor feeding, sepsis
Cystic fibrosis	Meconium ileus, intestinal obstruction
Severe combined immune deficiency	Recurrent infections

Abbreviations: HMG, 3-hydroxy-3-methylglutaryl; CoA, coenzyme A; PT, prothrombin time; PTT, partial thromboplastin time.

^aMost of these conditions may not be asymptomatic outside of the neonatal period.

^bMany neonates with these disorders are completely asymptomatic.

^c“Asymptomatic” covers the first month of life and does not exclude very rare case reports of neonatal presentation.

Clinical Presentation

Most infants with disorders detected by newborn screening are clinically asymptomatic in the first 2 weeks of life, but the remainder may have significant signs and symptoms (see Table 20-1). The presence of such features may lead to a more urgent workup and/or

hospitalization. Unfortunately, severe forms of some metabolic disorders may cause coma and encephalopathy by 48 hours of age. In these cases, the newborn screening results are critical, for they will suggest a probable diagnosis and will allow early optimization of therapy.

Differential Diagnosis

While newborn screening techniques are continually improved, both false-positive and false-negative errors occur. Mislabeled specimens, technical errors, and reporting errors can occur in any laboratory. Any specimen collected before 12 hours of age is at risk for a false-negative metabolic result or a false-positive hypothyroidism result. Premature infants have a reduced metabolic capacity and therefore exhibit higher metabolite levels and increased false-positive results compared with term infants. Anemia or polycythemia can affect the amount of serum per blood spot and increase false-negative results, and transfusion may alter galactosemia and hemoglobinopathy testing. Infants on hyperalimentation may have increased amino acid and lipid levels, especially if the newborn screen is drawn from a central line. To ensure accurate and uniform testing, it is imperative to communicate relevant clinical information to the state newborn screening office.

Newborn Screening Practices

Parental Education and Consent

All parents should therefore be informed of the state screening program either at the prenatal visit or during the initial newborn examination. Written materials that explain the screening program are available from the state screening office, and online materials explaining abnormal results are available on fact sheets at Web sites such as <http://pediatrics.aappublications.org/cgi/content/full/118/3/e934>. Health care providers are responsible for educating parents regarding the method for obtaining the blood specimen, the risks and benefits of the screening tests, the conditions to be screened, and the implications of positive results.

It is important to tell parents that positive results do not necessarily mean that their infant has a particular disorder; the results must be confirmed by more specific tests. In addition, parents should know that disorders in some children are missed either because of sampling errors, faulty testing, or inadequate accumulation of the abnormal metabolite at the time of testing.

Newborn screening is mandatory in all states, although many states allow exemptions for religious beliefs or other reasons. In most states, parents have given informed consent if practitioners have discussed the state-mandated program with them and they have agreed to participate. A few states require signed consent to opt into the newborn screening program, and several more require consent to disclose identifiable information. Providers should document parental refusal regardless of state laws.

Specimen Collection and Handling

Proper specimen collection and handling are essential components of a successful screening program. All newborns should be screened before discharge from the hospital, ideally between 48 to 96 hours of age. Early screening increases the chance of a false-negative metabolic result or a false-positive hypothyroidism result. For this reason,

some states have a mandatory second screen between 1 and 6 weeks of age, while others require a second screen only if the first screen is obtained before a specified time (12–48 hours depending on the state). Late screening increases the sensitivity of metabolic testing, but also increases the chances for a delay in diagnosis of life-threatening conditions such as galactosemia. If possible, blood samples should be obtained prior to any transfusions or dialysis. Otherwise, screening tests should still be performed as outlined previously, and arrangements should be made to have them repeated at an appropriate time. It is likely that guidelines that recommend screening premature and/or sick newborns at birth, 48 to 72 hours, and 28 days/discharge will be considered for implementation into state newborn screening programs in the near future.

Only a few drops of blood are needed for each disk on the filter paper, but the sample must saturate the paper evenly. The use of needles and glass capillary tubes for blood collection is discouraged because they may cause hemolysis or microtears in the filter paper. The specimens must be individually air-dried in a horizontal position, thus avoiding contamination and excessive exposure to heat. They should be mailed to the laboratory within 24 hours of collection. Inadequate specimen collection and handling can lead to test inaccuracies, delays in reporting results to physicians, and unnecessary repetition of screening tests. Therefore, all individuals who are involved in the newborn screening process should adhere strictly to the procedures set forth by their state program.

Reporting of Results

In most states, all results of neonatal screening tests, whether normal or abnormal, are reported to the physician of record. Normal results are mailed to the physician for placement in the patient's medical record. Abnormal results are usually reported by telephone or letter, depending on the severity of the potential condition. Results are also sent to the hospital where the infant was born for inclusion in the medical record. The physician of record is responsible for contacting the parents regarding the need for confirmatory testing and, if necessary, referral to an appropriate subspecialist. If a newborn is no longer under the care of this physician or if the family cannot be located, state and local public health departments can be called on to assist in the search for the infant and family.

Diagnostic and Therapeutic Considerations

A health care team consisting of a primary care physician and staff, state newborn screening office personnel, the state newborn screening laboratory, local laboratories, and subspecialty physician is responsible for care and follow-up of patients with positive newborn screening results. All infants with abnormal results, whether borderline or clearly significant, should be evaluated by the primary care physician. A complete history and physical examination as well as a family history should be obtained. Abnormal results for some newborn screening tests, such as very long-chain acyl-coenzyme A (CoA) dehydrogenase deficiency, may normalize with a second screen. Therefore, most follow-up evaluation centers on targeted

diagnostic tests. Depending on the nature of the suspected disorder, initiation of treatment before confirmatory laboratory results are known may be appropriate. For example, prophylactic antibiotics should be administered if sickle cell anemia is suspected. After confirmatory results have been received, the treatment can be modified or halted.

Potentially life-threatening conditions in the newborn period, such as galactosemia, maple syrup urine disease, and congenital adrenal hyperplasia, are particularly important to evaluate and treat emergently. Depending on the clinical picture, the suspected disorder, and the experience of the practitioner, telephone consultation with a specialist or immediate referral to a regional medical center may be necessary.

Nearly all of the diseases in the current newborn screening panels are inherited in an autosomal recessive manner. Families of affected infants should be offered genetic counseling for future pregnancies, in addition to written information about the newly diagnosed condition. Depending on the condition, older siblings may need to be evaluated. In some conditions, such as 3-methylcrotonyl-CoA carboxylase deficiency, a positive newborn screen may reflect an affected asymptomatic mother whose metabolites have passed to her infant.

Current Issues and Future Challenges

Protecting patient privacy is of the utmost importance, and nearly all programs have laws to protect a patient's personal information, blood spots, and genetic information. There is great concern amongst parents and providers that insurance companies will use newborn screening information to discriminate against children and their families.

There is no dispute that newborn screening saves lives. Additionally, the cost of newborn screening programs is outweighed by the reduction in morbidity and mortality from a purely economic standpoint. However, some diseases under consideration for newborn screening, such as lysosomal storage disorders, have extremely costly treatments, which may total several million dollars over the lifetime of the patient and produce significant morbidity. Cost-benefit analysis will be crucial to shaping future newborn screening panels. Pediatricians and other health professionals need to advocate for insurance coverage for newborn screening panels because patients may be charged up to \$130.

Currently a large percentage of false-positive results occur in premature infants, in part due to the lack of age-specific laboratory values for all metabolites. In several states, a lack of appropriate cutoff values led to a large number of false-positive results among babies in neonatal intensive care units that strained the state programs. In the future, careful pilot testing of new tests in infants of all gestational ages will be needed to improve the screening process.

There is debate about the benefit of early detection of disorders such as cystic fibrosis. While recent studies have suggested that patients benefit from early therapy, it is unclear how much early detection improves the long-term pulmonary or nutritional status

of affected children. Some disorders, such as short-chain acyl-CoA dehydrogenase deficiency, are asymptomatic in most individuals and have a high rate of false-positive tests due to the presence of common polymorphisms in the population. The lifelong treatment of patients who would otherwise remain asymptomatic, the added burden of a genetic diagnosis, and family stress caused by a false- or true-positive result have led several countries to remove this disorder from their newborn screening panels. Fortunately, there has been a large amount of progress made in reducing false-positive results using new algorithms for second-tier testing.

Several newborn screening tests detect asymptomatic carrier status in infants. While the knowledge of a patient's carrier status may be of some advantage for childbearing, it has no immediate benefit for the infant and may lead to discrimination and stigmatization. Parents of affected infants (who are usually asymptomatic carriers) face the same dilemma and should be given the option to refuse testing for carrier status.

New challenges will emerge as genetic technology advances toward the ultimate goal of sequencing a patient's entire genome. Practitioners will have to weigh the decision of whether to inform parents about non-treatable or late-onset conditions. The AAP Committee on Bioethics advises against screening for such conditions, but the debate has been reopened as testing for spinal muscular atrophy has been developed. Finally, some conditions that are caused by a complex interaction between genetics and environment, such as celiac disease, may require screening at school age. Pediatricians should be involved in decisions concerning the addition of new disorders to existing newborn screening programs because they are key players in the implementation of these programs.

CASE RESOLUTION

This patient should have a full evaluation, including an electrolyte panel, due to the possibility of salt wasting congenital adrenal hyperplasia. Confirmatory testing, including measurement of precursor hormones such as 17-hydroxyprogesterone and subsequent molecular testing, and glucocorticoid therapy should be considered in consultation with a pediatric endocrinologist.

Caring for Twins and Higher-Order Multiples

Sabrina D. Diaz, MA, and Lynne M. Smith, MD

CASE STUDY

An expectant mother visits you. She has been advised by her obstetrician that an ultrasound shows she is pregnant with twins. She asks about care of twins and what special considerations she should keep in mind as she looks forward to the delivery. In particular, she is concerned about the feeding schedule and whether she will be able to breastfeed.

Questions

1. What is the incidence of multiple births?
2. What is the difference between fraternal and identical twins?
3. What major medical problems may affect twins and higher-order multiples?
4. What developmental and behavioral problems are associated with raising multiples?

With the advent of artificial reproductive therapy, the incidence of twins and higher-order multiples is increasing. Counseling the parents of multiples provides a unique opportunity for pediatricians. Much of what is known about caring for multiples comes from work with twins. Many societies have been fascinated with twins, and many myths and superstitions surround their birth. Some people believe that a mother of twins must have been unfaithful to her husband because a father cannot sire 2 children. Native Americans of the Iroquois nation believed that one twin was good and the other was evil. To prevent the recurrence of twins, the Khoikhain removed one of the father's testicles.

Parents of multiples often have many questions regarding the care of their children, but they rarely pose them to health care providers. In one study where 18 out of 29 mothers breastfed their twins, only 3 received information about breastfeeding from their physicians. One mother had been told by her obstetrician that she could not breastfeed her twins. Physicians should become knowledgeable about caring for multiples and the unique challenges they present to parents related to feeding, sleeping, and behavior.

Epidemiology

Since 1980 there has been a 101% increase in twin deliveries in the United States, and the number of higher-order multiples has increased 5-fold. Twinning rates have also increased in Finland, Norway, Austria, Sweden, Australia, Hong Kong, Japan, Canada, Singapore, and Israel. A major contributor to the increase in multiple births is that women are starting their families later than in previous generations. Because of the increased risk of infertility with advanced maternal age, more couples are choosing to conceive with

assisted reproductive technologies, including ovulation-stimulating drugs, in vitro fertilization (IVF), and intracytoplasmic sperm injection. Assisted reproductive technology results in multiple gestations in approximately 50% of pregnancies and accounts for 18% of all multiple births nationwide. Single embryo transfer has lower success rates than multiple embryo transfer, increasing the likelihood of multiple births. In addition, advanced maternal age is associated with increased follicle-stimulating hormone levels and the release of multiple eggs by the ovary, increasing the chance of multiple births.

The overall natural incidence of twin births is about 1 in 87. Twins account for just slightly more than 1% of all births, and 20% of infants born under 30 weeks' gestation are twins. The average incidence of monozygotic or identical twins, which is the same for all women regardless of race and age, is about 1 in 300 births. The incidence of dizygotic or fraternal twins varies among different groups and method of conception. In the United States, African Americans and whites have comparable incidences of live-born twin deliveries and both have significantly higher rates than Hispanic women. A maternal family history of dizygous twins correlates most strongly with an increased incidence of twinning. A family history of monozygous twins or a paternal family history of dizygous twins does not increase the risk of twins.

Pathophysiology

Higher-order multiples, conceived either naturally or via artificial reproductive technology, may be fraternal or a combination of monozygotic twins and fraternal siblings. Monozygotic twins result from the splitting of a single egg. They may share a placenta (monochorionic, Figures 21-1A and 21-1B) and in rare cases may

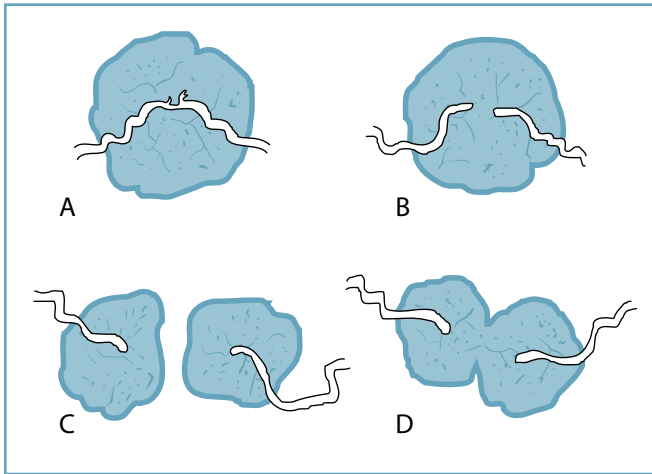

Figure 21-1. Variations in placentas in twin births. **A.** Monochorionic placenta, cords close together. **B.** Monochorionic placenta, cords farther apart. **C.** Dichorionic placentas, separate. **D.** Dichorionic placentas, fused.

also share an amniotic sac (monoamniotic). When splitting occurs early (after several cell divisions of the zygote), each fetus develops its own chorion and amnion, leading to dichorionic and diamniotic placentas. Dizygotic twins result from 2 eggs, and each egg is fertilized by a different sperm. Dizygotic twins have 2 placentas (Figure 21-1C). Although these placentas may fuse together like 2 pancakes, they are almost always dichorionic and diamniotic (Figure 21-1D). Sonography at 14 weeks or less has been found to be 96% predictive of monochorionicity, and can also predict amnionicity, anomalies, and syndromes.

Following the birth, many parents want to determine whether twins are monozygotic or dizygotic. Different sex twins are almost always dizygotic, although monozygotic twins of different sexes have been reported in the literature. This occurs when one twin loses a Y chromosome and becomes a phenotypic female with Turner syndrome (XO). Occasionally the male twin may be XXY and have Klinefelter syndrome.

To determine whether twins are monozygotic or dizygotic after birth, a number of procedures can be undertaken. Visual or pathologic examination of the placenta is helpful. About two-thirds of monozygotic twins have a common chorion and share one placenta. Finding a single chorion usually means the twins are monozygotic, unless the placentas of dizygotic twins have fused together. DNA testing is the preferred method for determining zygosity. Most commercially available testing involves examining DNA obtained from buccal swabs from each child. Identification of short tandem repeats via polymerase chain reaction is typically accurate 99% of the time and is similar to techniques used in forensic medicine. Commercial laboratory charges range from \$150 to \$500, though prices vary significantly.

Differential Diagnosis

Diagnosing multiples is not difficult, but physicians should be aware of the problems these newborns may experience.

Perinatal Complications

Multiple births are associated with a significantly higher risk for perinatal complications relative to singleton births. The maternal complication most commonly reported with multiples is pregnancy-induced hypertension. Maternal preeclampsia rates are higher in twins and increased nearly 5-fold with triplets. In addition, mothers of twins who conceived via IVF have a higher rate of preeclampsia than mothers of twins who conceived naturally. Other maternal complications include placenta previa, antepartum hemorrhage, gestational diabetes mellitus, anemia, uterine atony, and maternal death.

Neonatal mortality is 4-fold higher in twins and 15-fold higher in higher-order multiples. Neonatal morbidity is much higher in multiple births because of the increased incidence of prematurity and growth restriction. The risk for these complications increases with the number of fetuses. The perinatal mortality of monozygotic twins is 8 times that of singletons and 4 times that of dizygotic twins. Twins and higher-order multiples are also at increased risk for cerebral palsy.

Monozygotic twins are at greater risk for death and cerebral palsy because of complications such as severe birth weight discordance and twin-to-twin transfusion syndrome (TTTS). Twin-to-twin transfusion syndrome is seen in 10% to 15% of monochorionic pregnancies and results from unbalanced blood flow due to vascular anastomoses within the shared placenta. The diagnosis is suspected by ultrasound when one fetus is growth restricted with oligohydramnios and the other fetus has evidence of volume overload with polyhydramnios. Both twins are ultimately at risk to become hydropic and/or die. Without treatment, TTTS-induced death of at least one twin is as high as 80% to 100%. Of additional concern, the death of one twin is associated with neurologic damage or subsequent death of the surviving twin, with 1 in 10 surviving twins developing cerebral palsy.

Until recently the treatment was drainage of amniotic fluid in the twin with polyhydramnios to reduce the risk of preterm delivery. Endoscopic laser ablation of placental anastomoses is emerging as the treatment of choice. Laser ablation addresses the primary pathology and results in an average gestation at delivery of 33 weeks, which is a significant improvement from the average 29 weeks with serial amniotic fluid reductions. Laser ablation is not without risks, however; reported complications include premature rupture of membranes, amniotic fluid leakage into the maternal peritoneal cavity, vaginal bleeding, and chorioamnionitis.

One percent of monozygotic twins are monochorionic-monoamniotic. Although monoamniotic twins have a lower risk of TTTS, they are at very high risk for cord accidents. Monoamniotic pregnancies are monitored closely, and once the fetuses reach viability, emergent delivery is indicated if fetal distress is noted to avoid

fetal death. Because fetal death significantly increases the risk of cerebral palsy and other neurologic disorders in the surviving twin, it is no longer recommended to allow fetal death in one monoamniotic twin to lengthen the gestation of the non-distressed twin.

Congenital Malformations

Twins and higher-order multiples have an increased risk of anomalies. Monochorionic twins have a higher risk of cardiac anomalies than dichorionic twins, increasing their need for fetal echocardiograms. Multiples conceived via IVF or intracytoplasmic sperm injection have increased risk for anomalies and aneuploidy. Disorders of genetic imprinting (eg, Beckwith-Wiedemann, Angelman syndrome) are also increased with intracytoplasmic sperm injection. These genetic complications are thought to be secondary to the underlying cause of the infertility instead of artificial reproductive technologies. Because the costs associated with infertility treatments are substantial, many couples choose not to obtain a comprehensive chromosomal analysis looking for deletions or translocations on themselves prior to using reproductive technologies. Nuchal translucency and chorionic villus sampling can be used to detect and confirm suspected aneuploidy as early as the first trimester. Chorionic villus sampling is not widely available and ranges from \$1,000 to \$2,000; however, many insurance companies will cover the procedure in women over 35 years of age or in women with risk factors that may increase the baby's likelihood of having a serious health problem.

In addition to the increased risks for malformations, multiples are at risk for deformations secondary to crowding, including torticollis, hip dislocation, plagiocephaly, and foot deformities. Monochorionic twins are also at risk for conjoined twinning, estimated to occur in 1:50,000 to 200,000 gestations, with more than 50% dying in utero or stillborn and 35% dying within the first 24 hours. Although monochorionicity is more common in males, conjoined twins are often female. Conjoined twinning occurs due to incomplete splitting of the embryo or after a secondary fusion between 2 previously separate embryos. Prenatal ultrasound is commonly used to diagnose this condition, and more recently prenatal magnetic resonance imaging has been used to evaluate the specific anomalies. Due to recent surgical advances, some parents continue the pregnancy with hopes the live-born infants can be separated, while others often terminate the pregnancy.

Postnatal Complications

Approximately 60% of twins and 90% of triplets are born prematurely, increasing the risk of morbidity and mortality. Though growth in twins tends to be normal until 30 to 34 weeks, growth restriction is commonly associated with multiple births. Twins conceived by IVF are more likely to be born low birth weight than spontaneously conceived twins. Smaller twins have an increased incidence of hypoglycemia in the newborn period and have higher rates of targeted learning deficits and school failures during childhood. In addition, children born growth-restricted have an increased risk for obesity and diabetes in later life. Selective intrauterine growth restriction

(IUGR), when only one twin is affected by IUGR, occurs in 10% of monochorionic twins. This occurs when the twin with IUGR has reversed flow or persistent absent flow in the umbilical artery.

Evaluation

History

A general medical history should be obtained, including a history of the pregnancy. Any specific medical complaints should also be addressed (Questions Box).

Questions

Caring for Twins

- Did the mother have any problems during the pregnancy?
- How long did the pregnancy last?
- Did the mother take any medications, including fertility drugs?
- Did the children have any problem after the delivery or in the newborn nursery?

Physical Examination

The initial evaluation of newly born twins involves assessment of gestational age and determination of the presence of any medical problems or anomalies (see Chapter 18). Older twins may undergo health maintenance visits where routine as well as specific complaints are addressed.

Laboratory Tests

Newborns should be assessed for the presence of anemia or polycythemia with a hemoglobin determination. Hypoglycemia may occur in the newborn period and should be assessed frequently until glucose levels are stable. If the twins are premature, they may have many of the problems seen in preterm infants, such as respiratory distress syndrome and necrotizing enterocolitis.

Older children should receive an appropriate evaluation for age, with a specific focus on any behavioral concerns.

Management

The focus of the management of multiples involves counseling the parents about issues related to routine care and the anticipated stress of caring for more than one newborn simultaneously. Parents often care for 2 or more children at the same time, but multiples present unique issues related to multiple children who are developmentally and chronologically at the same point. Many parents experience anxiety regarding the upcoming challenges they will face. Baby care books that specifically deal with birthing and raising multiples are available. Support groups and Web sites also provide information for families of multiples.

Feeding multiple newborns is often an exhausting challenge for parents, and consultation with a lactation expert is recommended.

The physical demands of feeding multiple newborns are often compounded by women recovering from prenatal complications such as preeclampsia. Because prematurity is common, the newborns may have an immature suck reflex, making feeding more challenging. Few multiples are still receiving human milk by 3 to 4 months of age, and common reasons cited for unsuccessful breastfeeding of multiples include maternal stress, depression, fatigue, perceiving they were producing insufficient milk, and time burden. Despite these obstacles, parents should know that breastfeeding is possible even for triplets and understand the benefits of breastfeeding to the newborns' health.

Some options for breastfeeding twins are as follows:

1. Feed both infants *at the same time*, with one on each breast. This method is recommended only after adequate breastfeeding has been established in each twin, typically not until after 1 week of age. It is advised that the baby having fewer problems latching be placed on the breast first so that the milk ejection reflex is already established for the poorer-feeding baby. Because the babies may not drink the same amount, it is important that they feed on the opposite breast for the next feeding to maximize milk production.

The infants may be put in a number of positions. The mother can be sitting and cradling one infant while holding the other infant like a football. Alternatively, the mother may cradle both infants, so that they are cross-positioned over one another, or she may have both infants under her arms in a football position. Breastfeeding pillows designed for feeding multiples are helpful, and electric breastfeeding pumps are essential.
2. Feed the infants *at different times*. The mother breastfeeds one infant and then the other. The mother starts with the more vigorous feeder. This approach may pose a problem; both infants may be hungry at the same time and maternal fatigue may inhibit success because the chance for sleep is diminished with this method.
3. *Breastfeed one infant and bottle-feed the other*, which gives the mother a free hand. Most parents use a combination of breastfeeding and bottle-feeding. A mother can let the first infant feed on demand but wake up the second one when the first one is done. Eighty percent of parents of twins acknowledge that they prop the bottle instead of holding it, and they should be counseled against this. There are several effective feeding positions that do not require bottle propping, and parents should be encouraged to adopt one of these positions.

Breastfeeding triplets and higher-order multiples is even more challenging than breastfeeding twins. Mothers of triplets exclusively breastfeeding report they feed 2 children, one on each breast, and the third follows on both breasts. Because the hind-milk has higher fat content, it is important to rotate the feeding order of the children. Another popular option is to breastfeed 2 and have the third bottle-feed simultaneously.

Feeding twins or higher-order multiples may decrease the amount of sleep a mother gets. Because sleep deprivation is associated with maternal depression and exclusively breastfeeding mothers of multiples report more sleep problems compared with mothers who do

not breastfeed or who formula-feed and breastfeed, these factors should be discussed when offering feeding options to the parents. Encouraging paternal involvement with feeding may alleviate some maternal stress and sleep deprivation.

Sleeping in the same crib is no longer recommended because of concerns regarding cosleeping. It is important to counsel parents about **car safety seats**. Parents who cannot afford the cost of multiple car safety seats may resort to placing one child in the car safety seat and the others on the seat of the car, a dangerous practice that is illegal throughout the United States. Parents should be advised about the need for car safety seats for all infants.

Bathing should be done separately in the interest of safety until infants can sit up.

Toilet training is reportedly easier with some twins because one twin learns from the other via modeling and/or peer pressure.

Maintenance of individuality for multiples may be challenging. Researchers suggest that mothers can bond to only one infant at a time, a concept called *monotropy*. In addition, mothers bond more strongly with the twin who leaves the hospital first. Twins are often dressed alike and given similar names as this may facilitate the bonding process. To help with individual development, physicians are encouraged to obtain history and examine each child individually. Physicians should attempt to distinguish the children from one another independent of parental reminders. Twins should not be referred to as “the twins” but by their respective names. As multiples get older, issues related to classrooms and birthday parties frequently arise, and they should be consulted concerning their preferences. Individual birthday parties and gifts should be considered. (Some multiples comment on their disappointment at receiving the same present for birthdays and holidays. There is no surprise in opening gifts if the other twin opened a gift first.)

Whether multiples should be placed in the same or different classrooms is unclear. Placement in different classrooms is advocated to support each child's individual development. However, there are no data to support separate classroom placement. It is currently recommended that school districts have a flexible policy regarding school placement of twins. A checklist has been created to assist families and schools determining the best school placement for twins (available at www.twinsandmultiples.org). Families with higher-order multiples are more likely to have children in separate schools because of the higher risk that some of the children will have developmental delays.

Sibling rivalry is common among co-multiples as well as other siblings within a family. Older siblings may resent the attention paid to the new babies, so family and friends should be reminded to shower attention on the older siblings. Because twins often exclude siblings and peers socially, parents are encouraged to schedule times when one twin and sibling are with one parent and the other twin is alone with another family member. Isolating twins (or 2 triplets from a third) fosters more sibling interaction and less dependency between the twins. These separations are encouraged to begin early in development because the later in development isolation is introduced, the less agreeable they are to the separations.

Developmental differences among multiples may also contribute to sibling rivalry. The smaller or more delayed child may become jealous of their co-multiple. Conversely, typically developing children may become frustrated when the sibling with special needs receives more attention than they receive.

Until age 3 years, **language development** is delayed in twins relative to singletons. Contributing factors to language delay include less time for individual facilitated play, which is helpful for language development. If twins communicate with a private language they have an increased risk of language and cognitive delays. Language delays usually become much less pronounced by mid-childhood.

The risk for **cerebral palsy** is increased with higher multiples because of the increased rates of prematurity and IUGR. Fetal death of a co-multiple and monochorionic placentas are the biggest risk factors for developing cerebral palsy.

Attention-deficit/hyperactivity disorder is more common in twins. The temper tantrums multiples display can be severe and are understandable given the heightened need to gain parental attention from their sibling. Having twins in the home is a risk factor for **child abuse**, either to a twin or to their siblings.

Prior to delivery, parents should be made aware that **maternal depression** is frequently reported after the birth of multiples. The physical stress of caring for multiple newborns can be overwhelming, and the parents often feel isolated at home. The incidence of depression is higher in mothers of twins than of singletons, with sleep deprivation being a cited contributing factor. It is important to suggest that parents of multiples obtain outside aid, including help from high school students after school and family members to decrease fatigue and increase their ability to experience respite even for short periods.

In addition to exhaustion and isolation, the increased financial demands that accompany multiple newborns can strain the parents' relationship. Mothers often have to leave work earlier in the pregnancy than women with singleton pregnancies, adding financial burden. The medical costs associated with prematurely delivered newborns can be substantial. To cover for the loss of income at a time of increasing family expenses, the father is often required to work more hours. This increased occupational stress comes at a time when child care demands at home have increased significantly. Financial burdens are especially difficult with multiples conceived artificially because of the cost associated prior to birth. This may be a contributing factor to why parents of twins conceived artificially reported less satisfaction than parents of twins conceived naturally.

Grief is another significant contributor to parental depression. Approximately 15% of children from multiple births grow up as a singleton survivor. Birthday celebrations serve as reminders to the parents of the death of the other child. Parents grieving the loss of one of their twins have comparable grief to those grieving the loss of a singleton pregnancy. It is imperative that physicians caring for the family acknowledge the parents' grief because family and friends often do not acknowledge the parents' pain if there is a surviving newborn.

Surviving children born prematurely and/or small for gestation are at increased risk for developmental delays. The stress of raising

a child with special needs is also a source of grief because parents mourn the loss of their dreams of having a normal child.

Prognosis

Although multiples have a higher incidence of perinatal problems, appropriate anticipatory guidance and routine health maintenance can help families optimize their children's outcome.

CASE RESOLUTION

The mother in the case scenario is advised that breastfeeding is not only possible but recommended. She is told about the options for timing and positioning of the infants. The issues of family history and child passenger safety are also discussed, and anticipatory guidance regarding the potential stress of raising multiples is given.

Circumcision

Lynne M. Smith, MD

CASE STUDY

An expectant mother visits you prenatally. She talks about circumcision in addition to issues relating to breastfeeding and car passenger safety. Her husband is circumcised. She is unclear about the medical indications for circumcision and asks your opinion about circumcision in the newborn period.

Questions

1. What are the benefits of circumcision?
2. What are the indications for circumcision in older children?
3. What are the techniques used to perform circumcision?
4. What are the complications of circumcision?

Male circumcision, a procedure in which the foreskin of the penis is removed, has been performed for more than 4,000 years. It is routinely performed in certain groups, most notably among Jewish and Muslim people. In many other cultures (eg, Abyssinian, Australian [aborigine], Polynesian), circumcision is presumably performed to facilitate intercourse. Circumcision can be viewed as a ritual procedure, but its role as a medical one is open to greater controversy.

The benefits of male circumcision have been debated for years. Over the past 20 years, even the American Academy of Pediatrics (AAP) has changed its official position on the medical indication for circumcision. In 1999 the AAP stated and then reaffirmed in 2005 that there are potential benefits to circumcision, though the procedure is not medically indicated. Disadvantages of routine circumcision in infants concern cost-effectiveness and the risk of complications. The procedure is sometimes viewed as an archaic and maiming ritual. Female circumcision, which may involve clitorrectomy or resection and closure of the labia minora or majora, is infrequently practiced in Western culture and is not discussed here. There are no medical benefits attributable to female circumcision.

Circumcision in newborns has been performed in a routine and preventive manner, much the same way immunizations are administered. Primary care physicians should be aware of the risks and benefits of the procedure to be able to counsel parents and make referrals to consultants when certain medical conditions arise.

Epidemiology

The prevalence of neonatal circumcision, a procedure that became increasingly popular in the United States in the 1950s and 1960s, once ranged from 69% to 97% depending on cultural mores. Changing cultural patterns have resulted in a lower frequency of circumcision to 56% in 2005, which reflects, in part, state Medicaid programs no longer covering circumcision. Rates also vary by race, religion, and geographic region. In 2005 the circumcision rate in the western

United States was 31%, compared with 75% in the Midwest, 65% in the Northeast, and 56% in the South. The higher Hispanic birth rate in the West contributes to these regional differences because Hispanic neonates are less likely to receive a circumcision. The prevalence of neonatal circumcision for Australian-born men is reported to be 69% (though only 32% in those aged 16–20); in Canada, 35%; and in the United Kingdom, 4%. Circumcision is the second most common surgical procedure after vasectomy in adult males. It is the most commonly performed operation in children.

A reported 10% of uncircumcised males ultimately require circumcision as adults because of complications of phimosis and balanitis. Uncircumcised males with diabetes are particularly prone to these complications.

Clinical Presentation

Most often parents will query their pediatrician about the advisability of a circumcision and the infant will not have any clinical symptomatology. Older infants and children in need of a circumcision can present with symptoms of phimosis, in which the foreskin balloons out on urination; paraphimosis, in which a retracted foreskin cannot be returned to its normal position; or recurrent problems of infection or inflammation of the foreskin (posthitis), glans (balanitis), or both (balanoposthitis).

Pathophysiology

In uncircumcised males, the foreskin adheres to the glans until about the age of 6 years. A gradual, normal lysing of the adhesive bands connecting the foreskin to the under portion of the glans then occurs. Non-physiological phimosis occurs as a result of scarring of the preputial wing. Lysing of adhesions in an effort to treat the phimosis usually leads to further adhesions. If the foreskin is retracted and remains in that position, paraphimosis develops.

Differential Diagnosis

The differential diagnosis relates to conditions that may be managed with a circumcision. Such conditions include phimosis, paraphimosis, and infection and inflammation of the penis. Conditions such as hypospadias may be mistaken for a partially circumcised penis because the condition is associated with absence of the ventral foreskin. A careful history will differentiate hypospadias from a circumcision.

Evaluation

History

In cases involving newborn infants, a history should include the presence of any coagulopathies involving family members, which would preclude the performance of a circumcision. In older infants and children, the history should include problems relating to voiding, such as ballooning of the foreskin or difficulty initiating the urinary stream.

Physical Examination

The physical examination should assess the genitalia, particularly to determine if there is evidence of hypospadias, in which the urethral orifice is not located at the tip of the glans. In such a situation, circumcision should be delayed because the foreskin is used to reconstruct the urethra. In cases of phimosis, the degree of phimosis should also be assessed.

Laboratory Tests

Routine laboratory tests are not indicated, although a urinalysis may be obtained in children with a history of prior urinary tract infection. Coagulation studies would be appropriate if there is a family history of a bleeding disorder.

Imaging Studies

Imaging studies are not indicated in most children undergoing a circumcision. Such studies would be relevant if there was concern that the urogenital anatomy was abnormal.

Prognosis

The prognosis is excellent with complications being exceedingly rare.

Benefits

It has been stated that circumcision facilitates penile hygiene by removing the foreskin, which may serve as a repository for bacteria, smegma, and dirt. Retractability of the foreskin increases with age (Table 22-1) and, thus, penile hygiene is easier to achieve in older children. The term **phimosis** refers to inability to retract the foreskin. In male infants beyond the newborn period, phimosis is the major indication for circumcision. Phimosis is normal in children up to about 6 years of age but is non-physiological if urination results in ballooning of the foreskin, regardless of age. When the retracted foreskin acts as a tourniquet in the midshaft of the penis, **paraphimosis**

Table 22-1. Retractability of the Foreskin in Boys (by Age)

Age	Percentage With Retractable Foreskin
Birth	4%
6 mo	15%
1 y	50%
3 y	80%
6 y	90%

occurs, preventing the return of lymphatic flow. Paraphimosis is commonly related to traumatic retraction of the foreskin, typically during cleaning or by medical personnel during bladder catheterization. Because of this, parents are no longer advised to retract the foreskin in an effort to lyse adhesions. The incidence of paraphimosis is increasing in adults secondary to body piercing. Newly placed penile rings can cause enough pain to prevent foreskin retraction.

Balanitis, or inflammation of the glans, is not uncommon in young infants. It is frequently associated with *Candida* infection, and the glans is swollen and erythematous. Posthitis, or inflammation of the foreskin, is also often secondary to *Candida* infection. Other organisms, including gram-negative microbes, may be associated with balanitis. The presence of recurrent balanitis is an indication for circumcision. In older males, indications for circumcision include phimosis, paraphimosis, balanitis, posthitis, and balanoposthitis.

Urinary tract infections (UTIs) reportedly occur 10 times more often in uncircumcised (1:100) than in circumcised infants (1:1,000). In young uncircumcised boys, UTIs are directly related to colonization of the foreskin with urotoxic organisms. Pyronephritogenic, fimbriated *Escherichia coli* bind to the inner lining of the foreskin within the first few days of life. Other bacteria preferentially bind to this mucosal surface, including fimbriated strains of *Proteus mirabilis* and non-fimbriated *Pseudomonas*, *Klebsiella*, and *Serratia* species. The incidence of UTIs has increased as the rate of circumcision has decreased. In addition, complications associated with UTIs, particularly bacteremia, meningitis, and subsequent death, have occurred.

In Western countries, penile cancer is reported in 0.7 to 0.9 per 100,000 men, but is as great as 4.2 per 100,000 men in Paraguay. These regional differences are thought to be related to lack of circumcision of the penis. Only a few isolated cases of cancer of the penis occur in circumcised men. The estimated lifetime risk of penile cancer is 1 in 600 in uncircumcised males compared with 1 in 50,000 to 1 in 12 million in circumcised males. From 1930–1990, 10,000 men died from penile cancer; there were 1,280 new cases found in 2007 with 290 deaths. The reported mortality of invasive penile cancer is 25%. Phimosis is strongly associated with invasive penile cancer, with other cofactors such as human papillomavirus (HPV) infection and poor hygiene possibly contributing. Smoking is consistently associated with penile cancer and is further reason to strongly advocate for smoking cessation programs.

Cervical carcinoma among the partners of uncircumcised men has been reported with increased incidence. In addition, current partners of circumcised men with a history of multiple sexual

partners have a decreased risk of cervical cancer compared with partners of uncircumcised men. Circumcision in adolescent boys and men in Uganda found a significantly decreased incidence of HPV and herpes simplex virus type 2 (HSV-2) infection. Circumcision has also been associated with a lower risk of HIV infections. Three randomized controlled trials conducted in South Africa, Kenya, and Uganda confirmed findings in observational studies that circumcision is protective against HIV infection. In addition, circumcision was not associated with increased HIV risk behavior. Based on these findings, in 2007 the World Health Organization stated that male circumcision should be part of a comprehensive strategy for HIV prevention. It remains critical, however, to promote the practice of safe sex as circumcision confers only partial protection from HPV, HSV-2, and HIV.

Risks

The risks related to circumcision are related to complications from the procedure. These are listed in Box 22-1 and discussed under Management.

Box 22-1. Complications Associated With Circumcision

• Bleeding	• Inclusion cysts
• Infection	• Penile lymphedema
• Repeat circumcision	• Urethrocutaneous fistulae
• Phimosis	• Penile cyanosis
• Skin bridges	• Penile necrosis
• Urinary retention	• Wound dehiscence
• Meatitis	

Parent Counseling

Parents of Newborns

In the newborn period, proper counseling of the parents, including a discussion of the risks and benefits of circumcision, is important. Opponents to neonatal circumcision cite psychological trauma to neonates from so painful a procedure. Local anesthesia minimizes this effect. Parents should be informed about the benefits of circumcision, including a reduction in occurrence of UTIs, sexually transmitted infections, and cancer of the penis and cervix. Problems related to the foreskin itself, such as phimosis, paraphimosis, posthitis, and balanitis, should also be discussed.

It is appropriate to tell parents that boys who are not circumcised in the neonatal period may need to be circumcised later in life. Parents should be informed about the risks associated with circumcision in newborns, which are discussed in greater detail in the following text. In older individuals, risks include hemorrhage, infection, and injuries to the penis and urethra. In addition, parents should be told that approximately 2% of circumcised neonates require a second circumcision due to inadequate foreskin removal.

Research has shown that parents are more influenced by the circumcision status of the father, religion, and race than by physician attitude regarding their ultimate decision about circumcision. Counseling during the second trimester of pregnancy results in no change in parents' decision about circumcision.

Parents of Older Infants

The need for circumcision in young male infants who present with UTIs is problematic. The evaluation usually tries to determine the existence of other predisposing conditions that could lead to the UTI. Investigators disagree on the need for circumcision following the initial UTI in uncircumcised boys. No clear-cut evidence indicates that circumcision at this time decreases the incidence of future UTIs, so the decision is parental rather than medical. In older children who present with significant phimosis or paraphimosis, circumcision is usually recommended to prevent recurrences of these problems. Medical management, including the use of topical steroids for phimosis, may obviate the need for surgery in some children. Such treatment involves the daily external application of betamethasone cream from the foreskin tip to the corona glans for 4 to 6 weeks. A history, including the duration of symptoms and whether the child has had similar episodes in the past, helps formulate the appropriate management.

Management

The medical attitude toward circumcision has changed over the last 40 years, with an initial inclination toward circumcision, followed by a move away from circumcision. The present position on circumcision as described by the AAP Task Force on Circumcision suggests that newborn circumcision has potential medical benefits and advantages as well as disadvantages and risks. When circumcision is considered, the benefits and risks should be explained to the parents, and informed consent should be obtained. Parents should be advised that the frequency with which third-party payers reimburse for circumcisions, particularly for routine circumcisions in the newborn period, has decreased.

Contraindications

Circumcisions should only be performed in completely healthy neonates. Contraindications to circumcision are well defined. Any abnormalities of the penis, such as hypospadias, absence of any portion of the foreskin, or chordee, preclude circumcision. Ambiguous genitalia and prematurity are contraindications. Circumcision should be delayed in premature and ill term newborns until they are ready for discharge. Patients with a personal or family history of bleeding diathesis should not be circumcised. Infants from such families should be assessed for evidence of coagulation problems. If these are present, circumcision should not be carried out.

Circumcision Procedure

Numerous techniques are used to perform circumcisions. These procedures may involve clamp techniques with Gomco, Mogen, or Plastibell clamps. Any of these techniques is believed to give

comparable results in the hands of trained, experienced operators. Formal surgical excision may also be carried out, usually in older children and adults. Three guidelines should be followed to decrease the incidence of complications: (1) marking of the coronal sulcus in ink, (2) dilation of the preputial wing, and (3) retraction of the foreskin so that the urethral meatus is visualized. This prevents cutting the meatus. Electrocautery should never be used in conjunction with metal clamps because of the danger of extensive injury.

Appropriate anesthesia in newborns undergoing circumcision is the standard of care. The pain and stress of circumcision is evidenced by changes in infant state and behavior. Local anesthesia is the preferred method of pain management. Dorsal penile nerve block, the subcutaneous injections of local anesthetic at the base of the penis, is effective at reducing pain responses during circumcision. Ring block, the subcutaneous circumferential injection of a local anesthetic around the midshaft of the penis, has been shown to be effective and avoids the potential complication of injecting local anesthesia toward the dorsal vessels. Topical application of lidocaine/prilocaine cream (EMLA) or oral sucrose solution on a pacifier also reduces pain and its associated stress, but to a lesser extent than local anesthesia. For older, prepubertal children requiring formal surgical excision, sutureless circumcision using tissue glues has been associated with reduced operative time and an improved cosmetic result.

Complications

A number of complications are associated with circumcision in newborns (see Box 22-1). The most common complication is **bleeding**, which may occur in 0.2% to 8% of cases. Bleeding can usually be controlled using local pressure. More significant bleeding may require local pressure with 1:1,000 adrenaline-soaked gauze or with the use of other topical agents such as Surgicel. The second most frequently seen complication is **infection**, reported in up to 8% of circumcised infants. Plastibell clamps are associated with a higher incidence of infection than Gomco clamps. Most infections usually respond to local treatment, though intravenous antibiotics should be considered because neonatal sepsis and necrotizing fasciitis may occur secondary to infections following circumcision.

Poor cosmetic outcome is also a complication of circumcision. **Phimosis** may occur if removal of the foreskin is insufficient. If the foreskin is inadequately freed up from the inner preputial epithelium, a concealed penis, with the shaft retracted backward into the abdominal wall, may develop. **Skin bridges** may form between the glans and the shaft, leading to accumulation of smegma or the tethering of the erect penis. Most post-circumcision adhesions are reported to resolve at the time of puberty with the onset of masturbation or sexual activity.

In the immediate postsurgical period, urinary retention may occur secondary to tight surgical bandages. This complication can be prevented by applying local pressure rather than tight bandages to obtain hemostasis. Meatitis and meatal ulcers possibly caused by irritation from ammonia or damage to the frenular artery at the time of circumcision are also reported in circumcised males. Inclusion

cysts that represent implantation of smegma are also seen. Additional injuries following circumcision may include penile lymphedema, urethrocutaneous fistulae secondary to misplaced sutures, penile cyanosis, and necrosis secondary to tight Plastibell clamps. Wound dehiscence, which involves separation of the penile skin from the mucous membrane, and denudation of the penile shaft may occur more frequently with Gomco than Plastibell clamps.

CASE RESOLUTION

In the case history at the beginning of this chapter, the risks and benefits of circumcision should be discussed with the mother. The father should be encouraged to participate in the decision-making process.

If the parents elect not to have their son circumcised, they should be instructed on the appropriate care of the uncircumcised penis, which involves gentle external washing without retraction of the foreskin.

Nutritional Needs

Wendy T. Hui, MD, and Geeta Grover, MD

CASE STUDY

At a routine health maintenance visit, a mother asks if she may begin giving her 4-month-old daughter solid foods. The infant is taking about 4 to 5 oz of formula every 3 to 4 hours during the day (about 32 oz per day) and sleeps from 12:00 am to 5:00 am without awakening for a feeding. Her birth weight was 7 lbs (3,182 g), and her present weight and length (13 lbs [5,909 g] and 25 in. [63.5 cm], respectively) are at the 50th percentile for age. The physical examination, including developmental assessment, is within normal limits.

Questions

1. What are some of the parameters that may be used to decide when infants are ready to begin taking solid foods?
2. Up to what age is breast milk or infant formula alone considered adequate intake for infants?
3. At what age do infants double their birth weight? At what age do they triple their birth weight?
4. What problems are associated with the early introduction of solid foods?

Good nutrition is essential for normal growth and development. The physician plays an important role not only in assessing the growth of children from infancy through adolescence but also in counseling parents regarding the nutritional needs of maturing children. The primary care physician should be knowledgeable about key nutritional concepts in children, including growth patterns and nutritional requirements of normal children and how they vary with age, feeding patterns of infants and children, assessment of nutritional status, and common feeding and nutritional disorders.

Growth Patterns and Nutritional Requirements of Normal Children

Monitoring the growth and nutritional status of infants and children is an integral component of well-child care. The average normal expected increases in weight, height, and head circumference for the first several years of life are listed in Table 23-1.

The energy and nutritional requirements of children vary with age. Postnatal growth is most rapid during the first 6 to 12 months of life. Hence, caloric and protein needs are very high at this time. The average daily energy and protein needs of children from birth to 18 years of age are presented in Table 23-2.

On average, newborns weigh 7.7 lb (3.5 kg), are about 20 in. (50 cm) long, and have a head circumference of 14 in. (35 cm). They lose about 5% to 10% of their birth weight during the first several days of life and usually regain this weight by the age of 10 to 14 days. During the first several months of life, weight gain serves as an important indicator of children's general well-being. Failure to gain weight during this time may be a clue to a wide variety of problems, ranging from underfeeding to malabsorption. Newborns gain about 30 g/day (roughly 1% of their birth weight per day) for

Table 23-1. Normal Expected Increase in Weight, Height, and Head Circumference of Infants and Children

Normal Weight Gain	
Age	Expected Weight Increase
0–3 mo	25–35 g/d
3–6 mo	12–21 g/d
6–12 mo	10–13 g/d
1–6 y	5–8 g/d
7–10 y	5–11 g/d
Normal Height Increase	
Age	Expected Height Increase
0–12 mo	10 in/y (25 cm/y)
13–24 mo	5 in/y (12.5 cm/y)
2 y–puberty	2.5 in/y (6.25 cm/y)
Normal Increase in Head Circumference	
Age	Expected Increase in Head Circumference
0–3 mo	2 cm/mo
4–6 mo	1 cm/mo
7–12 mo	.05 cm/mo
Total increase	12 cm in the first year

the first 3 months of life, and about 10 to 20 g/day for the rest of the first year. Infants double their birth weight by 6 months of age and triple their birth weight by 12 months of age. On average, children weigh about 10 kg at 1 year of age, 20 kg at 5 years of age, and 30 kg

Table 23-2. Energy and Protein Needs of Children

Age (y)	Calories (kcal/kg/d)	Protein (g/kg/d)
0–1	90–120	2.5–3.0
1–7	75–90	1.5–2.5
7–12	60–75	1.5–2.5
12–18	30–60	1.0–1.5

at 10 years of age. A rough rule of thumb that can be used to estimate the expected weight of a child based on age is $2 \times (\text{age in years}) + 10 = \text{weight (kg)}$.

Feeding Patterns of Infants and Children

Liquid Foods

Breast milk or one of the several iron-fortified infant formulas provides complete nutrition for infants during the first 4 to 6 months of life. During the first month or two of life, infants take about 2 to 3 oz of formula (approximately 10 minutes on each breast) every 2 to 3 hours.

Because human milk is more easily digested than formula, it passes out of the stomach in 1½ hours. Formula may take up to 4 hours. Therefore, during the first 4 to 6 weeks of life, breastfed infants want to feed more frequently (8–12 times in 24 hours) than formula-fed infants (6–8 times in 24 hours), with an increased number of nighttime feedings as well. By about 3 to 5 months of age, breastfed and bottle-fed infants do not differ in the number of nighttime feedings, although some breastfed infants continue to awaken out of habit.

Most infants 6 months of age or younger consume about 4 to 5 oz per feeding every 4 to 5 hours. Under routine circumstances, human milk is preferred to infant formulas because it has emotional, nutritional, and immunologic advantages. Breastfeeding allows infants and mothers to develop a unique relationship that can be emotionally satisfying (see Chapter 24).

The composition of human milk varies over time. Colostrum, the first milk produced after delivery, is high in protein, immunoglobulins (Igs), and secretory IgA. Colostrum gradually changes to mature milk 7 to 10 days after delivery. The nutrient content of human milk of mothers who deliver preterm compared with those who deliver at term may vary considerably. Individual assessment may be necessary to determine the appropriateness of human milk for preterm infants.

Nutritionally, human milk is uniquely tailored to meet the specific needs of infants. Human milk provides approximately 20 kcal/oz, the same as routine infant formulas. Table 23-3 compares the composition of human milk and several infant formulas. Human milk has relatively low amounts of protein compared with cow's milk (1% vs 3%), yet the levels are sufficient to provide for satisfactory growth of infants.

Qualitative differences also make human milk more desirable. The casein-whey ratio in human milk is about 40:60, making it easier to digest than most infant formulas, which tend to have higher casein-whey ratios. Lactose is the major carbohydrate of both human and cow's milk, but it is present in higher concentrations in human milk. Fat is the primary source of calories in human milk. The fat in cow's milk, which contains primarily saturated fatty acids, is not as well digested by infants as human milk fat, which is predominantly composed of polyunsaturated fats. Recently, the long-chain polyunsaturated fatty acids docosahexaenoic acid (DHA) and arachidonic

Table 23-3. Composition of Human Milk and Select Infant Formulas
(Calories: 20 kcal/oz)

Formula	Protein	Carbohydrate	Fat
Human milk (mature)	40% casein and 60% whey	Lactose	Human milk fat
Cow's milk	80% casein and 20% whey	Lactose	Butterfat
Enfamil Lipil	Nonfat cow's milk and whey	Lactose	Palm olein, soy, coconut, and high-oleic sunflower oils; DHA, ARA
Similac Advance	Nonfat cow's milk and whey	Lactose	High-oleic safflower oil, coconut and soy oils, DHA, ARA
ProSobee Lipil	Soy protein and methionine	Corn syrup solids	Palm olein, soy, coconut, and high-oleic sunflower oils
Isomil Advance	Soy protein and methionine	Corn syrup solids and sucrose	High-oleic safflower oil, soy and coconut oils; DHA, ARA
Nutramigen Lipil	Casein hydrolysate, cystine, tyrosine, tryptophan	Corn syrup solids and cornstarch	Palm olein, soy, coconut, and high-oleic sunflower oils; DHA, ARA
Pregestimil Lipil	Casein hydrolysate, cystine, tyrosine, tryptophan	Corn syrup solids, modified cornstarch, and dextrose	MCT, high-oleic safflower and soy oils, DHA, ARA
Alimentum Advance	Casein hydrolysate, cystine, tyrosine, tryptophan	Sucrose modified tapioca starch	Safflower oil, MCT, soy oil, DHA, ARA

Abbreviations: ARA, arachidonic acid; DHA, docosahexaenoic acid; MCT, medium-chain triglycerides.

acid (ARA) have been added to most infant formulas to simulate the higher levels found in human milk. Although research suggests that DHA and ARA supplementation may enhance visual and cognitive development in formula-fed infants, the exact degree of effect remains unclear.

Human milk from well-nourished women should provide adequate amounts of all vitamins and other micronutrients. However, vitamin K, vitamin D, iron, and fluoride are not present in sufficient quantities to satisfy all nutritional needs over a prolonged period, and supplementation should be considered. The American Academy of Pediatrics recommends that all newborns receive a prophylactic dose of 0.5 to 1 mg of parenteral vitamin K in the immediate newborn period to help prevent bleeding disorders. Even though the vitamin D content of human milk is low compared with cow's milk, infants of healthy mothers have generally not been observed to develop rickets if there is sufficient exposure to sunlight. The newborn requires about 1 minute of exposure to sunlight on the face to produce enough vitamin D. However, adequate sun exposure is difficult to assess, and there are increasing concerns over the harmful effects of sunlight. Compared to the previous recommendation of an average intake of 200 IU of vitamin D per day, the 2010 Institute of Medicine recommendation calls for an average intake of 400 IU of vitamin D per day to meet the needs of most infants younger than 12 months. Although human milk contains less iron than iron-fortified formulas (fortified to about 12 mg/L of iron), the bioavailability of the iron in human milk is greater. Breastfed infants do not need iron supplementation until 6 months of age. Exclusively breastfed infants and infants who are fed ready-to-eat formulas or formulas prepared with bottled water should all receive supplementation with 0.25 mg of fluoride per day starting at 6 months of age (see Chapter 26).

Human milk has several immunologic advantages, which are both allergy protective and infection protective, over standard cow's milk-based formulas. Its allergy protective characteristics are attributed, in part, to the decreased intestinal permeability associated with human milk compared with standard formulas. The host defense factors present in human milk include Igs, complement, and cellular components (eg, macrophages, neutrophils, lymphocytes). Studies have shown that the incidences of both viral and bacterial illnesses are lower in exclusively breastfed infants compared with their formula-fed peers.

Breastfeeding is the recommended method of infant feeding during the first 6 months of life, but it is not always possible and is occasionally contraindicated. Although maternal infection is usually not a contraindication to breastfeeding, maternal HIV infection is one exception to this recommendation in the United States. This is not necessarily true, however, in many developing countries, where the risk of death during the first year of life without breastfeeding is greater than the risk of HIV infection. Antibiotics are generally safe during breastfeeding, but certain other drugs are contraindicated.

Solid Foods

Supplemental foods may be added to infants' diets between the ages of 4 to 6 months. Solid foods should be introduced as soon as infants require the additional calories and are developmentally mature (eg, infant can sit and support the head). Early introduction of solid foods has been associated with an increased incidence of food allergy and may contribute to overeating and obesity. Factors that indicate infants may be ready for solid foods include (1) current weight twice that of birth weight, or about 13 lbs; (2) consumption of more than 32 oz of formula per day; (3) frequent feeding (regularly more than 8–10 times per day or more often than every 3 hours); and (4) persistent dissatisfaction due to hunger.

The quantity of formula should be limited to no more than 32 oz to allow for the introduction of solid foods. An iron-fortified infant cereal, most commonly rice cereal because it does not contain gluten, is usually the first solid food offered to infants. Other single-grained cereals, such as barley cereal or oatmeal, are also appropriate early supplemental foods. Fruits and vegetables may be introduced within a few weeks. The order is not as important as the need to add only one new food at a time—no more than 1 to 2 new foods per week. Meats may be introduced after 6 months of age.

Although commercially prepared infant juices are an important source of vitamin C for infants and may provide a smooth transition to solid foods, excessive juice intake may be associated with diarrhea and growth failure. About 2 oz of apple juice can be given at 4 to 6 months of age. This can be gradually increased to about 4 oz/day. Once infants have accepted the juice, juice can be mixed with a small quantity of cereal and offered to infants with a spoon. Solid foods should not be mixed in the bottle; caregivers should wait until the infant can accept spoon feedings. The vitamin C in the juice increases the bioavailability of the iron in the cereal. It is not unusual for infants to reject their first several spoonfuls of cereal because the tastes and textures are new. If they refuse the feeding, it should be stopped. Solid foods should be reintroduced in 1 week.

Precooked infant cereals, such as rice cereal, can be mixed with a variety of liquids, including human milk, formula, infant fruit juices, or water. Initially, the cereal should be mixed to a thinner consistency (eg, about 1 tablespoon of cereal to 2 oz of liquid), and once infants have accepted the new taste and texture, the mixture should gradually be worked to a thicker consistency. By about 7 to 8 months of age, infants should be taking 4 to 6 tablespoons of cereal mixed with enough liquid to give the mixture the consistency of mustard. Mixed cereal grains may be given to older infants.

A wide variety of commercially prepared baby foods designed to be developmentally appropriate and labeled by stage (ie, first, second, third stage) are available. The jars of different stages contain the amount of food that an infant at a given age should be able to eat at one sitting. This is not always the case, however, and opened jars of baby food may safely be stored in the refrigerator for 2 to 3 days. Infants should not be fed directly from the jar, because saliva on the spoon mixes with the remaining food and digests it, causing it to

liquefy. Vegetables and meats may be offered at room temperature but should be warmed slightly for greater palatability. Fruits and desserts may be at room or refrigerator temperature.

First-stage foods, for infants 4 to 6 months of age, include strained infant juices; single-grain cereals; and puréed strained fruits and vegetables, such as bananas, carrots, and peas. These foods contain no egg, milk, wheat, or citrus, to which some infants may be sensitive. Second-stage foods, for infants from about 6 to 9 months of age, are smooth, mixed-ingredient foods, such as mixed vegetables, or meat dinners, such as chicken noodle. Third-stage foods, or junior foods, are for infants about 9 to 10 months of age who can sit well without support, have some teeth, and have begun self-feeding. These more coarsely textured foods contain a wider variety of nutrients, such as vegetable and meat dinner combinations. Finger foods, such as crackers, cheese wedges, or cookies, can also be introduced by 9 to 10 months of age, once infants have developed a pincer grasp. Most infants are eating the same meals as the rest of the family (table foods) by about 1 year of age. Foods that can easily be aspirated, such as raw carrots, nuts, and hard candies, should be avoided, however, until children are older than 4 years.

Baby foods can be prepared at home as long as they are finely puréed or strained and contain enough liquid to make them easy for infants to swallow. One danger of preparing foods at home is that sugar, salt, or spices can be easily added to make foods palatable to adults. These ingredients are not necessary for infants. In addition, homegrown, home-prepared vegetables may be contaminated with high levels of nitrates (eg, due to contaminated well water) and nitrites (eg, in vegetables such as carrots, beets, and spinach). Nitrates and nitrites have been implicated in the development of methemoglobinemia, especially in infants younger than 6 months. Methemoglobinemia decreases the oxygen-carrying capacity of the blood, leading to anoxic injury and death.

Weaning from the breast or bottle to a cup usually occurs at 6 to 12 months of age but may be delayed up to 18 months of age in some children. Homogenized, vitamin D–fortified cow’s milk may be given at 12 months of age. Skim milk or low-fat milk (2% milk fat) should not be given before 2 years of age.

Diet of Children and Adolescents

The caloric and protein needs of children decrease in the second year of life, paralleling the decrease in growth rate during this time. Milk intake also decreases, and may drop to 16 oz/day by 24 to 36 months of age. Except for increased caloric requirements, the diet of school-aged children and adolescents should be similar to that of normal adults. Evidence that foods eaten during childhood may have long-lasting effects on adult health is increasing, and it is important that children develop healthy eating habits early in life. Atherosclerosis, osteoporosis, and obesity are some of the diseases that may have their beginnings during childhood.

A major revision to the US Department of Agriculture’s (USDA) dietary guidelines and food pyramid for ages 2 and older was released in 2005. This new pyramid emphasizes physical activity,

moderation, gradual improvement, personalization, portionality, and variety in food groups. A child-friendly version of this pyramid has been incorporated in the highly interactive Web site of these new dietary guidelines.

To promote lifelong heart healthy habits, the American Heart Association (AHA) released a statement of dietary recommendations for children and adolescents. It recognizes that children are often offered nutrient-poor foods that are high in fat and sugar and overly processed. The AHA recommendations support the USDA guidelines and include eating fruits and vegetables daily while limiting juice intake, using vegetable oils and soft margarines low in saturated fat and trans-fatty acids instead of butter or other animal fats, eating whole grain rather than refined grain breads and cereals, using nonfat or low-fat milk and dairy products, eating more fish, and reducing salt intake. The AHA also encourages behaviors for parents/caregivers that promote healthy habits for the whole family. These recommendations ask parents/caregivers to choose mealtimes, to provide a social context for eating by having regular family meals, to lead by example in their own eating habits, and to allow children to self-regulate food intake and not to force them to finish meals if not hungry.

Children who consume a varied diet do not need routine vitamin supplementation. However, children and teens who are considered “picky eaters,” as well as children at nutritional risk, may benefit from supplementation. This includes children and teens who are anorexic or those who follow fad diets, those with chronic diseases, those who consume a vegetarian diet, and those with failure to thrive. A standard pediatric vitamin-mineral supplement should contain no more than the dietary reference intakes of its components. Parents should be counseled to teach their children that the supplements are not candy and to keep them out of reach. Serious overdoses can occur, especially with iron-containing formulations.

Bone health is determined by calcium and vitamin D intake, as well as weight-bearing physical activity. Recent data suggest the possibility of other important health benefits throughout life of these key nutrients, in addition to bone growth and development. The 2010 Institute of Medicine Guidelines call for a recommended daily allowance of 600 IU per day of vitamin D for children older than 1 year and 1,300 mg of calcium per day for children 9 to 18 years of age. Unfortunately, calcium intake for most US children, and particularly adolescents, is generally below the recommended levels. Barriers to adequate calcium intake may be due to the preference of sweetened juice and soft drinks over milk as well as lactose intolerance in certain populations. Nondairy calcium sources include salmon, white beans, broccoli, and calcium-fortified foods such as orange juice, breakfast cereals, and soy milk. Adequate calcium intake can be achieved by eating 3 (or 4 for adolescents) age-appropriate servings of dairy products or other calcium-rich food per day. In children and adolescents who do not consume adequate amounts of calcium from dietary sources, a calcium supplement is recommended. This can be in the form of a multivitamin in the younger child or in the form of calcium carbonate tablets with or without vitamin D for the adolescent.

Adolescence is a period of tremendous physical and emotional growth, both of which greatly affect nutritional needs and habits. Although their rapid physical growth requires increased energy and nutrients, the common eating habits of teens do not always support their needs. Teens tend to skip meals, eat outside the home, consume fast food and snacks, and experiment with different restrictive diets that are fad diets or various forms of vegetarianism.

Teen athletes also have their own unique nutritional concerns. They want to maximize performance while maintaining the desired physique for their particular sport or weight class. While there are many nutritional supplements, such as creatinine, carnitine, various amino acids, and dehydroepiandrosterone, that claim to enhance athletic performance, none has thus far been fully evaluated scientifically. Instead, teen athletes should be counseled on the importance of a basic nutrient: water. Proper hydration does enhance performance and prevents heat injury. Approximately 4 to 8 oz of fluid for every 15 minutes of exercise is recommended regardless of actual thirst. Carbohydrate loading before competition is believed to enhance performance; however, this practice has no effects on non-endurance events and may confer only a modest effect for endurance events by prolonging time to exhaustion. In counseling a teen athlete, specific questions should also be directed to elicit any unhealthy practices to maintain or lose weight.

Vegetarianism is gaining popularity among adolescents. Reasons for choosing vegetarianism are varied, including health benefits, means for weight loss, animal cruelty concerns, and religious beliefs. It is important to ask the vegetarian their specific restrictions as these relate to their nutritional risks. Semi-vegetarians are those who avoid red meat but eat fish and chicken in moderation. Lacto-ovo vegetarians consume animal products, such as dairy and eggs, but avoid animal flesh. Vegans do not eat any animal products, such as dairy, eggs, honey, or gelatin. Those who follow a macrobiotic diet restrict not only animal products but also refined and processed foods, foods with preservatives, and foods that contain caffeine or other stimulants.

A well-planned vegetarian diet can provide for all of the necessary nutrients; however, many teens experiment with vegetarianism in a nonvegetarian household and require guidance. The nutrients that may be deficient in a vegetarian diet are protein, calcium, vitamin D, vitamin B₁₂, iron, and zinc. Protein intake is usually not a concern for lacto-ovo vegetarians because eggs and dairy have high-quality proteins. Vegans and macrobiotic followers have a variety of plant-based protein sources from which to choose, such as legumes, cereals, nuts, seeds, and fruits. Since vitamin B₁₂ is only found in animal-based foods, vegans and macrobiotic followers must ensure adequate intake by taking supplements or consuming vitamin B₁₂-fortified foods, such as soy and nut beverages and cereals.

Lastly, familiarity with the latest fad diets is an asset for any primary care practitioner. These diets are usually restrictive in certain nutrients and recommend unusual dietary patterns that are inconsistent with current USDA guidelines. Although there are some suggestions that these diets work for some adults, there are almost no

scientific data for children and adolescents. Popular plans include Atkins and other high-fat/low-carbohydrate diets; the Zone Diet, which emphasizes a very specific ratio of protein and carbohydrates; the Ornish diet, which is extremely low fat; the South Beach Diet, which alters the types of carbohydrates for an optimal glycemic index; and the more exotic liquid or detoxification plans. To keep abreast of the latest fads, the reader is referred to the American Dietetic Association's Web site (www.eatright.org), which maintains an annual review of such popular fad diets.

Evaluation

History

Nutritional assessment begins with a complete dietary history. The dietary assessment should emphasize the quantity, quality, and variety of foods in the diet. Any special or restricted dietary habits should be noted (eg, vegetarian diet). A 3-day food record listing the types and quantities of food eaten throughout the day can be very helpful in evaluating the dietary history.

In addition, the child's routine medical, family, and social history all may influence nutritional status. For example, the economic status of families may affect the variety and type of foods that they may be able to purchase, and the level of education of parents influences their ability to understand the concepts of a healthy diet. Poverty and ignorance regarding nutritional needs are among the most common reasons for malnutrition in children. Family access to food can be estimated by asking parents about how often the family skips meals during the average month. Such information assesses food insecurity within a household. Specific cultural food preferences and feeding practices should also be included in the history.

Physical Examination

Weight, length or height, head circumference, weight for length, and body mass index (BMI) should be measured or calculated routinely and plotted on a longitudinal basis on appropriate growth curves. In addition to the charts provided by the Centers for Disease Control and Prevention, additional charts are available for special populations for which growth is altered, such as infants and children with low birth weight and prematurity, Down syndrome, Turner syndrome, William syndrome, and several other chromosomal and genetic disorders. Changes in the rate of growth over time are more useful than a single measurement in time in the assessment of nutritional problems. Calculation of the height age (age for which the child's height is at the 50th percentile), weight age (age for which the child's weight is at the 50th percentile), and ideal weight for actual height may be useful when deviations from normal are noted.

In addition to the overall impression regarding nutritional status, certain findings on physical examination may be characteristic of particular nutritional disorders. The evaluation of the hair, skin, eyes, lips and oral mucosa, dentition, and musculoskeletal system should be emphasized because the examination of these areas is most likely to show the effects of malnutrition. Muscle wasting;

hepatosplenomegaly; skeletal deformities; decayed teeth; rough, dry skin; easily pluckable hair; and irritability may all be clues to inadequate nutrition.

Laboratory Tests

Suspected malnutrition or nutrition-related disorders, based on history and physical examination, can be further investigated with laboratory studies. Tests that may be used in the evaluation of anemia, one of the most common nutrition-related disorders seen in children, include a complete blood cell count, reticulocyte count, serum iron, ferritin, and total iron-binding capacity. Investigation of suspected malnutrition begins with an assessment of protein status, with measures of indicators such as serum albumin, total protein, and prealbumin. Liver function tests and a lipid profile may also be useful in the evaluation of suspected malnutrition. Screening tests that may be used in the evaluation of failure to thrive (FTT) include thyroid function studies, urinalysis, and bone age (see Chapter 129). More specific tests, such as serum vitamin levels (eg, folate or vitamin B₁₂ levels in suspected malabsorption) or hormone assays (eg, growth hormone levels in the evaluation of short stature), may be obtained in certain instances.

Common Feeding and Nutritional Problems of Childhood

Several gastrointestinal (GI) problems have been attributed to diet. A small amount of spitting up is seen in most children, especially during the first 6 months of life. However, vomiting can be a sign of several disorders, ranging from viral GI tract infections to more severe illnesses, such as pyloric stenosis, urinary tract infection, and GI obstruction (see Chapter 107). Constipation, which is seen more commonly in formula-fed than breastfed infants, may be due to insufficient fluid intake (see Chapter 111). The simple addition of 4 to 6 oz of water to an infant's diet or temporary use of apple or prune juice may solve the problem. Enemas and suppositories should not be recommended routinely.

Chronic nonspecific diarrhea of childhood, or "toddler's diarrhea," may be seen in infants and children 6 months to 5 years of age with low dietary fat intake and excessive fruit juice consumption (see Chapter 110). Failure to absorb sugars, especially sorbitol and fructose, can lead to an osmotic diarrhea.

Underfeeding or a diet that is not nutritionally balanced may result in FTT (see Chapter 129). The opposite problem, obesity, is one of the most common nutritional problems of children in the United States (see Chapter 135). The prevalence of this condition in children 6 to 11 years of age is estimated to be about 20% to 25%. Finally, the eating disorders anorexia nervosa and bulimia nervosa are estimated to affect about 1 in 100 adolescent females 16 to 18 years of age (see Chapter 133).

The "picky eater" is a common parental concern in the primary care setting. For practitioners who work with the Latino population, the child who "no come nada," literally translated as the child "does not eat anything," is a similar common parental concern. Parents can be reassured by their child's normal weight for height or BMI and

growth velocity. They should be counseled that it is normal for preschoolers to exert their individuality by limiting food preferences, the fact that it may take up to 10 exposures for a child to accept a new food, the difference between child and adult portion sizes, and the concept that children can self-regulate food intake to sustain normal growth and health.

Nutritional disorders include malnutrition and deficiencies of vitamins and minerals. Iron deficiency anemia is one of the most common nutrition-related problems seen in children and adolescents. Malnutrition is one of the leading causes of childhood morbidity and mortality worldwide. Although primary protein-calorie malnutrition (PCM) is rare in most parts of the United States, surveys conducted on pediatric wards have demonstrated that about one-third of pediatric inpatients with chronic disease have evidence of some degree of PCM. The most common deficits were weight for height below 90% of standard (ie, evidence of acute malnutrition) and height for age below 95% of standard (ie, evidence of chronic malnutrition). The 2 forms of PCM are marasmus (severe caloric depletion) and kwashiorkor (inadequate protein intake). Untreated PCM can result in impaired growth, poor intellectual development, and impaired immune functioning.

CASE RESOLUTION

The infant described in the case history is probably ready to begin some solid foods because she is consuming 32 oz of formula per day and continues to be hungry. In addition, she has reached a weight of 13 lbs and has almost doubled her birth weight. The mother is counseled to begin feeding her daughter a single-grain infant cereal mixed with either formula or juice. (The cereal should be fed by spoon, not given in a bottle.) Within a few weeks, once the infant is taking the cereal well, other first foods, such as fruits and vegetables, may be introduced.

Breastfeeding

Julie E. Noble, MD

CASE STUDY

A 25-year-old female, pregnant with her first child, comes into your office with her husband for a prenatal visit. She would like to know what advice you can give her regarding breastfeeding. She expects a normal delivery, has had no breast surgery, and is not on any medications, but does smoke cigarettes occasionally. She plans to return to work when the baby is 4 months old.

Questions

1. What is the normal physiology of lactation?
2. What are the benefits of breastfeeding?
3. What are the contraindications to breastfeeding?
4. What management maximizes a mother's success at breastfeeding?
5. How do you manage some of the common problems that may arise during breastfeeding?

Human milk is the natural food source for human infants. It is a complete nutritional product made specifically for human infants, and all **formulas** are incomplete attempts to try to replicate it. **Human milk** is made of water, fat, lactose-containing carbohydrates, and protein, as well as vitamins, **immunoglobulins**, enzymes, hormones, and even phagocytes and lymphocytes. It is a dynamic fluid that changes in composition as the infant grows. From the early **colostrum**, which is high in lactose and protein in the form of casein and whey and very immunologically active, it matures through lactogenesis to a substance in much greater quantity with lower protein, but still immunologically active.

Epidemiology

In previous generations, infants were totally dependent on breastfeeding by their mother or a wet nurse for their survival. When formula feeding was attempted at founding hospitals in Europe and the United States in the 1800s, the infant mortality rate was as high as 85%. Thus the advantages of breastfeeding were recognized and still promoted in the early 1900s. Following the advent of pasteurization, cow's milk formula became much safer. Formula development allowed more mothers to enter the workforce, which became a necessity during World Wars I and II. With poorer urban mothers working outside the home and upper-class mothers choosing not to breastfeed preferring the freedom that formula feeding allowed, breastfeeding rates declined over the course of the 20th century. **Formula** feeding became the norm and formula companies successfully marketed formulas as the better method to feed an infant. But current scientific understanding of the many benefits of breastfeeding for both infant and mother has been the impetus to again promote breastfeeding as the preferred food source for infants.

In the United States today following the **Healthy People 2010 initiative**, which included a national agenda calling for an increase in the rate of breastfeeding, 75% of mothers are initiating breastfeeding. But the rate of mothers sustaining breastfeeding to 1 year of age is only 22%. Rates of breastfeeding are lower in low socioeconomic groups and among women with lower levels of education. The rates also vary with different ethnic groups; in the United States the African American community has the lowest rate of breastfeeding.

Multiple health professional organizations have endorsed breastfeeding. In 1991 the World Health Organization and UNICEF developed the Baby-Friendly Hospital Initiative delineating 10 steps to undertake in the hospital to promote successful breastfeeding. This initiative is used worldwide to improve breastfeeding rates. The American Academy of Pediatrics published its policy statement, "Breastfeeding and the Use of Human Milk" in 2005. This policy endorses breastfeeding and delineates the physician responsibility to promote and support it. In 2011 the US Department of Health and Human Services issued *The Surgeon General's Call to Action to Support Breastfeeding*. There is now an imperative to promote breastfeeding in this country.

Anatomy and Physiology of Lactation

During pregnancy the breast responds to **estrogen**, **placental lactogen**, **prolactin**, and **progesterone** by enlarging. There is an increase in breast lobules and alveoli where milk is produced; and the **ductile system** grows, leading to 10 to 15 milk duct openings in the nipple. The nipples develop and the surrounding areolas enlarge. Prolactin from the anterior pituitary is inhibited by progesterone and estrogen. With the drop in these hormones after delivery, the **prolactin** is free to stimulate increased milk production. With the stimulus

of suckling, **oxytocin** is released from the posterior pituitary and causes contraction of myoepithelial cells, which squeeze milk from the alveoli. Production of **milk** is dependent on infant suckling. The more the infant feeds and the more the breast is effectively emptied, the more milk will be produced.

Benefits of Breastfeeding

For the infant, the benefits to being breastfed are myriad. Studies have demonstrated that breastfed infants have a decreased incidence and severity of **infectious illnesses**, including diarrhea, respiratory infections, otitis media, bacterial meningitis, and urinary tract infections. The incidence of otitis media is 100% higher in formula-fed infants than exclusively breastfed infants. There have also been studies demonstrating better performance on **cognitive testing** among breastfed infants. Among preterm infants fed human milk, the incidence of necrotizing enterocolitis is also significantly reduced. Breastfeeding in infancy also reduces the later incidence of **atopy**, **allergies**, **asthma**, **childhood obesity**, **type 2 diabetes**, and even **childhood cancer**. Decreased rates of **sudden infant death syndrome** (see Chapter 59) have also been documented.

For the mother, an immediate benefit to breastfeeding is oxytocin-induced decreased postpartum blood loss and enhanced infant bonding. Lactation amenorrhea may serve subsequently as birth control. Breastfeeding has also been associated with decreased risk of breast cancer, ovarian cancer, and osteoporosis in the mother. There is also some evidence to suggest that breastfeeding decreases the risk of postpartum depression.

Societal benefits from breastfeeding include markedly decreased annual health care costs. An estimated savings of \$10.5 billion dollars yearly could be generated if 80% of American families breastfed exclusively for the first 6 months. A decreased incidence of illness among infants would also enable mothers to miss fewer workdays, increasing their productivity and benefiting the workplace. In addition, with an increased breastfeeding rate there would be a reduction in environmental waste from bottles and **formula** containers.

Barriers to Breastfeeding

There have been many studies evaluating the barriers in the United States to breastfeeding. Understanding these barriers is essential to devising strategies for effective interventions to improve breastfeeding rates. With effective physician, nursing, and peer support, most mothers should be able to breastfeed successfully. One of the most important barriers is the lack of knowledge in pregnant women about the benefits of breastfeeding. Education beginning at the first prenatal visit is vitally important. Campaigns encouraging breastfeeding through public health venues can help with education of the general populace.

Some mothers experience embarrassment at breastfeeding. Identifying this issue and helping these mothers become more comfortable with their own body through counseling can be useful for these mothers. Physicians can also counsel the mother and family about ways to preserve privacy while breastfeeding.

Many new mothers have poor family support for breastfeeding, and sometimes the whole family needs to be included in breastfeeding counseling. The mother will not be successful if her mother is negative to the proposal.

Some mothers find that their place of employment does not make accommodations for a breastfeeding mother. It may be that the workplace needs to be reminded of laws promoting breastfeeding in the workplace. The Affordable Care Act provided a provision that the workplace needed to provide a private place for nursing mothers to pump for up to 1 year.

Hospitals may have practices or policies that interfere with successful breastfeeding, including high cesarean delivery rates or no rooming-in policy. Physicians should work with their hospitals to minimize these potential barriers.

Contraindications

The true contraindications to breastfeeding are few but need to be addressed. If an infant has **galactosemia** as detected by newborn screening, and is therefore unable to metabolize lactose or galactose, he may not breastfeed. Infants can also inherit defects in protein metabolism that may call for a special diet, precluding breastfeeding. In most states, newborn screening now includes testing for most of these metabolic disorders.

Maternal infections prohibiting breastfeeding include active, untreated tuberculosis; HIV; and human T-cell lymphotropic virus types I and II. If herpetic vesicles are present on the breast, the mother should not breastfeed.

Many medications are safe for a mother to use while breastfeeding, but each should be reviewed for potential contraindications before administering because most medications pass into **human milk**. Chemotherapeutic agents, antimetabolites, and radioactive isotopes are all contraindicated for breastfeeding. Drugs of abuse are definitely contraindicated in a breastfeeding mother, although a mother with a history of drug use may benefit from breastfeeding as long as her toxicology results are closely monitored and are negative.

Breastfeeding Management

The management of breastfeeding should begin in the prenatal period. The US Preventive Services Task Force endorses promotion and support for breastfeeding at all health care encounters. The pregnant woman should be educated by both her pediatrician and obstetrician on the benefits of breastfeeding. Her history should be reviewed for potential contraindications. If none exist, she should be encouraged to breastfeed. If she commits to breastfeeding before the baby is born, she is more likely to be successful. Involving her partner in these discussions has also been shown to improve breastfeeding success rates.

At the time of delivery if there are no complications, the infant should be dried, assigned Apgar scores and, after a screening physical examination, be placed skin-to-skin on the mother's abdomen or chest for warmth and contact. He will find his way to the breast and latch on. This early breastfeeding experience will greatly facilitate

further breastfeeding. The infant should not be separated from the mother except for medical reasons. A hospital policy for rooming-in will greatly facilitate breastfeeding. A healthy full-term infant has no medical need for formula supplements.

During the hospital stay, the infant should breastfeed every 1 to 2 hours on both breasts for as long as he wants. Without pacifiers or supplemental feeds, the infant will learn to breastfeed more quickly. The mother should be counseled regarding appropriate latch-on, positioning of the infant, and manual expression of milk. Breastfeeding support should be available from all involved hospital staff, and a certified lactation consultant can be very helpful. Generally the infant should nurse at least 8 times a day. The infant should be monitored for weight, evidence of jaundice, and urination and stool patterns. A successful breastfeeding infant should urinate 3 to 5 times per day and stool 3 to 4 times per day by 3 to 5 days of age and not lose more than 7% of his birth weight. By day 5 to 7 of life he should urinate 4 to 6 times per day and pass 3 to 6 stools per day.

Vitamin K (1.0 mg intramuscularly) is indicated within the first 6 hours of life to prevent hemorrhagic disease of the newborn. The only supplement to breastfeeding that is needed is vitamin D 400 IU daily after 2 months of age to prevent rickets.

After hospital discharge the breastfeeding infant should be seen by his physician at day 3 to 5 of life and again at 2 weeks of age to support breastfeeding. Early assessment may prevent many breastfeeding problems and will allow the physician to intervene early if problems arise, preventing discontinuation of breastfeeding. New mothers need encouragement and reassurance. At each visit, the infant should be assessed for weight, feeding schedules, voiding and stooling patterns, and jaundice. The mother's breasts should be examined and a feeding observed.

The infant should exclusively breastfeed until 6 months of age. At that time an iron source is needed, and iron-fortified cereal can be given with a gradual introduction of other puréed foods. The recommendation is that breastfeeding continue until at least 1 year of age or as long as the mother and infant are content.

If a mother is returning to work, she should be counseled to initiate breastfeeding and establish a schedule. When breastfeeding is well established, she can introduce a bottle of expressed milk when the infant is about 2 months of age. When separated from the infant, she should pump her breasts at regular intervals. The milk can be saved in the refrigerator for up to 8 days or in the freezer for up to 6 months (ideal) or even 12 months (acceptable) for later use. Milk should be used within 4 to 6 hours if at room temperature. In general milk should be stored in 2- to 4-ounce bags or containers, which are labeled with the date. Many states have legislation to ensure that working mothers have time and an appropriate place in the work environment to pump. When she is back with the infant, she should put the infant to breast at the usual interval. Many mothers can work and breastfeed well past the infant's first birthday.

Sometimes pediatricians will be consulted about weaning the breastfed infant. There is no age at which weaning must occur, and in many cultures toddlers nurse until the age of 3 to 4 years. While

some infants readily give up the breast, others are more reluctant to do so. There are no easy solutions to dealing with a reluctant toddler, and some suggestions include the adage, "Don't offer but don't refuse." Lactation consultants may be a valuable resource at this time.

Potential Problems

Attachment

Latching-on is the first step that is essential for successful breastfeeding. An infant with a correct latch will have the nipple and significant portion of the areola under the nipple in his mouth with his lips flanged outward. If an infant is not latching effectively, the mother will experience pain and the infant should be removed from the nipple and attached again. If problems persist, a medical professional should evaluate the mother–infant dyad for problems. Causes can include inverted nipples, flat nipples, ankyloglossia (tongue-tie), small mandible, or nipple confusion. Treatment may consist of help with positioning, nipple shields, frenectomy, or syringe feeding until the infant learns to latch.

Sore Nipples

Breastfeeding should not be painful. If the mother is experiencing pain, the infant is probably not latching correctly and may be chewing on the nipple. This may cause cracked and even bleeding nipples. The infant should be positioned on the breast to get as much of the areola in the mouth as possible. Cracked nipples can be treated with lanolin and/or hydrogel pads and repositioning. Expressed milk left to dry on cracked or bleeding nipples has healing properties. If there is significant bleeding the mother may need to pump that breast for 24 hours, while the nipple heals. The infant can be syringe fed if necessary to avoid nipple confusion. Occasionally sore nipples are secondary to a candidal infection and should be treated with an antifungal medication, such as nystatin.

Engorgement/Mastitis

When there is milk stasis for any reason, a mother may become **engorged**. The breast will appear full, firm, lumpy, and tender. Treatment is to empty the breast, and the infant is the most effective breast pump. Warm packs or a hot shower before feeding can be helpful. Sometimes an electric breast pump expedites emptying, softens the breast, and facilitates infant latching.

If a mother develops **mastitis**, a breast infection with erythema and fever, she should continue to breastfeed. Again, emptying the breast is important. Oral antibiotics and rest are mandatory. There are isolated reports of breastfed infants acquiring a bacterial infection if the mother has mastitis. Mastitis involves a cellulitis of the breast, and the organisms are usually not in the ducts or **milk**. Infants may refuse to breastfeed on an affected breast if the taste of the milk is affected. The mother may then elect to breastfeed the infant on the unaffected side and pump the affected breast. Ineffective treatment of mastitis may cause it to progress into a breast abscess. Treatment may include intravenous antibiotics and surgery. If there is frank pus

coming from the nipple, the infant should not breastfeed until the discharge has resolved. The mother should pump the affected breast to empty the milk supply.

Hyperbilirubinemia/Dehydration

If infants lose more than 7% of their birth weight, they are at risk for becoming significantly dehydrated and have a higher likelihood of significant jaundice. Increased intake is necessary, and the frequency of feeds should be increased. If infants are not latching on well, expressed **milk** can be given by syringe. Infants should be closely monitored, and **formula** can be offered after breastfeeding if milk supply is insufficient. The mother should be assisted in increasing her milk supply. This may be accomplished using a breast pump because increased demand increases supply. If the infant appears significantly jaundiced, blood levels of bilirubin should be obtained. Physiological jaundice is related to hepatic immaturity with decreased conjugation of bilirubin as well as decreased excretion and mild dehydration. Breastfeeding infants tend to have higher levels of unconjugated bilirubin. Increased feeding will frequently resolve the problem as hydration status improves and frequency of stooling increases. Occasionally, especially in late preterm infants, treatment with phototherapy is needed. The infant should be evaluated for any other causes of jaundice and should be followed closely (see Chapter 113) and treated as indicated.

Resources for the Breastfeeding Mother

Many hospitals and health care organizations have lactation specialists who can assist nursing mothers and answer questions related to lactation. Health facilities may loan **electric breast pumps** to new mothers to help establish a good supply of milk. Some mothers may choose to purchase such pumps, especially if they are planning to continue to breastfeed after returning to work or to have additional children. Recent legislation has designated breast pumps as medical devices that are covered by health insurance.

Access to information can also be obtained through community agencies or national organizations such as the **La Leche League** (www.lalecheleague.org) or the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) program. Such agencies provide a resource to the clinician in assisting mothers with breastfeeding.

CASE RESOLUTION

In the case presented, the mother should be informed of the many benefits of breastfeeding to the baby, herself, and society. She should be encouraged to breastfeed because she has no contraindications. You recommend she stop cigarette smoking completely for her own health as well as the baby's. In the hospital she should request she be given her infant to breastfeed in the delivery room and continue to room-in to breastfeed every 2 hours. Reassure her that both the hospital and your office will give her support and guidance with breastfeeding. Even though she is anticipating going back to work, she should initially breastfeed exclusively. She can begin to introduce the bottle with pumped milk at 2 months of age. Her workplace should provide an area for nursing mothers to pump and refrigerate the milk. You encourage her to explore the lactation policies at her place of work.

Sleep: Normal Patterns and Common Disorders

Geeta Grover, MD

CASE STUDY

During a routine 6-month health maintenance visit, a mother states that although her 6-month-old son falls asleep very easily at about 10:00 pm every night while breastfeeding, he wakes every 2 to 3 hours and cries until she nurses him back to sleep. A review of the dietary history reveals that the infant is breastfed about every 3 hours and was begun on rice cereal 2 weeks ago. His immunizations are current. The boy has no medical problems, and his physical examination is normal.

Questions

1. How old are most infants when they can begin to sleep through the night (at least 5 hours at a stretch) without a feeding?
2. What factors contribute to frequent nighttime wakings during infancy?
3. What advice can be given to parents to facilitate an infant's sleeping through the night?
4. What are sleep disturbances experienced by older children and adolescents?

Sleep disorders are common during infancy and childhood. Getting children to go to bed, fall asleep, stay asleep, and stay in bed can be no small challenge. Parents frequently ask pediatricians about sleep-related problems at routine health maintenance visits. Age-appropriate suggestions on how to help children sleep well are usually welcomed by parents.

Epidemiology

Sleep problems are one of the most common concerns seen in pediatric practice. Bedtime struggles and frequent night wakings occur in 20% to 25% of children younger than 3 years. In preschool-aged children, nighttime fears (eg, fear of noises, fear of the dark) or separation anxiety often contributes to these problems. Estimates of parent-reported sleep problems in school-aged children range between 11% and 40%. As children get older, nightmares and night terrors may contribute to night wakings. About 5% of individuals experience nightmares, which usually begin before the age of 10 years and are seen more often in girls than in boys. Night terrors are a specific form of partial night waking from deep sleep that may begin during the preschool years. The incidence in children is reported to be between 1% and 4%, with the greatest frequency between 5 and 7 years of age. Such terrors are more common in boys than in girls, and a familial tendency has been reported. Febrile illness and obstructive sleep apnea may be predisposing factors.

In most Western countries, children are expected to sleep in their own beds. However, in many cultures, it is not uncommon for infants

and young children to sleep in their parents' bed (the "family bed"). Bedsharing in infants younger than 10 to 12 weeks is associated with a higher incidence of sudden infant death syndrome, especially if the mother smokes. Accidental asphyxia from overlaying or the presence of soft bedding or overheating may contribute to bedsharing-related deaths. Parents should always be advised about safe sleeping practices (see Chapter 59). In older infants and children, cosleeping is not a problem in and of itself, and the decision to cosleep, like the decision to breastfeed or bottle-feed, is an entirely personal one. Most infants who share a bed with their parents have sleep-onset associations to facilitate falling asleep. Therefore, parents who share a bed with their young children commonly have to lie down with them for 20 to 30 minutes to get them to fall asleep. Several studies have shown that cosleeping infants are 2 to 3 times more likely to have night awakenings than those who sleep alone. Furthermore, infants who are both breastfeeding and bedsharing sleep the shortest periods prior to awakening. Parents who only plan on cosleeping with their infants for a limited period will need a clear transition plan, such as ending this practice by 5 to 6 months of age, before the infants are old enough to object excessively. For children with sleep problems, bedsharing is not a good solution. However, in the absence of any preexisting sleep problems or psychological concerns, cosleeping, as a lifestyle choice, has not been associated with any long-term developmental, behavioral, or psychological problems in the cosleeping children.

Clinical Presentation

Parents may raise concerns about their child's sleep pattern during a routine health maintenance visit. Because some parents may be reluctant to "bother" their physician with such seemingly minor concerns, the physician should routinely question parents about their children's sleep patterns and offer anticipatory guidance as appropriate.

Pathophysiology

To understand disturbances associated with sleep, the physiology of normal sleep and the development of normal sleep behavior in children must be understood.

Sleep States

Normal sleep has 2 distinct states, **rapid eye movement (REM)** and **non-rapid eye movement (NREM)** sleep. Rapid eye movement sleep develops at about 29 weeks' gestation and then persists throughout life. It is an active, lighter stage of sleep that occurs in association with rapid eye movements. Other features of REM sleep include suppression of muscle tone; rapid, irregular pulse and respiratory rate; and body twitches. Dreams occur during REM sleep. The electroencephalogram (EEG) pattern of REM sleep is very similar to stage 1 NREM sleep.

Non-rapid eye movement sleep begins at about 32 to 35 weeks' gestation. During NREM sleep, pulse and respiratory rates are slower and more regular, and body movements are minimal. Most of the restorative functions of sleep occur during this state. After the first several months of life, NREM sleep may be divided into 4 stages ranging from drowsiness to very deep sleep. Each stage represents a progressively deeper state of sleep and has a characteristic EEG tracing: stage 1 has low-voltage, fast activity; stage 2 is notable for the presence of sleep spindles and K complexes against a low-voltage background; and stages 3 and 4 are identified by varying amounts of high-amplitude, slow waves known as delta waves.

The Sleep Cycle

Rapid eye movement and NREM sleep together make up the sleep cycle. Typically, the deepest sleep takes place during the first several hours of the night, with lighter stages of NREM sleep and REM sleep occurring during most of the rest of the night. Although sleep stages are the same in both infants and adults, several differences concerning the onset and duration of REM and NREM sleep between infants and adults exist. First, the sleep cycle is shorter in infants (50–60 minutes) than in adults (90–100 minutes), which means that infants have more periods of active REM sleep compared with adults. Second, the total amount of time spent in REM sleep decreases with increasing age. Term newborns spend about 50% of their total sleep time in REM sleep (up to 80% in premature infants); this decreases to about 30% by 3 years of age and to 20% by adulthood. Third, infants may have very little REM latency, entering their first REM cycle very shortly after falling asleep. Adults, in comparison, generally enter their first REM period about 90 minutes after the onset of sleep.

Sleep-Wake Patterns

Sleep patterns follow a normal developmental sequence in children; the amount of sleep children need changes with maturation (Figure 25-1). Healthy term newborns sleep 16 to 17 hours per day. Because they are unable to sleep for more than a few hours at a time, sleeping and waking periods are fairly evenly distributed throughout the day and night. Many infants are able to sleep through the night (at least 5 hours uninterrupted) by the age of 3 months; most infants are capable of this by 4 months. Brief arousals are a normal part of the sleep cycle at all ages, but children should be able to return to sleep on their own without requiring parents' attention. Children should definitely be able to fall asleep on their own by the age of 4 to 6 months. Otherwise, parental participation to fall asleep becomes required at every awakening throughout the night.

By 12 months of age, infants sleep about 14 hours per day, divided into 2 naps during the day, and a period of about 10 hours at night. During the second year of life, most children stop napping in the

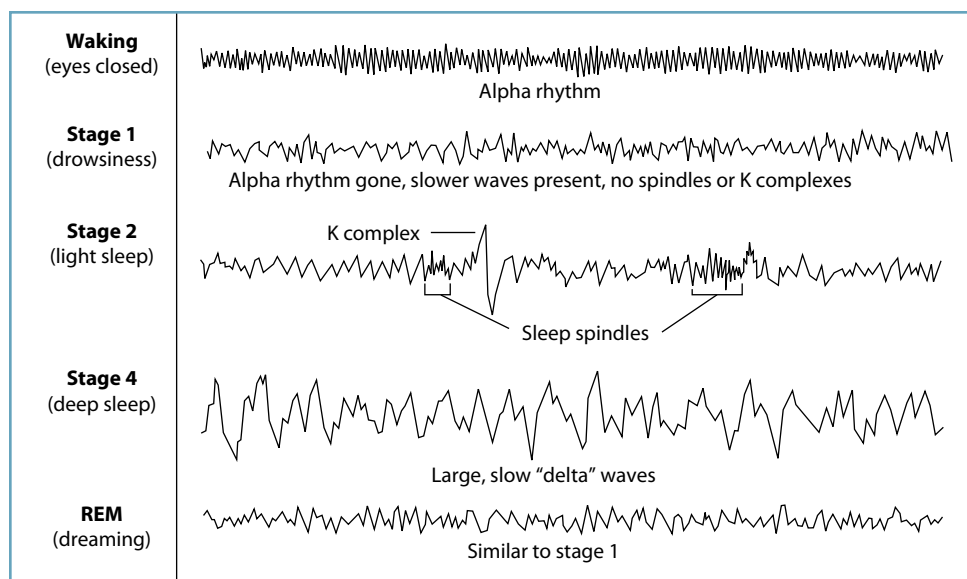

Figure 25-1. Typical sleep patterns in childhood. (Reproduced with permission from Ferber R. *Solve Your Child's Sleep Problems*. New York, NY: Simon & Schuster; 1985:19.)

morning. By 2 years of age, they require about 13 hours of sleep per day (1–2 hours in an afternoon nap and 11–12 hours at night). Most children take an afternoon nap until 3 years of age, and some children continue this until 5 years of age. The amount of nighttime sleep children need gradually continues to decline, decreasing from about 12 hours during the preschool years to about 8 to 9 hours during adolescence.

Sleep Abnormalities

The etiology of sleep disorders can be complex, involving the interaction of children's temperamental characteristics, psychosocial stressors in the home, parental childrearing philosophies, and the developmental nature of normal sleep states and sleep cycles.

Differential Diagnosis

The differential diagnosis of sleep disorders may be distinguished by problems associated with falling asleep or frequent night wakings (Box 25-1). Falling asleep may present 2 types of difficulties: problems associated with settling children to sleep and bedtime refusal.

In infants, **inappropriate sleep-onset associations** are the most common reason for difficulty settling to sleep. These infants require parental participation (eg, holding, rocking, feeding) to fall asleep. They have not learned the critical skills of self-calming and initiating sleep on their own. Because these infants do not have the self-soothing behaviors necessary to fall back asleep after normal nighttime arousals, they may also have nighttime wakings. Brief arousals are a normal component of sleep. Nighttime wakings are different, because parents' participation is needed to resettle children. The difficulty that the children experience falling back to sleep on their own, not the waking itself, is the problem.

An example of an inappropriate sleep-onset association is the child who needs to be breastfed or bottle-fed to fall asleep. The term **trained night feeder** has been coined to describe children who need to be fed before going back to sleep after normal nighttime awakenings. Although they are developmentally old enough to receive all nutrition during the day, they have become conditioned to require nighttime feedings. These children are often breastfed or bottle-fed until they fall asleep and only then placed in the crib. They are conditioned to require feeding to initiate sleep, and when they experience normal nighttime arousals, they require the breast or bottle to go back to sleep.

The term **trained night crier** refers to children who, like trained night feeders, lack the self-comforting and self-initiating skills necessary to fall asleep on their own. Trained night criers awaken; cry; and want to be held, comforted, or entertained before they can go back to sleep.

Acute illness may also be a cause of sleep disturbances. Children with otitis media may awaken at night because of pain. They may continue to experience awakenings after the infection has resolved, however, and require comforting or some sort of attention to fall asleep again.

Box 25-1. Practical Approach to the Differential Diagnosis of Sleep Disorders in Children

Difficulty Falling Asleep

Circadian and sleep schedule disturbances

- Irregular sleep-wake patterns
- Advanced sleep phase
- Delayed sleep phase
- Regular but inappropriate sleep schedules without phase shifts (eg, late evening naps)

Habits, associations, and expectations

- Inappropriate sleep-onset associations
- Bedtime refusal/bedtime struggles
- Poor or inconsistent limit setting

Overstimulation

Psychosocial

- Separation anxiety
- Nighttime fears (eg, fears of the dark, monsters)
- Family and social stresses

Medical

- Acute illness
- Underlying medical problems
- Medications (eg, antihistamines, stimulants, codeine, anticonvulsants)

Nighttime Waking

Normal variation (eg, breastfed infant)

Habits, associations, and expectations

- Inappropriate sleep-onset associations (eg, age-inappropriate night wakings for feeding)

Psychosocial

- Nighttime fears
- Family and social stresses

Medical

- Acute illness
- Underlying medical problem
- Medications

Nightmares

Arousal disorders (eg, night terrors, sleepwalking, and sleep talking)

Miscellaneous Sleep Disorders

Intrinsic sleep disorders

- Narcolepsy
- Sleep apnea (obstructive or central)
- Restless leg syndrome
- Periodic leg movements

Sleep-wake transition disorders (eg, head banging, rocking)

In children between the ages of 9 and 18 months, **separation** and **separation anxiety** may also affect sleep patterns. Children may cry when parents leave the room and have difficulty settling to sleep. Ability to climb out of the crib or bed can be associated with nighttime wakings in older toddlers. The transition from a crib to a bed is usually made between 2 and 3 years of age. Children who can climb out of their cribs or beds may come out of their rooms repeatedly for drinks of water, trips to the bathroom, or to sleep in the parents' bed. Such factors as nighttime fears of the dark influence sleep behaviors during the preschool years (3–5 years of age). Children's growing needs for autonomy and control over their environment may lead to bedtime refusals during both the toddler and preschool years.

Disorders of the sleep-wake cycle may contribute to sleep schedule irregularities. Circadian rhythms govern the regularity and degree of wakefulness and sleepiness. The circadian clock inherent in humans is not an exact 24-hour pattern but can be modified or entrained onto one by environmental cues. Regular and consistent structure needs to be provided by parents because development of children's sleep-wake rhythms depends on an interaction of the child's inherent biological rhythms with the environment. Entrainment requires predictable occurrence of time cues such as light and dark, mealtime, and bedtime. A consistent waking time in the morning is one of the most important of these cues.

Irregular sleep-wake cycles may be seen in children living in chaotic environments with irregular mealtimes and sleep-wake schedules. A delayed sleep phase and regular but inappropriate sleep-wake schedule are the most common forms of sleep rhythm disturbance. Children with **delayed sleep phase** have a resetting of their circadian rhythm; they are not sleepy at bedtime and have excessive morning sleepiness. This is a common problem because the inherent circadian clock has a cycle closer to 25, not 24, hours. This clock has not been entrained to a 24-hour schedule in these children.

Examples of **regular but inappropriate sleep-wake schedules** include children who nap at the "wrong" time (eg, a child who regularly naps at 7:00 pm for 1 hour and then has trouble going to bed at 9:00 pm) and infants who seem to have day and night confused. These children sleep most of the day and stay up most of the night.

Night terrors (*pavor nocturnus*), **sleepwalking** (*somnambulism*), and **sleepwalking** (*somniloquy*) are all forms of partial awakenings that occur during deep or stage 4 NREM sleep, most often during the transition from stage 4 NREM sleep to the first REM sleep period. Sleepwalking and sleepwalking usually occur during the school-aged years, whereas night terrors begin during the preschool years.

Both nightmares and night terrors may begin during the preschool years and may continue throughout childhood. Night terrors are different from nightmares and occur during a different stage of the sleep cycle (Table 25-1). With night terrors, children usually sit up in bed and cry or scream inconsolably for up to 15 minutes. They may appear dazed and have signs of autonomic arousal, such as tachycardia, tachypnea, and sweating. These children cannot be consoled. When they finally go back to sleep, they do not remember

Table 25-1. Nightmares Versus Night Terrors

<i>Characteristic</i>	<i>Nightmare</i>	<i>Night Terror</i>
Time of night	Late	Early, usually within 4 hours of bedtime
Sleep stage	Rapid eye movement sleep	Partial arousal from deep non-rapid eye movement sleep
State of child	Scared, but consolable	Disoriented, confused, and inconsolable
Memory of event	Clear recall of dream	Usually none
Return to sleep	Reluctant because of fear	Easily, unless fully awakened
Management	Reassure child	Reassure parents

the event in the morning. Because parents are often frightened by the experience, they may think the child is having a seizure or is suffering from an emotional disturbance and may seek medical advice. Although attacks may be precipitated by stressful events or fatiguing daytime activities, night terrors do not indicate excessive stress or emotional disturbance in children's lives unless they recur.

Nightmares usually occur during the last third of the night during REM sleep, whereas night terrors more often take place during the early part of the night. Nightmares are scary dreams that may awaken children, who can often remember them. Children can usually be consoled by parents but are reluctant to go back to sleep because of their fears.

Excessive daytime sleepiness can be a symptom of medical problems such as depression, sleep apnea, narcolepsy, or illness. Viral illness is perhaps the most common medical cause of such sleepiness in children. Inadequate sleep at night may also be a potential cause of sleepiness during the day. Screening for daytime impairments (eg, decline in academic performance or inattention) is important in children suspected of having sleep disorders. Primary sleep disorders, such as obstructive sleep apnea, have been shown to be associated not only with excessive daytime sleepiness, but also with cognitive deficits and impaired attentional capacity.

Narcolepsy, a disorder of excessive sleepiness, is characterized by an overwhelming desire to sleep during the daytime despite adequate sleep at night. Its symptoms include excessive daytime sleepiness, cataplexy, sleep paralysis, and hypnagogic hallucinations. Cataplexy is an abrupt loss of muscle tone that is usually precipitated by an emotional reaction, such as laughter or anger. Sleep paralysis is an inability to move or speak that occurs as patients fall asleep or awaken. Hypnagogic hallucinations, which can be visual or auditory, occur while falling asleep. Narcolepsy affects about 0.05% to 0.1% of the general population. The prevalence increases to 50% of family members when the family history is positive. The exact genetic basis of inheritance is unknown. The age of onset is usually between 10 and 20 years. The diagnosis is often delayed or missed for months to years in some cases because not all symptoms may

be present initially. Diagnosis is important because pharmacologic therapy with central nervous system (CNS) stimulants may provide some symptomatic relief.

Sleep-related breathing disorders (SRBD) occur across a spectrum with habitual snoring as the least severe form and **obstructive sleep apnea syndrome (OSAS)** as the most severe form. Risk factors associated with the development of SRBD include obesity, presence of chronic sinus problems, recurrent wheezing, nasal allergies, family history of obstructive sleep apnea, and certain disorders that present with craniofacial abnormalities (eg, Down syndrome and Prader-Willi syndrome). Obstructive sleep apnea syndrome in children is a disorder of breathing during sleep. It is characterized by prolonged partial upper airway obstruction and/or intermittent complete obstruction (obstructive apnea) that disrupts normal gas exchange and normal sleep patterns. Risk factors for OSAS include adenotonsillar hypertrophy, obesity, craniofacial anomalies, and neuromuscular disorders. Obstructive sleep apnea syndrome is thought to be secondary to a combination of adenotonsillar hypertrophy and reduced neuromuscular tone of the upper airway during sleep. Large tonsils and adenoids alone do not necessarily indicate that the child has OSAS. Symptoms include nightly snoring (often with intermittent pauses or gasps), disturbed sleep, and daytime neurobehavioral problems. Obstructive sleep apnea syndrome should be distinguished from **primary snoring**, which is defined as snoring without obstructive apnea, arousals from sleep, or abnormalities in gas exchange. Obstructive sleep apnea syndrome can not only disturb the quality of sleep but can also cause potentially serious complications, such as failure to thrive and, in severe cases, cor pulmonale.

Restless leg syndrome, or periodic leg movements, is a recently described condition characterized by uncomfortable creeping or crawling feelings, mainly occurring in the lower extremities, when the child is resting or inactive and relieved by movement. The condition may be attributed to growing pains in younger children (see Chapter 103) and can be associated with delayed sleep onset.

Evaluation

History

Evaluation of children with sleep difficulties begins with a thorough, detailed sleep history taken from both parents and children, if old enough (Questions Box). The use of a specific screening questionnaire, such as the Children's Sleep Habits Questionnaire by Judith Owens, MD, may facilitate the evaluation. It is designed to screen for the most common sleep problems in children aged 4 to 12 years and is available online at www.kidzzzsleep.org. It is not intended to be used to diagnose specific sleep disorders, but rather to identify children possibly needing further evaluation. Dr Owens has also developed a simple screening acronym, "BEARS" (bedtime resistance/sleep onset delay; excessive daytime sleepiness; awakenings at night; regularity, patterns, and duration of sleep; and snoring and other symptoms), which can be useful as an initial screen to determine if further assessment may be necessary.

Questions

Sleep

- Does the child have regular nap times and bedtimes, or do these depend on changing parental schedules?
- What time does the child go to bed?
- What does the child do in the hour before bedtime? Is there a consistent bedtime routine?
- Where does the child sleep (eg, ask about cosleeping, noise, temperature)?
- Is the child able to fall asleep on his or her own, or does he or she require the parent's participation?
- Does the child require feeding or fluids at night?
- When does the problem occur relative to bedtime and what does the child do (detailed explanation)?
- How often does the problem occur?
- How long has the child been having sleep problems?
- How does the parent respond?
- Does the child snore?
- When does the child wake up in the morning? Is the child difficult to awaken?
- Is the child sleepy during the day?
- How much caffeine does the child consume (eg, in coffee, tea, soda, chocolate)?
- Is the child taking any medications?
- Is there a family history of sleep disturbances?
- Is there any stress within the home due to marital or financial difficulties that may affect the home environment and cause the child to be anxious or stressed?

Evaluation should also include an assessment of children's temperament and psychological well-being. Children's developmental status and level of function should also be evaluated. Children with developmental, neurologic, and psychological concerns have higher rates of sleep disturbances. For example, it is estimated that 25% to 50% of children with attention-deficit/hyperactivity disorder seen in clinical practice will have sleep problems, especially difficulties in initiating and maintaining sleep.

Physical Examination

Physical examination is important to rule out organic causes of sleep difficulties. Special attention should be paid to the airway and nervous system. Acute illness (eg, otitis media), obstructive sleep apnea resulting from adenoidal or tonsillar hypertrophy (most commonly), colic, gastroesophageal reflux, and any CNS disease or abnormality may all alter the sleep-wake cycle.

Laboratory Tests

In most cases, a detailed history and physical examination should be sufficient to establish the reason for the sleep disturbance. Laboratory assessment is usually not necessary. Further evaluation, when warranted, should be tailored to the child's clinical presentation. An EEG may be useful if a central abnormality, such as a seizure disorder, is

suspected. Polysomnography, the simultaneous monitoring of EEG, electrocardiogram, chin muscle tone, eye movements, and respirations during a night of sleep in a sleep laboratory, may be very useful in certain children when significant sleep disturbances, such as nocturnal seizures, narcolepsy, or OSAS, are suspected. Any child suspected of a sleep-related breathing disorder (eg, history of snoring or abnormal breathing during sleep) should be evaluated for OSAS.

Management

The goal of management is to help children develop a healthy pattern of sleeping, not simply eliminate the immediate problem. Healthy sleep associations include providing a consistent schedule of naps and bedtime, along with a pleasant bedtime routine. It is important to put infants in their cribs while they are relaxed and drowsy but not already asleep. This gives them the opportunity to develop skills to put themselves to sleep. If they become accustomed to being fed or rocked until they fall asleep, they will seek the same means of falling asleep every time they normally wake up during the night. In addition, overstimulation in the evening may make settling to sleep difficult for toddlers or young children. Instead, a routine such as a bath followed by a story in the child's bedroom with a clearly defined endpoint when the parent leaves the child in the crib or bed sleepy but awake may help facilitate sleep. Children must learn to fall asleep on their own.

Trained night feeders and trained night criers are infants who have not learned to fall asleep on their own. The basic treatment for these children is to put them in their cribs when they are sleepy but awake and ignore the subsequent crying. Their last memory before falling asleep should not be of their mothers holding or feeding them. If the crying persists, the contact with the infants should be brief and boring. Scheduled awakening is a technique in which infants are slightly aroused by the parent 15 to 60 minutes before an expected spontaneous awakening in an effort to prevent spontaneous awakening. Scheduled awakenings may be an effective treatment alternative for some trained night criers. If infants awaken for a feeding, parents should try to stretch the interval between waking and feeding so that children have an opportunity to practice self-calming techniques. Specific sleep disorders can be addressed individually. Older toddlers and preschoolers who delay going to bed or refuse to stay in their rooms at night need clear, firm limits. It is important that these children have consistent bedtime routines and nighttime interventions for when they awaken. A gate may need to be installed in the bedroom doorway to prevent children who refuse to stay in their rooms at night from moving about the house and potentially hurting themselves or disturbing others. Parents of children who have night terrors may require reassurance that their children are not suffering from significant emotional problems or stressors. A night-light may help alleviate the anxieties of preschoolers who are unable to sleep at night because of their fears of darkness. Disturbances of the sleep-wake schedule can be corrected over time by gradually shifting children's schedules in the desired direction. For example, children with a delayed sleep phase who go to bed very late can have their morning

wake-up time progressively advanced about 15 minutes per day; this is followed by a progressive advancement in their bedtime until the desired schedule is reached.

Implementation of good sleep hygiene practices is an important first step for school-aged children and adolescents who are experiencing sleep problems, especially sleep-onset problems. Sleep hygiene refers to the establishment and maintenance of schedules and conditions conducive to healthy, restorative sleep. Good sleep hygiene practices are outlined in Box 25-2. It is important to remember that adolescents require at least as much sleep as they did as pre-adolescents—about 9 hours of sleep per night. Referral to a sleep specialist may be necessary for some children, especially when significant sleep disturbances, such as narcolepsy, nocturnal seizures, or OSAS, are suspected.

Prognosis

Unfortunately, infants with sleep problems tend to grow into children with sleep problems. Researchers have found that about 40% of infants with sleep problems at the age of 8 months still had a problem at 3 years. It is to the parents' advantage to help their children develop healthy sleep habits rather than ignore the problems and hope that the children outgrow them.

Box 25-2. Good Sleep Hygiene

Environment

- Dark
- Quiet
- Comfortably cool

Schedule

- Regular bedtime
- Regular waking time
- Naps, if needed, should be early in the day with consistent time and duration

General

- No frightening/stimulating television or stories and no vigorous physical activities in the hour before bedtime
- Limit caffeine, especially after lunchtime
- Consistent and calming bedtime routine
- Consistent soothing methods
- Children put to bed drowsy but awake

CASE RESOLUTION

The 6-month-old infant described in the case history has disordered sleep associations. He has been conditioned to nighttime feedings, although he is old enough not to require them for nutrition. The physician suggests several things the mother can do to try to solve her son's sleep problem. She can begin by gradually lengthening the interval between daytime feedings to 4 to 5 hours. When he cries at night, she can wait progressively longer before feeding him and can then eventually eliminate the feedings altogether. He will learn to fall asleep on his own without requiring feeding.

Oral Health and Dental Disorders

Charlotte W. Lewis, MD, MPH

CASE STUDY

The parents of a 9-month-old girl bring her to the office because they are concerned that their daughter has no teeth yet. Growth and development have proceeded normally, and the physical examination is unremarkable.

Questions

1. What is the mean age and range for the eruption of the first tooth?
2. What is meant by *mixed dentition*?
3. When should oral hygiene using a toothbrush begin?

Dental caries comprises the most common chronic disease of childhood. Pediatricians and other health care providers often see young children multiple times before children have their first dental visit. Primary care providers are thus in a prime position to counsel families on preventive oral health and to identify early signs of dental decay so that timely treatment can occur. In 2003 the American Academy of Pediatrics issued a recommendation that pediatricians and other pediatric health care providers begin regular oral health anticipatory guidance and risk assessment before patients are 6 months old. This recommendation affirms the essential need for clinicians to educate themselves on normal and abnormal patterns of dental eruption and occlusion, early and advanced signs of dental caries and its complications, and appropriate preventive oral hygiene practices. Establishing collaborative partnerships with community dentists is helpful in promoting ongoing clinician and family education and appropriate patient referrals.

Epidemiology

Among 5- to 17-year-olds, dental caries is 5 times more common than asthma. Sixty percent of children have at least one or more filled or decayed primary teeth by the age of 5 years and three-quarters of all 17-year-olds have experienced at least one carious lesion in their permanent dentition. Certain groups are at increased risk for earlier and more severe dental caries. Both individual and population risk factors for caries are listed in Box 26-1. Toothache, a complication of dental caries, afflicts millions of US children; in 2007, 14% of 6- to 12-year-olds had experienced a toothache within the previous 6 months. Toothache disproportionately affects children who are poor, minority, and have special health care needs. Occlusal abnormalities are also common in children. At least 30% of the population is estimated to have moderate to severe orthodontic needs.

Box 26-1. Population and Individual Risk Factors for Dental Decay

Population Risk Factors

- Low socioeconomic status
- Recent immigrant
- Latino, Native American, and other non-white race/ethnicity
- No dental insurance or limited access to professional dental care

Individual Risk Factors

- Currently active decay or history of decay in patient
- History of high amount of dental decay in mother or siblings
- Frequent and/or prolonged intake of foods containing fermentable carbohydrate (or frequent/ongoing use of liquid medications prepared with sucrose)
- Presence of visible plaque on the teeth
- Exposed root surfaces
- Impaired ability to maintain oral hygiene (eg, developmentally disabled or otherwise handicapped individuals)
- Inadequate exposure to fluoride
- Reduced salivary flow
- History of radiation therapy to head and/or neck
- Wearing of orthodontic appliances or prostheses

Clinical Presentation

Dental development begins in utero. Subsequently, the teeth erupt into the upper or **maxillary** jaw and into the lower or **mandibular** portion of the jaw. Teeth have a crown and root section (Figure 26-1). The **crown** is the visible portion of the tooth. The **root** is that part contained within the socket of the alveolar bone. The outer, hard coating of the crown is the **enamel**. Beneath the enamel is the

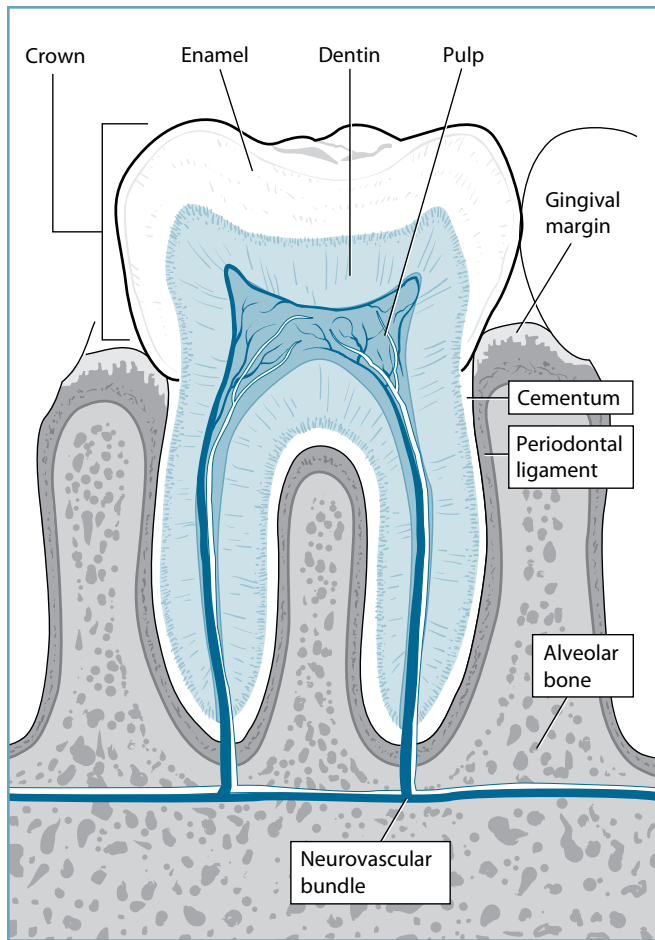

Figure 26-1. Tooth anatomy.

dentin, composed of microtubules for transport of nutrients from the pulp to the outer portions of the tooth. The **pulp** contains nerves and vascular structures critical for the health and viability of the tooth. Teeth are anchored to the jaw through **periodontal ligaments**.

There are 20 **primary or deciduous teeth**, which erupt between approximately 6 and 36 months of age (Figure 26-2). The first primary teeth to erupt typically are the lower **central incisors**. These teeth erupt on average at 6 to 10 months of age. A simple but not always precise rule of thumb is that the first tooth erupts at 6 months of age and then one tooth per month erupts until all primary teeth have erupted by about 24 to 30 months of age. In the normal pattern of primary tooth eruption, the incisors erupt followed by eruption of the first molars, then canines (cuspid), and finally the second molars (hence the helpful mnemonic for primary eruption order in each quadrant of the mouth: forward-forward-back-forward-back for incisor-incisor-first molar-cuspid-second molar). There is variation in the timing of tooth eruption in the population, and normal tooth eruption can vary by 6 to 12 months from average. The eruption process may occasionally be preceded by a bluish discoloration to the gum, called an **eruption hematoma**, a benign process. More often eruption of the primary teeth is associated with more generalized symptoms, such as fussiness and drooling. These symptoms are commonly referred to as *teething*. **Teething** does not cause diarrhea, respiratory infections, or true fever, although these entities may be present coincidentally with tooth eruption in infants.

The primary teeth are replaced by the **permanent teeth** (Figure 26-2), which begin eruption at approximately 6 years of age. Both permanent and primary teeth are present during the **mixed dentition phase**, which occurs between 6 and 13 years of age. Early mixed dentition is sometimes referred to as the “ugly duckling” stage

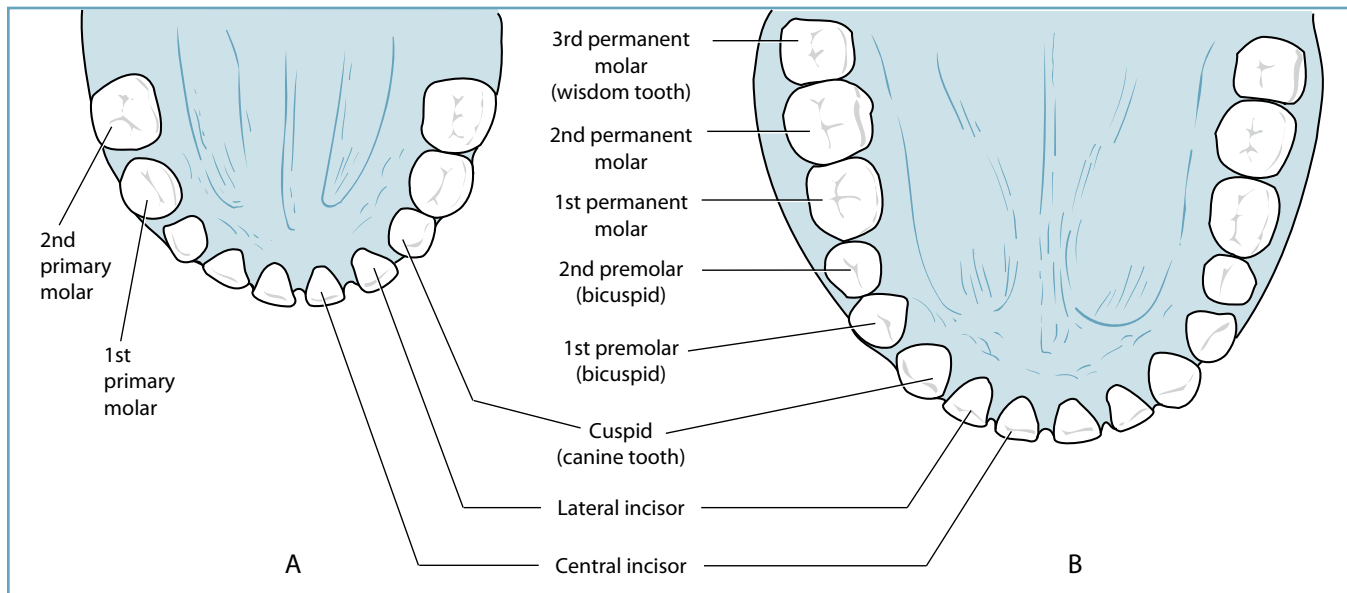

Figure 26-2. A. Primary dentition. B. Permanent dentition.

because the permanent dentition looks large and awkward relative to the remaining primary teeth and because there may be transient malpositioning of the teeth. There are normally 32 permanent teeth; the last to erupt are the **third molars**, commonly known as **wisdom teeth**, at about 17 to 21 years of age.

Variations from the normal in number of teeth are not uncommon. **Hypodontia** refers to fewer than normal teeth. The most common teeth to be congenitally absent are the third molars, second premolars, or maxillary lateral incisors. Congenital absence of a central incisor is distinctly uncommon and should raise concern for the presence of other midline defects. Several teeth may be missing in disorders such as **Down syndrome** or **ectodermal dysplasia**. **Anodontia** is the congenital absence of teeth. Extra teeth are called **supernumerary teeth**. Children may be born with teeth already erupted, known as **natal teeth**. Teeth that erupt shortly after birth are referred to as **neonatal teeth** if their eruption occurs in the first month of life. These teeth are usually incisors, and at least 90% represent normal dentition, rather than supernumerary teeth. The presence of natal or neonatal teeth may be familial, and on rare occasion may suggest an underlying syndrome. In addition to variations in number of teeth, teeth may also demonstrate variations in color and structure due to abnormalities in the tooth development, trauma, or extrinsic factors.

Caries may occur anytime after eruption of the teeth. **Early childhood caries** (ECC), a more general term referring to what in the past was called *baby bottle tooth decay* or *nursing bottle caries*, affects a substantial portion of children. The pattern of decay seen in ECC is different from that seen in the teeth of older children and adults. Typically ECC first affects the maxillary incisors and spares the lower incisors. This pattern of decay is hypothesized to result from prolonged and frequent exposure of the teeth to sweet liquids, for example, falling asleep with a juice bottle in the mouth, whereby the beverage pools around the upper incisors but the lower teeth are protected by the overlying tongue. The **pit and fissure surfaces** of the molars are more likely sites of decay in older children. Fermentable carbohydrates, particularly those of a sticky nature, become embedded in these surfaces and are not easily reached by the bristles of a toothbrush. This allows for prolonged action of acid-producing bacteria and subsequent caries formation.

In its earliest stages, caries appear on physical examination as white, opaque areas at the gum line (**white spot lesions**). At this early stage the lesion is potentially reversible if remineralization can occur. However, once the decay has eroded the enamel, irreversible damage has occurred. Symptoms differentiate the degree and depth of caries involvement; however, young children often have difficulty localizing dental pain. A cavity into the dentin may produce intermittent pain, especially on exposure to temperature change or pressure on the affected tooth. Once cavitation has extended into the pulp, the resulting pulpitis may cause severe, persistent, often throbbing pain in the affected tooth, possibly awakening the child from sleep. Eventually the pulp undergoes necrosis and pain may disappear. However, the infection is still present and may spread around the tooth apex, forming a periapical abscess or fistula. Dental infection

can progress to involve the maxilla or mandible and then move into the fascial planes of the head and neck, producing facial cellulitis, abscess, and airway obstruction.

The relationship of the maxillary to the mandibular dentition has both functional and aesthetic implications. **Malocclusion** is an abnormal relationship between the upper and lower teeth and may be developmental, genetic, or environmental in etiology. Children with craniofacial disorders often have significant occlusal problems and facial asymmetries necessitating early referral for craniofacial team care. Other children may have milder malocclusion that needs orthodontic care. Normal occlusion occurs when the maxillary incisors are slightly in front of the mandibular incisors and the posterior molars interdigitate (Figure 26-3). This is called **Class I occlusion**. **Class II occlusion** occurs when the maxillary teeth project too far anteriorly from the mandibular teeth. This may be associated with an **overjet**, commonly known as *buck teeth*, which can predispose to dental injury when children fall. **Class III occlusion** occurs when the mandibular teeth are anterior to the maxillary. This is also commonly referred to as an *underbite*. Other common forms of malocclusion include an **anterior open bite**, whereby the posterior teeth come together but there is an opening between the top and bottom anterior teeth. A **crossbite** occurs when some of the upper teeth are located inside of the lower teeth during occlusion.

Pathophysiology

Hypodontia may be familial or occur secondary to an underlying syndrome. However, failure of one tooth to erupt is also commonly caused by another tooth in the path of eruption or insufficient space in the dental arch. Defects of tooth structure have a variety of causes. Medications, infection, jaundice, metabolic disorders, and irradiation may adversely affect normal tooth formation or mineralization. The permanent teeth begin to develop in utero and mineralize after birth, making them susceptible to both prenatal and postnatal exposures. **Intrauterine infection** with rubella, cytomegalovirus, or syphilis may adversely affect tooth structure. Local oral infection, for example, a periapical abscess involving a primary tooth in early childhood, can damage the developing permanent tooth bud resulting in a malformed permanent tooth.

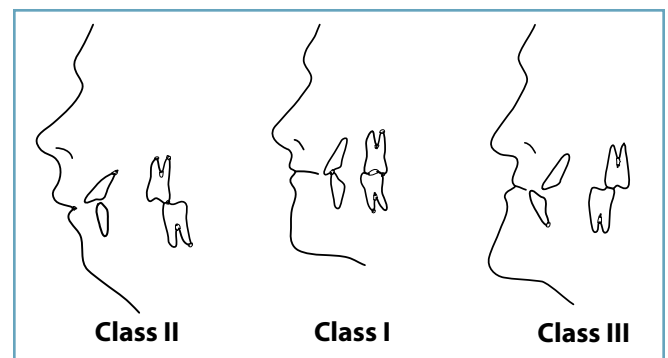

Figure 26-3. Classes of occlusion. Class I (middle) is considered most desirable from a functional and aesthetic perspective.

Discolored teeth may be due to intrinsic or extrinsic factors. Tetracycline given to pregnant or lactating women or children younger than 8 years can cause intrinsic staining of the permanent teeth. Exposure to high levels of fluoride during early childhood can cause **fluorosis** of the permanent dentition. Fluorosis, when it occurs in the United States, is usually mild, characterized by white striations on the permanent teeth. Children with mild fluorosis have teeth that are less prone to dental decay. Teeth more severely affected by fluorosis may display hypoplastic enamel.

Inherited enamel or dentin defects may cause abnormal color of the teeth. These conditions may be isolated to the teeth, as in the case of **dentinogenesis imperfecta**, or as part of a systemic disorder, such as porphyria or osteogenesis imperfecta. A single dark tooth is usually non-vital or has bled within the tooth structure after dental trauma. Extrinsic staining is superficial and is usually due to poor oral hygiene; smoking; chewing tobacco or betel nuts; certain beverages such as coffee, tea, or wine; or medications such as liquid iron supplements.

Malocclusion can be caused by tooth crowding, an underlying craniofacial condition, abnormal jaw growth relationship, or malpositioning of the teeth, most commonly as the result of digit (usually the thumb) sucking. The most common types of malocclusion associated with digit sucking are **anterior open bite**, overjet, or posterior crossbite.

Dental decay is the most common disorder of the teeth and is a transmissible infectious disease. Caries results from bacterial action on teeth. Bacteria coat the teeth in the form of plaque or biofilm. Cariogenic bacteria are acquired early in life, usually before 2 to 3 years of age, through transmission from caregivers via contact with and transfer of oral fluids. ***Streptococcus mutans***, believed to be one of the cariogenic bacteria, produce acid as the end-product of metabolism of carbohydrates. These acids dissolve the calcium-phosphate mineral of the tooth enamel or of the dentin in a process called *demineralization*. If not reversed or halted, this process results in formation of a carious lesion.

Differential Diagnosis

It can be difficult to differentiate tooth staining from a carious lesion, particularly when there are small areas of discoloration on the pit and fissure surfaces. If the lesion disappears with cleaning, staining is the etiology; however, staining is not always readily removed and examination by a dentist and radiographs can help evaluate such lesions. White spots on the teeth also can have multiple etiologies. When the white spot is chalky in appearance and located along the gingival margin, one needs to consider demineralization that could progress to frank decay. On the other hand, small intrinsic defects of the enamel may also appear as white spots; however, these are usually located throughout the crown and not just along the gingival margin and they also reflect light like the rest of the teeth (ie, not chalky).

Evaluation

History

Dental pathology is diagnosed primarily through history and physical examination. Many physicians have not traditionally included the teeth and supporting structures as part of their routine physical examination. However, pediatricians and other health care providers caring for children are generally the first, and often the only, health care providers to examine a child during the early years of life and therefore play a key role in identification of dental pathology. This is particularly true in settings where access to professional dental care is limited. Early diagnosis facilitates timely referral to dental specialists who provide definitive management.

Physical Examination

During each well-child visit, the medical provider should closely assess the mouth and its structures for the pattern of eruption and dental development; the presence of caries, plaque, gingivitis, and other oral lesions (see Chapter 71); and malocclusion. Physicians should examine the gingiva of children, particularly those with dental decay and/or toothache, to assess for evidence of periapical abscess, which may need antibiotic therapy and/or incision and drainage.

The oral cavity of a young child can be examined most easily with the caregiver and examiner in a **knee-to-knee position**, with the child's head in the examiner's lap and the legs wrapped around the caregiver's waist. Older children can be examined on the examination table or while seated in a chair. It is useful to have a disposable mouth mirror and a good light source. A toothbrush can be used to prop the mouth open to allow for examination of the teeth and oral cavity. The toothbrush can later be used to demonstrate good tooth brushing techniques.

A child's occlusion is best examined by looking at the child face from the anterior and lateral perspectives and watching the child's front and back teeth as the child opens and then bites down. Having the child bite down on a tongue depressor placed horizontally between the child's upper and lower teeth will demonstrate if there is a cant or asymmetry of the occlusion. The lateral profile of a child's face can be particularly revealing. Constructing an imaginary line between the bridge of the nose, the base of the nose, and the tip of the chin defines the shape of the lateral profile. In preschool and older children, a slightly convex profile is preferable both from a functional and aesthetic perspective. A concave profile is never normal and may be due to midface underdevelopment or from protrusion of the mandible. These children usually have a class III malocclusion. An overly convex profile may be due to an overjet or to mandibular retrusion. These children usually have a class II malocclusion.

Laboratory Tests

An ill-appearing child with a dental abscess or facial cellulitis of odontogenic etiology should have a complete blood cell count and a blood culture obtained.

Imaging Studies

Dental radiographs are useful in evaluating for the presence and extent of dental decay. They can also aid in determining whether a tooth that has not erupted as expected is absent or prevented in some way from erupting. Finally, when there is concern for pathology, imaging, particularly a Panorex or computed tomography scan, can be useful in evaluating the facial skeleton.

Management

Much of the definitive management of dental disorders falls to dental professionals. However, physicians play an important role in educating families about prevention, identifying pathology, and in facilitating dental referrals. Some dental conditions commonly fall into the realm of the primary care practitioner. For example, teething symptoms can be alleviated by giving the child a cold teething toy to suck on or with acetaminophen or ibuprofen given orally. Over-the-counter topical anesthetic agents often contain alcohol and are not recommended.

The American Academy of Pediatric Dentistry recommends the first professional dental care visit by 12 months of age. This is particularly important for children at high risk for dental caries. Occasionally, very young infants require a dental consultation. For example, if the natal/neonatal teeth interfere with feeding or are so loose as to pose an aspiration risk, they should be extracted; otherwise they require no intervention. When no teeth have erupted by 18 months of age, a dentist may choose to take radiographs to determine the status of the child's future dentition. If few developing teeth are seen, this can point to other diagnoses where hypodontia or anodontia occur. Most superficial extrinsic tooth stains can be removed during professional cleaning. Intrinsic stains can be treated by a dentist with abrasion and bleach techniques or application of a composite veneer. Malocclusion, when not reversible or self-limited, often is treated with orthodontics. More severe cases may require orthognathic surgery.

In some communities it may be difficult to find a dental provider who will care for a child younger than 3 years, and this further emphasizes the importance of medical providers in monitoring children's teeth and surrounding structures. Publicly insured children may also encounter difficulty accessing professional dental care. Clinicians should be aware of the closest source of specialized pediatric dental care if it is not within their own community. Dental schools or pediatric dental residency training programs generally offer specialized dental care for children, including sedation or anesthesia that may be needed to provide appropriate care.

Particularly in settings of limited access to dental care, physicians play an important role in educating families about the prevention of caries through advice about cariogenic food and beverages, regular tooth cleaning, and appropriate use of fluoride. Although physicians commonly advise parents not to allow their child to take a bottle to bed, it is particularly important that the child not take a bottle with **juice** or other sweetened beverages to bed. The evidence that breast milk, formula, or cow's milk causes caries is equivocal.

Physicians can also actively intervene if early caries lesions or white spots are identified. Application of **fluoride varnish** to the teeth can help to remineralize and reverse early caries lesions. When a child has more advanced caries, prompt referral to a dental provider is indicated. Pulpal involvement and abscess formation may result if a carious lesion is ignored. If dental care is not immediately available, antibiotics (penicillin V or clindamycin) and analgesics (eg, ibuprofen) may alleviate symptoms temporarily; however, more definitive treatment (**root canal** or extraction) is necessary to remove the source of infection and prevent resurgence of symptoms and further complications. When an abscess has spread to involve the cheek, face, or neck, admission to the hospital for intravenous antibiotics and surgical drainage is usually indicated.

Prevention

Prevention of dental disorders and promotion of good oral health are the combined responsibility of the primary physician, child, family, and dentist. Protection against virtually all decay is theoretically possible. Important preventive practices include regular home oral hygiene; access to routine dental care; sound dietary practices, including avoiding frequent and/or prolonged exposure to fermentable carbohydrates, especially sucrose; sealant application; and, importantly, regular use of **fluorides**. Increasing availability of fluoridated water and fluoride-containing toothpaste has dramatically decreased the prevalence of decay in the United States and other developed countries over the last 50 years. Nevertheless, for many in the lay public, fluoride evokes controversy and undue concerns for adverse health effects. Pediatricians have an important role to play in educating families about the safety, effectiveness, and appropriate use of fluoride. Fluoride can reverse or arrest early carious lesions through (1) enhancement of tooth mineralization and (2) reversal of tooth demineralization. The composition of the fluoride-containing enamel, fluoroapatite, is harder and less acid soluble than the original enamel that it replaces. Fluoride works best at remineralizing teeth when it is provided in a topical rather than systemic form (eg, fluoride drops are a systemic form of fluoride). Topical exposure to fluoride occurs through drinking fluoridated water and other beverages manufactured with fluoridated water, using fluoride toothpaste, and professional applications. There have been 2 recent changes to fluoride policies in the United States. First, the optimal fluoride level in drinking water to prevent tooth decay has been decreased to 0.7 mg of fluoride per liter of water (or parts per million [ppm]), which replaces the previous recommended range of 0.7 to 1.2 mg/L. This change has been enacted because of expanded availability of fluoride from sources other than community water fluoridation and concerns for increasing incidence of dental fluorosis. Second, the American Dental Association will now recommend fluoride supplements only for children who are at high risk for caries instead of for all children living in communities without optimal water fluoridation.

Tooth cleaning should begin with first tooth eruption. By the age of about 7 years, most children have developed sufficient fine

motor skills to begin flossing and brushing their teeth independently. Until then, parents should help their children brush and floss. It is not necessary to floss while there are still spaces between a child's teeth, as is the usual case in young children with only primary teeth. As additional teeth erupt and become closely approximated, flossing is important in order to remove plaque between the teeth that can contribute to gingivitis and later periodontal disease. The right age to begin using fluoride toothpaste depends on whether a child is at risk for caries. Parents of high-caries-risk children should use a small amount (small pea or rice grain sized) of fluoride toothpaste beginning at first tooth eruption. Parents of low-caries-risk children should wait until after 2 years of age before starting fluoride toothpaste to avoid excessive fluoride intake that can contribute to fluorosis. **Sealants** placed on the pit and fissure surfaces of the permanent molars can also be an important defense against caries in these surfaces. Children should be seen by a dentist for evaluation for sealant placement within 6 to 12 months of eruption of their first permanent molars.

Certain types of malocclusion are preventable. Because caries and trauma can both lead to premature tooth loss and subsequent loss of spacing and overcrowding, prevention of these entities will minimize the need for later orthodontic treatment. Prolonged digit sucking contributes to malocclusion. If children can discontinue these practices before age 4, digit-associated malocclusion is usually reversible. Dentists can employ specific devices and treatment to help stop digit sucking if other methods, including behavior modification, are unsuccessful (see Chapter 51).

Prognosis

Many dental disorders are preventable. Early identification and prompt referral can prevent complications. In the past, edentulism in adulthood resulting from dental decay and periodontitis was common. Fluoride use and increased attention to preventive oral hygiene have reduced this condition as well as the incidence of permanent teeth caries; however, substantial disparities continue to adversely impact the oral health of low-income, minority, and special needs children and adults in the United States.

CASE RESOLUTION

The parents of the infant in the case history should be reassured that the absence of teeth in their 9-month-old daughter is normal. Her first tooth may not appear until she is 12 months old. As long as she is growing and developing normally, there is no cause for concern.

Normal Development and Developmental Surveillance, Screening, and Evaluation

Geeta Grover, MD

CASE STUDY

The parents of a 12-month-old child are concerned that she is not walking yet. They report that she sat independently at 7 months and began crawling at 8 months. She can pull herself up to stand while holding on but is not cruising. Her birth and medical history are both unremarkable. The physical examination is within normal limits, and review of your records reveals no concerns on a developmental screening test administered at 9 months of age.

Questions

1. What are the major areas in which development is assessed?
2. What are the gross motor, fine motor, and personal/social milestones for a 12-month-old child?
3. What developmental screening tests could you administer to further assess her development?
4. How is developmental delay in children defined?

Development refers to the acquisition of functional skills during childhood. Monitoring the growth and development of children is an integral part of the assessment of pediatric patients. Recording the acquisition of developmental milestones provides a systematic approach by which to observe the progress of children over time. For ease of monitoring, these developmental milestones may be divided into 5 major domains or areas: gross motor, fine motor/adaptive, personal/social, language, and cognitive. This chapter discusses these major areas of development and the principles that govern them.

Four principles apply to all aspects of development. First, motor development is a continuous process that proceeds in the cephalocaudal direction and parallels neuronal myelination; therefore, developmental milestones reflect the maturation of the nervous system. Second, the sequence of development is the same in all children, but the rate of development may vary from child to child (eg, all children must walk before they run, but the age at which children walk or run varies from child to child). Third, the rate of attainment of milestones in one area may not parallel that in another. Fourth, certain primitive reflexes must be lost before corresponding voluntary movements can be attained (eg, the asymmetrical tonic neck reflex must disappear before children can roll over).

Pathophysiology

Development is influenced by both biological and environmental factors. Biological factors such as prematurity, exposure to drugs in utero, or the presence of chronic disease may place children at increased risk for developmental problems and delays. Environmental factors influencing development include parental attitudes and actions, sociodemographic factors, and cultural and societal influences. The quality of parental stimulation may influence the rate of acquisition of certain skills, especially cognitive and language abilities in preschool-aged children. Poverty and other socioeconomic factors may make it difficult for parents to provide their child with an optimal environment for growth and development.

Development in Newborns and Infants

Normal, full-term newborns enter the world capable of responding to visual, auditory, olfactory, oral, and tactile stimuli. They can be quieted and can even soothe themselves. Newborns can signal needs (eg, crying when hungry or wet), but they have a limited ability to respond to caregivers, primarily exhibiting disorganized and seemingly purposeless movements when stimulated. The newborn's reflexive generalized symmetrical movements (eg, arm waving and kicking) in response to environmental stimuli are eventually replaced by cortically mediated voluntary actions in older infants

and children. Additionally, in newborns, certain primitive reflexes can be elicited by appropriate peripheral stimuli. Eventually, primitive reflexes are replaced by reactions that allow children to maintain postural stability in response to a variety of sensory inputs (proprioceptive, visual, and vestibular).

Primitive reflexes are mediated by the brain stem; they are involuntary motor responses that are elicited by appropriate peripheral stimuli. They are present at birth and disappear during the first 6 months of life. Normal motor development seems to be related to the suppression of these reflexes (Figure 27-1). Persistence or reappearance of these reflexes may indicate the presence of brain damage. **Postural reactions**, which are ultimately smoothly integrated into adult motor function (Figure 27-1), appear between 2 and 9 months of age. These reactions help maintain the orientation of the body in space and the interrelationship of one body part to another. The 3 major categories of postural reactions are righting, protection, and equilibrium.

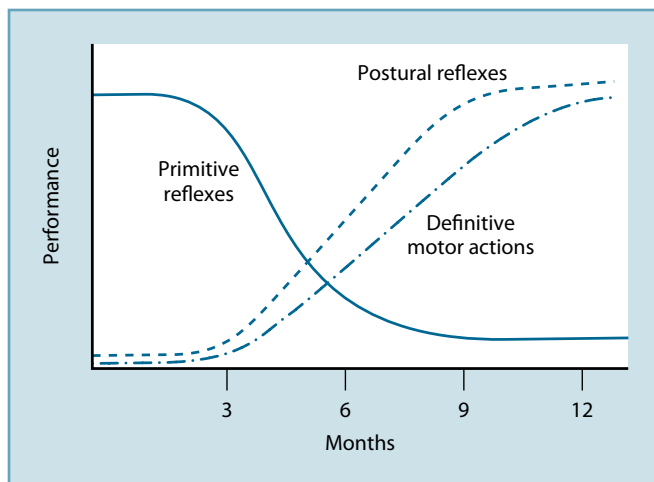

Figure 27-1. Primitive reflex profile. (Reproduced with permission from Capute AJ, Accardo PJ, Vining EPG, Rubenstein JE, Harryman S. *Primitive Reflex Profile*. Baltimore, MD: University Park Press; 1978:10.)

The profile generated by combining primitive reflexes and postural reactions can be used to monitor the course of normal development and identify cases of problematic development. Persistence of primitive reflexes or failure of development of postural reactions can signal developmental problems. Authorities estimate that there are more than 70 primitive reflexes and postural reactions. Researchers do not agree on which of these reflexes or reactions are the most useful in the monitoring of development. The 7 most commonly used primitive reflexes are described in Box 27-1, and selected postural reactions are presented in Box 27-2.

Normal Development

A developmental assessment should include an evaluation of milestones in each of the 5 major areas. **Gross motor skills** are overall movements of large muscles (eg, sitting, walking, running). **Fine motor–adaptive skills** involve use of the small muscles of the hands, the ability to manipulate small objects, problem-solving skills, and

Box 27-1. Selected Primitive Reflexes

Moro Reflex

Allowing the infant's head to drop back suddenly results in abduction and upward movement of the arms followed by adduction and flexion. This reflex disappears by 4 months of age.

Rooting Reflex

Touching the corner of the infant's mouth results in lowering of the lower lip on the same side and movement of the tongue toward the stimulus.

Sucking Reflex

Placing an object in an infant's mouth causes vigorous sucking.

Grasp Reflex

Placing a finger in an infant's palm causes the infant to grasp it; the infant reinforces the grip as the finger is drawn upward. A similar response is seen in the foot grasp. Both of these reflexes disappear by 2 to 3 months of age.

Placing Reflex

Stroking the anterior aspect of the tibia against the edge of a table results in the lifting of the infant's leg to step onto the table.

Stepping Reflex

Holding the infant upright and slightly leaning forward produces alternating flexion and extension movements of the legs that simulate walking. This reflex disappears by 5 to 6 weeks of age.

Asymmetrical Tonic Neck Reflex

With the infant lying supine, turning the head to one side results in extension of the extremities on that side and flexion of the opposite extremities (fencer position). This reflex disappears by 3 to 4 months of age.

Box 27-2. Selected Postural Reactions

Righting Reactions

These allow the body to maintain normal postural relationships of the head, trunk, and extremities during all activities. The different reactions appear at different ages, beginning shortly after birth and ranging up to 12 months of age.

Protection and Equilibrium Reactions

Protective Equilibrium Response

When gently pushed toward one side while in a sitting position, infants increase trunk flexor tone toward that side to regain their center of gravity and extend the arm on the same side to protect against falling. This response usually emerges at about 4 to 6 months of age.

Parachute Reactions

When held in ventral suspension and suddenly lowered (downward parachute), infants extend their arms as if to protect themselves from a fall; similar reactions are seen with forward and backward stimulation. These reactions appear at 8 to 9 months of age.

eye-hand coordination. **Language skills** include hearing, understanding, and use of language. **Personal–social skills** involve socialization and ability to care for personal needs. **Cognitive skills** involve the ability to use higher mental processes, including comprehension, memory, and logical reasoning.

Table 27-1 outlines the normal pattern of development with regard to each of these skills. The table lists the average age of attainment of these skills as well as the normal ranges where available. Development is an orderly and sequential process, and children must proceed through several stages before any given milestone is attained. Therefore, the physician should document not only *what* children can do but *how* they do it. For example, to sit without support, children first achieve head control. Several stages later they are able to sit in a “tripod” position with arms extended in front for support, and finally sit with the head steady and back straight without support (Figure 27-2).

Figure 27-2. Stages in the development of sitting. A. Head control. B. “Tripod sitting.” C. Head steady and back straight without support.

Gross Motor Skills

During the first year of life, the ultimate goal of gross motor development is walking. The first step toward this goal is head control. By 6 months of age, children are able to sit without support for a few seconds. At 9 to 10 months of age children are able to pull themselves to a standing position, and by 12 to 17 months of age they are able to walk. Children then learn to run, negotiate stairs, hop on one foot, and skip—in that order.

Fine Motor Skills

Development of the 2-finger pincer grasp is the major goal of fine motor development during the first year (Figure 27-3). The hands primarily remain in a fist position until 3 months of age. Infants

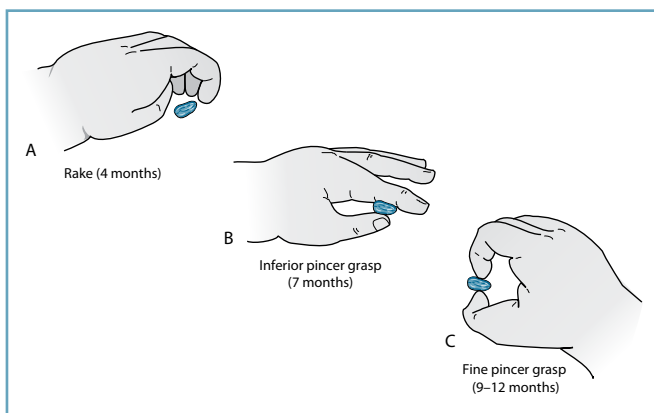

Figure 27-3. Development of the pincer grasp. A. Rake (4 months). B. Inferior pincer grasp (7 months). C. Fine pincer grasp (9–12 months).

also discover the midline at this age, and shortly thereafter they may play with the hands in the midline. Four-month-old children begin reaching for desired objects; by 6 months of age they are able to transfer objects from one hand to the other. By 7 months they have a 3-finger pincer grasp, and by 9 to 10 months they have developed the 2-finger grasp, which allows them to manipulate small objects such as raisins and pencils. By 14 months they begin to scribble, and by 3 to 5 years they are able to copy geometric shapes. Children with early preference for the use of one hand over another, especially prior to about 18 months of age, should be assessed for the presence of paresis or other neuromuscular problems. Handedness may develop by 3 years but often is not firmly established until the age of 4 to 5 years.

Language Skills

The development of normal speech and language skills is discussed in Chapter 28.

Personal–Social Skills

These skills enable children to interact and respond to the surrounding world. Deficits in the development of age-appropriate social skills/social relatedness (eg, social orienting, social referencing, joint attention, and pretend play) are a defining feature of the autism spectrum disorders (ASDs). For children within this spectrum, the development of social skills is characteristically “out of sync” with their overall level of functioning. Joint attention is the inclination to share enjoyment, interests, or achievement with other people, and like other developmental skills, seems to develop in graduated stages (early skills include reciprocal smiling at the sight of a familiar person followed by later emerging skills like the ability to isolate one’s index finger and point by 12–15 months of age). Lack of joint attention seems to be a core deficit in ASDs; it also seems to be specific to ASDs. (ASDs are discussed fully in Chapter 124.)

Cognitive Skills

These abilities allow children to think, reason, problem-solve, and understand the surrounding environment. The concept of object permanence or object constancy, the realization that objects may exist even if they cannot be seen, develops at approximately 7 to 9 months of age. The understanding of time comes much later. Children develop the concept of “today” at 24 months of age, “tomorrow” at 30 months, and “yesterday” at 36 months. It is extremely important that health care providers realize that children’s perception and understanding of pain, disease, and illness are guided by their stage of cognitive development. The psychologist Jean Piaget generated complex generalizations by observing what children did and how they did it; his theories are the cornerstone of knowledge in this area. Piaget’s 4 stages of cognitive development are presented in Box 27-3.

Developmental Delay

Children are said to be developmentally delayed if they fail to reach developmental milestones at the expected age. This age ranges widely because of the wide variation among normal children. Individual children may be delayed in one area or several areas of development.

Table 27-1. Normal Pattern of Development^a

<i>Skill</i>	<i>Mean Age</i>	<i>Normal Range</i>
Gross Motor Skills		
Reflex head turn; moves head side to side	Newborn	0–3 mo
Lifts head when prone	1 mo	1–4 mo
Lifts shoulders up when prone	2 mo	1–4 mo
Lifts up on elbows; head steady when upright	3 mo	2–5 mo
Lifts up on extended hands; rolls front to back; no head lag when pulled to sitting from supine position	4 mo	3–6 mo
Rolls back to front	5 mo	4–7 mo
Sits independently (≥ 30 s)	6 mo	5–9 mo
Crawls on hands and knees	8 mo	6–11 mo
Pulls to stand	9 mo	6–12 mo
Cruises	11 mo	9–14 mo
Walks	12 mo	9–17 mo
Walks backward	15 mo	13–17 mo
Runs	15 mo	13–20 mo
Kicks a ball	24 mo	18–30 mo
Walks up and down stairs (taking one step at a time and holding on)	24 mo	
Stands on one foot	30 mo	
Walks up stairs alternating steps	30 mo	28–36 mo
Peddles a tricycle	3 y	30–48 mo
Walks down stairs alternating steps/hops on one foot	4 y	
Skips	5 y	
Fine Motor-Adaptive Skills		
Tracks horizontally to midline	1 mo	
Tracks past midline/tracks vertically	2 mo	1–3 mo
Unfisted for $>50\%$ of the time; tracks 180 degrees; visual threat; discovers midline	3 mo	3–4 mo
Reaches for bright object; brings object to mouth	4 mo	
Transfers object from one hand to the other	6 mo	4–7 mo
3-finger pincer grasp	7 mo	6–10 mo
Neat pincer grasp	9 mo	7–10 mo
Bangs cubes in midline	9 mo	7–11 mo
Tower of 2 cubes; scribbles spontaneously	14 mo	14–20 mo
Tower of 4 cubes	18 mo	17–24 mo
Copies vertical and horizontal line; tower of 6 cubes	2 y	
Copies circle	3 y	
Copies cross (†)	4 y	
Copies square; draws person with 3 parts	5 y	
Copies triangle; draws person with 6 parts	6 y	
Personal-Social Skills		
Regards face	Newborn	
Spontaneous social smile	6 wk	1–3 mo
Discriminates social smile; relates to parent with real joy	6 mo	
Displays stranger anxiety; plays peek-a-boo	7 mo	7–9 mo

Table 27-1. Normal Pattern of Development^a, continued

<i>Skill</i>	<i>Mean Age</i>	<i>Normal Range</i>
Personal-Social Skills, continued		
Orients to name, uses gestures to get needs met	12 mo	
Drinks from a cup	15 mo	10–18 mo
Uses a spoon, spilling a little	15 mo	12–18 mo
Uses sounds, pointing, or other “showing” gestures to draw attention to object of interest	15 mo	12–15 mo
Simple pretend play (eg, feeding doll)	18 mo	
Imitates housework	18 mo	14–24 mo
Helps with undressing	2 y	22–30 mo
Washes and dries hands	2 y	
Parallel play; enjoys being next to other kids	2 y	12–30 mo
Undresses self	3 y	30–40 mo
Toilet training		24–36 mo
Imagines self as different characters	3 y	
Cooperative play	3 y	24–48 mo
Dresses without assistance	5 y	
Language Skills		
Alerts to bell	Newborn	
Searches with eyes for sound	2 mo	
Cooing	3 mo	1–4 mo
Turns head to voice or bell; laughs	4 mo	3–6 mo
Babbles	6 mo	5–9 mo
Mama/Dada nonspecific	8 mo	6–10 mo
Understands the word “no”	10 mo	
Mama/Dada specific	10 mo	9–14 mo
Follows 1-step command with gesture; 3–5-word vocabulary	12 mo	10–16 mo
Follows 1-step command without gesture	15 mo	12–20 mo
Can point to several body parts	18 mo	12–24 mo
50-word vocabulary	2 y	
2-word sentences; pronouns indiscriminately	2 y	20–30 mo
States first name	34 mo	30–40 mo
250-word vocabulary; 3-word sentences; speech intelligible to strangers 75% of time	3 y	
Uses pronouns appropriately	3 y	30–42 mo
Cognitive Skills		
Sensorimotor		Newborn–2 y
Preoperational		2–6 y
Concrete operational		6–11 y
Formal operations		>11 y
Miscellaneous Cognitive Milestones		
Concept of today	24 mo	
Concept of tomorrow	30 mo	
Concept of yesterday	36 mo	
Concept of right and left	7 y	

^aDetailed language milestones are presented in Chapter 28, Table 28-1.

Box 27-3. Stages of Development of Piaget**Sensorimotor (Birth–2 Years)**

Children approach the world through sensations and motor actions. They develop a sense of object permanence, spatial relationships, and causality.

Preoperational (2–6 Years)

Children's mental processes are linked to their own perception of reality. They do not separate internal and external reality.

Concrete Operational (6–11 Years)

Children can perform mental operations in their heads if they relate to real objects. They develop concepts of conservation of mass, volume, and number.

Formal Operations (>11 Years)

Children develop the capacity for abstract thought.

Differential Diagnosis

Three factors are involved in the differential diagnosis of children with developmental delays: (1) determination of the area or areas of development in which delay is apparent; (2) if motor delay is evident, determination of whether the condition is progressive or nonprogressive; and (3) assessment to see if developmental milestones previously achieved are lost or if age-appropriate milestones were achieved at all.

Children with an early history of normal development who subsequently experience a slowing of developmental progression, often associated with cognitive delays or seizures, may have a metabolic defect. Children who attain developmental milestones and subsequently lose them may have a neurodegenerative disease (eg, multiple sclerosis, adrenoleukodystrophy) or a lesion of the spinal cord or brain. The presence of habitual rhythmic body movements (eg, body rocking, head banging) may be a sign of a pervasive developmental disorder such as autism.

Cerebral palsy, the classic example of nonprogressive motor abnormality, is a form of static encephalopathy characterized by abnormal movement and posture. The type of cerebral palsy depends on which area of the brain is injured. Spastic cerebral palsy, seen most commonly, is secondary to upper motor neuron injury. The ataxic form of the disease is related to lesions of the cerebellum or its pathways. Dyskinetic cerebral palsy manifests as uncontrolled and purposeless movements that often result from a basal ganglia lesion (eg, athetosis following bilirubin deposition in the basal ganglia [kernicterus]). The onset of symptoms is either in infancy or early childhood. The key factor in making the diagnosis is establishing that the motor deficits are static and nonprogressing.

Evaluation

When evaluating children for possible delays in development, it is important to remember that there is a great deal of variation in the age of attainment of milestones. In addition, the rate of acquisition of milestones in one area of development may not parallel that in another. Routine and ongoing assessment of a child's level of development at all periodic health maintenance visits through observation,

history, physical examination, and screening tests allows the physician to form a longitudinal view of the child. The physician is thus able to identify and differentiate true deficits and delays from temporary setbacks.

History

Evaluation of children for suspected delays in development includes a complete history (Questions Box). Family history is important because other family members may have relatively delayed attainment of milestones. Perinatal factors that place children at high risk for developmental difficulties include a history of maternal drug or alcohol use during pregnancy, prematurity in the infant, and congenital infections. Other historical risk factors for developmental delay include history of seizures, sepsis or meningitis, exposure to lead or other toxins, and poor feeding or growth. Environmental factors, such as stressful home conditions, history of abuse or neglect, and lack of stimulation, may also contribute to delayed development.

Physical Examination

Both height and weight should be checked. Abnormal growth (ie, height or weight <5th percentile or head circumference either <5th percentile or >90th percentile) may be a marker for developmental delay. The presence of congenital anomalies (eg, cataracts, hypertelorism, spina bifida) or neurocutaneous lesions (eg, café-au-lait spots) may be suggestive of chromosomal anomalies or other genetic diseases. Neuromuscular examination should emphasize age-appropriate milestones. Abnormalities in muscle tone (eg, hypotonia, hypertonia), bulk, or strength may be clues to the presence of neuromuscular disease (eg, muscular dystrophy), cerebral palsy, or Down syndrome.

Laboratory Tests

Age-appropriate assessment of the child's vision and hearing should be performed if signs of motor, cognitive, or language delays are apparent. Chromosomal studies may be conducted if dysmorphic features are noted on the physical examination. Evidence of cognitive or motor delays may warrant metabolic studies (eg, organic and amino acids).

Questions**Normal Development**

- Has anyone in the child's family had developmental problems or delays?
- Did the mother use any drugs or alcohol during pregnancy?
- Was the child premature?
- Does the child have a history of seizures?
- Has the child had meningitis or sepsis?
- Does the child have any history of not feeding well or poor growth?
- Is the child's home environment characterized by any stresses (eg, divorce, limited financial resources)?

Imaging studies of the head, such as magnetic resonance imaging scans or electroencephalograms, may be necessary if the child has a history of seizures or an abnormal neurologic examination.

Developmental Surveillance, Screening, and Evaluation

Early detection of developmental delays is a responsibility of all pediatric health care professionals. Unfortunately current detection rates of developmental disorders are lower than their actual prevalence. About 20% of children between the ages of 3 to 17 years will have one or more developmental, learning, or emotional disorders, with 4% to 5% having developmental delays. Without the use of specific developmental screening tools, only about 30% of developmental disabilities are identified, but with the use of tools this identification rate increases to 70% to 80%.

Developmental surveillance, the ongoing process of monitoring individual children's developmental status, should be incorporated at each health maintenance visit. Surveillance involves eliciting and attending to parental concerns about their children's development and usually involves age-specific queries, such as whether the child is walking, talking, or pointing. Surveillance has been referred to as a kind of developmental growth chart. Recognition of children who may be at risk of developmental delays is the goal of developmental surveillance.

Developmental screening is the administration of a brief standardized tool to identify children at risk of a developmental disorder. Box 27-4 lists frequently used developmental screening tools. A formal developmental screening should be performed when developmental surveillance elicits a risk factor for developmental delay; in the absence of established risk factors or parental concerns, the administration of a general developmental screening tool is recommended by the American Academy of Pediatrics (AAP) at the 9-, 18-, and 30-month (or 24-month) health maintenance visits (AAP, 2006). The AAP further recommends that in addition to a general developmental screening tool, an autism-specific screening tool should

also be administered at the 18-month visit. (See Chapter 124 for a listing of autism-specific screening tools.) Periodic screening is necessary to detect emerging disabilities as children grow. Screening instruments should have a broad developmental focus and should be brief, inexpensive, valid, and reliable. Screening tests are not diagnostic. A failed screening test should lead to a referral for a further developmental evaluation.

Developmental evaluation (developmental assessment) is performed when surveillance or screening identifies a child as being at high risk of a developmental disorder. The aim is to identify the specific developmental disorder or disorders affecting the child. Developmental evaluation is performed by trained examiners. Unlike developmental screening, which is not diagnostic, developmental evaluation is diagnostic.

The Bayley Scales of Infant Development II, first published in 1933 by Nancy Bayley, is one of the most commonly used developmental evaluation tools. It has 3 sections: mental, psychomotor, and a behavior rating scale. The Bayley II may be used for children 1 to 42 months of age. Developmental tests, like the Bayley II (emphasizing sensorimotor-based skills), have a poor correlation with later measures of intelligence (emphasizing language and abstract reasoning), especially before 24 to 30 months of age. As such, developmental tests are best used as measures of current developmental functioning, rather than as predictors of future functioning. Intelligence tests, achievement tests, personality tests, or behavior rating scales may be used for preschool- and school-aged children having behavioral or emotional concerns, learning disabilities, or developmental disabilities.

Management

Children with identified developmental delays in one or more areas should be referred to the appropriate specialist, agency, or state program for further testing and assessment. Detailed neurologic examination may be necessary if gross motor delays are identified. Language delays may warrant formal hearing and speech assessment by an audiologist or speech pathologist. Cognitive impairment requires formal psychometric assessment, which in some cases can be performed through the child's school.

Prognosis

The early identification of children with developmental delays is critical. Early identification of developmental problems allows for early intervention, thereby making it possible for individual children to reach their maximum potential. Identification and treatment of underlying disease (eg, hypothyroidism or infection) prevents further damage. Removal of children from adverse home environments or placement of children from impoverished home environments in early intervention programs can greatly stimulate their developmental potential. The prognosis for children with mild developmental delays can sometimes be improved greatly from participation in such infant stimulation programs.

Box 27-4. Frequently Used Developmental Screening Instruments

Developmental Screening Instruments Relying on Information From Parents

- Child Development Inventories
- Child Development Review—Parent Questionnaire (CDR-PQ)
- Infant Development Inventory
- Ages and Stages Questionnaire (ASQ)
- Parent's Evaluation of Developmental Status (PEDS)

Screens Relying on Eliciting Skills Directly From Children

- Bayley Infant Neurodevelopmental Screen (BINS)
- Batelle Developmental Inventory Screening Tool, 2nd Edition
- Brigance Screens—II
- Denver Developmental Screening Test II (Denver II)

CASE RESOLUTION

The parents of the child described in the case history may be reassured that their child is developing normally for her age. Although most children begin walking at about 12 months of age, commencement of walking anywhere up to the age of 17 months is considered to be within normal limits. The AAP recommends that standardized developmental screening should be performed when developmental surveillance identifies high risk factors and routinely at the 9-, 18-, and 30-month health maintenance visits. Administration of a formal screening tool is probably not necessary at this visit, but can be considered again at the 15-month visit if there is a lack of progression in her gross motor skills or if any other risk factor is identified at that time.

Speech and Language Development: Normal Patterns and Common Disorders

Geeta Grover, MD

CASE STUDY

The parents of a 3-year-old girl bring her to see you. They are concerned because their daughter has only an 8- to 10-word vocabulary, and she does not put words together into phrases or sentences. They report that she seems to have no hearing problems; she responds to her name and follows directions well.

In general, she has been in good health. Her development, aside from delayed speech, is normal. During the physical examination, which is also normal, the girl does not speak.

Questions

1. What language skills should children have at 1, 2, and 3 years?
2. Approximately how many words should 3-year-olds have in their vocabulary?
3. By what age should children's speech be intelligible to strangers at least 75% of the time?
4. What factors may be associated with delayed speech development?
5. What tests are used to assess children's hearing, speech, and language development?

The ability to communicate through language is a uniquely human skill. Speech refers to the production of sounds, whereas language involves both comprehension and expression; it is the use of words, phrases, and gestures to convey intent. **Receptive language** refers to the ability to understand others, while **expressive language** is the ability to produce communication to convey meaning to others. Normal hearing is essential for the development of speech and language.

Speech disorders include problems in the production of speech sounds. Speech disorders may affect articulation (phonological disorders), fluency (stuttering), or voice (tone, pitch, and volume). The development of language skills in a normal sequence but at a slower pace than normal is referred to as language delay; language delays may affect only receptive or expressive language or both (eg, a mixed receptive-expressive language delay). An atypical sequence of language skill acquisition is referred to as a language disorder. Children with developmental language disorders have persistent and significant limitation in their ability to receive and/or express language.

The development of normal speech and language skills is an extremely important developmental milestone that is eagerly awaited by parents. Normal patterns of language development should be as familiar to pediatricians as all other aspects of child development (see Chapter 27). It is important that children with suspected language

delays be referred to specialists as early as possible. Children with delayed speech or language development should be suspected of having a hearing deficit. Diminished hearing is an important cause of delayed language development. Delays in language development can also be seen in the context of global developmental or cognitive delays, or associated with autism spectrum disorders (ASDs).

Epidemiology

The prevalence of specific language impairment in school-aged children, who have no hearing loss, or obvious genetic or neurologic condition, is about 7%. Speech and language disorders are more common in boys than in girls, and are more common in children who have a family history of language, speech, or reading disorders. There is good evidence now that early language impairment is associated with later difficulties learning to read.

Clinical Presentation

Lack of response to sound at any age, failure to achieve age-appropriate expressive language skills, and parental concern regarding a child's hearing are the most important signs of hearing or language impairment. Deaf infants coo normally and may even babble; therefore, an infant's vocalizing does not preclude a hearing loss.

Pathophysiology

The left hemisphere of the brain is responsible for language skills in 94% of right-handed adults and approximately 75% of left-handed adults. Peripheral auditory stimuli are transmitted to the primary auditory areas in both temporal lobes. Sounds then undergo a series of analyses, primarily in 3 main areas in the left cerebral cortex: Wernicke area (or auditory association area), which is responsible for the comprehension of language; Broca area (or motor encoding area), which is responsible for the preliminary conversion of language into motor activity; and the primary motor cortex and supplementary motor cortex, which control the movements necessary for speech. This complex process is responsible for the comprehension and production of language.

Speech and language develop in a predictable, orderly sequence. Language skills can be either receptive or expressive. Early receptive milestones refer to ability to hear and respond to sound, whereas later milestones reflect ability to understand spoken words. Early expressive milestones relate to speech production; later, children use language to convey their intent to others. In the first year of life, receptive skills are more advanced than expressive skills.

Knowledge of normal receptive and expressive language skills (Table 28-1) is essential to recognition and identification of developmental delays. Box 28-1 lists “danger signals” that indicate possible delays and serves as a guide for referral to specialists. It is most important to remember that by the age of 3 years, 75% of children’s speech should be intelligible to strangers.

Differential Diagnosis

The various causes of delayed language development include hearing loss, disorders of central nervous system (CNS) processing, anatomical abnormalities, and environmental deprivation (Box 28-2). Although birth order (eg, the belief that younger children speak later than first-born children because older siblings speak for them), laziness (eg, “Don’t give him what he wants when he points. Make him ask for it”), and bilingualism are commonly believed to lead to speech and language delay, their contributory role has never been proved. For a complete discussion of hearing loss, refer to Chapter 73.

Disorders of CNS processing include global developmental delay, mental retardation, ASDs (see Chapter 124), and developmental language problems. Developmental language disorders produce speech or language delays in children in the absence of hearing loss, anatomical abnormalities of the vocal tract, mental retardation, or global developmental delay. “Late talkers,” or children who have normal comprehension but simply begin speaking late, have mild developmental language problems. Children who are completely nonverbal have more severe problems.

Anatomical abnormalities may also result in both speech and language delays. Cleft palate is the abnormality most commonly associated with difficulties in speech production. Children with cleft palate characteristically have hypernasal speech secondary to velopharyngeal incompetence (eg, dysfunction of the soft palate). In

Table 28-1. Receptive and Expressive Language Milestones (Birth to 3 years)

<i>Skill</i>	<i>Mean Age</i>	<i>Normal Range</i>
Receptive Milestones		
Alerts to sound	Newborn	
Orients to sound/turns to voice	4 mo	3–6 mo
Responds to name	4 mo	4–9 mo
Understands “no”	10 mo	9–18 mo
Follows 1-step command with gesture	12 mo	10–16 mo
Follows 1-step command without gesture	15 mo	12–20 mo
Points to several body parts	18 mo	12–24 mo
Follows 2-step command with gesture	24 mo	22–30 mo
Expressive Milestones		
Cooing (vowel sounds)	3 mo	1–4 mo
Laughs	4 mo	3–6 mo
Babbling (consonants added to vowel sounds)	6 mo	5–9 mo
Dada/Mama nonspecifically	8 mo	6–10 mo
Dada/Mama specifically	10 mo	9–14 mo
3–5 word vocabulary	12 mo	
Immature jargonizing (gibberish with inflection)	13 mo	10–18 mo
Mature jargonizing (gibberish with occasional word)	18 mo	16–24 mo
50-word vocabulary	24 mo	
2-word phrases	24 mo	20–30 mo
Uses pronouns indiscriminately	24 mo	22–30 mo
States first name	34 mo	30–40 mo
Uses pronouns appropriately	36 mo	30–42 mo
250-word vocabulary	36 mo	
75% of speech intelligible to strangers	36 mo	

Box 28-1. Danger Signals in Language Development

- Inconsistent or lack of response to auditory stimuli at any age
- No babbling by 9 months
- No intelligible speech by 18 months
- Inability to respond to simple directions or commands (eg, “sit down,” “come here”) by 24 months
- Speech predominantly unintelligible at 36 months
- Dysfluency (stuttering) of speech noticeable after 5 years
- Hypernasality; inappropriate vocal quality, pitch, or intensity at any age

Box 28-2. Causes of Delayed Language Development

- Hearing impairment
- Perinatal risk factors leading to hearing impairment
- Disorders of central nervous system processing
 - Global developmental delay
 - Mental retardation
 - Autism spectrum disorders
- Developmental language disorders
- Disorders of language production
 - Articulation disorder
 - Dysarthria
 - Verbal apraxia
- Presence of anatomical abnormalities (eg, cleft lip, cleft palate)
- Environmental deprivation

In addition, conductive hearing losses may result from chronic serous otitis media, which is common in these children. The presence of a submucous cleft palate, characterized by a bifid uvula, diastasis of the muscles in the midline of the soft palate with intact mucosa, and notching of the posterior border of the hard palate, should be considered in children without an overt cleft palate who have recurrent symptomatic serous otitis media and phonation difficulties.

Environmental deprivation is another cause of delayed language development, especially in families where children are not spoken or read to. Sometimes there is additional historical or physical evidence of deprivation (eg, profound failure to thrive, physical or sexual abuse) or emotional trauma (eg, domestic violence).

Evaluation

History

When evaluating children younger than 3 years, pediatricians must rely primarily on parental reports of children's language capabilities (Questions Box). Children who are 3 years of age and older can usually be engaged in conversation during the visit, but younger children are more likely to be uncooperative or remain silent when confronted by strangers or new situations. Historical factors, such as a family history of childhood deafness, exposure to ototoxic agents (eg, aminoglycoside antibiotics), neonatal asphyxia, hyperbilirubinemia, maternal cocaine abuse, or low birth weight, provide valuable information in the identification of high-risk infants (see Boxes 28-1 and 28-3).

Physical Examination

Examination should include a thorough assessment of the head and neck region. Microcephaly may indicate the presence of mental retardation or structural abnormalities. Abnormalities of the external ear (eg, microtia) may be associated with sensorineural hearing loss. Otolaryngologic examination of the ear is essential. Presence of a middle ear effusion may be associated with a conductive hearing

Questions

Language Development

- Are the child's language capabilities appropriate for age?
- Do the parents feel that their child has difficulty hearing?
- Is there any family history of childhood deafness?
- Has the child been exposed to any ototoxic agents (eg, aminoglycoside antibiotics)?
- Is there a history of neonatal asphyxia, hyperbilirubinemia, or low birth weight?
- Has the child ever had bacterial meningitis?
- Did the mother have a TORCHS infection (toxoplasmosis, rubella, cytomegalovirus, herpes simplex, syphilis) during pregnancy?

Box 28-3. High-Risk Indicators for Hearing Loss in Children (Birth–24 months)^a

Neonatal Period (Birth–28 days)

- Family history of sensorineural hearing loss (SNHL)
- In utero infection associated with SNHL (eg, TORCHS infections [toxoplasmosis, rubella, cytomegalovirus, herpes simplex, syphilis])
- Anatomical malformations of the head and neck region
- Hyperbilirubinemia at a level requiring exchange transfusion
- Low birth weight (<1,500 g)
- Bacterial meningitis
- Low Apgar scores
- Respiratory distress (eg, meconium aspiration)
- Mechanical ventilation for 10 days or more
- Exposure to ototoxic medications (eg, aminoglycoside antibiotics) for more than 5 days or in combination with loop diuretics
- Stigmata of syndromes known to be associated with hearing loss (eg, Down syndrome)

Infants and Children (29 days–24 months)

- Parental concern about hearing, speech, language, or developmental delay
- Recurrent or persistent otitis media with effusion for at least 3 months
- Severe head trauma (associated with fracture of the temporal bone)
- Infections associated with SNHL (eg, bacterial meningitis, mumps, measles)
- Neurodegenerative disorders or demyelinating diseases
- Any of the newborn risk factors listed above

Hearing assessment in infants and children: recommendations beyond neonatal screening. *Pediatrics*. 2003;111:436–440.

loss. The tympanic membrane should be examined for evidence of scarring or perforation, often secondary to recurrent otitis media. Pneumatic otoscopy provides subjective assessment of tympanic membrane mobility (compliance) when it is subjected to a pulse of air. Tympanometry (impedance audiometry) performed in the office can provide objective information regarding the mobility of the tympanic membrane and the presence of middle ear effusions (Figure 28-1). Tympanometry is not a hearing test but rather an assessment of middle ear functioning that uses sound energy to determine the compliance of the tympanic membrane and pressure in the middle ear. Physical stigmata of any syndromes that may be associated with deafness (Box 28-4) should be noted.

Laboratory Tests

The advantages of early identification of hearing loss cannot be over-emphasized. The Joint Committee on Infant Hearing's Year 2000 Position Statement, which was endorsed by the American Academy of Pediatrics, endorses universal hearing evaluation of all infants prior to 3 months of age. High-risk indicators for hearing loss (see Box 28-3) serve 2 purposes. First, they help identify infants, living in areas where universal newborn hearing screening is not yet available, who should receive an audiological evaluation. Second, these risk indicators help identify infants who require ongoing medical and audiological monitoring because normal hearing at birth in these children may not preclude the development of later hearing loss (eg, delayed onset).

The evaluation of any child with delayed language development or suspected hearing loss begins with a hearing assessment. Various techniques are available, depending on the child's age and the degree of sophistication required. (A detailed discussion of the various tests used to evaluate children's hearing is presented in Chapter 73.) In addition to a hearing evaluation, a full speech, language, and communication assessment (eg, assessment of pragmatic language skills) should be performed on children with suspected language delays. In the pediatric office, parent report inventories may be used to validate parental concerns, and office-based language assessment may be aided by the use of screening tests such as the Clinical Linguistic and Auditory Milestone Scale or the Early Language Milestone Scale. These tests are used to supplement the clinical history of a child's language abilities. Children, who in addition to speech or language impairments also have signs of possible cognitive or social skills impairments, should receive a comprehensive, multidisciplinary developmental assessment.

Management

The first 3 years of life are extremely important to language development. Hearing impairment is one of the most common causes of delayed language development in young children. The history, physical examination, and initial screening can be used to suggest referral to various specialists (eg, audiologists, speech pathologists, child psychologists, otolaryngologists) for further clarification of hearing, speech, or language deficits and treatment. Early identification of hearing impairment and its degree of severity allow for early

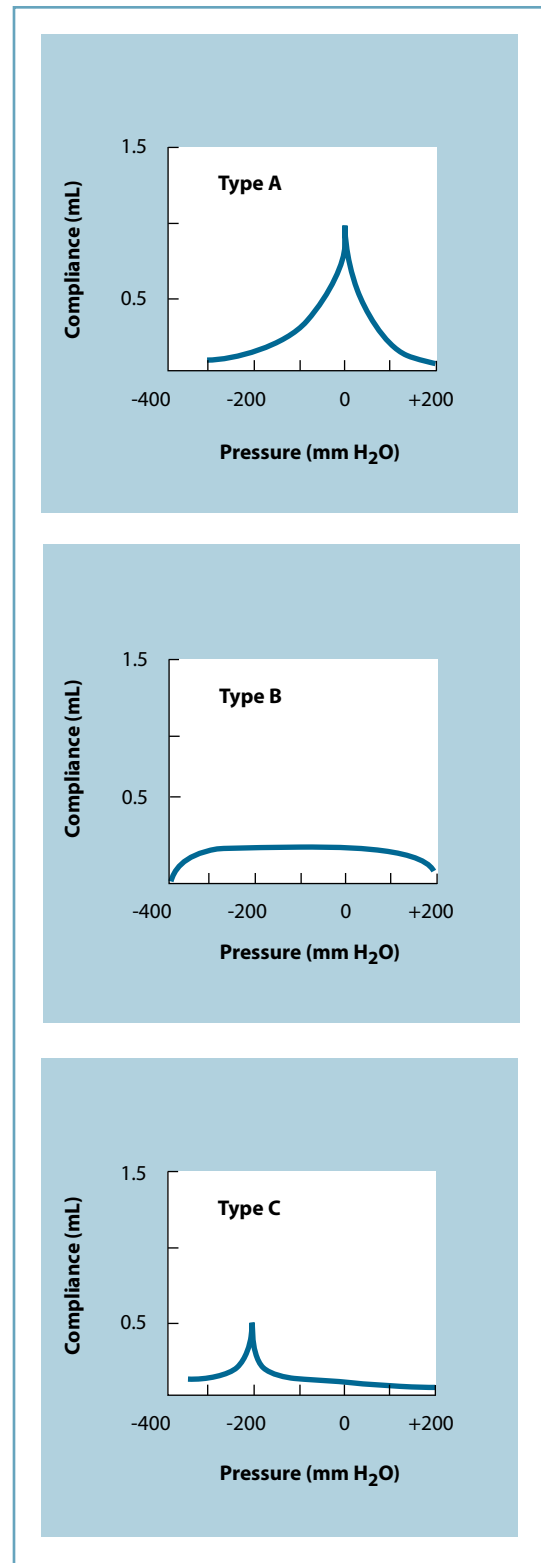

Figure 28-1. Basic tympanometry curves. The Type A curve indicates a normally compliant tympanic membrane (TM). The Type B curve indicates little or no motion of the TM and can be seen with middle ear effusion, a scarred TM, or a cholesteatoma. The Type C curve indicates negative middle ear pressure and may be seen with a resolving middle ear effusion or eustachian tube dysfunction. Other variations can occur in these basic curves that are not illustrated here.

Box 28-4. Syndromes Commonly Associated With Hearing Impairment

Autosomal-Dominant Conditions

- Brachio-otorenal syndrome
- Goldenhar syndrome (facioauriculovertebral dysplasia)
- Stickler syndrome
- Treacher Collins syndrome
- Waardenburg syndrome

Autosomal-Recessive Conditions

- Alport syndrome
- Jervell and Lange-Nielsen syndrome
- Pendred syndrome
- Usher syndrome

Chromosomal Disorders

- Trisomy 13 syndrome
- Trisomy 18q syndrome

Miscellaneous Disorders

- CHARGE association (coloboma, congenital heart disease, choanal atresia, growth and mental retardation, genitourinary anomalies, ear anomalies, and genital hypoplasia)
- TORCHS syndrome (toxoplasmosis, rubella, cytomegalovirus, herpes simplex, syphilis)

intervention in the form of amplification of sound, special education for children, and counseling and support services for the families with affected children. (See Chapter 73 for further information on management of hearing impairment.)

Special education is of prime importance in the management of children with language difficulties. The Education for All Handicapped Persons Act, federal legislation passed in 1975, and its subsequent more comprehensive reauthorization as the Individuals with Disabilities Education Act (IDEA) in 1990 requires that public schools provide individualized and appropriate education for all children with disabilities. Knowledge of available community resources (eg, special schools) can aid pediatricians in providing **support services** such as special community agencies and support groups for disabled children and their parents. Children with language delay in the context of global developmental or cognitive delays, or ASDs, require prompt referral to early intervention services.

Prognosis

Children with a history of speech and language delays should be monitored carefully for the emergence of reading difficulties. Reading is a language-based skill that requires the appreciation of subtle differences among speech sounds (eg, phonological awareness) and the ability to link these sounds to written symbols. The emergent literacy model of reading development assumes that reading, writing, and oral language develop concurrently from interactions in social contexts.

Children with speech and language delays require long-term monitoring of academic, emotional, and behavioral functioning.

Treated early, speech and language delays and disorders generally improve over time. The final prognosis is dependent on the nature and severity of the underlying cause and the interventions provided.

CASE RESOLUTION

The child described in the case history has delayed development of expressive language skills. At the age of 3 years, she should have a 250-word vocabulary and speak in 3-word sentences; in addition, her speech should be primarily intelligible to strangers. Because of the delay, she should be referred immediately for a hearing assessment and speech and language evaluation. Hearing loss is an important diagnosis to rule out. Simply because her parents report no hearing problems does not mean she does not have a deficit. She may have learned to respond to nonverbal cues, or she may hear only some things.

Literacy Promotion in Pediatric Practice

Lynn Hunt, MD

CASE STUDY

You are seeing a 6-month-old boy for the first time for a well-child visit. The child has a completely negative history and seems to be thriving. The patient's mother works part-time as a housekeeper and his father is a seasonal worker in agriculture. The infant is up to date on his immunizations except for his 6-month shots. The family

history is noncontributory, but his mother mentions that her 6-year-old daughter needs to repeat kindergarten. Teachers have advised the mother that her oldest daughter is cooperative, but she has not mastered letters and early reading yet. They feel with "a little more time" she will be fine. The mother does not seem terribly concerned.

Early literacy promotion in the office setting is now recognized as an essential part of pediatric primary care. Both the American Academy of Pediatrics and the Canadian Paediatric Society encourage providers to include literacy promotion in the routine clinical care of toddlers and young children.

Literacy promotion should begin well before a child is ready to learn to read. Eventual mastery of reading will depend on skills such as language ability, imagination, and familiarity with books and the reading process. Children develop many of these skills in the first few years of life before they go to school or even to preschool. In fact, a child's language ability at 3 years of age is strongly correlated with later academic performance. Parent-child interactions are crucial, and guidance for parents regarding literacy promotion activities at home should begin before a child learns to speak.

Reading aloud to children on a regular basis is one of the most effective ways to promote early literacy and language development. Language skills are the foundation for later reading ability and are dependent largely on the amount and quality of language exposure. The architecture of a developing brain is physically altered by experiences during infancy. At birth a baby's brain contains 100 billion neurons, which go on to form trillions more connections. Those connections that are stimulated by frequent use will persist, while less-used synapses will be eliminated as the brain matures. Reading aloud and book sharing may help ensure the preservation of brain connections associated with skills such as memory, creativity, comprehension, and language.

Reading aloud exposes children to vocabulary they don't hear in daily conversations (3 bears, beanstalks, etc). Reading aloud also stimulates the imagination (cows jumping over the moon). Over

time, children learn that the abstract letters on the page represent words, and they become aware of different smaller sounds making up words. All of these experiences lead to reading readiness.

Consequences of Low Literacy

There are significant consequences to low literacy as children get older. Poor academic skills are consistently linked with higher dropout rates, entrance into the juvenile justice system, and unemployment. One-third of all juvenile offenders are reported to read below the fourth-grade level and more than 80% of adult prison inmates are high school dropouts.

Literacy level and health outcomes are also intimately related. Health literacy is defined as the degree to which individuals can obtain, process, and understand the basic information they need to make appropriate health decisions. Multiple studies have demonstrated that low literacy impacts health and well-being negatively. Individuals with limited health literacy are more likely to engage in risky behavior and less likely to receive the care they need. Adolescents with low reading ability are more likely to smoke, use alcohol, carry a weapon, and be in a physical fight requiring medical treatment. Conversely, higher levels of literacy are associated with positive health outcomes such as appropriate use of inhaled asthma medication or choosing to breastfeed an infant.

Promoting literacy is good medicine not only for the individual but also for society. Besides the societal impact of school failure, individuals with limited literacy incur medical expenses that are up to 4 times greater than patients with adequate literacy skills. Low literacy costs the health care system billions of dollars every year in preventable visits and hospital stays.

Literacy Promotion in the Medical Office

The model of literacy promotion supported by Reach Out and Read is widely used in many pediatric settings. The Reach Out and Read model has 3 main components.

1. *Anticipatory guidance:* During regular well-child visits, health care providers encourage parents to read aloud to their young children at home. The advice is age-appropriate, and concrete examples are provided or modeled by the provider.
2. *Books:* A new developmentally and culturally appropriate book is given by the doctor at each well-child visit so that parents have the tools to follow their provider's advice.
3. *Waiting rooms:* Literacy-rich waiting rooms contribute to the literacy message. Gently used books for parents to read to their child while waiting and displays or information about local libraries are encouraged. When possible, community volunteers read aloud in the waiting rooms, modeling for parents the pleasures and techniques of reading aloud to very young children.

Reach Out and Read had its origins in an urban clinic serving a high proportion of low-income families and has always had a special focus on children growing up in poverty. For complex reasons, poverty is a powerful predictor of children's exposure to language. Children in low-income homes are 40% less likely to be read to on a daily basis than other children. Pioneer researchers Hart and Risley estimate that by age 4, children living below the poverty line will hear 30 million fewer words in total than those growing up in higher-income households.

Providing advice to parents is easiest and most effective when the book is brought in at the beginning of the visit. That way, physicians can naturally weave in guidance that is appropriate to the age of the child (see Box 29-1 and Table 29-1). Advice should be brief and to the point, supportive, and part of a general conversation about the child's development and behavior.

Another advantage of presenting the book early in the visit is the amount of developmental and relationship information that can be observed. The book is a tool that can speed informal developmental surveillance. If a 2-year-old exclaims, "doggie says wow-wow!" there is no doubt she is putting 2 words together. If a 1-year-old uses an index finger to point and looks to see if his mother is watching, the provider can gain information about fine motor ability and the child's social interaction in only a few moments.

Children benefit from storytelling and book time in whatever fashion is most comfortable for the parent. Ideally books should be in the family's preferred language or bilingual. It is best for parents to use the language that is easiest for them because it is more important for children to hear a language with rich vocabulary and complex sentences than to learn English first. If no book is available in the appropriate language or the parents are not confident with their own reading skills, the primary care provider should encourage parents to look at books, name pictures, and talk about what is going on in the pictures with their children. Provider knowledge of

Box 29-1. Anticipatory Guidance for Parents^a

Specific guidance can help parents with age-appropriate expectations for how their children will handle books and respond to stories.

- **Newborns and very young babies** need to hear a parent's voice as much as possible: talking, singing, and telling stories are all good.
- **6-month-olds** may put books in their mouths; this is developmentally normal and appropriate and is why we give them chewable board books. It is not in any way an indication that the child is too young for a book!
- **12-month-olds** may point with one finger to indicate interest in a picture; parents should see this as developmental progress.
- **18-month-olds** may turn board book pages and may insist on turning back again and again to a favorite picture.
- **2-year-olds** may not sit still to listen to a whole book, but will still enjoy looking at individual pages, or having parents read them stories bit by bit
- **3-year-olds** may retell familiar stories and may memorize their favorite book.
- **4- and 5-year-olds** may start to recognize letters or their sounds. They can understand and follow longer stories.
- **School-aged children** will start to be able to read to you—but don't stop reading to them, and enjoy taking turns.

local programs for adult literacy and English as a second language is often useful because parents may ask for resources when literacy is discussed in the examination room.

Primary Care Providers Can Make a Difference

The primary care setting is the ideal venue for literacy promotion for several reasons. First, almost all parents will bring in their child for immunizations, so there is an opportunity to reach a broad group, not just those seeking learning experiences for their children. In fact, 96% of all children younger than 6 years see their doctor at least once annually. Second, each child is seen for multiple visits from a very young age, providing repeat opportunities to discuss reading aloud during the critical first years. Further, suggestions supporting literacy-focused activities are a logical extension of the advice about growth and development parents are already receiving at these visits. And, when parents trust and value the advice from their primary care provider, early literacy messages assume greater credibility.

The effectiveness of this primary care model to promote reading aloud to young children has been demonstrated in multiple research studies. Parents who received even one book were much more likely to read aloud to their children and report reading as a favorite activity of their child. The effect was greatest for the poorest families, an important finding for children who may need this intervention the most. The outcome was similar for non-English-speaking families, and the findings held even if the book was given in English. Finally, and most encouraging, toddlers and preschoolers who had received

care in clinics applying the Reach Out and Read model had higher scores on language and vocabulary assessments than children not served by the program.

Literacy promotion and the Reach Out and Read model of giving books along with advice provide benefits for all concerned. Medical providers have a tool to assist with development surveillance and a way to build stronger bonds with families. Parents receive important information about reading aloud and advice tailored to the age of their child. And most importantly, children receive the benefits of reading aloud as well as beautiful, developmentally appropriate books.

CASE RESOLUTION

You speak to the mother about the value of reading aloud to her children. You give the 6-month-old a board book with pictures of baby faces. You demonstrate, showing how the 6-month-old is interested in the pictures and watches intently as you turn the pages. At the end of the visit you also find a gently used rhyming book that the mother can take home for her 6-year-old.

Gifted Children

Iris Wagman Borowsky, MD, PhD

CASE STUDY

A 3-year-old girl is brought to your office for well-child care. Her parents believe that she may be gifted because she is much more advanced than her sister was when she was the same age. The parents report that their younger daughter walked at 11 months of age and was speaking in 2-word sentences by 18 months. She is very “verbal,” has a precocious vocabulary, and constantly asks difficult questions such as, “How do voices come over a radio?” The girl stays at home with her mother during the day but recently began going to a preschool program 2 mornings a week. She enjoys preschool and plays well with children her own age. She also likes to play with her sister’s friends from school.

The girl is engaging and talkative. She asks questions about what you are doing during the examination and demonstrates impressive knowledge of anatomy. The physical examination is normal.

Questions

1. How are gifted children identified?
2. What characteristics are associated with giftedness?
3. What are the best approaches for dealing with the education of gifted children?
4. What is the role of the pediatrician in the management of gifted children?

Giftedness has been defined in several ways. The psychometric definition of giftedness is based on scores obtained on standardized intelligence tests. The 2 most frequently used cutoff points are 2 standard deviations above the mean (IQ = 130–135) and 3 standard deviations above the mean (IQ = 145–150). Children with these scores are in the upper 2% and 0.1% of the IQ distribution, respectively. IQ, which is considered to be fairly stable after the age of 3 or 4 years, is the best single predictor of scholastic achievement at all levels, from elementary school to college.

A second definition of giftedness is based on real-life achievements or performance of exceptional skills rather than on test scores. Children with special talents (other than general intelligence) in areas such as music, mathematics, ice skating, chess, or drama fit this description. Other definitions of giftedness recognize motivation, commitment, perseverance, high self-esteem, and creativity as personality traits that allow children with above-average ability to develop exceptional talents.

Epidemiology

The prevalence of giftedness depends on the somewhat arbitrary definitions of giftedness and the varied approaches for identification of gifted children. Traditional screening systems identify 3% to 5% of students for participation in gifted programs in schools. Some schools use an alternative system, where 10% to 15% of children are recognized as above average. In an effort to foster giftedness in these children, schools offer them enriched programs.

Intellectual giftedness in children has been associated with the social, economic, and educational background of their families.

Factors that correlate with higher IQ scores in children are more years of parental education, higher IQ scores of mothers, increased family income, smaller family size, and longer intervals between siblings. Children from low-income and minority backgrounds are less likely to be identified as gifted than other children. African American, Hispanic, and Native American students are underrepresented by 30% to 70% in gifted programs in the United States.

Larger head size at 1 year of age and greater height and weight at 4 years of age have also been reported in children with high IQs. Although researchers have found that academically gifted children, as a group, begin to walk, verbalize, and read earlier, such factors are not useful for predicting giftedness in individual children.

Evaluation

One of the primary goals of child health promotion is **developmental monitoring**. The early identification of developmental delays, which allows for prompt intervention, is one of the primary purposes of such monitoring. Techniques for developmental assessment include **review of developmental milestones** with parents and discussion of parental concerns, **informal observation** of children in the office, and **formal screening with standardized tests**, such as the Denver II.

Identification of Gifted Children

Although parents’ first concern is usually to confirm that their child is developing normally, it is not uncommon for parents to ask if their child is gifted. Such questions are typically motivated by parents’ desire to optimally encourage their child’s development. Sharing

information and observations with parents during developmental monitoring may facilitate parent–child interaction and child development. In a competitive society, the pediatric provider should look for signs that above-average abilities are the result of undue pressures placed on children, such as incessant teaching or over-scheduling of time.

Infancy and early childhood may not be the best time to determine whether a child is gifted. Age of attainment of developmental milestones and performance on standardized tests (eg, Bayley Scales of Infant Development) during the first 2 years of life are both unreliable predictors of intellectual giftedness. Reasons for this lack of reliability may include weaknesses in the tests and variable rates of child development that result in transient precocity or delay. Tests that focus on visual memory tasks in infants may be better predictors of later academic intelligence; this possibility requires more research. In addition, many special talents that comprise giftedness, such as creativity or artistic or musical ability, may not manifest themselves until children are older.

The determination of giftedness in older children may involve several factors (Box 30-1). The early identification of giftedness allows for the development of an appropriate educational program that is optimally matched to a particular child’s ability to learn. Without early identification and intervention, intellectually gifted children may become disillusioned with school, lose interest in learning, fail to develop study skills because they are never challenged to think and work hard, and develop a pattern of underachievement that may be difficult to reverse by the middle grades.

Special Groups of Gifted Children

Giftedness is harder to identify in some children. In **physically disabled children**, giftedness is often obscured by their obvious physical disability, which demands attention. These children may participate in special programs where their physical needs are the major concern at the expense of their academic or artistic potential. In addition, poor self-esteem associated with the disability may prevent these children from realizing their potential. To identify giftedness in physically disabled children, parents and teachers must make a concerted effort to search for potential and encourage its

development. Strengthening a child’s capacities may involve training in the use of a wheelchair or computer or taking frequent breaks to prevent fatigue.

Giftedness also commonly goes unnoticed in children who are **learning disabled**. It is quite possible for exceptional and poor abilities to coexist in a given child. In fact, an estimated 10% of gifted children have a reading problem, reading 2 or more years below grade level. Albert Einstein, Auguste Rodin, and John D. Rockefeller are famous examples of brilliant individuals who had reading and writing problems. An extreme example of the occurrence of both extraordinary and deficient abilities together in one individual is the child savant. Affected children possess amazing abilities in one area (eg, music, drawing, mathematics, memory), but they are delayed in other respects. In addition, they have behavioral problems that resemble autism, such as repetitive behavior, little use of language, and social withdrawal.

Learning disabilities may obscure children’s talents, thus preventing awareness of their potential. Conversely, children’s giftedness may mask their weaknesses, depriving them of needed help. Worst of all, gifted children who are learning disabled may manage to barely “get by” in the regular classroom setting and fail to receive recognition for strengths or weaknesses. Large differences on intelligence and achievement tests between scores in different areas, such as language and spatial abilities, may indicate both giftedness and a learning disability. Attention should be given to both weaknesses and strengths. Research suggests that programs that focus on strengths, not deficits, however, enhance self-esteem in gifted children who are learning disabled and can be extremely beneficial in their academic development.

The identification of giftedness is also difficult in **underachieving children**. Parents may approach the pediatrician with the following frustrating problem: Their child is doing poorly at school, although they believe that the child is bright because of the child’s abilities and participation in advanced activities at home. Underachievement may result from a learning disability; poor self-esteem; lack of motivation; or the absence of rewards, either at home or at school, for succeeding in academics.

As previously stated, giftedness is less likely to be recognized in children from low-income or ethnically diverse families. Many of the tests used to identify giftedness have been “normed” on white, English-speaking, middle-class children. In the absence of tests that are sensitive to socioeconomic differences, other means for identifying giftedness, such as assessment of creative work and teacher and student nominations, should be stressed. Schools with students from low-income or minority backgrounds tend to use their limited resources to help students who are doing poorly in school, rather than gifted students. Research has shown that programs for gifted children from such backgrounds benefit all students by creating positive role models and promoting the school as a place for the cultivation of excellence.

Box 30-1. Factors Used in the Identification of Giftedness in Children

- Intelligence tests
- Standardized achievement tests
- Grades
- Classroom observations
- Parent and teacher rating scales
- Evaluation of creative work in a specific field (eg, poems, drawings, science projects)

Management

At Home

Loving, responsive, stimulating parenting should be encouraged for all children, including gifted children. Parents of gifted children may feel inadequate, fearing that their child is smarter than they are. The pediatrician can provide **parental reassurance** by telling parents, “You must have been doing something right for your child to have been identified as gifted.” Children’s librarians, periodicals written for parents and teachers of gifted children (eg, *The Gifted Child Today*), and the local chapter of the National Association for Gifted Children are good resources for parents.

Parents are often overwhelmed with complex questions from their precocious preschool children about issues ranging from homelessness and world hunger to theology and the creation of the universe. The pediatrician should tell parents that they (1) should not be afraid to admit that they do not know all the answers and (2) should work together with their child to find the answers.

The pediatrician may need to warn parents about putting too much pressure on their gifted children. For example, enrolling children in multiple classes often leaves little free time for unstructured play. Play affords many opportunities for self-learning, interaction with peers, and development of creativity and initiative. Parents of infants, toddlers, and preschoolers should be encouraged to take cues from their children. If children have a rich environment with plenty of objects and books to explore, diverse experiences, and stimulating interactions, they will develop their own interests. Other educational materials and special instruction can then be provided in a particular area of interest.

Gifted children are often mistakenly considered to fit the stereotype of troubled, socially awkward “nerds.” With the exception of children at the genius extreme (IQ>180), gifted children are generally more sociable, well-liked, trustworthy, and emotionally stable than their peers, with lower rates of mental illness and delinquency. Nevertheless, they have the same emotional needs as other children. Gifted children may prefer to play with older children whose interests and abilities are closer to their own. This should be allowed as long as these relationships are healthy.

Parents should be encouraged to treat gifted children the same way they do their other children. Siblings of gifted children may become resentful if attention is centered on their brother or sister. They may feel inferior, particularly if gifted children surpass them in school. Tensions may be magnified if gifted children become friends with their older sibling’s friends. To preserve a sense of self-worth and competence in siblings, the pediatrician should recommend to parents that they set aside special time to spend with each of their children. Parents should encourage other talents (eg, musical or athletic abilities) in siblings. Older siblings should receive the special privileges and responsibilities that come with age, such as staying up later or doing different chores. Any tensions within the family should be openly discussed and addressed.

At School

Parents often seek advice from their pediatrician about educational planning for gifted children. A learning environment with the optimal degree of challenge—hard enough to require new learning and stave off boredom, but not so hard as to be discouraging—is the goal for all children. Parents of young children should look for preschools with flexible programs and capable teachers to accommodate children with precocious skills. Parents of school-aged children must decide whether **acceleration** (starting school earlier or skipping grades) or **enrichment** (staying in the same grade but supplementing the regular curriculum) is more appropriate (Table 30-1). The choice depends on the particular child.

Parents and teachers of gifted children are usually concerned that children in accelerated programs may have problems with social adjustment if their classmates are older. Existing evidence, however, suggests that gifted children benefit socially from acceleration. Gifted children in accelerated programs participate in school activities (except contact sports) more often than gifted children placed with classmates of the same age. Even when gifted children are placed with children their own age, they tend to make friends with older children with whom they share more interests. Gifted children also make up any curricular content missed by grade skipping. Because the process may be difficult to reverse, acceleration may not be the best option when the decision is a borderline one.

Table 30-1. Acceleration Versus Enrichment in Gifted Education

	<i>Advantages</i>	<i>Disadvantages</i>
Acceleration	May provide suitable academic challenge	Difficult to reverse
	May have social benefits	May have to skip more than one grade to be properly challenged
	Can be offered by all schools	
	Inexpensive	
Enrichment	Classmates are same age	May be expensive
	May expose children to subjects they would not otherwise learn	Inadequate for highly gifted children
	Appropriate for mildly gifted children	May isolate gifted from non-gifted children and encourage “elite” label
		May lead to excessive homework if children have to make up work of regular class

Enrichment involves keeping gifted children with same-age classmates, but supplementing the regular curriculum. Regular class placement with a teacher who is willing to offer extra work (eg, special projects) in addition to grade-level assignments, part-time programs to supplement regular class work (eg, field trips, foreign language classes), honors classes that group bright children together for their basic curriculum, and independent study by the family at home are all examples of enrichment programs. These programs may work well for some gifted children, depending in large part on the resources and funding available and the experience, creativity, and enthusiasm of the teachers involved.

Some enrichment programs may isolate gifted from non-gifted children, however, and encourage labeling of the gifted students as elite. If children are required to make up the regular class work that they miss when they are involved in the enrichment program, they may find themselves overloaded with homework.

Often a **combination of acceleration and enrichment** programs is the best option. Either acceleration or enrichment alone may not be enough for the brightest children. Acceleration may not be sufficient for markedly advanced children who would have to skip 2 or 3 grades to be appropriately challenged. The pediatrician should recommend that parents work closely with teachers to achieve the best learning environment for their children. Some factors that should be considered are age, physical size, motor coordination, emotional maturity, personality, and particular areas and degrees of giftedness of the child. Acceleration may be a better option for a large, outgoing child than for a small one. Gifted children should be asked what they would like to do.

When evaluating the suitability of an educational situation for their gifted child, parents should watch for some warning signs. Excessive homework should neither be expected nor tolerated because it cuts into the child's time to play and develop socially. The emphasis in gifted education should be on broadening perspectives, not increasing busy work. If gifted children are developing a sense of elitism or peer animosity, the nature and philosophy of the program should be questioned. Boredom with schoolwork, not needing to study, signs of depression, or symptoms suggestive of school phobia, such as recurrent abdominal pain or headaches on school mornings, should prompt investigation into the suitability of the child's program.

Home schooling, either partial to complement classroom curricula or full time, is an educational alternative. To decide if this is the best choice for their family and gifted child, recommend that parents who are considering home schooling gather as much information as possible, including talking to other parents who are home schooling their children, reviewing sample curricular materials, and contacting school districts and state departments about requirements and specific steps.

Prognosis

Gifted children are a diverse group, comprising children with exceptional academic, artistic, or other abilities, combined with the creativity and commitment to achieve their potential. Gifted children may be gifted in one area and average or even below average in another area. The purpose of identifying gifted children is to provide them with an educational environment to help maximize their potential. The prognosis for gifted children is excellent. Pediatricians can serve as a resource for parents in raising their gifted child, and help the child and family to obtain appropriate evaluation, educational programs, and supportive resources.

CASE RESOLUTION

In the case presented, the physician should reaffirm the parents' observations that their child is gifted. The parents should be encouraged to explore programs in which their daughter's talents may be fostered, but at the same time, they should understand that even gifted children need time for play and unstructured activities.

Children and School: A Primer for the Practitioner

Martin Baren, MD, and Geeta Grover, MD

CASE STUDY

An 8-year-old boy is brought in by his parents in early April because his third-grade teacher informed them that he is currently failing in school and may not be promoted to the fourth grade. Review of his medical, developmental, and school histories reveals that he was a very colicky infant and continued to be difficult as a toddler. His language skills were somewhat delayed, although not enough to warrant a full evaluation. His preschool teacher felt that he was easily distracted when doing seat work. In kindergarten he had some difficulty learning all of his letters, numbers, and sounds. Early reading was difficult in kindergarten and first grade, but improved by the end of the year. Second grade was fairly good except for continued concerns regarding inattention and distractibility. By third grade he was struggling more, especially with writing, and not reaching grade level in several areas. He also continued to be inattentive and distractible in his classroom.

Examination reveals a well-developed and well-nourished boy whose growth parameters are within normal limits for his age. He appears somewhat anxious in the examination room, and when asked about school he tells you that he feels he is just not as smart as the other children in his class.

Questions

1. Should grade retention be considered when a child is failing in school?
2. What are the advantages and/or disadvantages of grade retention?
3. What is the differential diagnosis of school failure?
4. What steps should be taken at this time by the parents and the school for the boy in the opening scenario?

Pediatricians, because of their routine contact with young children and their families, are often the professionals most knowledgeable about child development. Pediatricians' longitudinal perspective on their patients' lives places them in a unique position to evaluate, diagnose, and manage not only children's medical needs, but also their developmental, social-emotional, behavioral, and educational ones. Traditionally, the 5-year-old health maintenance visit has been regarded as the "school readiness" visit. However, waiting until this date to address concerns regarding educational readiness is too late. **School readiness** must be promoted from infancy through early childhood.

During the school-aged years, pediatricians should continue to monitor children's school progression by inquiring about academic, social-emotional, and behavioral development. Parents often turn to pediatricians for advice regarding their children's behavioral or academic difficulties at school, which may be leading to **school failure**. The evaluation and management of school failure requires a multidisciplinary approach under the guidance, support, and advocacy provided by pediatricians. It is important that pediatricians have an understanding of the evaluation and management of both children's school readiness needs and school difficulties, should such arise.

Epidemiology

School readiness is the term used to describe those qualities and traits that are considered prerequisites for a child to be ready to be successful in school. According to national surveys of kindergarten teachers, about one-third of children are not ready for school when they enter, and of these children, 25% will repeat either kindergarten or first grade. Language deficiencies and problems with emotional maturity are cited most often as the factors that most restrict school readiness.

School failure is a multifaceted issue and epidemiologically complex. Overall, about 20% of children have one or more developmental, learning, behavioral, or emotional disorders. Only 10% to 15% of children in the United States are receiving special education services because of difficulties with school performance. Finally, we know that children with concerns such as these are 2 to 3 times more likely to drop out of school than children without any of these concerns.

Approximately 10% to 15% of school-aged children repeat or fail a grade in school. Children who have disabilities are nearly 3 times more likely to repeat a grade than children without disabilities. About 1 in 5 children who repeat a grade in school has some identifiable

disability. Grade failure is also more common among boys, children living in poverty, minorities, and those in single-parent homes.

Given that the average child in the United States spends nearly 50% of his or her waking day in a school or a similar learning situation for approximately 12 or 13 years, it follows that a lack of success in these settings will lead to difficulties for much, or all, of adult life. Undetected school difficulties can create a lifelong pattern of frustration and failure. Children with **attention-deficit/hyperactivity disorder (ADHD)** are 2 to 3 times more likely to drop out of high school than their peers without ADHD; children with ADHD who attend college are less likely to graduate than their non-ADHD peers (see Chapter 125). About 40% of all juvenile offenders have learning disabilities; many have never received any help for their disabilities. Even more alarming is that 85% of juvenile delinquents and 75% of adult prisoners are functionally illiterate—somehow these children slipped through the cracks of our educational system.

Clinical Presentation

Defining **school readiness** is not an easy task because the intellectual, physical, social, and emotional development among kindergarten-aged children varies tremendously. Generally school readiness means that children are adequately prepared to participate in formal schooling. It is the term used to describe those traits that are considered prerequisites for a child to be ready to succeed in school (Box 31-1). Readiness implies not only adequate pre-academic skills, but also adequate physical, developmental, language, social-emotional, and behavioral skills to allow children to be successful in the formal schooling environment.

With regard to **school failure**, the non-specificity of children's presenting signs and symptoms and of parental complaints make it challenging to determine a specific etiology. For instance, parental concern regarding a child's inability to focus could suggest an attention disorder, learning disability, mood disorder, or perhaps all 3. Parental concerns can be categorized into 3 broad areas: learning (eg, learning disability or problems with higher-order cognition including mental retardation), attention (eg, ADHD), and emotional/behavioral (eg, anxiety, depression, or serious emotional disturbance). Signs of school failure are presented in Box 31-2. It is important to look not only at academic skills, but also at other components of the educational experience, such as social and emotional experiences. Finally, it is important to ascertain the basis for the perception that a child is failing. Does the problem exist in the eyes of the student, parent, teachers, or everyone?

Academic achievement across subjects must be assessed, especially in the areas of reading, mathematics, and writing. In addition, it is also important to evaluate students who have good skills but fail to perform satisfactorily in the areas of writing, planning, organization, project completion, test taking, or classroom participation. Difficulty with academic performance may lead to school failure in spite of satisfactory academic skills.

In addition to academic skills and performance, the development of good social skills and peer relations is equally important. Some

Box 31-1. Kindergarten Readiness Skills

Academic

- Counts to at least 10
- Recognizes some printed letters and perhaps a few words (eg, name)
- Beginning to understand connection between oral and written language (evidence of phonological skills)
- Recognizes and matches shapes and colors that are the same/different, etc

Personal, Social, Emotional, and Developmental

- Able to separate from parents for several hours at a time
- Takes care of personal hygiene and toileting
- Verbally communicates personal needs
- Able to relate personal experiences, ideas, thoughts, and feelings with words
- Sustains attention to task for 10 to 15 minutes
- Able to understand and follow directions with 2 or 3 steps
- Able to communicate and play cooperatively with other children (eg, shares and takes turns)
- Copes with anger and frustration

Motor

- Uses pencil, crayon, and scissors
- Runs, jumps, hops, skips, and throws ball
- Draws a person and basic shape

Box 31-2. Signs of School Difficulties

- Grade retention
- Loss of self-esteem
- Short attention span/hyperactivity
- Not able to follow directions, pay attention, or finish a task
- History of speech-language problems
- Not able to carry thoughts or ideas to paper
- Not able to read, write, or spell appropriate to age and educational level
- Requires excessive time to complete homework/excessive parental involvement with homework
- Previously tested but not eligible for special education (eg, child may be a "slow learner")
- Child hates school/psychosomatic symptoms
- Child has few, if any, friends or change of friends
- Sudden change in behavior
- Depression
- Substance use

students have difficulties "fitting in," which leads to a disappointing educational experience in spite of academic excellence.

Pathophysiology

Developmentally there is support for the concept of promoting **school readiness** from a young age. The developing brain continues to make new synaptic connections and "prune" away underused connections from birth to about age 5—well before formal schooling begins. For example, we know that children who grow up without

being read to and with little exposure to books or printed language during the first 5 years of life are at an increased risk of developing reading failure and subsequent school failure (see Chapter 29). School readiness must be promoted from infancy throughout early childhood—waiting for the 4- to 5-year-old well visit is too late. Most children with learning disabilities experience language, motor skills, or behavior problems well before they encounter difficulties in the classroom.

School failure is a complex issue with a wide variety of causes. Both intrinsic, or child-related causes, and extrinsic, or environmental-related causes, relating either to the home or the school setting must be considered (Box 31-3). In most cases, school failure is the result of a complex interaction between child, family, and school-related variables, and not simply the result of a single factor (eg, ADHD). Before looking for specific learning disabilities or disorders or intellectual problems, investigate any type of external situation that may be causing the problem. Medical problems should always be considered. Neurologic, psycho-emotional, and behavioral disorders based in the central nervous system may be responsible for school failure.

Unrecognized ADHD, learning disorders, and learning disabilities are common causes of school failure. Learning disorders are defined problems within the central nervous system that prevent children from learning to their full potential. The brain has difficulty handling information (processing skills), which therefore affects the child's ability to learn and/or perform in school. Some of these processes include memory, language, attention, and coordination. A specific learning disability is a particular type of learning disorder that is defined as a significant difference between a child's natural ability (intelligence—IQ) and his level of achievement, as defined by federal and state laws. This difference is determined by psycho-educational testing performed by psychologists and educators.

Federal law (Public Law 101-476: Individuals with Disabilities Education Act [IDEA]) defines specific learning disability as “a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, that may manifest itself in an imperfect ability to listen, think, speak, read, write, or to do mathematical calculations, including conditions such as perceptual disabilities, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia.” Operationally, specific learning disabilities are characterized by a discrepancy between ability (as measured by intelligence tests) and actual academic achievement (as measured by school performance). However, specific learning disability does not include children who have “learning problems that are primarily the result of visual, hearing, or motor disabilities, mental retardation, emotional disturbance, or environmental, cultural, or economic disadvantage.”

Another important reason for school failure is an unsatisfactory student/teacher relationship. A poor “fit” with either teacher or classroom placement may cause major damage to a child's program.

Finally, there are students who are labeled “lazy” by school personnel. These students are usually found to have one or more of the

Box 31-3. Causes of School Failure

Intrinsic

- Low cognitive skills (intellect)
- Learning disorders
- Specific learning disabilities
- Attention-deficit/hyperactivity disorders
- Speech and language disorders
- Mood and anxiety disorders
- Low self-esteem
- Social–emotional difficulties
- Neurodevelopmental delays
- Motor coordination disorders
- Chronic or serious medical illness (eg, seizure disorders, cystic fibrosis, asthma)
- Vision, hearing, or speech difficulties
- Poor nutrition
- Sleep problems
- Substance use/abuse
- Genetic history (eg, family history of school problems)

Extrinsic

- Language/cultural differences
- Serious psychosocial concerns: parental depression, history of abuse or neglect
- Disruption in the family (eg, many moves)
- Poor school readiness/absence of enrichment prior to school entry (eg, early book exposure)
- Parental or school expectations not commensurate with child's abilities
- School, classroom placement (poor “fit” or poor teaching)

previously mentioned school difficulties but have never been properly diagnosed. Rarely a student is found who has no major identifiable problem but just isn't motivated to take part in the educational experience. Alternative placement or home schooling may be an answer for these students.

Evaluation

History

In the past, pediatricians assessed **school readiness** during the 5-year-old health maintenance visit. Clinical approaches to early identification of children at risk for school failure include risk assessments and developmental surveillance and screening. Children most at risk for school problems are those from economically and socially disadvantaged backgrounds. Developmental surveillance and screening (see Chapter 27) allows pediatricians to identify children with developmental, behavioral, and emotional delays, and to provide appropriate anticipatory guidance, as well as referral to early intervention programs.

Historical factors associated with an increased risk of school-related problems include **prematurity; low birth weight; small**

for **gestational age**; and **maternal history of tobacco, alcohol, or illicit substance abuse** during pregnancy (Questions Box: School Readiness). Developmental risk factors especially include delays in the acquisition of language skills. Medical factors that may impact school readiness include lead poisoning, iron deficiency anemia, and failure to thrive. The presence of chronic medical conditions (eg, asthma, diabetes mellitus, and seizure disorders) may impact school readiness either directly or indirectly via absenteeism, medication effects, or self-esteem issues. Environmental risk factors include poverty and lower socioeconomic status, parental depression, domestic violence, substance abuse, or a family history of school problems or learning disabilities.

School Failure

When evaluating for **school failure**, historical information should be sought from parents, schools, teachers, and the children themselves (Questions Box: School Failure). A review of present and past report cards not only provides information regarding academic progress, but also the behavioral and social-emotional assessments. Teacher behavior rating forms and evaluations and results of any psycho-educational evaluations should also be reviewed.

Physical Examination

With regard to **school readiness**, the most important aspect of the 5-year-old health maintenance physical examination includes careful hearing, vision, speech, and language assessments.

The physical examination in the evaluation of **school failure** has a limited but important role. Signs of short attention span, distractibility, overactivity, sadness, or anxiety should all be noted. Special attention should be paid to head circumference, minor congenital anomalies, abnormal facies, and skin lesions suggestive of neurocutaneous disorders (eg, multiple café-au-lait spots or ash leaf spots). The pediatrician should assess for vision, hearing, speech and language, and other appropriate evaluations as suggested by the history.

Neurodevelopmental Assessment

School readiness assessment begins with routine pediatric surveillance and screening (see Chapter 27). Several brief school readiness tests have been developed for use by pediatricians (eg, The Pediatric Examination of Educational Readiness). However, because their reliability and ability to detect subtle learning disabilities or arrive at more complicated diagnoses is not established, it is difficult to recommend any of them for routine use. If a specific school readiness evaluation is warranted, it is best to make a referral either to the school district or to an independent specialist (eg, developmental and behavioral pediatrician or educational psychologist) for a full evaluation.

Neurodevelopmental assessment can help identify the etiology of **school failure**. Neurodevelopmental assessment surveys a child's abilities across the different areas of development (eg, fine motor, language, visual-spatial, and memory skills) and helps to identify areas of strength and weakness. Such an assessment can be performed by professionals such as a developmental and behavioral pediatrician

Questions

School Readiness

- Has the child had any preschool or group child care experience and how has the child responded in these settings?
- Were any behavioral, developmental, or emotional concerns raised during those group care experiences?
- Does the child play well with age-appropriate peers or does the child seem to consistently prefer to play with younger or older children/adults?
- Is the child's speech understandable to strangers and can the child hold a conversation about everyday topics of interest?
- Can the child sit and listen to stories or sustain attention to a quiet activity for 10 to 15 minutes?
- Can the child identify colors, shapes, and some letters and numbers?

Questions

School Failure

- How many days of school has the child missed?
- Have any behavioral or attentional concerns been raised by the classroom teacher?
- Is the child having problems in all academic areas or are there particular subjects that are especially difficult for the child?
- Has any testing (eg, psycho-educational evaluation) been performed either by the school district or privately?
- Is the child receiving any special services (eg, speech therapy) or accommodations at school?

or a psychologist. Psycho-educational assessment is also critical in the evaluation of children with school failure. Such an assessment includes an evaluation of the children's cognitive abilities, academic achievement across subjects (eg, reading, writing, and mathematics), and assessments of perceptual strengths and weaknesses and social and emotional functioning. This can be accomplished either through the public school system via the **Individualized Education Plan (IEP)** process, as mandated by federal law (**IDEA**) or privately by an educational psychologist.

Management

The first aspect of management is the counseling or demystification of parents and children. Empowering parents with knowledge gives them the confidence to interact positively with their children's schools and allows them to advocate effectively for their children's educational needs. For children, the process of demystification should begin with the assurance that all people have strengths and weaknesses—mentioning one's own weaknesses or citing famous or successful people that have dealt effectively with their own learning concerns helps “humanize” and destigmatize the situation for children. It is important to use an optimistic tone. In addition to addressing the needs of families and children, the physician also serves an important advisory role for the school regarding behavioral

consequences of a child's disorder (eg, Should this child have a seizure or a behavioral outburst in the classroom, how should the situation be managed?) or the educational implications of chronic medical conditions.

Early intervention is the key to success with regard to children's **school readiness**. For many at-risk children, early childhood education programs such as Head Start and other preschool compensatory programs may come too late. Programs for younger children and their families (eg, Early Head Start) that promote good parenting, language stimulation, and learning through play are valuable and available in some communities.

Reading aloud to children is one of the most important parental interventions that physicians can promote, and it builds the child's skills required for eventual success in reading (see Chapter 29). Reading promotes language mastery, and language mastery, in turn, is one of the keys to school readiness.

The pediatrician can assist families with children who have clear developmental disabilities, such as mental retardation, cerebral palsy, or autism, to access special education services as mandated by the **IDEA of 1990 and the Amendments of 1997 and 2004**. These laws require public schools to provide a free and appropriate education in "the least restrictive environment" for all children with a disability and require schools to use the IEP process (or Individualized Family Service Plan for children <3 years of age) to identify and evaluate the educational needs of children in order to develop an appropriate educational program to meet each child's needs. Pediatricians should be familiar with their local laws so that they can advocate for these children at the time of school entry if needed.

Children who are at increased risk for school readiness problems because of medical, social-emotional, behavioral, or environmental concerns should be monitored carefully. If these children do not appear to demonstrate age-appropriate skills, they should be referred for further evaluation. Despite early intervention, some children may still not be ready for school at the age-appropriate time. Options for these children include delaying school entry or special educational programs. Delaying school entry may not be the best solution if children remain in the same environment that failed to produce readiness in the first place. In addition, studies have shown that students who are older than their classmates because of delayed school entry have higher rates of behavior problems, substance abuse, and other health risk behaviors in adolescence. An alternative is for these children to enter school along with their same-aged peers, and provide special classrooms or programs for those having difficulties.

The management of school failure requires a multidisciplinary approach. Information from the school, including school reports, teacher conferences and notes, testing that has been completed, and input from other school officials, if appropriate, should be requested. The primary care physician can assist the child and family to work with the school system to obtain the appropriate services. The primary physician may also refer to appropriate resources in the community (eg, educational psychologist or developmental and behavioral pediatrician).

Not infrequently, external factors such as social, family, and school-based issues may be very difficult to alter. Knowledge of the educational laws and community services, as well as ongoing developmental surveillance and screening by the primary care physician, is necessary to build a base from which the prevention of failure in school is possible.

Grade retention is often suggested as the treatment for school failure. At the end of each school year, from kindergarten through 12th grade, the question of promotion is addressed. Though school personnel may regard this decision as "business as usual," the impact of this decision can be far-reaching. Evidence that retention in kindergarten or first grade is helpful in affording mastery of critical reading and other skills is lacking. Retention in higher grades has not been shown to be effective because educational gaps (eg, lack of mastery of first-grade skills) are not readdressed by retention in a higher grade. It is unlikely that "more of the same" will ensure mastery of needed skills.

In fact, data suggest the effect of grade retention on most students is adverse. Most retained students do not improve and many are worse after retention. Self-esteem problems, evident in many cases, often lead to self-destructive behavior and, in later grades, problems such as substance abuse, behavior difficulties, sexual promiscuity, and early drop out from school. In addition, children characterize retention as bad as losing a parent.

To minimize the adverse effects of grade retention, each child's needs and strengths should be addressed and educational programs individualized. Educational alternatives to retention include extra support in the form of classroom accommodations (**section 504 of the Rehabilitation Act of 1973** and also the **Americans with Disabilities Act**) or special education services (**IDEA**). In addition, educational therapy, counseling, or one-on-one tutoring may be beneficial for some children. Equally as important as remediating the areas of weakness is recognizing the child's areas of strength (eg, the idea of using a child's strengths to leverage his weaknesses).

Finally, the pediatrician's role in advocacy can never be underestimated. Examples of advocacy roles for physicians include involvement with the assessment team processes at children's schools, consulting with local school districts, and participation in local or state early intervention interagency councils.

Prognosis

In most cases, most children who show signs of school failure fall into the group of mild to moderate learning and/or neurobehavioral disorders with average cognitive skills. With proper support from educational, medical, family, and psychological sources, most of these students should be able to overcome their particular problems and enjoy successful school careers. Students who may have endured major socioeconomic upheavals will often continue to struggle unless changes in their entire support system are instituted early in their lives. The progress of children who have significant cognitive and/or neurobehavioral or psychological processing problems depends

on the severity of their problems and the intensity and timing of the interventions they receive.

Irrespective of its cause, school failure can have lifelong consequences if not properly diagnosed and addressed. Failing students are more likely to drop out of school and/or engage in behaviors that are dangerous to their health as adolescents. Pediatricians can make a significant difference in outcomes by helping families advocate for their failing students to receive appropriate assessment and intervention services.

CASE RESOLUTION

The pediatrician should advise the family to request in writing a psycho-educational evaluation from the school. The pediatrician can also institute an evaluation for ADHD by gathering information from both the family and the school. All of this information should then be discussed with the parents so that formal diagnostic procedures and interventions may be instituted. Ideally the pediatrician will have the time, interest, and training to guide the family through this entire process. However, if this is not possible, referral to an appropriate professional is indicated. With the data from the educational evaluation and the medical workup, an appropriate plan of treatment can be developed.

Immunizations

ChrisAnna M. Mink, MD

CASE STUDY

A 20-month-old boy who emigrated with his family from Botswana is brought in for a checkup. He has his World Health Organization Expanded Immunization Programme card from his homeland showing that he received a bacille Calmette-Guérin (BCG) vaccine at birth; 3 diphtheria, tetanus, and pertussis vaccines; 3 doses of live oral poliovirus vaccine at 2, 3, and 4 months of age; 3 doses of hepatitis B vaccine at birth and 2 and 9 months of age; and a monovalent measles vaccine at 9 months of age. It is August and his parents plan to enroll him in child care and have brought him for a checkup. His parents report that he is a healthy boy with no immune problems. They report that his uncle, who is infected with HIV, lives with them. The boy has had a 3-day history of a runny nose, cough, and tactile fever. His examination is normal other than mild clear coryza and a rectal temperature of 37.9°C (100.3°F). What immunizations may be given?

Questions

1. What are the different kinds of vaccines?
2. What are the mechanisms of action for live and inactivated vaccines?
3. What are the routinely recommended immunizations for *healthy* pediatric populations?
4. What are the considerations for immunizing selected pediatric populations, such as preterm infants, immunocompromised children, immigrants, international adoptees, and travelers?
5. What are reliable resources for up-to-date information about immunizations?

The Centers for Disease Control and Prevention (CDC) considered immunizations among the top 10 greatest health accomplishments of the 20th century, and vaccines continue to play a major role in the improvement of the health of the world's population. In the United States, almost all of the pathogens for which there are routine vaccinations have decreased in incidence by 95% to 100% since the early 1900s. The only exception to this is pertussis, which has had approximately an 80% reduction. In 2008 the immunization rates for children in the United States remained stable at high levels, with nearly 80% of children aged 19 to 35 months immunized for the 4:3:1:3:3 series [4 diphtheria, tetanus, and acellular pertussis (DTaP): 3 polio: 1 measles, mumps, and rubella (MMR): 3 *Haemophilus influenzae* type b (Hib): 3 hepatitis B virus (HBV)]. Worldwide, the percentage of children immunized with 3 doses of diphtheria, tetanus, and pertussis (DTP) and oral polio vaccines and a measles-containing vaccine is approaching 70%, which is nearly a 3-fold increase in the past 20 years. Since 1990 there has been a decline in the mortality rate for children younger than 5 years in every region in the world, and this is directly related to increased immunizations. Generally, immunizations are safe, well tolerated, and cost-effective, with range of \$5 to \$16.50 saved for every dollar spent.

Another less recognized benefit of vaccinations is that the schedule has essentially provided the backbone for routine pediatric care in the United States, with regular visits scheduled around the recommended intervals for immunizations. These visits have afforded health care providers opportunities for serial evaluation of infants

and young children, as well as education and anticipatory guidance for parents. Increasing availability of new vaccines targeted for older children and adolescents should permit opportunities for improved health care delivery to these older age groups, who have often been medically underserved. Additionally, health care practitioners for adults have a growing appreciation of the critical role of vaccinations for protecting their patients, as well as all members of the family.

General Principles

When considering providing immunizations for an individual, 2 important factors to consider are the health status of the recipient and the type of immunization to be given. The risks and benefits of using the vaccine in the specific host should be weighed carefully. Vaccines are intended for a host who is capable of mounting an appropriate immune response, who will likely benefit from the protection provided and ideally incur little or no risks.

Types of Immunizations

The 2 major types of immunizations are passive and active.

Passive Immunization

Passive immunization refers to the delivery of preformed antibodies, usually as immune globulin (Ig), which may be a general formulation or hyperimmune Ig developed with high concentrations of antibodies against a specific disease, such as HBIG for hepatitis B.

Delivery of Ig may be useful in 3 settings.

1. A host is not able to make antibodies (eg, congenital immunodeficiency).
2. Preventive (pre-exposure or postexposure), especially when the host may not be able to mount an antibody response (eg, immunocompromised child with an acute exposure to hepatitis A [HAV]).
3. Treatment—Ig may be used to ameliorate symptoms when disease is already present (eg, intravenous Ig for Kawasaki disease).

Active Immunization

With **active immunization**, all, part, or a modified product (eg, toxoid or purified antigen) of a microorganism is given to the host to elicit an immune response. The intact organisms may be inactivated (killed) or live-attenuated (weakened). The elicited immune response usually mimics the response to natural infection and, ideally, this occurs with little or no risks to the recipient.

Inactivated Vaccines

Inactivated vaccines may contain **inactivated or killed organisms**, purified components (subunit), or inactivated toxins (toxoids) of the organism. These vaccines are not capable of replication in the host. Most inactivated vaccines are delivered by the intramuscular injection. Generally, inactivated vaccines may be administered simultaneously with other inactivated vaccines, as well as live viral vaccines.

A few viral vaccines are inactivated, including trivalent influenza (TIV), HAV, HBV, inactivated polio (IPV), and human papillomavirus (HPV), and rabies vaccines. Toxoid vaccines that are used routinely include tetanus and diphtheria toxoids alone or in combinations with whole-cell or acellular pertussis components (eg, DTaP, DTP, Td, and Tdap). The acellular pertussis vaccines are composed of one or more purified antigens of *Bordetella pertussis*, in contrast to the whole-cell pertussis vaccines, which are made with killed, whole *B pertussis* organisms. Diphtheria and tetanus toxoids combined with whole-cell pertussis (DTP) vaccines are no longer marketed in the United States, but are used in most developing areas of the world. Other inactivated bacterial vaccines include capsular polysaccharide (CPS) vaccines, such as the 23-valent pneumococcal vaccine and tetravalent meningococcal CPS vaccine.

Conjugate Vaccines

Capsular polysaccharide antigens have been chemically linked to a protein carrier, which converts the T-cell independent polysaccharides to T-cell dependent antigen that can trigger an immune response, even in young infants. The first CPS-protein conjugate vaccine available was for Hib. The Hib bacterium is covered with a CPS, polyribitol-phosphate (PRP). Children younger than 2 years are not efficient at mounting antibodies to the PRP CPS, but with linkage to a protein carrier, the CPS is immunogenic. Since licensure for infants of the Hib conjugate vaccines in 1991, there has been a more than 95% reduction in Hib disease. With the success of the Hib CPS-protein conjugate vaccines, conjugation techniques have been used

for other CPS pathogens including *Streptococcus pneumoniae* and *Neisseria meningitidis*.

Live-Attenuated Vaccines

Live-attenuated vaccines are infectious agents that replicate in the host to elicit an immune response. The administration is generally not IM but by other delivery routes, such as oral, intranasal, or subcutaneous. The live vaccines are often viral, including MMR, varicella-zoster virus (VZV), rotavirus, live-attenuated influenza virus (LAIV, FluMist), oral polio (OPV), and yellow fever (YF) vaccines. Two live bacterial vaccines are available including oral typhoid (Ty21) and BCG used against *Mycobacterium tuberculosis*.

Following measles vaccination, there is a transient suppression of T-cell immunity in the 2- to 4-week postvaccination period. Because of this, when vaccinating with live viral vaccines, give 2 or more live vaccines at the same time or wait at least 4 weeks between vaccines. This principle is also true for tuberculosis skin testing; place the purified protein derivative at the same time as a live viral vaccine or wait at least 4 weeks to avoid a false-negative skin test because of the T-cell suppression. Although this has not been extensively studied with live viral vaccines other than measles, following the same guidelines with other live viral vaccines is recommended.

Vaccination Schedule

Factors for developing the schedule include

- Host ability to respond (eg, lost maternal antibody)
- Need for multiple doses (eg, IPV)
- Minimal intervals needed between serial doses
- Available products (eg, combination vaccines)

A synchronized immunization schedule is posted annually from the American Academy of Pediatrics (AAP) Committee on Infectious Diseases (*Red Book: 2009 Report of the Committee on Infectious Diseases*), American Academy of Family Practitioners, and the Advisory Committee for Immunization Practices of the CDC. Since 2007, 2 immunization schedules have been posted for the pediatric age groups: one for children younger than 7 years and one for individuals 7 through 18 years of age. A separate schedule is available for adults older than 18 years. The US schedules are posted each January at <http://www.cdc.gov/vaccines/recs/schedules/child-schedule.htm>. Schedules for countries worldwide are available at www.who.int/immunization_monitoring/en.

Vaccine Recipients

Healthy Pediatric Populations

Routine immunizations on the synchronized schedule are targeted for healthy infants, children, and adolescents. All licensed vaccines have undergone review by the US Food and Drug Administration (FDA) and have proven safety and immunogenicity and/or efficacy for the targeted population. However, no vaccine is completely free of adverse events nor will provide 100% protection for every recipient. Every effort should be made to provide immunizations when

the recipient is healthy and has the best chance to mount an optimal immune response without delaying vaccination or risking a “missed opportunity.”

Special-Risk Pediatric Populations

Although immune responses to vaccinations are likely most favorable in healthy recipients, a growing segment of the pediatric population has underlying health problems. Because of congenital or acquired immune dysfunctions, some individuals should not receive immunizations as directed by the routine schedules. Special accommodations need to be made for immunizing these individuals, such as adjusting the schedule or possibly not administering some agents. There are no indications for giving decreased or partial doses of vaccines. Some of the selected populations for whom special consideration is indicated are discussed below.

Immunocompromised Child

The plan for vaccination of an **immunocompromised** child should be determined by the nature and degree of immunosuppression. The health care practitioner should weigh risks and benefits for each child individually, keeping some general principles in mind. For example, live vaccines should not be given to severely compromised individuals because of the possible risks. Generally inactivated vaccines may be safely administered to nearly all recipients; however, immunocompromised individuals may not mount an optimal immune response. In this setting, try to adjust timing of vaccination to optimize the chance of a good immune response. Guidelines include waiting for 3 to 4 weeks post-chemotherapy and white blood cells greater than 1,000 cells/mm³ for chemotherapy patients, 4 weeks after stopping high-dose steroids (dose equivalent ≥ 2 mg/kg/day of prednisone for ≥ 14 days), and sufficient time after receipt of Ig (see *AAP Red Book*).

Types of Immunodeficiency

Infants and children may have abnormalities of any arm of the immune system, which may affect their ability to receive vaccinations. Weighing the risks (of the disease, as well as vaccine) and benefits of protection is essential. A reasonable approach to developing a vaccination plan for children with immune abnormalities is to consider the pathogenesis of immune defense against the vaccine agents and if the needed defense mechanism is deficient, then immunizing with that agent may not be appropriate. For example, **cellular immunity** is essential in defending against **viral agents**. Thus children with abnormalities of their cell-mediated immunity (primary or acquired) may not be candidates for receipt of live viral vaccines.

Primary immunodeficiencies are generally inherited and secondary ones are acquired, such as infection with HIV, malignancy, illnesses (such as malnutrition and uremia), or related to medications (eg, chemotherapy or immunosuppressive agents), among others. For primary humoral immunity abnormalities (not able to make antibodies), OPV is contraindicated but MMR vaccine may be indicated for some individuals. For cell-mediated abnormalities, generally live viral vaccines should not be used. With complement

abnormalities, receipt of live viral vaccines is acceptable for most individuals. For abnormal phagocytic function, live bacterial vaccines should not be given. For individuals with asplenia (traumatic or surgical), vaccination with pneumococcal, meningococcal, and Hib vaccines is indicated and should be considered emergently in the case of trauma. Chemoprophylaxis may also have a role in protection for compromised individuals.

For immunocompromised household contacts of pediatric vaccinees, it is generally acceptable to give MMR, VZV, and oral rotavirus vaccines. Some live vaccines should not be given, including OPV and LAIV in some settings. Additionally, use of some vaccines, such as TIV, is encouraged to protect the vaccinee, as well as the compromised contacts.

Pregnancy

Pregnancy is associated with **some impairment of cell-mediated immunity**. With this decreased immunity, pregnant women may not have protective immune responses to some infectious agents. With this in mind, generally no live vaccines should be administered to pregnant women, though the risks and benefits should be weighed for individual cases. Rubella vaccine should not be given to pregnant women, though there have been no reported cases of rubella embryopathy following inadvertent immunization of a pregnant woman.

Some immunizations are recommended during the second or third trimester to provide protection for the mother (ie, TIV) and possibly the infant (eg, tetanus and diphtheria toxoids combined with acellular pertussis vaccine [Tdap]). Residing with a pregnant household contact is generally not a contraindication for a child to receive live viral vaccines, a question often asked of pediatricians.

Preterm (<37 Weeks) and Low Birth Weight (<2,000 g) Infants

In general, medically stable premature and low birth weight infants may be immunized at the same dose, schedule, and postnatal age as full-term infants.

Special consideration should be given to use of HBV vaccine in infants that weigh less than 2,000 g as follows:

- Hepatitis B surface antigen (HBsAg)-positive or unknown status in mom \rightarrow Give vaccine and HBIG, then give 3 additional vaccine doses.
- HBsAg-negative mom \rightarrow Give HBV vaccine at 30 days (sooner if the infant is stable for discharge), and then follow the usual schedule, such that the infant receives a total of 3 doses.

Other Conditions Affecting Immunization Schedule

Egg-Allergic Child

For children with known anaphylactic reactions to eggs or egg components, special consideration is warranted for use of vaccines prepared using egg products. Current measles and mumps vaccines are prepared using chick-derived cell lines, but do not contain significant amounts of proteins that cross-react with egg proteins. Children with egg allergies, including severe hypersensitivity, are at low risk of anaphylaxis from measles- or mumps-containing vaccines.

Additionally, skin testing against these antigens is not predictive of an adverse reaction. Thus, egg-allergic children may be immunized with measles and mumps vaccines alone or in combination preparations (eg, MMR, MMR and varicella) without skin testing. Influenza (TIV, LAIV) and YF vaccines are prepared in eggs and may contain egg proteins, and may rarely induce an immediate allergic reaction. For children with a history of anaphylaxis to eggs or egg components, both TIV and LAIV are generally contraindicated because of the risk of an adverse event and the need for annual immunization. For YF vaccine, skin testing before use is recommended in children with a history of anaphylaxis to eggs.

International Adoptees, Travelers, Immigrants, and Refugees

It is important to remember that travelers are from all socioeconomic strata, so inquiries about foreign travel should be included in routine visits in all clinical settings. First, the health care practitioner should review the child's record to ensure that all routine vaccines are up to date for age. The child should receive vaccinations and other preventive measures (eg, malaria prophylaxis) targeted for his or her destination. There may be a need for accelerated schedule (eg, early MMR for infants 6–12 months of age traveling to a measles-endemic area). Use of Ig prophylaxis should be considered for individuals susceptible to HAV and not candidates for active immunization (eg, too young to receive HAV vaccine or immunocompromised). To help ensure healthy travel, the health care practitioner should check the current recommendations at <http://wwwnc.cdc.gov/travel/default.aspx> and <http://www.who.int/countries/en/>.

Immigrants, refugees, and international adoptees may present with additional health concerns. Many of these children have been in poor living conditions and exposed to health hazards of environments like refugee camps and orphanages. Their health status, possible intercurrent illnesses, and need for immunizations should all be evaluated soon after arrival. The United States requires proof of the first dose of vaccines for entry into the country, though there are exemptions for adoptees younger than 10 years and refugees at entry. These high-risk children often have not been immunized or have missing records. Written, dated, and appropriate records (eg, age, dates, interval, and number of doses) may be considered valid, and subsequent immunization may resume according to the US schedule. Another option, especially when documentation is questionable, is to perform serologic studies for vaccine-induced antibodies.

Adolescents

Although the AAP has recommended a routine health visit at 11 to 12 years of age, historically compliance with this visit had been low. Until recently, no immunizations were routinely recommended in this age group. In the late 1990s, hepatitis B catch-up immunization was the first vaccine encouraged at this age and became required for middle-school entry in several states. Now several vaccines are available for protecting teens. One of these vaccines is Tdap for use as a single booster dose in adolescents 11 to 18 years of age who have previously received a series of DTP-containing vaccines.

Two kinds of meningococcal vaccines are available for use in the United States: the CPS vaccine (MPSV4, Menomune) and the CPS-protein conjugate vaccine (MCV4, Menactra and Menveo), with the latter formulation being preferred by the AAP. Both vaccines contain 4 serotypes (A, C, Y, and W135). Meningococcal immunization with MCV4 is recommended routinely at age 11 to 12 years with a booster dose at 16 years of age. MCV4 is also recommended for catch-up dosing for older adolescents who have not been immunized and for individuals 2 to 55 years of age who are at increased risk of meningococcal diseases.

Two HPV vaccines are available in the United States for immunizing females against cervical cancer. Both HPV2 and HPV4 are composed of virus-like particles prepared from recombinant L1 capsid protein of HPV. One of the currently licensed vaccines is HPV2 (Cervarix, GlaxoSmith Kline), containing serotypes 16 and 18, which is available for vaccinating females 10 to 25 years of age. Human papillomavirus 16 and 18 cause about 70% of cervical cancers. The other licensed vaccine is HPV4 (Gardasil, Merck & Co., Inc.), containing serotypes 6, 11, 16 and 18, which is licensed for females aged 9 to 26 years and also for males aged 9 to 26 years for protection against genital warts and anal and penile cancers. Both HPV2 and HPV4 are given in a 3-dose regimen at day 0, 1 to 2 months, and 6 months, and are recommended for routine use in adolescents at 11 to 12 years of age, ideally before their sexual debut.

In addition, at the adolescent visits (including precollege visits), the provider should review the teen's records to ensure that he or she has received all recommended vaccines, inquire about household contacts of infant or compromised host, and provide anticipatory guidance for safe and healthy living for the teen and the parent.

Immunizations Received in Other Countries

Most vaccines used worldwide are produced with adequate quality control and may be considered reliable. Healthy individuals immunized in countries outside of the United States should receive vaccines according to the recommended schedule for age in the United States. In most cases, only written documentation should be accepted as proof of previous vaccination. Written, dated, and appropriate records (eg, correct age, dates, interval, and number of doses, etc) may be considered as valid, and immunizations may resume according to the US schedule.

Although most vaccines are acceptable, there may be some concerns for vaccine potency due to unsuitable storage and handling. Other concerns include inaccurate documentation and possibly inadequate response in some children due to other factors (eg, malnutrition or underlying illnesses). If vaccination status is uncertain, the options include vaccinating with the antigen in question or checking serologic testing against the vaccine antigen, if testing is available. Generally, receipt of additional doses of diphtheria and tetanus toxoids alone or in combination with a pertussis-containing vaccine (ie, DTP, DTaP, Td, and Tdap) may lead to an increase in reactions (especially injection site reactions), and checking antibody titers against diphtheria and tetanus toxoids is encouraged. At this

time, no FDA-approved assays for pertussis antibodies are available, and testing for pertussis antibodies is not recommended. For other vaccines, if the status is unknown, vaccination may be performed because extra doses are generally well tolerated. Most developing countries do not have VZV, conjugated pneumococcal, or Hib vaccines, and these should be given as indicated per the US schedule.

Adverse Events and Vaccine Information

Adverse Events

As noted previously, no vaccine is completely free of adverse events, and the known adverse events should be discussed with vaccinees (non-minors) and/or parents/legal guardians. In addition to discussing the risks and benefits of vaccination, the health care practitioner should include education about the risks associated with the natural disease. This is especially important in current times, when many individuals have not seen the diseases for which vaccines have been successful in controlling or eradicating.

In addition to safety information from the AAP and CDC, the manufacturer's package insert provides information about the rates of adverse events and contraindications for the specific vaccine. Most adverse events observed following routine immunizations are local injection site reactions such as erythema, swelling, and pain, and systemic reactions such as fever or fussiness. Although most of these adverse events are mild and self-limiting, some may be associated with significant dysfunction for the child (eg, not using a limb due to pain).

Rarely, serious adverse events may occur following immunization, and these may be associated with permanent disability or life-threatening illness. The occurrence of an adverse event after immunization does not prove a cause-and-effect relationship of the vaccine and the event, but a temporal relationship. If a vaccine recipient experiences a serious adverse event, a complete evaluation for all plausible causes, including the role of the vaccine antigen, should be performed. Additionally, all clinically significant adverse events should be reported to the Vaccine Adverse Event Reporting System (VAERS) at <http://vaers.hhs.gov/>, which is maintained by the CDC and FDA. Adverse event reporting is important because it helps identify possible unexpected events that were not observed in the prelicensure clinical trials.

Precautions and Contraindications

The Vaccine Information Statement (VIS) and package insert provide information for health care practitioner, vaccinees (non-minors), and parents/legal guardians about the precautions and contraindications for specific products.

A **precaution** suggests that careful analysis of risks and benefits of the vaccine should be done, and if benefits outweigh risks, the vaccine may be given. A **contraindication** means that a vaccine should not be administered. An example of a contraindication is known anaphylaxis to any component of the vaccine. Breastfeeding does not interfere with oral immunization with rotavirus or OPV vaccines and is not a contraindication.

Minor illness without fever (temperature $\leq 38^{\circ}\text{C}$ [100.4°F]) should not be considered a contraindication to vaccination. Fever above 38°C (100.4°F) may not be a contraindication, depending on the physician's assessment of the child, the illness, and the vaccine to be given. If the child is early in the disease and the course is not predictable or the illness is moderate to severe, delaying immunization is reasonable. Deferring immunization without appropriate justification can cause a missed opportunity and may lead to inadequate immunization of the child.

Informing Vaccine Recipients and Parents

Vaccine recipients and parents should be informed about the risks and benefits of vaccination and about the disease for which the vaccine is designed. The National Childhood Vaccine Injury Act of 1986 requires that parents receive a VIS each time a child receives a vaccine covered under this legislation, whether the vaccine was purchased with public or private funds. The VISs are available from the CDC at the National Immunization Program site at <http://www.cdc.gov/vaccines/pubs/vis/default.htm>. The health care practitioner should document in the patient's chart the vaccine manufacturer, lot number, and date of administration and that VISs were provided and discussed with the vaccinee (non-minor) and parent/legal guardian.

Vaccine Information

Information about current immunizations for health care practitioners and for laypersons is available from many resources, including the CDC, AAP, FDA, and the World Health Organization, among others. A list of Web sites is provided in Table 32-1.

CASE RESOLUTION

The boy was appropriately immunized for Botswana recommendations through the age of 9 months, though now his immunization would be considered delayed for age on the US schedule. He is past due for the fourth dose of DTaP, MMR, and VZV vaccines. Additionally he has not received any conjugate vaccines or HAV vaccine. The dose of monovalent measles vaccine does not change his need to receive 2 doses of MMR and varicella vaccines after the age of 12 months as listed on the US schedule. His uncle's immune status does not affect the use of MMR or varicella vaccines. His current respiratory illness is considered mild, and he does not have significant fever ($<38^{\circ}\text{C}$ [100.4°F]), so this is not problematic for receiving the needed immunizations.

During this visit, he may receive DTaP, MMRV #1, one dose of Hib conjugate vaccine, dose 1 of 2 of conjugate pneumococcal vaccine (2 months apart), and dose 1 of 2 of HAV (at least 6 months apart). All VISs should be provided. He is scheduled to return in 2 months in October for his next dose of conjugate pneumococcal vaccine and dose 1 of 2 of inactivated influenza vaccine. He may not receive the LAIV because of his young age (LAIV is licensed for children ≥ 24 months of age), as well as his uncle's immunocompromised status. He will need a fourth dose of inactivated poliovirus vaccine before school age. He is too old to receive the oral rotavirus vaccine.

Health Maintenance in Older Children and Adolescents

Monica Sifuentes, MD

CASE STUDY

Before a 13-year-old girl enters a new school, she is required to have a physical examination. She has not seen a physician in 5 years and has been healthy. Currently she has no medical complaints. Her examination is completely normal.

Questions

1. What are the important components of the history and physical examination in healthy older children and adolescents?
2. What immunizations are recommended for older children and adolescents?
3. What laboratory tests should be performed at health maintenance visits? Why?

Older children and adolescents are generally healthy individuals who infrequently visit physicians. Visits are often for acute complaints, such as upper respiratory infections or sports-related injuries, and are therefore very problem-oriented. Statistics regarding health maintenance visits in this age group are not readily available because patients go to several different sites for health care and often do not receive comprehensive care at any of these places. Older children and adolescents seek treatment for both acute and chronic conditions in private offices, public health clinics, public hospitals, and emergency departments. It is estimated that less than 15% of adolescents consistently go to pediatricians for health care in general, and the same percentage probably applies to older children as well.

This all too common practice contributes to missed opportunities for anticipatory guidance, health education, and screening for preventable conditions. Screening tests also can be used to identify treatable conditions such as hypertension, anemia, and tuberculosis. Ideally, older children and adolescents should receive recommended immunizations beginning at 11 to 12 years of age; counseling concerning sexual activity, contraception, and sexually transmitted infections (STIs), including HIV; reassurance to address their emotional well-being; guidelines for adequate nutrition; education about tobacco, illicit drugs, and alcohol; and information about physical fitness and exercise as well as violence and injury prevention.

Guidelines for preventive child and adolescent health care have been published by the American Academy of Pediatrics (AAP) Committee on Practice and Ambulatory Medicine, the federal Child Health and Disability Prevention Program, the AAP Section

on Adolescent Health, and the American Medical Association. Box 33-1 is a brief summary of these guidelines for older children and adolescents.

The Health Maintenance Visit

The purpose of the health maintenance visit for an older child or adolescent is to assess their general health and well-being and establish a relationship of open communication and trust for future visits. Initial questions asked during this visit should be simple and focus on how the patient feels in general about their health, physical growth, and development, and existing relationships with family and friends. More specific questions can then be formulated depending on the patient's responses. In healthy patients, the medical history can be obtained using a questionnaire that parents and children complete in the waiting room. If this method is used, a separate form should be given to adolescents if he or she is accompanied by one or both parents. The information is then reviewed at the start of the interview. Chronic medical conditions also should be addressed at this time.

Medical History

Older children and adolescents should always be questioned directly about their medical history (Questions Box: Screening in Older Children and Adolescents). Parents should be encouraged to participate only after their child has responded to questions or if invited by the child or adolescent themselves. The degree of parental participation also is influenced by the current cognitive and developmental stage of the patient.

Box 33-1. Guidelines for Adolescent Health Maintenance Evaluation

<i>Screening History</i>	<i>Physical Exam</i>	<i>Universal and Selective Screening Labs/ Studies</i>	<i>Anticipatory Guidance and Counseling</i>
Eating disorders	Body mass index	Snellen test	Parenting/communication
Sexual orientation	Blood pressure	Audiometry	Pubertal development
Sexual activity	Comprehensive exam	Hemoglobin or hematocrit	Diet/nutrition
• Consensual and nonconsensual	Genital exam	Tuberculin skin test	Exercise
Tobacco use	Pelvic exam ^b	Cholesterol	Injury prevention
Alcohol use/abuse		• If the patient is obese or there is a significant family history of hyperlipidemia, consider other labs such as fasting glucose, lipid panel	Educational plans/goals
Drug use/abuse (CRAFFT questionnaire ^a)		If sexually active,	Lifestyle modifications
School performance		• Urine hCG	• Gender identity
Depression		• Urine NAAT for GC/chlamydia,	• Abstinence
Risk for suicide		• Serum HIV, RPR, hepatitis B and C	• Safe sexual activity
		• Pap smear ^b	• Other reproductive health issues
			• Contraception
			• Avoidance of tobacco, alcohol, and illicit drugs
			• Identifying feelings of sadness/anger

Abbreviations: GC, gonorrhea; hCG, human chorionic gonadotropin; HIV, human immunodeficiency virus; NAAT, nucleic acid amplification testing; RPR, rapid plasma reagin.

^aSee Chapter 132 for CRAFFT questionnaire.

^bA pelvic examination with a Pap smear is recommended within 3 years of the onset of sexual activity (American Cancer Society) or age 21 (ACOG). Indications for a pelvic examination, see Chapter 40.

^cIf patient engaged in injection drug use or young men having sex with men.

Questions

Screening in Older Children and Adolescents

Questions for both the patient and parent

- How has the child or adolescent been doing lately? Does the parent have any complaints or concerns?
- How does the child or adolescent like school? How are they doing academically and socially? What are their future goals?
- What activities does the child or adolescent currently participate in?
- Does he or she have any hobbies?
- With whom does the child or adolescent live?
- Are there any significant illnesses in the immediate or extended family, such as hypertension, diabetes, or cancer?
- Does the child or adolescent take any medications, herbs, or supplements (prescribed or over the counter) regularly?

Questions for the child or adolescent alone

- Do you have any questions or concerns?
- How are things at home? Are there any problems with parents or siblings? Do you feel safe at home and at school?
- Are you attending school?
- Do you like school? Who do you hang out with at school?
- Have you ever been truant, suspended, or expelled?
- What do you like to do for fun?
- See Chapter 6, Questions Box, for the rest of the interview.

Psychosocial History

The psychosocial component of the interview should be conducted with older children or adolescents alone as well as together with parents after the issue of confidentiality has been reviewed (Questions Box: Screening in Older Children and Adolescents). General questions about school, outside activities or hobbies, and family are often less threatening than inquiries about friends and tobacco use. More sensitive topics relating to drug use/abuse, sexuality, and sexual activity should be addressed after parents have left the room. Subjects initially discussed with parents should be reviewed once again with the teenager alone.

A useful tool for conducting the psychosocial interview has been developed and refined by physicians who specialize in pediatrics and adolescent medicine. Known by the acronym **HEADDSSS**, it reviews the essential components of the psychosocial history: *home* environment, *employment* and education, *activities*, *diet*, *drugs*, *sexual activity/sexuality*, *suicide/depression*, and *safety* (see Chapter 6).

Dietary History

A general dietary history should be obtained, with particular focus on eating habits, level of physical activity, and body image. Dietary restrictions, if any, should be investigated. Daily calcium, vitamin D, and iron intake also should be reviewed, especially in adolescent females. Adolescent males should be asked about nutritional supplements.

Family History

Significant illnesses, such as hypertension, hyperlipidemia, obesity, and diabetes, in first- and second-degree family members should be reviewed. Family use of alcohol, tobacco, and illegal as well as prescribed substances also should be determined. Age and cause of death in immediate family members should be recorded.

Medications and Allergies

Prescription as well as nonprescription (over-the-counter) medications, herbs, and supplements should be reviewed along with the indications and frequency of usage.

Physical Examination

The height and weight of patients should be plotted on a growth curve, with particular attention paid to the velocity of growth and the body mass index (BMI = weight (kg) / [height (m)]²). The blood pressure also should be noted and compared to age- and height-related normative values.

Aspects of the physical examination that are influenced by puberty should be emphasized. The skin should be carefully inspected for acne and hirsutism; clinicians should offer treatment whether or not patients acknowledge that they have skin problems. Tattoos, piercings, and signs of abuse or self-inflicted injury (cutting) also should be noted. The oropharynx should be examined for any evidence of gingivitis or other signs of poor dental hygiene or malocclusion. The neck should be palpated for adenopathy and the thyroid gland for hypertrophy or nodules, especially in adolescent females. The back should be examined for any evidence of scoliosis, which is important to diagnose during this time of rapid growth.

Assessment of the pubertal development of the breasts and genitalia in preadolescent or adolescent females and the genitalia, including presence of pubic hair, in adolescent males is essential. The sexual maturity rating (SMR) (Tanner stage) can then be correlated with other signs of puberty, such as the appearance of acne and body odor. For example, the adolescent female with SMR 4 breasts and immature pubic hair distribution may have an underlying problem, such as testicular feminization syndrome.

The abdomen should be palpated for organomegaly and the testicles for masses, hydroceles, hernias, or varicoceles. Lesions such as warts or vesicles also should be documented. The external female genitalia should be inspected for similar lesions and to document Tanner stage development. A speculum examination should be performed in females who are sexually active and complain of vaginal discharge, unexplained vaginal bleeding, or lower abdominal pain. (See Chapter 40 for additional indications for a pelvic examination.) In general, virginal girls do not require a speculum examination; gentle inspection of the external genitalia is adequate in most cases, with special attention to hymenal patency. A rectal examination is generally reserved for patients with chronic abdominal pain or other specific acute gastrointestinal complaints.

Immunizations

Many recent additions have been made to the preadolescent/adolescent vaccination schedule (Table 33-1). As always, practitioners should verify that patients have completed the primary immunization series. If not, they should be given catch-up doses according to the latest Centers for Disease Control and Prevention (CDC) recommendations. The newest vaccines, tetanus and diphtheria toxoids and acellular pertussis (Tdap) (Adacel, Boostrix), human papillomavirus (HPV) (Gardasil, Cervarix), and meningococcal conjugate vaccine (MCV4) (Menactra) should be given to preteens at the 11- to 12-year visit. The Tdap vaccine replaces the tetanus/diphtheria booster previously given at this age. Pertussis was added to the booster because immunity to pertussis has been noted to wane 5 to 8 years after vaccination, and there has been an increasing prevalence of pertussis detected in adolescents and adults with chronic cough in many communities. A conjugate vaccine against *Neisseria meningitidis* (MCV4 or Menactra) was also approved by the US Food and Drug Administration in 2005. The Advisory Committee on Immunization Practices now recommends that MCV4 be given to all 11- to 18-year-olds. Finally, 2 different vaccines (Gardasil and Cervarix) are currently licensed in the United States to protect against 2 of the HPV types that cause most cervical cancers, oncogenic types 16 and 18. The quadrivalent vaccine, Gardasil, also protects against genital warts caused by nononcogenic HPV types 6 and 11. While there has been some controversy surrounding the HPV vaccine, current recommendations state that the 3-dose series of the quadrivalent or bivalent vaccine should be given routinely at 11 to 12 years of age and to all young women and girls between the ages of 13 and 26. The vaccine is approved for patients as young as 9 years. The quadrivalent vaccine also may be given to males between 9 and 26 years of age. Ideally the vaccine should be administered before the initiation of sexual activity, but it also may be given to adolescents who are already sexually active.

Table 33-1. Recent Changes to the Recommended Immunization Schedule Affecting Adolescents^a

	Recommended Age (y)	
	11–12	13–18
Tetanus, diphtheria, pertussis	Tdap	Tdap (catch-up)
Human papillomavirus	HPV (3 doses)	HPV (catch-up) (3 doses)
Meningococcal	MCV4	MCV4 (booster at 16 years)
Varicella	Varicella 2-dose series	
Influenza	Influenza annually	

Abbreviations: HPV, human papillomavirus; MCV4, meningococcal conjugate vaccine; Tdap, tetanus and diphtheria toxoids and acellular pertussis.

^aModified from Centers for Disease Control and Prevention. Available at <http://www.cdc.gov/vaccines/recs/schedules/default.htm>.

Recommendations regarding some of the older traditional vaccines have changed as well. A second dose of the varicella vaccine is now part of the primary vaccine schedule for persons aged 7 through 18 years without evidence of immunity. Therefore, if an adolescent or preadolescent has only received one dose, a second dose should be administered. Similarly, if the adolescent has not had the disease or been vaccinated, he or she should receive the 2-dose series. Routine vaccination against hepatitis B also is recommended, regardless of sexual activity, if it has not been administered previously. The 2-dose hepatitis A series should be given to all teenagers not previously vaccinated if they reside in high-incidence communities. Influenza vaccine should be given annually to all children and adolescents and to those who come into close contact with individuals with high-risk conditions. Pneumococcal vaccine should be offered to high-risk groups as well. In addition, a Mantoux skin test for tuberculosis should be placed. (For complete recommendations, refer to Chapter 32.)

Laboratory Tests

A hemoglobin level should be obtained to evaluate for anemia and a urinalysis performed to assess for protein, blood, and pyuria. Other suggested screening tests include hearing and vision tests, and a cholesterol and lipid profile. Although cholesterol screening remains somewhat controversial, it is important to consider in patients who are overweight or obese or have a positive family history for hyperlipidemia or premature atherosclerotic heart disease.

In addition to the above laboratory tests, sexually active adolescents should be screened for STIs. If a pelvic examination is performed, an endocervical specimen should be obtained for nucleic acid amplification testing (NAAT) for gonorrhea and chlamydia. However, if a pelvic examination is not indicated, routine screening for gonorrhea and chlamydia may be performed with a urine sample alone using NAAT methods. The 2010 recommendations from the CDC state that all sexually active women younger than 26 years should be screened annually. Males should be screened if they are symptomatic or have a history of multiple partners and unprotected intercourse. In addition, a rapid plasma reagin test for syphilis and an HIV test should be obtained, especially if another STI is suspected or confirmed. All of the above tests should be offered in the clinically appropriate setting after patients have received pretest counseling with a follow-up visit scheduled to discuss the results.

Patient Education

At the conclusion of the health maintenance visit, positive as well as negative findings should be reviewed with patients and their parents. Depending on the nature of these findings and the age of the patient, practitioners may initially choose to address these findings with the patient alone keeping in mind issues of confidentiality. All recommended screening laboratory studies and immunizations also should be reviewed before their administration, including the need for further follow-up. Subsequent vaccine doses must be outlined for patients and parents. The timing of the next visit and reasons for this visit should be discussed.

The remainder of the visit should be spent addressing any specific concerns of patients and parents, highlighting health care problems

(eg, obesity, high blood pressure), and identifying any factors that may be contributing to high-risk behavior, such as drug or alcohol use. Older children or adolescents who are not participating in any deleterious activities should be praised for their positive behavior as well as provided with information regarding injury prevention.

Preparticipation Physical Evaluation for School-aged and Adolescent Athletes

The preparticipation physical evaluation (PPE) is essentially the “sports physical” that many schools require for participation in organized athletic programs. The primary objective of the PPE is to assess the young athlete’s readiness to compete safely and effectively in a given sport. Ideally, it also should identify athletes at risk for injury or sudden death, as well as those with an underlying medical condition that may preclude athletic participation.

Controversy exists about the appropriate location for performance of the PPE. Community physicians are often asked to perform limited en masse examinations at schools, or a group of clinicians is asked to perform the examinations in the gymnasium using “stations.” Either way, the patient does not truly receive a complete physical examination or assessment, and neither approach lends itself to privacy. In addition, parents have a false sense of security and believe that their children have received adequate medical care. Ideally, primary care physicians should perform the PPE annually in their office during a scheduled visit at least 4 to 6 weeks before the beginning of the athletic season. Pediatricians can use this required visit as an opportunity to perform an annual comprehensive health maintenance examination on older children and adolescents, including the various screening tests.

History

The medical history for the PPE should primarily focus on previous athletic participation and any injuries that may have occurred (Questions Box: Preparticipation Physical Evaluation). A standard questionnaire codeveloped by the AAP for this purpose may be used in the office setting. In addition, many practitioners record the results of the physical examination as well as their recommendations regarding the degree of athletic participation on this standard form (Figure 33-1).

Questions

Preparticipation Physical Evaluation

- What sport(s) does the child or adolescent wish to participate in?
- Has the child or adolescent ever experienced a sports injury? If so, how much time did the athlete refrain from sports activities as a result of this injury?
- Has the athlete ever suffered a lapse of consciousness or concussion?
- Does the child or adolescent have a significant underlying health problem?
- Is the child or adolescent taking any prescribed or over-the-counter medications?
- Does the child or adolescent have any allergies?
- Has the child or adolescent ever had syncope, palpitations, or angina during exercise?
- Does the child or adolescent have a family history of sudden, early, non-traumatic deaths?

PREPARTICIPATION PHYSICAL EVALUATION HISTORY FORM

(Note: This form is to be filled out by the patient and parent prior to seeing the physician. The physician should keep this form in the chart.)

Date of Exam _____

Name _____ Date of birth _____

Sex _____ Age _____ Grade _____ School _____ Sport(s) _____

Medicines and Allergies: Please list all of the prescription and over-the-counter medicines and supplements (herbal and nutritional) that you are currently taking

Do you have any allergies? Yes No If yes, please identify specific allergy below.

Medicines Pollens Food Stinging Insects

Explain "Yes" answers below. Circle questions you don't know the answers to.

GENERAL QUESTIONS	Yes	No	MEDICAL QUESTIONS	Yes	No
1. Has a doctor ever denied or restricted your participation in sports for any reason?			26. Do you cough, wheeze, or have difficulty breathing during or after exercise?		
2. Do you have any ongoing medical conditions? If so, please identify below: <input type="checkbox"/> Asthma <input type="checkbox"/> Anemia <input type="checkbox"/> Diabetes <input type="checkbox"/> Infections Other: _____			27. Have you ever used an inhaler or taken asthma medicine?		
3. Have you ever spent the night in the hospital?			28. Is there anyone in your family who has asthma?		
4. Have you ever had surgery?			29. Were you born without or are you missing a kidney, an eye, a testicle (males), your spleen, or any other organ?		
HEART HEALTH QUESTIONS ABOUT YOU	Yes	No	30. Do you have groin pain or a painful bulge or hernia in the groin area?		
5. Have you ever passed out or nearly passed out DURING or AFTER exercise?			31. Have you had infectious mononucleosis (mono) within the last month?		
6. Have you ever had discomfort, pain, tightness, or pressure in your chest during exercise?			32. Do you have any rashes, pressure sores, or other skin problems?		
7. Does your heart ever race or skip beats (irregular beats) during exercise?			33. Have you had a herpes or MRSA skin infection?		
8. Has a doctor ever told you that you have any heart problems? If so, check all that apply: <input type="checkbox"/> High blood pressure <input type="checkbox"/> A heart murmur <input type="checkbox"/> High cholesterol <input type="checkbox"/> A heart infection <input type="checkbox"/> Kawasaki disease Other: _____			34. Have you ever had a head injury or concussion?		
9. Has a doctor ever ordered a test for your heart? (For example, ECG/EKG, echocardiogram)			35. Have you ever had a hit or blow to the head that caused confusion, prolonged headache, or memory problems?		
10. Do you get lightheaded or feel more short of breath than expected during exercise?			36. Do you have a history of seizure disorder?		
11. Have you ever had an unexplained seizure?			37. Do you have headaches with exercise?		
12. Do you get more tired or short of breath more quickly than your friends during exercise?			38. Have you ever had numbness, tingling, or weakness in your arms or legs after being hit or falling?		
HEART HEALTH QUESTIONS ABOUT YOUR FAMILY	Yes	No	39. Have you ever been unable to move your arms or legs after being hit or falling?		
13. Has any family member or relative died of heart problems or had an unexpected or unexplained sudden death before age 50 (including drowning, unexplained car accident, or sudden infant death syndrome)?			40. Have you ever become ill while exercising in the heat?		
14. Does anyone in your family have hypertrophic cardiomyopathy, Marfan syndrome, arrhythmogenic right ventricular cardiomyopathy, long QT syndrome, short QT syndrome, Brugada syndrome, or catecholaminergic polymorphic ventricular tachycardia?			41. Do you get frequent muscle cramps when exercising?		
15. Does anyone in your family have a heart problem, pacemaker, or implanted defibrillator?			42. Do you or someone in your family have sickle cell trait or disease?		
16. Has anyone in your family had unexplained fainting, unexplained seizures, or near drowning?			43. Have you had any problems with your eyes or vision?		
BONE AND JOINT QUESTIONS	Yes	No	44. Have you had any eye injuries?		
17. Have you ever had an injury to a bone, muscle, ligament, or tendon that caused you to miss a practice or a game?			45. Do you wear glasses or contact lenses?		
18. Have you ever had any broken or fractured bones or dislocated joints?			46. Do you wear protective eyewear, such as goggles or a face shield?		
19. Have you ever had an injury that required x-rays, MRI, CT scan, injections, therapy, a brace, a cast, or crutches?			47. Do you worry about your weight?		
20. Have you ever had a stress fracture?			48. Are you trying to or has anyone recommended that you gain or lose weight?		
21. Have you ever been told that you have or have you had an x-ray for neck instability or atlantoaxial instability? (Down syndrome or dwarfism)			49. Are you on a special diet or do you avoid certain types of foods?		
22. Do you regularly use a brace, orthotics, or other assistive device?			50. Have you ever had an eating disorder?		
23. Do you have a bone, muscle, or joint injury that bothers you?			51. Do you have any concerns that you would like to discuss with a doctor?		
24. Do any of your joints become painful, swollen, feel warm, or look red?			FEMALES ONLY		
25. Do you have any history of juvenile arthritis or connective tissue disease?			52. Have you ever had a menstrual period?		
			53. How old were you when you had your first menstrual period?		
			54. How many periods have you had in the last 12 months?		

Explain "yes" answers here

I hereby state that, to the best of my knowledge, my answers to the above questions are complete and correct.

^aConsider ECG, echocardiogram, and referral to cardiology for abnormal cardiac history or exam.
^bConsider GU exam if in private setting. Having third party present is recommended.
^cConsider cognitive evaluation or baseline neuropsychiatric testing if a history of significant concussion.

- Cleared for all sports without restriction
- Cleared for all sports without restriction with recommendations for further evaluation or treatment for _____
- Not cleared
- Pending further evaluation
 - For any sports
 - For certain sports _____
- Reason _____
- Recommendations _____

I have examined the above-named student and completed the preparticipation physical evaluation. The athlete does not present apparent clinical contraindications to practice and participate in the sport(s) as outlined above. A copy of the physical exam is on record in my office and can be made available to the school at the request of the parents. If conditions arise after the athlete has been cleared for participation, the physician may rescind the clearance until the problem is resolved and the potential consequences are completely explained to the athlete (and parents/guardians).

Figure 33-1

Physical Examination

A complete physical examination should be performed when possible. If circumstances preclude this, specific attention should be paid to the eyes, heart, abdomen, skin, and musculoskeletal system. Height, weight, blood pressure, and visual acuity also should be measured. Examination of the eyes is essential to document physiological anisocoria (different papillary diameters). A thorough cardiac evaluation should be performed for murmurs, abnormal heart sounds, or arrhythmias. The abdomen should be palpated for an enlarged liver or spleen, especially in the adolescent with a recent viral illness that could suggest mononucleosis. In males, the genitalia should be examined for sexual maturity in addition to assessing for abnormalities, such as atrophy, absence of a testis, or presence of a testicular mass or inguinal hernia. The skin should be inspected for lesions, such as tinea corporis, impetigo, or herpes simplex infection.

The 2-minute orthopedic examination consists of a head-to-toe assessment of all muscle groups and joints; any deformities, anomalies, or evidence of previous injuries should be noted (Table 33-2). Recent studies suggest expanding this examination to include a more detailed evaluation of high-risk areas for injury, such as the knee, ankle, and shoulder.

Laboratory Tests

Routine laboratory screening tests, except for those performed during the general health maintenance visit, are not recommended for the PPE. Screening young athletes for anemia or proteinuria has not been found to be particularly helpful. Such screening may be useful with highly competitive professional athletes, however. Although controversial, some groups believe that an electrocardiogram should be a routine part of the PPE as well.

Exclusion Criteria

The most common causes of unexpected death during athletics include cardiomyopathies, anomalous coronary arteries, heart valve defects, primary cardiac rhythm disorders, and pulmonary hypertension, and part of the PPE is geared toward determining if a patient has risk factors for any of these conditions. Medical exclusion criteria for athletic participation are based on information obtained in the medical as well as family history. Significant historical clues include a family history of sudden, non-traumatic death; premature coronary artery disease in a first- or second-degree relative; a history of palpitations, angina, or syncope during exercise; and recent, documented infection with the Epstein-Barr virus. Controversy exists regarding when athletes can return to collision sports after infectious mononucleosis. A history of a recent or suspected concussion or multiple concussions in the past also requires close consideration regarding when the athlete is cleared to participate in a given sport. Current clinical and research data regarding adolescents and concussions support the mantra, "When in doubt, sit them out." Patients with concussions should rest, both physically and cognitively, until their symptoms have resolved at rest and with exertion, according to the AAP Council on Sports Medicine and Fitness. In most cases, typical recovery occurs in 7 to 10 days, although some athletes require weeks to months to completely recover. The long-term effects of concussions in athletes of all ages is still under intense investigation.

Findings discovered during the physical examination, such as stature consistent with Marfan syndrome, a cardiac arrhythmia, or the midsystolic click of mitral valve prolapse, could preclude the adolescent from participation in a particular sport. Specific conditions, such as the athlete with one eye or one kidney, should be evaluated on an individual basis by a physician qualified to assess the safety of the particular sport for the athlete (contact/collision versus limited contact).

Table 33-2. The 2-Minute Orthopedic Examination

<i>Instructions</i>	<i>Points of Observation</i>
Stand facing examiner	Acromioclavicular joints, general habitus
Look at ceiling, floor, over both shoulders; touch ears to shoulders	Cervical spinal motion
Shrug shoulders (examiner resists)	Trapezius strength
Abduct shoulders 90 degrees	Deltoid strength
Full external rotation of arms	Shoulder motion
Flex and extend elbows	Elbow motion
Arms at sides, elbows 90 degrees flexed; pronate and supinate wrists	Elbow and wrist motion
Spread fingers; make fist	Hand or finger motion and deformities
Tighten (contract) quadriceps; relax quadriceps	Symmetry and knee effusion; ankle effusion
"Duck walk" 4 steps (away from examiner with buttocks on heels)	Hip, knee, and ankle motion
Back to examiner	Shoulder symmetry, scoliosis
Knees straight, touch toes	Scoliosis, hip motion, hamstring tightness
Raise up on toes, raise heels	Calf symmetry, leg strength

Special circumstances to consider during the PPE are menstrual disorders and the female athlete; exercise-induced bronchospasm; anabolic steroid use; and eating disorders that may be associated with certain activities, such as gymnastics, ballet, and wrestling.

CASE RESOLUTION

The young adolescent described in the case history should first be interviewed with the parent and then alone. Her medical and psychosocial history should be reviewed. A complete physical examination should be performed as well as a pelvic examination if she is sexually active and has a history of lower abdominal pain, abnormal vaginal bleeding, or discharge. If she is sexually active and asymptomatic or not sexually active, only general laboratory screening tests should be performed and the results reviewed with the patient. The remainder of the visit should be spent discussing issues such as nutrition, exercise, illicit substance abuse, sexuality and sexual activity, and safety. Results of the physical examination and screening tests should then be discussed with the parent who accompanied her to the office. If necessary, a follow-up visit should be scheduled. Otherwise, the adolescent should be seen annually.

Health Care for International Adoptees

ChrisAnna M. Mink, MD

CASE STUDY

Jaxon is a 14-month-old boy adopted from Thailand. His biological mother was a 26-year-old commercial sex worker who entered a maternity house during her pregnancy to receive care and to relinquish the baby for adoption. His mom reported that she was physically and sexually abused as a child and became a street child when she was 14 years old. She used illicit drugs 5 years ago, but none since. She identifies the father as a European customer, but has no other information. Jaxon was born at 32 weeks' gestation and was placed in an incubator but did not have any respiratory problems. He has been in foster care in a Thai family's home with his care supervised by an internationally respected adoption organization. He was selected by his parents at the age of 4 months, and they have received monthly progress reports on his growth, development, and medical status. Reportedly he has had several "colds" and one ear infection but otherwise has been growing and developing well. Before departure to pick up Jaxon, his adoptive parents met with you to prepare for his arrival.

From the Bangkok airport, the parents placed a call to you because Jaxon would not stop crying. They report that on the morning that his foster mom left him with them, he cried quite a bit but had settled by bedtime and seemed to be adjusting well during the week. However, over the past 12 hours he hasn't stopped crying and refuses to eat. They question if his discomfort is related to teething because he has been drooling, but they have not noticed any other symptoms. They are gravely concerned that he doesn't like them and is having attachment difficulties.

Questions

1. What factors influence the prevalence of international adoption?
2. What are some of the potential health problems of international adoptees?
3. What is an appropriate medical evaluation for international adoptees?
4. What is the pediatrician's role in caring for the child and the newly formed family?

From 1998 through 2008, annually approximately 20,000 children were adopted internationally by parents in the United States. Although these children come from a wide range of birth countries, many of their health-related issues are similar. Many of the children have lived in orphanages in impoverished areas of the developing world and have incurred the maladies associated with poverty and deprivation.

Epidemiology

From 1971 to 2001 a total 265,677 children were adopted internationally into the United States. Most of these children (90%) are from Asia (China and South Korea most commonly), Eastern Europe, and South America (Guatemala and Colombia). From 2000–2009, China, Russia, and Guatemala were the 3 leading countries of origin for children adopted into the United States. A decline in the number of international adoptions has been seen since 2009 due to multiple factors, including economic downturn in the United States; ethnic pride in birth countries; and stricter policies governing

adoption, such as The Hague Convention (international guidance for standardizing intercountry practices to promote protection of children available for adoption).

Many factors influence adoptive parents to choose international adoption. In the United States, delays in childbearing and associated infertility have increased the demand for adoptable children. At the same time, more readily available birth control and growing acceptance of single motherhood have decreased the number of US infants available for adoption. In addition to the shortage of **adoptable** children in the United States, additional factors for parents choosing international adoptions include real and perceived risks of domestic adoption (eg, failure of birth parents to relinquish rights), fear of adopting a special needs child from the domestic system, and limited availability of children with desired traits (eg, specific age and ethnicity). In addition, prompt termination of rights of birth parents in international adoption is cited as a factor in the choice.

The advent of **intercountry adoption (ICA)** in the United States occurred with World War II and the large number of orphaned children in Europe, many of whom were fathered by American soldiers.

The second, and more formalized, wave of ICA occurred with the Korean War. Because of the need to care for unwanted orphans, primarily of mixed ethnicities also fathered by American soldiers, South Korea established a foster care system and the children became available for adoption to Americans. War and political turmoil are still factors for children becoming available for adoption. For example, the fall of communism was a significant factor for Russia and other states of the former Soviet Union becoming common birth countries for adoptees in the 1990s and the early part of this century. Recently, with worsening poverty and political strife, more children are being adopted from African countries.

Societal values are also factors for influencing adoption practices. China is often the leading birth country for **adoptees** because of the population control initiatives of the government mandating that families have only one child. With this practice and the desire to have a male heir, some newborn girl infants are abandoned and subsequently become available for adoption. In some countries, local laws and/or cultural practices are prohibitive for adoption, especially for foreigners and, thus, these countries are infrequent birth countries. The United States is the birth country for about 500 children adopted into other countries. Absolute statistics for children adopted out of the United States are not available because the government does not track the number of exit visas issued for adopted children. These US children are often males of African American or mixed ethnicity and are adopted by families in Canada and Western Europe. The children are available purportedly due to the low desire for these infants by adoptive parents in the United States.

The status of the country of origin (ie, war, turmoil, poverty, and societal values) aside, there is significant overlap in the reasons that children from foreign countries and from the United States become available for adoption (eg, parental substance use, abandonment, chronic neglect, abuse, and domestic violence).

Until the 1990s, most international **adoptees** were from South Korea, which had in place an excellent **foster care** system and health care. Since the 1990s, nearly two-thirds of **adoptees** come from institutions in poor nations without a developed foster care system, resulting in a significant decline in the health and well-being of the **adoptees**.

Clinical Presentation

Most internationally adopted children are female (64%), in part reflecting the adoption of girls from China, as well as a preference among some adoptive parents (especially single women) to adopt a girl. International adoptees are young, with approximately 46% being younger than 1 year and 43% between 1 and 4 years of age.

Pre-Adoption

Some **adoptees** become known to the US health care provider “**only on paper**” during the **pre-adoption stage**. Adoptive parents may ask their health care provider for help in assessing the child’s medical status. Often parents receive a written health report (varying in the quantity and the quality of information) and photos or videos of the child they are considering adopting. The written documents may be

in a foreign language or not translated by an experienced medical translator. Some countries prohibit international adoption of healthy children, so diagnoses may be embellished to improve the child’s chances for adoption. Additionally, some medical records contain diagnoses that are nonsensical in US medicine but represent terms used in the country of origin. For example, **adoptees** from Russia often have neurologic diagnoses such as **perinatal encephalopathy**, which suggests serious brain injury and would carry a grave prognosis in Western medicine; in Russia this term may reflect a minor deprivation or a lack of prenatal care and not a specific neurologic injury. However, at other times, a term may have the same meaning and intent to Russian physicians as to US physicians. These inconsistencies are therefore quite challenging when trying to evaluate the medical records of potential **adoptees**. Many physicians may not feel comfortable with reviewing medical records given so many limitations; however, even with all of the caveats, review of the records may still provide insight into the health status of the potential adoptee.

Also during the **pre-adoption stage**, the health care provider may provide information for parents and families for preventive health measures to prepare for travel to a developing area of the world. The Centers for Disease Control and Prevention (CDC) traveler’s information Web site (www.cdc.gov/travel) is a good resource for health care providers and the parents. Up-to-date information may also be obtained from the World Health Organization and the US State Department (Table 34-1). Additionally, parents should be informed about the possible infections seen in international adoptees, and they should receive appropriate education and vaccinations (eg, hepatitis B because of the increased risk of the child being positive for hepatitis B surface antigen [HBsAg], seen in 1%–5% of adoptees).

US Child Welfare	Adoption information and procedures	www.childwelfare.gov

During the Adoption Trip

All internationally adopted children are required by the US State Department to have a **physical examination** before admission into the country; however, this examination is quite limited in scope and performed primarily to rule out severe impairments or certain communicable diseases that may pose a public health threat (eg, active tuberculosis). This examination should not be considered as a complete medical evaluation for an individual child. Some health care providers are able to provide support for families during travel via e-mail or telephone, similar to telephone consultations performed in general practice.

Post-Adoption

After the adoption, the health status of the children on presentation to the American health care provider is quite variable, ranging from well (eg, infants from Korean foster care) to severely ill with acute infections or chronic diseases (eg, malnutrition and tuberculosis). The adopted child should be seen by the physician within 2 to 3 weeks of arrival in the United States, or sooner if he or she has an acute illness. This 2-week period allows for the child (and parents) to recover from jet lag and to become more familiar with each other, permitting a better assessment at the visit. If an acute illness visit is required, a separate appointment for a comprehensive evaluation should be scheduled.

Health Care Issues

In addition to the problems commonly related to **poverty** and **deprivations**, many health issues are specific to the country of origin (eg, increased risk of **fetal alcohol spectrum disorder [FASD]**

in children from Russia, malaria from Africa, etc). Published data regarding health care issues are limited for children from recent countries of origins (eg, Ethiopia, China, and Russia) (Figure 34-1).

Generally, the health care issues for **adoptees** are extensive, including acute illnesses (eg, respiratory infections), chronic illnesses (eg, anemia, malnutrition, poor dental hygiene, tuberculosis, asthma, and parasite infestation), delayed or unknown immunizations, psychosocial challenges, and impaired growth and development.

Some children have assigned birth dates (eg, **abandoned infants** and **street children** for whom the birth dates are not known), and they may have small growth parameters, making it difficult to know their true age and expected development. **Developmental delay**, most commonly language delay, is frequently identified. Assessment of development may be even more difficult in infants and young children who are nonverbal and older children who speak their native language.

Growth delay is common for **adoptees**. Many children are malnourished or have failure to thrive (FTT), and these afflictions are often multifactorial in origin, including poor prenatal environment (maternal stress, malnutrition, drug and alcohol abuse), inadequate calories, inadequate nurturing, unrecognized genetic or congenital disorders (eg, FASD), and untreated chronic illnesses (eg, rickets). Institutionalized children may suffer from **psychosocial dwarfism**, and may lose 1 month of linear growth for every 3 to 4 months spent in the orphanage. Delay in puberty may be observed in adolescents from deprived environments, such as **orphanages**.

Immunization records may not be available, may be incomplete, or may be in a foreign language, which hinders assessing the vaccination status of adoptees. Additionally, many vaccines available in the United States are not available in the developing world

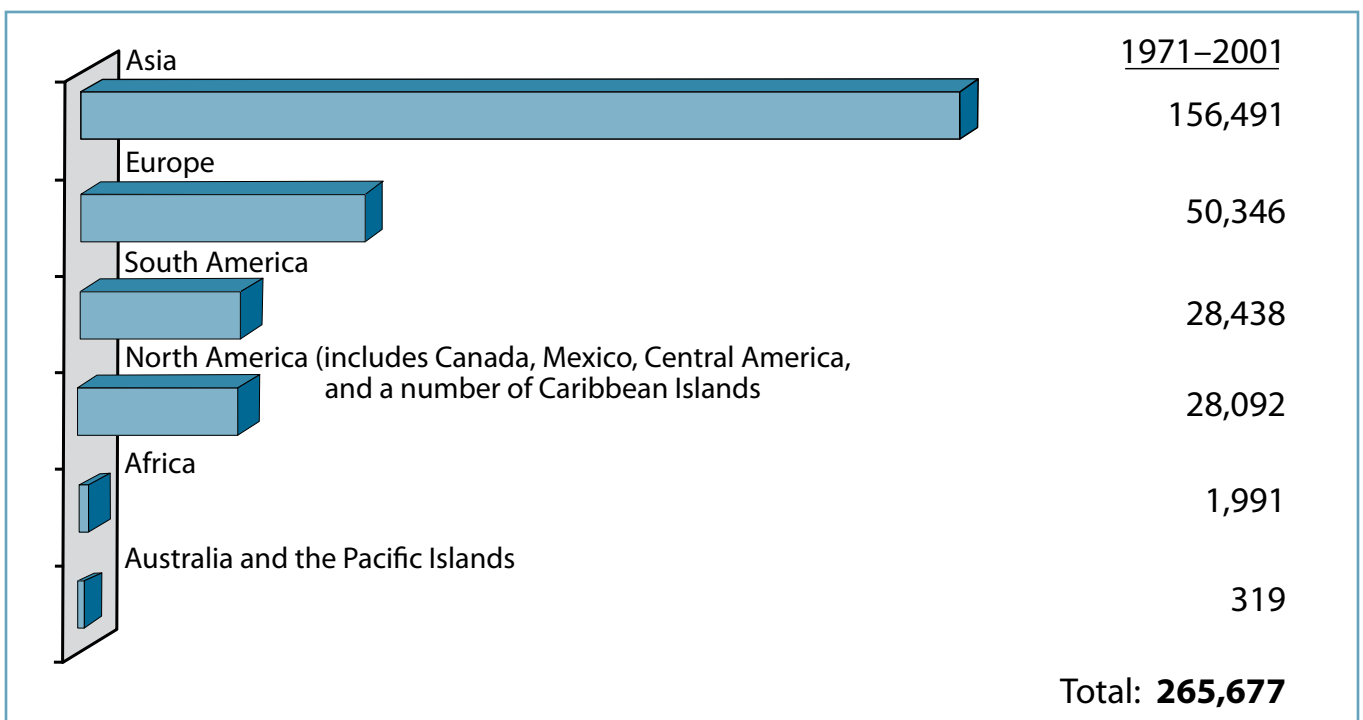

Figure 34-1. Countries of origin for children adopted by parents in the United States.

(eg, *Haemophilus influenzae* type b [Hib] and pneumococcal conjugate vaccines) and, thus, children will not have had them. Adopted children immigrating to the United States who are younger than 10 years are exempt from the Immigration and Nationality Act regulations requiring proof of immunizations before arrival; however, adoptive parents are required to sign a waiver that they will comply with US recommended immunizations after arrival.

Psychosocial, emotional, and mental health problems are some of the more challenging problems to assess. The spectrum of mental health problems is related to age and previous life experiences for the child. Children may have suffered from physical and/or sexual abuse prior to placement in an institution, where the potential for such abuse also exists. This may be inflicted by adult caretakers or bigger children when supervision is inadequate. Attachment disorders are some of the most concerning abnormalities for adoptive parents, adoption professionals, and health care providers. Because the fundamentals for learning healthy attachments are greatly influenced by early infant–caretaker relationships, many international adoptees have difficulties bonding, in part because they have not had secure caretaker relationships. Issues for attachment and bonding may be especially problematic for children who have resided in an orphanage and/or had multiple caretakers from an early age. Because the children have had multiple caretakers, they may be indiscriminately friendly, which poses risks for their safety. Other common mental health problems include depression, attention-deficit/hyperactivity disorder (ADHD), post-traumatic stress disorder, abnormal behaviors (eg, self-stimulating behaviors, hoarding food, sleep disturbances), and oppositional–defiant disorder. As mentioned previously, communication with the child may be difficult due to language barriers, causing another obstacle to assessing the mental health of the child.

Sensory integration difficulties are increasingly recognized in adoptees. The children may have adverse responses to touch (including new clothing, hugs and kisses, bathing, etc) or textures (such as new foods). Individual or all of the senses (hearing, vision, taste, or smell) may be notably increased or decreased, and some children have decreased sensation to physical pain leading to an increased risk for injuries. Dyskinesia (clumsiness or injury prone) has also been observed.

The most common identified medical issues are **infectious diseases**. These include acute illnesses (eg, upper respiratory infection, bronchitis, otitis, and infectious diarrhea, among others), as well as longer-term infections, such as tuberculosis and parasite infestations (scabies and *Giardia* are common). Because of their biological mother's lifestyle and their time residing in institutions, many adoptees are at increased risk of exposure to infectious diseases such as syphilis, HIV, and hepatitis B and C.

Preventive care considered “routine” in the United States is unlikely to have been part of the child's care and needs to be performed as appropriate for age. This includes newborn screening laboratory studies and assessments of hearing, vision, dental, and mental health. Anticipatory guidance for the new parents should be incorporated into the initial, and all, visits.

Evaluation

The initial office visit with the physician should be scheduled for an extended period because of the complexity of the evaluation and the additional time needed for parental education. If the physician's schedule does not permit extended visits, ancillary staff (eg, nursing, dietitian, and therapists) may perform parts of the evaluation and education.

Observation of the child's behavior, development, and interactions with the adoptive parents and health care provider is a critical element of the evaluation. Most health care providers include such observations in their visits routinely, but particular attention is necessary for new adoptees. Things to notice include the child's behavior. Are they easily engaged or withdrawn? Do they make eye contact with the parent or health care provider? Do they make any vocalizations or words, depending on the child's age? Do they play with toys? Are they too friendly or afraid of strangers? Do they seek comfort from the new parents?

History

Limited medical information is available from most birth countries, though there are some exceptions (eg, from foster care in Korea). Family history and birth history are rarely obtainable for adoptees. Immunization histories are becoming increasingly available. Previously, vaccine records were considered unreliable; however, in recent years, data have emerged to suggest that well-documented immunizations may be considered valid. Written records showing the age of the child when vaccinated, the date of administration, dose given, and proper intervals between dosing that are consistent with the World Health Organization schedules or are comparable to US schedules may be considered acceptable for proof of immunization. (See under Management for guidelines when vaccine records are not available.)

Dietary history is important for assessing the child's nutritional status. Questions to ask include, What food and formula/milk is the child receiving? Has he or she received adequate calories? Is there known or suspected food intolerance (eg, lactose intolerance is more common in Asian ethnicities)? Are there abnormal behaviors associated with food or eating (eg, preoccupation with food, hoarding, food refusal, or gorging)?

An interim medical history may be available because many children are selected by their adoptive parents several months before immigrating to the United States. The interim medical history may be provided from the orphanage or foster care provider through the adoption agency. Parents should be encouraged to solicit as much information as possible from the caretakers of the child. At a minimum, this history should include serial growth parameters, known illnesses, hospitalizations, surgeries, allergies, and immunizations given while the child was under their care. Parents should also ask the caretakers about any food preferences, special fears, toys, or friends from the current placement. If the child has a special “lovey,” the parents should request to bring it with the child for a transitional object.

Physical Examination

A complete unclothed physical examination should be performed on infants and children of all ages. However, due to previous trauma, such as sexual abuse, some parts of the examination may have to be done over a series of visits to minimize the possibility of additional trauma from an examination. All aspects of the physical examination are absolutely essential. Accurate measurements of height, weight and, depending on age and size, head circumference should be obtained. Plotting of parameters on the growth curves for the United States (compared with birth country) should be used, with few exceptions. The child should be closely inspected for unusual scars or bruises, evidence of fractures (old or recent), rachitic changes, and genital or rectal scars. The skin should be examined for rashes, lesions, and a bacille Calmette-Guérin (BCG) scar (typically on the upper deltoid). A developmental screen should be performed, and a more complete developmental assessment should be scheduled at a separate visit (when the child is not distressed or acutely ill). A dental examination should be included and referral for a formal dental evaluation will likely be necessary. Screening evaluations of hearing and vision should be performed, and formal testing may be needed depending on the age of the child and ability to cooperate.

Laboratory Testing

Laboratory testing should include complete blood cell count, lead levels, and thyroid function testing (iodine is not in many diets in Asia) (Box 34-1). Additionally, testing for illnesses associated with specific countries of origin, findings on examination (eg, comprehensive metabolic panel for malnourished child), and as directed by the child's age (eg, newborn screening for metabolic disorders in infants) should be performed.

Because of the **increased risks of exposures**, laboratory screening for infectious diseases should be undertaken. Serum samples should be tested for syphilis (non-treponemal and treponemal antibodies), hepatitis B panel (HBsAg, hepatitis B surface antigen antibody [HBsAb], hepatitis B core antibody), hepatitis C antibody, and HIV 1 and 2 antibodies. HIV polymerase chain reaction may be indicated in some children (eg, those who may not make specific antibodies due to malnutrition or immunocompromise). Stool samples should be sent for ova and parasite examination (at least 2 times) and *Giardia* and *Cryptosporidium* antigen testing. Stool for bacterial pathogens (eg, *Salmonella* and *Shigella*) should be sent from children from some regions, such as the Indian subcontinent. Because cytomegalovirus infection is ubiquitous, routine testing is not recommended. Testing for acute infection with hepatitis A virus (HAV) by measuring immunoglobulin M anti-HAV antibodies should be performed for adoptees from HAV-endemic areas, as infants and young children may be asymptomatic but contagious. Administering HAV vaccine, as recommended in the United States, is not problematic for children who may have had previous HAV infection.

Tuberculosis (TB) skin testing (ie, purified protein derivative [PPD]) should be performed on all children; history of receipt of BCG

Box 34-1. Recommended Laboratory Testing for International Adoptees^a

Hepatitis A IgM
Hepatitis B virus serologic testing <ul style="list-style-type: none"> • Hepatitis B surface antigen • Antibody to hepatitis B surface antigen • Antibody to hepatitis B core antigen
Hepatitis C virus serologic testing
Syphilis serologic testing <ul style="list-style-type: none"> • Nontreponemal test (RPR, VDRL, or ART) • Treponemal test (MHA-TP or FTA-ABS)
HIV 1 and 2 serologic testing
Complete blood cell count with differential and red blood cell indices
Stool examination for ova and parasites (3 specimens)
Stool examination for <i>Giardia intestinalis</i> and <i>Cryptosporidium</i> antigen (1–3 specimens)
Tuberculin skin test ^b
Consider antibody testing to select vaccine antigens (if written records are unreliable) ^c
Additional testing: thyroid function tests, lead level and others as directed by history and physical exam (see text).
<small>Abbreviations: ART, automated reagent test; FTA-ABS, fluorescent treponemal antibody absorption; HIV, human immunodeficiency virus; IgM, immunoglobulin M; MHA-TP, microhemagglutination test for <i>Treponema pallidum</i>; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratories.</small>

is not a contraindication to skin testing. Bacille Calmette-Guérin vaccinations are usually given at birth in most developing nations, and its influence on skin test status is controversial. Generally, BCG given within the previous 1 to 2 years may contribute to a positive PPD skin test; however, a positive PPD test is more likely reflective of true infection with *Mycobacterium* with or without active disease and merits further evaluation. Latent TB infection has been reported from 0.6% to 30% of international adoptees, which is not surprising because most adoptees come from TB-endemic areas.

Management

Counseling for the Transition

Education and preparation for the parents and all family members is a priority. Generally, countries of origin for adoptees are in the developing world, and parents should prepare for healthy travel for themselves by receiving immunizations and following travel guidelines from the CDC and the US Department of State.

Parents should provide consistent structure and boundaries in a loving milieu for the adoptees. A scheduled regimen may be

especially important to previously institutionalized children because it has been their way of life, but even noninstitutionalized children benefit from a predictable routine. Parents should maximize their one-on-one interactions with the adoptee, while still allowing time for themselves and other family members (not an easy task with multiple children). Touching and affection may initially need to be tempered as directed by the child's tolerance. Parents should try to enhance bonding and attachment by frequently identifying themselves as "Mom" or "Dad." Other strategies to enhance attachment include initially limiting contact with individuals outside of the family and not "handing" the child to others, including non-household family members, because they are strangers to the child. Frequent verbal reassurances and talking to the child about the people and the new world around them should be encouraged. In caring for the child, parents should be encouraged to "meet the child" at his or her developmental level and not the chronological age.

Growth and Nutrition

When children are identified as malnourished or FTT, a multidisciplinary treatment plan is recommended, including parents, physician, nutritionist, and therapists (eg, occupational therapist for feeding difficulties). The child should be offered familiar foods, if that is his or her preference, and each meal may include a new, more nutritional offering. Children should be offered frequent meals and snacks because they may not be able to eat much at one sitting. Foods should be calorie dense (eg, added butter, cheese, avocado, or peanut butter, depending on age and previous dietary history). Dietary supplements, such as PediaSure, may be indicated.

Precocious puberty has been observed in female international adoptees, more than males, and is thought to be related to the rapid improvement of nutrition. If signs of precocious puberty are observed, evaluation by a pediatric endocrinologist is recommended.

Development

Because developmental delays are so common, most adoptees should have a developmental assessment. Language delays, especially expressive, are frequent and, when identified, formal audiology testing should be part of the assessment. However, performing developmental assessments of language pose difficulties, as most are conducted in English, which is rarely the child's primary language. Repeating the testing after a period of adjustment may be helpful. Language barriers do not preclude audiology testing.

Mental Health

Mental and emotional health problems are common and may manifest early or late, or occur as relapses. Initial problems seen may include sleep disorders, fears and phobias, bizarre behaviors, and self-stimulating behaviors. Unless the behaviors pose a safety risk, the parents should tolerate them because most dissipate with time in a secure environment. At times of emotional distress, parents may observe a relapse of behavior problems. The health care provider may

provide guidance for parents for the milder disorders; however, moderate and severe disorders merit prompt referral to a mental health professional, ideally someone with expertise in adoption.

Immunizations

If vaccinations are considered valid, as described previously, resuming immunizations per the US schedule (see Chapter 32) is appropriate. If immunization status is unknown or incomplete, repeating immunizations or checking antibody concentrations to vaccine antigens is an acceptable option. Most areas of the world routinely administer BCG, polio (oral), and vaccines containing diphtheria and tetanus toxoids with pertussis (often whole-cell) components. Receipt of additional diphtheria, tetanus, and possible pertussis antigens may be associated with an increase in adverse events; measuring antibodies to diphtheria and tetanus is warranted to minimize adverse events. There are no US Food and Drug Administration–approved antibody tests available commercially for pertussis antibodies. Receipt of additional doses of inactivated polio vaccine is not usually associated with adverse events. Testing for HBsAb should be performed on all adoptees, and the results will guide the plan for further immunizations. Hepatitis B vaccine will only elicit HBsAb; the presence of antibodies to other hepatitis B antigens suggests natural infection. For measles, mumps, and rubella (MMR), various formulations and combinations (1- and 2-component more commonly than 3-component) vaccines are available worldwide. Checking antibodies to these antigens is possible, but likely administering a US-licensed combination (eg, MMR) may be necessary to ensure protection against all 3 antigens. Most of the other vaccines available in the United States are not available in the developing world (eg, Hib and pneumococcal conjugates, varicella, HAV, etc), and the child should receive these vaccines as recommended for age per the US schedule.

Infectious Diseases

Any acute identified infectious disease (eg, scabies, otitis) should be treated following standard practice, keeping in mind the possibility that different antibiotic resistance patterns exist in other parts of the world. Thus, if the child does not have the predicted response to treatment, consultation with a pediatric infectious diseases specialist should be considered. For other infectious diseases screening noted previously, additional evaluation and possible treatment should be initiated promptly (eg, penicillin therapy for syphilis) and pediatric infectious diseases consultation may be considered.

For TB evaluation, any positive PPD skin testing merits further investigation for true infection with *Mycobacterium tuberculosis*. A compounding problem is that some children may be anergic due to malnutrition, giving a false-negative PPD test. If malnutrition is suspected, consider a chest radiograph even if the PPD is negative, and consider repeating the PPD when the child's nutritional status has improved. In addition, routinely repeating the PPD 6 months after the child's arrival is advisable if the child is from an endemic area because late exposure to an infected individual is possible.

Prognosis

Being prepared for the complex needs related to international adoption has been identified as the best determinant for parents to consider the adoption experience as positive, regardless of the number or severity of the medical needs of the adoptee.

With improved nutrition and environment, most children have significant catch-up growth; however, up to one-third of adoptees may have unrecoverable loss in linear growth. For intellectual development, by 1 year of age nearly all children in orphanages have one or more areas of delay. However, their prognosis is generally good, with an increase in 2 developmental quotient points per month after arrival in the United States. After 3 years of age in an orphanage, the length of time institutionalized and delays noted at age 11 months correlate negatively with IQ (8 months in orphanage, average IQ = 90; 2 or more years in orphanage, average IQ = 69).

Many children have ongoing mental and psychosocial problems, and some disorders do not manifest until the children are older (eg, ADHD or learning disorders when the child is school-aged). Ongoing attachment disorders seem to occur with greater frequency in children with lower IQs, more behavior problems, and adoptive families with a lower socioeconomic status.

Assessment of the overall outcome for children who spent 8 or more months in institutional care in Eastern Europe, when evaluated at least 3 years after adoption, showed about one-third had multiple serious problems (including IQ \leq 85, insecure attachment, and severe behavior problems), about one-third had a few serious problems but were thought to be making progress, and about one-third had progressed very well. The best predictors of major problems were (1) greater length of time in the orphanage, (2) increased number of children adopted at same time, (3) younger adoptive mother, (4) lower socioeconomic status of mother, and (5) father alone selected the child. Although the impact of these risk factors may not be identical for all birth countries, they do provide some insight. Reviewing these risk factors with adoptive parents during the pre-adoption period may aid in their decision-making.

Pediatrician's Role

The pediatrician's role is not to tell the adoptive parent whom to adopt; the parents are essentially choosing life partners, which is an individual decision. Pediatricians, however, can assist the parents in reviewing the available medical information, which may aid them in making an informed decision about proceeding with an adoption.

During the adoption process, the health care provider must assume an active role as a child advocate, as well as parental advocate and educator. This may be the first parenting experience for the adoptive parents and, thus, they need the basics for child care, no matter what the age of the adoptee. This might include feeding and routine care (eg, estimate the number of diapers needed if traveling to an area with no access to supplies), as well as discipline techniques for a traumatized child. Preparation for caring for illnesses is needed because many adoptees are ill at the time of the adoption and

travel. The pediatrician can facilitate emotional preparation because the parents may be isolated from their usual support systems while embarking on the new role of parent.

After returning home, the pediatrician has a role as primary care provider, as well as serving as a referral source for other needed specialists (eg, subspecialists, mental health providers, post-adoption support services, developmental interventions, and nutritionists, among others).

Counseling Adoptive Parents About the Expectations

Parents should be informed that it is unlikely that an institutionalized child will emerge unscathed. With this in mind, parents may make preliminary preparations for treatments and rehabilitation for the child. Families should be counseled that it is OK to say "no" to a potential adoptee. No one has benefited from adoption of children by families that do not have the resources needed to care for them. Most importantly, parents should be reassured that optimism is appropriate. Being prepared matters!

CASE RESOLUTION

In talking with the parents, they report that they have not observed any injuries and no areas seem tender when they examine Jaxon, as you have suggested. They elect to give him some diphenhydramine and take the flight home with the plan to come see you on arrival. Although they are exhausted, they come directly to your office for an acute visit. They report that he remained inconsolable and that the flight home was miserable for him (and everyone around them). On entering the examination room, Jaxon was screaming and noticeably uncomfortable but trying to find comfort in his dad's arms.

His temperature was 38.9°C (102°F) axillary; pulse rate, 144 beats per minute; and respiratory rate, 30 breaths per minute. His examination was notable for extensive oral and pharyngeal vesicular lesions with erythema, but there were not labial lesions. He had multiple shotty cervical nodes, and the rest of the examination was noncontributory. A diagnosis of herpangina was made. He was given a dose of ibuprofen, and 15 minutes later he was quiet, able to swallow electrolyte solution, and was cuddling in his dad's arms. His parents were given reassurance that this was an acute infection and not an indication of poor bonding; in fact he was already seeking comfort from them. Additional testing for infections included obtaining antibodies to HIV, rapid plasma reagin for syphilis, and hepatitis C and a hepatitis B panel, especially with his biological mother's history of being a commercial sex worker. Other testing included complete blood cell count, lead level, and thyroid function tests. He was given an appointment in 2 weeks to complete the assessment, including a developmental assessment, because this was deferred since he was acutely ill.

Health Care Needs of Children in Foster Care

Kelly Callahan, MD, MPT; ChrisAnna M. Mink, MD; and Sara T. Stewart, MD

CASE STUDY

A 9-year-old boy is brought to your office by his foster parent for a general physical. The foster parent states that the boy has been living in her home for the past week. When he was initially brought by the social worker, his skin was dirty, and he was wearing dirty clothes. There are no medical records and no immunization records available for your review, and the child states that he “doesn’t remember the last time he went to the doctor.” The boy states that he sometimes went to school, but that he did not return at the end of the last school break. He gets angry when he is asked about his family, and states that he doesn’t want to be in foster care, but that he does not want to return to live with his mother right now. He states he misses his brothers and sisters and wants to live with his father, whom he has not seen in 4 years. The only history known by the foster parent is that the child required some type of special services in school, and that the social worker found drug paraphernalia in his home at the time of his removal. The foster parent also states that 2 nights ago, the patient broke a dish and punched a wall when he became angry.

On physical examination, the patient is alert and refuses to stay in the examination room. His weight is greater than the 95th percentile for his age and his height is in the 25th percentile for his age. He has poor dentition with multiple dental caries. He has a few basilar wheezes on lung examination and has scattered bruises on his anterior shins.

Questions

1. What are the medical, psychological, and behavioral issues that commonly affect children in the foster care system?
2. What is the role of the primary care provider in providing a medical home for the child in foster care?
3. How does a child’s legal status as a child in foster care affect how medical care can be delivered?
4. What are the appropriate health care referrals and community resources to access for a patient who is in foster care?

The term **foster care** refers to the **temporary placement** of a child in the home of another caretaker or **foster parent** due to a threat to the child’s safety or well-being in the original home environment. Placement of a child in foster care results from an investigation of the child’s home environment by **child protective services (CPS)** and may be arranged via voluntary agreement of the parent or through court sanction. The foster parent may be related to the child or may be a nonrelative. For those children in voluntary placement, the biological parent retains the right to terminate the placement at any time. For those placed by **legal sanction**, a series of court hearings give parents, the child, and the CPS agency the opportunity to present their perspectives on the circumstances surrounding the allegations and their respective views on interventions to ensure the child has access to the best home environment.

Children in **foster care** may present to the primary care provider soon after placement in foster care, or may present after having been with a foster parent for a long time. In either scenario, it is recognized that as a subpopulation of pediatric patients, children in foster care have a significant number of **unmet medical** and **mental health**

needs and should be considered to be a “**special needs**” patient population. At the time of initial removal, the CPS worker may not be able to obtain a medical history or essential information about medications for the child. Changes in foster care placement may interrupt continuity of care with a health care provider, and frequent changes in the assigned social services caseworker can create barriers to consistent communication among foster parents, health care providers, and caseworkers. These children have rates of medical and mental health disorders that are higher than those of children from equivalent socioeconomic backgrounds who are not in foster care. There has traditionally been a lack of appreciation within the general medical community as to the complexity of the needs of this patient population, and due to low reimbursement rates, there has been difficulty allotting sufficient time in an office visit to complete the comprehensive evaluation needed by these children. For those children with identified mental health needs, there is often a paucity of available psychiatric and psychological resources. This is particularly true for children younger than 5 years.

These unmet needs have long-lasting effects on the well-being of children, even after exiting the foster care system. Because of their complex health care issues and vulnerability to fragmented care, these children merit a medical home, providing comprehensive, multidisciplinary services and medical case management.

Epidemiology

At any point during a given year, between 400,000 and 500,000 children nationwide are in the foster care system. Approximately 300,000 children enter the system annually, and reasons for placement, in descending order of prevalence, include neglect, physical abuse, psychological or emotional abuse, and sexual abuse.

Foster children are of all ethnicities, but there is disproportionate representation of children of color within the foster care population. The age distribution is bimodal, with children younger than 5 years of age and adolescents comprising most of the population. Over the past several decades an increasing percentage of new entrants into foster care are children in the youngest age bracket, particularly infants younger than 1 year. Many of these infants are exposed prenatally to illicit substances and are placed in foster care due to a combination of factors related to the maternal drug use.

Approximately 70% of children leave foster care within 2 years of placement, and more than half of them are reunited with their biological parent or primary caretaker. Thirteen percent remain in foster care for more than 5 years, and approximately 35% of all children leaving foster care reenter the system at some time due to a new report. The number of adoptions from foster care has increased since the late 1990s to account for 17% of those leaving the child welfare system, and an additional 9% of those leaving foster care are emancipating out of the system by reaching 18 years of age without ever attaining a permanent placement. Many of these teenagers later report being incarcerated or homeless at some point after emancipation. Twenty-five percent of the children in foster care will experience 3 or more placements, which leads to further fragmentation of their health care and education. Multiple foster care placements are more common for those children with behavioral, emotional, or coping problems.

As a population, children in the foster care system come from home environments that experience high rates of poverty, parental mental illness, parental substance abuse, low levels of education, high rates of unemployment, and frequent involvement with the criminal justice system. These children have high rates of exposure to domestic violence, and many are victims themselves of physical abuse, sexual abuse, and neglect. Their biological parents often have limited parenting skills, and the children experience inconsistent parenting behaviors along with minimal developmental stimulation and emotional support. All of these factors combine to cause unpredictable, stressful, and unsafe home environments for these children, prompting their removal and placement into foster care.

Clinical Presentation

Medical Issues

Children in the foster care system have been shown to have high rates of both **acute and chronic illness** at the time of their initial medical evaluations after placement (Dx Box). In one study in Utah, more than half of children entering the foster care system had at least one medical problem. Common maladies include obesity; **asthma; vision or hearing problems;** neurologic disorders; **gastrointestinal diseases; dental caries;** and other inadequately treated chronic illnesses, such as **eczema and anemia**. Acute infections are also common, including respiratory tract infections, skin infections, otitis media, sexually transmitted infections (STIs), and intestinal infestations with parasites. Low immunization rates are also a frequent occurrence.

Many children entering foster care have growth delay with a weight, height, or head circumference measurement less than the fifth percentile for age. This may be due to a combination of factors, including inadequate nutrition, environmental deprivation, prenatal alcohol exposure, genetic predisposition, or underlying illness, such as HIV infection. Environments that are chronically stressful or that lack the necessary stimulation and support for a child may also lead to behaviors such as rumination and social withdrawal. (For further discussion of failure to thrive, see Chapter 129.) Overweight (body mass index [BMI] 85th–95th percentile for age) and obesity (BMI >95th percentile for age) are also frequently seen in foster care children. Depression, dysfunctional coping skills, and a lack of family connectedness are thought to contribute to this chronic disease state.

Dx Common Issues of Children in Foster Care

- Acute infection
- Undiagnosed or inadequately treated chronic illnesses
- Dental caries
- Growth delay and failure to thrive
- Incomplete immunization histories
- Prenatal or perinatal exposure to sexually transmitted infections
- Effects of prenatal substance exposure
- Physical sequelae of physical and sexual abuse
- Developmental delay
- Attention-deficit/hyperactivity disorder
- Post-traumatic stress disorder
- Anxiety
- Depression
- Conduct and oppositional defiant disorders
- Attachment disorders
- Educational disabilities

Many children placed in foster care have a history of **prenatal exposure** to illicit drugs, alcohol, and tobacco. These children have high rates of premature birth and of prenatal or perinatal exposure to infections such as **hepatitis C, hepatitis B, HIV, syphilis, and herpes simplex**. This risk of exposure to infectious agents is related to maternal drug use and its frequent association with prostitution, needle sharing, and drug use in sexual partners.

Children who have been placed in foster care may present with physical sequelae of prior physical or sexual abuse. Physical abuse may result in skin trauma, skeletal fractures, head trauma, abdominal trauma, and chest trauma. Sexual abuse may result in genital trauma or symptoms of STIs.

Developmental and Mental Health Issues

A high prevalence of developmental delay, behavioral disorders, and educational difficulties has been noted in foster children of all age groups. These disorders are more common in children with a history of neglect or abandonment than in those who have suffered other forms of child maltreatment. Of children younger than 6 years entering foster care, 23% to 60% have significant developmental delays and 25% to 45% have behavioral difficulties, with 15% of children taking at least one psychotropic medication. Speech and language difficulties, delayed fine motor skills, and poor social–adaptive skills are common, and up to one-fifth of school-aged children entering foster care had been receiving special education services prior to the time of placement.

Common mental health issues in the foster care population include attention-deficit/hyperactivity disorder, depression, anxiety, and suicidal ideation. **Post-traumatic stress disorder** is common and is more prevalent in those who have experienced or witnessed family violence. Adolescents in foster care may “act out” as a manifestation of mental health difficulties, resulting in sexual promiscuity, substance abuse, and truancy, their rates of conduct and oppositional defiant disorders are higher than those in the general adolescent population.

Attachment disorders are seen more frequently in the foster care population and account for a portion of the behavioral difficulties in these children. A secure attachment to a primary caretaker is necessary to the development of emotional security and the sense that one’s needs are important. Children who are removed from violent homes, or who may have suffered abuse or neglect, are unlikely to have developed a secure attachment to a primary caretaker in that home environment and, therefore, may have difficulty bonding with a foster parent. This problem is then compounded if the child is moved among multiple foster homes, prohibiting development of a healthy attachment to a caretaker. In addition to their lack of emotional reciprocity, these children may exhibit self-stimulatory behaviors or sleep disturbances.

The behavioral difficulties that children in the foster care system manifest are often due to multiple factors. These children may be predisposed to behavioral disorders by a history of prenatal drug

or alcohol exposure or by a history of abuse or neglect. It can also be difficult to determine whether a child’s behaviors predate placement in foster care, or whether they are a response to the removal from his or her home. As a result of placement in foster care, children often experience fear, sadness, and a feeling of guilt or responsibility for the family discord that resulted in their removal. Foster placements are invariably sudden and unexpected, involve the loss of a familiar caretaker, and are traumatic for children of all ages.

Evaluation

It is important for a provider to be familiar with the **medical consent legalities** concerning foster children in his or her geographic locale. While specifics vary by locality, generally foster parents have the authority to provide consent for routine medical care. The placement of a child in foster care does not supersede the right of a biological parent to participate in the medical decision-making for his or her child, and many do retain the authority to consent for medical tests and procedures. Any medical procedure or test that requires specific written consent is likely to require **authorization** by the **legally recognized parent** (eg, child welfare agency, the courts, or the biological parent). Two common clinical scenarios that frequently require consent beyond the foster parent’s authority are HIV testing and the administration of psychotropic medications.

History

Children in foster care may be brought for medical evaluation by an authorized caregiver, which may include a foster parent, a relative of the foster parent, or the social service caseworker. Often the biological parent is absent from the visit, and the child’s medical records are not available at the time of the evaluation. Obtaining past medical records can be difficult, but the caseworker can be of assistance in this process. It is important to ascertain the circumstances that prompted a child’s placement in foster care, as this may modify portions of the evaluation.

The biological family history is useful to evaluate for the presence of genetic disorders and communicable diseases. A maternal history regarding drug use or STIs will assist in identifying those children who may have had prenatal exposures to infectious agents.

Birth history should include any history of prenatal care and complications, such as prematurity or drug withdrawal. The results of routine newborn screening (eg, hearing, inborn errors of metabolism, thyroid function, hemoglobinopathies, etc) should also be obtained. The birth weight and gestational age at birth are critical when assessing for growth disturbances.

A complete medical and surgical history should be gathered, including the identification of a regular health care provider if the child has one. Older children and adolescents may be able to provide some of their own histories. Known medications and allergies should be documented, and all available immunization records should be obtained. Documentation of a child’s immunization history is frequently unavailable, so all possible sources of records,

such as biological parents or school districts, should be identified. Feeding history and nutritional assessments should include the type and amount of formula or breast milk for infants, and types and quantities of foods for older children.

The psychosocial history includes a history of a child's current and prior foster placements or living arrangements, and whether there was exposure to domestic violence, physical abuse, or sexual abuse (Questions Box). Verbal children may also be able to discuss their feelings about their current foster placement. Adolescents should have a confidential screening (eg, HEADDSSS [home environment, employment and education, activities, diet, drugs, sexual activity/sexuality, suicide/depression, and safety] examination) (see Chapter 6) to address drug, alcohol, and tobacco use; issues related to the home and school; sexual activity; violence; and gang involvement.

The **developmental history** should include the results of prior developmental assessments, as well as a listing of therapeutic or early intervention services received. The behavioral history should also include results of prior assessments, mental health services used, and any psychotropic medications prescribed. The foster parent, biological parent, or CPS caseworker may be able to provide useful observations regarding the child's developmental capabilities, behavioral patterns, and social interactions. The biological parent or CPS caseworker may also be able to assist in collecting records from prior assessments.

Educational history is often not available at the time of the medical evaluation. It is helpful, however, to know a child's history of prior evaluations by the school system, special education services provided, or prior therapeutic services (eg, physical therapy, occupational therapy, speech therapy) received through the school district.

Physical Examination

A complete, unclothed physical examination should be performed on each child. Growth parameters, including height, weight, occipitofrontal head circumference (for children <2 years), and BMI (for children ≥ 2 years) should be plotted on a reference chart, and a close inspection should be performed for signs of prior trauma. The child should be assessed for **dysmorphic features** consistent with prenatal alcohol exposure or other genetic syndromes. The physical examination should include a **genital examination** to also assess for signs of trauma in children of all ages, and sexually active females should have a pelvic examination if there are any reports of abdominal pain, vaginal discharge, or other concerns. (See Chapters 127 through 129 for further descriptions of physical findings.)

Immunizations

Immunizations should be given as appropriate for age, and if immunization records cannot be located, the child should be considered to be unimmunized. In this situation, the options include restarting the vaccination series or checking the antibody titers for selected vaccine antigens (see Chapter 32).

In addition, all children should also receive a purified protein derivative to screen for tuberculosis.

Questions

Psychosocial

- When was the child placed in foster care?
- Why was the child placed in foster care?
- Has the child had prior foster placements? If so, when? Why did placement change?
- Was there prior exposure to domestic violence? Physical or sexual abuse?
- Does the child have siblings in foster care?
- How does the child feel about the current foster placement?
- How has the child integrated into the foster family?
- Has the child previously received mental health services? Therapeutic services for developmental delay or educational difficulties?
- What is the child's social service plan? Parental visits? Reunification? Termination of parental rights?

Additional Assessments

All children should undergo both mental health and developmental screenings and should be referred for comprehensive testing if abnormalities are noted. Vision and hearing screenings should also be performed on all children old enough to cooperate. A referral for expert vision or hearing evaluation should be made if it is indicated by history or physical examination, or the patient is unable to perform the screening procedure (eg, infant or developmentally delayed child).

Laboratory Tests

Routine screening laboratory tests should be performed on foster children just as they are indicated for the general pediatric population. For example, hemoglobin level should be checked annually in all infants, toddlers, and preschool-aged children. Serum lead levels should be checked according to local guidelines but should be checked at least once for a child during the toddler years. A urinalysis should also be recorded at least once in all children at the time of entry into kindergarten and once during adolescence.

For infants with a history of prenatal drug exposure or other known risks for maternal STI, at least a rapid plasma reagin, hepatitis C antibody, hepatitis B surface antigen and surface antibody, and HIV test should be performed.

Adolescents who are considered to have at-risk sexual behaviors, patients with signs or symptoms consistent with an STI, and children with a history of sexual abuse that could result in the transmission of infection should be tested for STIs. Often adolescents are able to sign their own consent forms for evaluations and treatment related to STIs; however, local statutes should be consulted.

Imaging Studies

If a child has a history or physical findings concerning for physical abuse, imaging such as a radiographic skeletal survey, computed tomography and magnetic resonance imaging of the head, or radionuclide bone scan may be indicated. (For more specific recommendations, see Chapter 15.)

Management

Given the breadth of health-related needs for this patient population, and given the frequency with which they change foster homes, **close case management** is an essential component of their health care delivery. There should be consistent communication with the child's caseworker to ensure that medical and mental health recommendations are incorporated into the child's social service plan. Ideally, a child should have a medical home and continuity with a health care provider over time, but changes in home placements often make this difficult. If continuity of care is broken, incorporation of the health care plan into a child's broader social service plan should ensure that medical history and medical and mental health recommendations are not lost. The use of **electronic health records** is a growing practice in many foster care systems and promotes continuity of care, even with logistical challenges.

Children and adolescents in foster care require frequent health visits. The American Academy of Pediatrics recommends a health screening within 72 hours of placement, a comprehensive medical evaluation within 30 days of placement, and a follow-up medical examination within 60 to 90 days after placement. Because of the prevalence of significant medical, social, and mental health issues affecting children in foster care, additional visits are often advisable. Anticipatory guidance should be provided to the caretaker, and age-appropriate issues should be discussed with older children and adolescents.

Children in foster care often need referral to medical subspecialists, dentists, dietitians, speech therapists, occupational therapists, mental health providers, and other service providers. Case management is necessary to track these referrals and to contact the foster family and/or caseworker if an appointment is missed.

Prognosis

The population of children in foster care has a spectrum of mental health and medical needs, spanning from the needs of a newborn to those of an adolescent emancipating from the child welfare system. Preliminary studies have documented improved physical health status, improved school performance, and improved adaptive functioning of young children after placement in foster care; however, these studies require replication. The strength of the bond between the foster parent and the child, as well as the consistency and predictability of the foster home environment, are significant to the development of that child's sense of safety and well-being.

To date, much of the research on the health status of children in foster care has focused on the delineation and description of the health-related issues that these children face. There has been more limited evaluation of the different models of health service delivery to the foster care population, as well as of the subsequent medical, developmental, and emotional outcomes for the children in these different models.

While there is a need for continued study of health care delivery to the foster care population, it is widely accepted that children in the foster care system benefit from the establishment of medical

homes with case management capabilities and providers who are well-versed in the complex medical and mental health issues that affect this vulnerable population.

CASE RESOLUTION

This case illustrates many of the common issues that affect children when they are placed in foster care. Medical and immunization records are frequently unavailable to the medical examiner, and chronic medical needs have often gone unmet. This child's lack of personal hygiene points to a history of parental neglect, and given the presence of drug paraphernalia, his parents were likely involved with substance abuse. This child should have a thorough assessment for behavioral problems, developmental delays, and education-related disabilities. The child is able to state that he does not want to return to his parents' care, but still misses his family members. This may be remedied through his child welfare plan, for example, by arranging for him to remain in contact with his siblings throughout their foster placement. Given his experiences in his prior home environment, he has anger management issues and is likely to have other unmet mental health needs that require referral to a mental health provider. He will also require evaluation by his new school system to determine his specific educational needs and appropriate grade placement.

He is obese and has poor dentition, both of which are common findings in the foster care population. He will require a nutritional evaluation and a referral for dental care. The presence of mild wheezing in a child who otherwise states that he feels fine is a likely marker for untreated reactive airway disease, and may be a reflection of poor continuity of medical care for the boy prior to his placement.

Working With Immigrant Children and Their Families

Alejandro Diaz, MD, and Carol Berkowitz, MD

CASE STUDY

A 7-year-old child presents with vomiting and clinical signs of dehydration. The family thinks he has *empacho*. You tell the family that you suspect that he has viral gastroenteritis. You want to draw some blood studies and give him fluids intravenously. The parents are skeptical; they refuse the blood work and want to leave against medical advice.

Questions

1. What are the ways that different immigrant families view illness and health?
2. What are barriers to accessing health care that children in immigrant families face?
3. What questions help the physician understand the health beliefs of immigrant families?
4. What are the considerations when dealing with parents who do not speak English?

Introduction

The United States is described as a nation of immigrants. Out of a population of 310 million, current estimates are that about 40 million, or approximately 10% of the current US population, are either foreign-born citizens or noncitizens. Half of these immigrants are Hispanic and 65% of Hispanics are of Mexican descent. During the 1990s, 70% of the US population's overall growth was influenced by a wave of recent immigrants, mostly from Latin America and Asia, and by the children born to these newcomers. The vast growth in the population of children living in immigrant families, whether foreign-born (first generation) or US-born (second generation), poses a unique set of challenges.

These children are more likely to live in families that live below the federal poverty level and families in which at least one parent did not graduate high school or is not fluent in English. They are also more likely to live in crowded housing (more than one person per room) and in a multigenerational household. While some immigrant children are citizens and eligible for safety net programs, their family's status directly influences whether these children will even access such care. There is also growing concern that the health status of some immigrant children, whether foreign-born or first generation, actually declines after settling in the United States. It is expected that by 2030, Hispanic children will account for most children living in the United States.

Demographics of Immigrant Children

There are 5 general categories of immigrants in this country, each benefiting from specific entitlements and services, and having certain legal rights: lawful permanent residents, naturalized citizens, refugees/asylees, nonimmigrants, and undocumented immigrants (Box 36-1).

In 2007 naturalized citizens made up approximately 32% of immigrants, lawful permanent residents characterized about 29%, undocumented immigrants another 29%, refugees 7%, and nonimmigrants about 3%. From 1980 to 2000, the children of immigrants increased from 5% to 20% of school-aged children, representing approximately 10 million of the estimated 60 million school-aged children in the United States.

By far the largest category of immigrants is nonimmigrants, or temporary visitors. Approximately 3 million children arrive mostly from Asia, Western Europe, and parts of North America, typically accompanying their parents who are seeking work. A smaller percentage are students or exchange visitors. While not technically immigrants, this special group may present for care with similarly unaddressed health issues depending on their country of origin.

The next largest group, almost a quarter-million children, enter the United States as lawful permanent residents, with most eventually becoming naturalized citizens. Although most arrive with or to meet family already residing in the United States, several thousand adolescents immigrate unaccompanied each year; most are female and many are married to a naturalized citizen at the time of

Box 36-1. Categories of Immigrants in the United States

Lawful Permanent Residents

- Carry a green card
- These are noncitizens with permission to permanently live and work in the United States
- May apply for naturalization after 5 years (or 3 years if they marry a citizen)
- Most international adoptees are in this group

Naturalized Citizens

- Born as noncitizens
- Having met certain English literacy requirements and demonstrating a basic knowledge of civics and a desirable moral character, are granted the same rights as natural born citizens
- However, are not eligible to hold the office of president or vice president

Refugees

- Granted permission from the US government before entry
- Fled their country of origin for fear of persecution due to their race, religion, social group, or political opinion
- Many unable or unwilling to return to country of origin
- Those granted permission to remain are deemed asylees
- After a year, both may apply to adjust their status to lawful permanent residents

Nonimmigrants

- Carry a visa
- Granted permission to enter for a specified time and a specific purpose (usually to work or study)

Undocumented Immigrants

- Entered the country illegally or even legally but then violated the terms of their stay and remained after their visa expired

immigration. Included in this group are children of refugees or asylees. More than 75,000 arrive each year, most recently from the countries of the former Yugoslavia and former Soviet Union, Vietnam, Somalia, and other war-torn regions. Numbers for the third largest group, undocumented immigrants, are based primarily on estimates. Most are from Mexico or other Latin American states. Some entered the United States legally but have overstayed their visa or lost their status by committing a crime.

Health Care Needs of Immigrant Children

When the child of an immigrant family presents for care, the primary concerns are about the presence of an infectious disease (due to exposures and possible lack of vaccination) or the presence of a hidden genetic or ethnic condition (such as hemoglobinopathies and glucose-6-phosphate dehydrogenase [G6PD] deficiency). Investigating the health status of a child, especially from undocumented immigrant families, is paramount as these children likely have not seen a doctor prior to immigrating. Similarly nonimmigrants, such as tourists and other temporary visitors, from many Western or Pacific

Rim countries are not required to have a medical examination performed as part of their application. Only visas for permanent residency require a health examination to be performed by an approved physician, and even then the focus of the examination is to exclude certain conditions such as active tuberculosis (TB), HIV, and other severe physical or mental handicaps. In children, laboratory testing may be limited and proof of vaccination status may be exempted for certain groups, such as international adoptees.

Lack of education and poverty, which results in relative food insecurity and inadequate, crowded housing conditions, poses an ominous threat to the health of these same children. Noncitizen children must wait at least 5 years before they are able to apply for public assistance. While most refugee children may receive some form of subsidized care, such as Medicaid, many of these benefits are time-sensitive. Even US-born children of undocumented mothers, while legally eligible as US citizens for benefits such as nutritional assistance programs, may not receive these owing to parental fears of detection and deportation. Physicians should ascertain that the family has adequate housing and access to food, 2 basic human needs. Is the food available in the families' neighborhood consistent with the traditional food that the family desires? Is the food healthful or does the family live in a "food desert" where there is a plethora of fast-food restaurants and a paucity of supermarkets or grocery stores (Box 36-2)?

Box 36-2. Risk Factors Affecting the Health of Immigrant Children

Social and Economic

- Inadequate or crowded housing
- Food insecurity
- Lack of insurance (due to ineligibility)
- Lack of access to insurance (eligible but unable or unwilling to apply)
- Educational level of head of household

Cultural

- Dietary preferences
- Lack of language fluency or literacy and translation/interpretation issues
- Disparate ideas regarding the causation and treatment of illness
- Expectations of the medical system
- Religious practices with a medical component
- Lack of access to traditional medical practitioners and treatments
- Importation drugs not approved in the United States

Physical

- Carriage of infectious disease and the possibility for repeated exposure via travel or living within one's immigrant community
- Presence of ethnic or genetic conditions
- Lack of vaccination
- Poor nutritional status

Mental Health

- Negative past living conditions, including exposure to violence or natural disaster
- Cultural adjustment (or the process of acculturation and enculturation)

It has traditionally been supposed that immigration itself imposes unique stresses on these children. Mental health challenges (eg, depression, anxiety, and grief) may be related to the reasons for their migration as well as to the inevitable process of acculturation. Stress is compounded by the potential loss of the immigrant's identity and separation from home support systems; inadequate language and literacy skills in a society intolerant of linguistic weakness; disparities between one's country of origin and the United States in economic, social, and professional standards and status; and the psychological and emotional trauma of war, persecution, or exploitation in one's country of origin.

Despite these challenges, epidemiological studies indicate that children in immigrant families experience better outcomes than those in their native countries who did not immigrate, especially in some areas. The most striking example is the lower rate of low-birth-weight children born to foreign-born mothers, especially among Hispanics and non-Hispanic black immigrants, compared with women in their native countries who did not immigrate. This positive effect related to immigration has been studied less in older children due to limited availability of data samples from second-generation children that does not exclude first-generation children.

General Approach to the Initial Medical Evaluation of an Immigrant Child

Ascertaining the "life history" of an immigrant child including any relevant travel history will help determine the extent of the medical evaluation (Box 36-3).

In general, most immigrants from industrialized nations have received comprehensive medical care and the only issues facing these children are routine, such as updating immunization status. In contrast, adoptees, refugees, and undocumented children often have received little or no care. While there is no single approach to the general medical evaluation for all immigrant children, some general principles apply.

Any and all existing medical records should be reviewed. While a complete translation is not always necessary, if an unusual diagnosis or a complicated history exists, use of clinical translational services

or a nearby university's academic language department may facilitate the process. Sometimes the records suggest that a diagnosis was considered but not confirmed and it may be appropriate to reevaluate the child for any suspected condition.

It is important to screen for certain infectious diseases. The most common among immigrants are TB, intestinal parasites, hepatitis B, syphilis, and HIV. In fact, the risk for TB is more than 100 times greater in immigrant children than in US children. Fifty percent of all newly identified cases of TB in the United States are diagnosed in immigrants, many within the first 5 years of life. If not clinically apparent (incubation period) or testing is negative but clinical suspicion exists, the TB testing should be repeated in 6 months. Intestinal parasitic infestations may be present without symptoms. Some clinics specializing in immigrant health advocate giving a single dose of albendazole as a more cost-effective approach than screening and diagnosis, but the safety and efficacy of this approach has not been substantiated in children.

Ethnic or genetic conditions should also be considered. Conditions like G6PD in Mediterraneans, Africans, and Southeast Asians may affect the child's health in the short term. Others like hemoglobinopathies and thalassemias, while common among certain ethnic populations, such as Southeast Asians, may not be of immediate importance. Overall, anemia is extremely common among immigrant children and the diagnostic workup of these children may uncover an underlying blood dyscrasia trait or lead intoxication. If iron therapy has been initiated empirically, repeat testing after treatment is paramount to ensure a response and confirm the diagnosis. Also, certain ritual cultural practices, such as female circumcision and tattooing, or the use of certain traditional healing techniques, such as cupping or coining, may have long-term implications. Understanding the risk for nutritional deficiencies based on the country of origin is important. For instance, nutritional disorders, such as rickets and iodine deficiency, are common in ethnic Chinese and children from the former Soviet Union.

Immunizations must be administered as appropriate and following the catch-up recommendations of the American Academy of Pediatrics and the Advisory Committee on Immunization Practices. Records of previous immunizations may be difficult to interpret. Shortened intervals or the administration of a vaccination at too early an age may not be readily apparent. Fraudulent records, especially amongst adoptees and children from institutional settings, often exist. In young children it is generally considered safe and cost-effective to simply give missing vaccines; however, determining serum immunity may be more cost-effective in older children.

Cultural and Linguistic Sensitivity

Bridging language differences using professional interpreter services is required to provide adequate patient care. Such linguistic services are mandated by agencies such as the Centers for Medicare & Medicaid Services for reimbursement from the federal government. The use of children or house maintenance staff is inadequate and potentially violates federal laws, including the Health

Box 36-3. Questions to Consider When Evaluating Immigrant Children

1. If parents are not present, does the child's current guardian have any personal knowledge of the child's social and medical history?
2. In which countries has the child resided and under what circumstances?
3. Have the child's living conditions changed dramatically in either the positive or negative recently?
4. Are there verifiable birth and medical records, especially vaccination status, to be reviewed? What age is the child? What quality of care did the child seem to receive in their home country?
5. Has the child undergone any recent procedures or treatments?
6. Was the child exposed to any potentially toxic occupational or environmental risks?
7. What educational level did the child achieve?

Insurance Portability and Accountability Act. Professional interpreters are taught to interpret and not carry on additional conversations with the patient or expound on the questions the physician asks. The physician should address questions directly to the patient, not the interpreter, maintaining eye contact with the patient.

Providing culturally competent care that considers cultural practices and beliefs about child health or illness when coming up with a treatment plan is also critical (see Chapter 10). Does the family access “healers” for medical problems (Box 36-4)? What are their views about medication use? Are there hierarchical structures that influence a parent’s acceptance of a physician’s advice (eg, father accepting advice from a female physician, or parent accepting advice from a young resident)?

Conclusion

There are numerous barriers that potentially interfere with achieving optimal health status for immigrant children. Trust is a core component of the physician–patient relationship, and establishing trust may be more difficult when the physician and family have different cultural values and expectations. It has been stated that in medicine the sacred trust that develops between a patient and their doctor should never be taken for granted. The development of trust forms the foundation of the therapeutic relationship. It provides credibility to the practitioner. The practitioner must act in a manner that elicits and fosters trust, and being knowledgeable and nonjudgmental about the beliefs and practices of one’s patients is pivotal.

Health care providers must work toward creating an atmosphere of trust so that parents feel comfortable revealing their beliefs, concerns, and fears. The threat of deportation should be considered when taking into account whether the patient or their family will follow up or adhere to medical recommendations.

It is unwise not to acknowledge the cultural divide that exists between most pediatric practitioners and the families they serve. Therefore, providers who are less familiar with the enrichment provided by a multicultural patient population may be less inclined to advocate for social reforms that may prove beneficial. We as physicians must approach families with an open mind, respect, and a sense of humility if we are to gain their trust, close the gaps that separate us, and promote the well-being of children.

Children are better served when their families receive information about federal, state, and community programs that provide resources to immigrant families. All children, regardless of their

Box 36-4. Questions for Understanding Someone’s Cultural Concept Regarding the Symptoms of Illness^a

1. What do you call the problem?
2. What do you think caused it?
3. Why do you think it started when it did?
4. What do you think the sickness does? How does it work?
5. How severe is it? Will it have a long or short course?
6. What are the chief problems the illness has caused?
7. What kind of treatment do you think they should receive? What are the most important results you expect from this treatment?
8. What do you fear most about the illness?

^aAdapted from Fadiman A. *The Spirit Catches You and You Fall Down*. New York, NY: Farrar, Straus and Giroux; 1997, quoting medical anthropologist Arthur Kleinman.

immigration or socioeconomic status, should receive compassionate, culturally competent, and linguistically effective care services. Such care requires that health care providers incorporate knowledge, attitudes, and skills in cultural and linguistic competence within their professional agenda.

The well-being of all children can be advanced through advocacy, especially on behalf of vulnerable children (see Chapter 2). Such advocacy (1) addresses outreach efforts to children who are potentially eligible for Medicaid and the Children’s Health Insurance Program but are not enrolled, (2) simplifies enrollment for both programs, and (3) expands state funding for those who are not eligible. The medical community must collaborate with legislators, families, and organizations representing underserved populations in order to increase the effectiveness of one’s own advocacy effort. All children should receive care in a medical home (ie, the establishment of comprehensive, coordinated, and continuous health care services). This is especially critical for immigrant children with chronic health care needs and mental health problems.

CASE RESOLUTION

You reach an agreement with the family that allows a community healer to come and perform a therapeutic massage while allowing you to place an intravenous line and administer fluids. The patient is significantly improved after the massage and intravenous fluids. The family appreciates that you respected their beliefs and agrees to return for a routine well-child visit in 2 weeks.

Well-Child Care for Children With Trisomy 21

Derek Wong, MD

CASE STUDY

A 6-month-old girl with trisomy 21 whom you have known since birth is brought to your office for well-child care. She and her parents have been doing well, although she has had several episodes of upper respiratory infections. Her medical history is significant for a small ventricular septal defect, which has since closed spontaneously, and one episode of otitis media at 5 months of age. Her weight gain has been good—along the 25th percentile on the trisomy 21 growth chart. She now sleeps through the night and has a bowel movement once a day. She has received all of the recommended immunizations for her age without any problems.

The infant smiles appropriately, grasps and shakes hand toys, and has some head control, but is unable to roll from supine to prone position. Since she was 1 month old, she has been enrolled in an early intervention program. An occupational therapist visits her at home twice a month.

On physical examination, she has typical facial features consistent with trisomy 21, a single palmar crease

on each hand, and mild diffuse hypotonia. Her eyes have symmetrical movement, and her tympanic membranes are clear. She has no cardiac murmurs.

Questions

1. What is the prevalence of trisomy 21 (Down syndrome) in the general population? What is the association of maternal age with trisomy 21?
2. What are the clinical manifestations of this syndrome?
3. What medical conditions are associated with trisomy 21 in the newborn period, during childhood, and in adolescence? When should screening tests for these conditions be performed?
4. What is the role of early intervention services for these patients and their families?
5. What specific psychosocial issues should be included in your anticipatory guidance and health education?
6. What is the prognosis for children with trisomy 21?

Trisomy 21, or Down syndrome, is the most commonly known genetic cause of mental retardation in children. The primary care provider is in a unique position to offer affected children routine health care maintenance and anticipatory guidance, follow-up of intercurrent illness and chronic problems, and information on the latest recommendations for screening for conditions associated with trisomy 21. In addition, the general pediatrician has the opportunity to develop rapport with children and families that is particularly important when considering the complex medical and social implications of raising these children. An important goal of the well-child visit is to provide children with trisomy 21 and their families with counseling about educational, social, and financial resources and support to ensure a healthy and productive transition into adulthood.

Epidemiology

The prevalence of trisomy 21 is approximately 1 in 800 to 1,000 live births. It is estimated that trisomy 21 is responsible for up to one-third of all cases of moderate to severe mental retardation. Trisomy 21 has a male to female ratio of 1.3:1.

Ninety-five percent of all cases of Down syndrome are caused by chromosomal nondisjunction, and most of these events occur in the mother. The chance of nondisjunction is determined by maternal age. A 25-year-old woman has a 1 in 1,240 risk of having a live baby with Down syndrome, and the risk increases to 1 in 340 at age 35 and 1 in 98 at age 40. It is estimated that approximately one-half of trisomy 21 embryos abort spontaneously. The risk of recurrence of nondisjunction Down syndrome in subsequent pregnancies is 1 in 100 until age 35, after which the risk determined by age takes precedence. Other family members are generally not at increased risk of bearing children with this type of Down syndrome.

Approximately 3% to 4% of Down syndrome cases are caused by Robertsonian translocations with another acrocentric chromosome (14/21, 15/21, or 21/21). Parental karyotypes should be obtained because balanced translocation carriers have an increased risk of Down syndrome in future children. Approximately 1% to 2% of Down syndrome cases are mosaic. These children are often less severely affected than those with “full” Down syndrome. A small percentage of affected children have a chromosomal rearrangement resulting in 3 copies of a portion of chromosome 21.

Recent advances in first and second trimester screening allow prenatal diagnosis of Down syndrome with a sensitivity of 80% to 90%. If a prenatal diagnosis of Down syndrome is made, and the general pediatrician is asked to participate in counseling the family, the points listed in Box 37-1 should be covered.

Box 37-1. Counseling the Family After a Prenatal Diagnosis of Down Syndrome

- Review the data that established the diagnosis in the fetus.
- Explain the mechanism of occurrence and risks for recurrence.
- Review the manifestations of trisomy 21, commonly associated conditions, and the variable prognosis based on the presence of these conditions.
- Discuss other modalities that confirm the presence of associated anomalies, such as a fetal echocardiogram in the case of congenital heart disease.
- Explore treatment options and interventions for associated conditions.
- Offer resources to assist the family with decisions related to completing or terminating the pregnancy.
- Refer the family to a clinical geneticist or genetics counselor.

Clinical Presentation

Infants and children with trisomy 21 have a characteristic appearance (Dx Box). They may be microcephalic, with flattening of both the occiput and face. The eyes have an upward slant, with prominent epicanthal folds, the ears are low set and small, the nasal bridge is flattened, and the tongue appears large. The feet, hands, and digits are small and stubby, and the fifth digit may be hypoplastic and turned in (brachyclinodactyly). A single palmar crease and wide spacing between the first and second toes may be evident. After the newborn period, diffuse hypotonia and developmental delay are universally seen.

Pathophysiology

Approximately 95% of cases of Down syndrome are caused by trisomy 21 resulting from meiotic nondisjunction. The remaining cases are translocations (3%–4%) and mosaics (1%–2%). The translocations are unbalanced and usually occur with another acrocentric chromosome, usually 14/21 or 15/21. Approximately 75% of these are new mutations, and 25% are the result of a familial translocation. Therefore, if a child has a translocation, the parents must be evaluated for a balanced translocation. Mosaicism implies the presence of 2 cell lines: one normal and one with trisomy 21. As might be expected, children with mosaic Down syndrome are usually affected less severely than children with other types of Down syndrome.

Recent research has focused on the role of individual genes, such as *DYRK1A*, in the pathogenesis of Down syndrome. It is likely that in the near future, pharmacologic agents that mitigate the effects of excess expression of such genes will lead to new treatments for Down syndrome patients.

Dx Trisomy 21

- Microcephaly, with flattening of both occiput and face
- Upward slant to the eyes with epicanthal folds
- Brushfield spots in eyes
- Small ears and mouth (therefore, tongue appears large)
- Low-set ears
- Flat nasal bridge
- Broad, stocky neck, with loose skin folds at the nape
- Funnel-shaped or pigeon-breasted chest
- Small, stubby feet, hands, and digits, with brachyclinodactyly of the fifth digits
- Single transverse palmar crease on each hand
- Wide space between first and second toes
- Fair, mottled skin in newborns; dry skin in older children
- Hypotonia

Evaluation

Routine health care maintenance for infants, children, or adolescents with trisomy 21 should cover the same issues in health education, prevention, and counseling that are discussed with other healthy patients and their families. The schedule of health maintenance visits for infants and young children with trisomy 21 is essentially the same as that recommended by the American Academy of Pediatrics for other children, while older children with Down syndrome should be evaluated annually. The following sections will emphasize additional medical and psychosocial conditions often seen in patients with trisomy 21.

Newborn Period

Verification of the diagnosis of trisomy 21 is perhaps the single most important focus of the initial family visit. Sometimes the diagnosis has been suspected prenatally due to abnormal biochemical markers and ultrasound, and verified by chorionic villus sampling or amniocentesis (Box 37-1). If there is no prenatal testing and the diagnosis is suspected due to clinical findings, a karyotype must be sent from the nursery and reviewed at the 1- to 2-week visit.

Several conditions that are associated with trisomy 21 are important to identify in the newborn period. They include hearing loss, congenital heart disease (most commonly endocardial cushion defect), duodenal atresia, Hirschsprung disease, congenital hypothyroidism, and ocular anomalies (cataracts, strabismus, and nystagmus). Hematologic abnormalities include polycythemia, leukemoid reactions that resemble leukemia but resolve during the first month of life and, rarely, leukemia.

History

A feeding history is critical because hypotonia often leads to swallowing difficulties (Table 37-1). A history of vomiting may be indicative of gastroesophageal reflux, or less commonly a

Table 37-1. Health Supervision for Children With Down Syndrome

	<i>Initial Evaluation</i>	<i>Subsequent Evaluations</i>
History and Physical Exam		
Developmental assessment	Newborn	Same as regular well-child care schedule until age 5, then annual evaluation
Visual and hearing assessment (subjective)		
Laboratory Assessment		
Karyotype	Newborn	None
Thyroid screen	Newborn screen	6 months, 12 months, then annually
Complete blood cell count	Newborn	Same schedule as other children
Celiac screen	2–3 years	Every 5 years ^a
Echocardiogram	Newborn	Depends on condition
Neck radiographs	Age 3–5 years	Sports activities or Special Olympics entry ^a
Audiological evaluation	Newborn	12 months, then annually (if no ear, nose, throat problems)
Consultation		
Genetics	Newborn	As needed ^b
Cardiology	Newborn	Depends on condition
Ophthalmology	6 months	Every 2 years until age 5, then annually
Ear-nose-throat	As needed	As needed
Dental	By 1 year of age	Twice per year

^aLack of expert consensus on evaluation.

^bDepending on experience and comfort level of primary care physician.

gastrointestinal malformation. Constipation may be the first indication of Hirschsprung disease or hypothyroidism. A detailed family and social history should also be obtained if this was not done in the hospital.

Physical Examination

A detailed physical examination should reveal some common features of newborns with Down syndrome (see Dx box). All growth parameters should be recorded and compared with those obtained at birth. The size of the fontanelles should be evaluated because of the increased incidence of congenital hypothyroidism. Bilateral red reflexes and conjugate gaze should be documented to exclude congenital cataracts or strabismus. A careful cardiac examination must be performed, noting any cyanosis, murmurs, irregular heart rates, abnormal heart sounds, or asymmetry of pulses. The abdomen should be palpated for organomegaly or any masses, and patency of the anus should be verified. An Ortolani and Barlow test should

also be performed for hip laxity. Finally, the infant should be evaluated for hypotonia.

Laboratory Tests

A karyotype is an important tool to verify the diagnosis and to assess recurrence risk. Newborn screening laboratory tests must be reviewed, especially hearing evaluations and thyroid screens. In addition, a cardiac evaluation for congenital heart disease should be performed, which may include an electrocardiogram, chest radiograph, echocardiogram, and formal cardiology referral. A complete blood cell count is indicated to look for hematologic abnormalities including leukemoid reaction, transient myeloproliferative disorder (pancytopenia, hepatosplenomegaly, and immature white blood cells), and neonatal thrombocytopenia.

Management

The primary care physician should discuss the increased propensity for respiratory infections in children with Down syndrome. Other important issues to address include those pertaining to available resources for children and families, such as early intervention programs and Down syndrome support groups in the community. Educational materials such as pamphlets and books may also be supplied at this time. Upcoming appointments with other physicians and allied health professionals should be reviewed.

Infancy and Early Childhood

History

Some additional historical issues to address include a detailed developmental assessment focusing on progress made since the last visit because most affected children have motor and speech delays (see Table 37-1). It is important to review any ancillary services, such as physical, occupational, and speech therapy, in anticipation of school entry. The parents should provide their assessment of the child's vision and hearing. A history of recurrent respiratory infections should raise concern about otitis media. Many children at this age develop constipation. A history of snoring and restless sleep may indicate obstructive sleep apnea and require a sleep study. Finally, it is extremely important to document any history of neck pain, gait changes, increased clumsiness, or other neurologic symptoms that would indicate spinal cord compression from atlantoaxial dislocation.

Physical Examination

All growth parameters should be plotted on growth charts for children with Down syndrome (Figures 37-1 through 37-4). Children with trisomy 21 are shorter than other children and may have poor weight gain in their first year. Later in life, obesity unrelated to the syndrome may become a problem, however. As with routine well-child visits in other infants and children, a complete physical examination should be performed at each patient encounter. Noteworthy aspects of the examination in infants and children with trisomy 21 are given in Box 37-2. In particular, the ear canals of these children

Box 37-2. Physical Examination of Children With Trisomy 21

- Look for dry, sensitive skin and alopecia, which develops in approximately 10% of children and resolves spontaneously.
- Monitor the size of the anterior and posterior fontanelles because delayed closure may indicate hypothyroidism.
- Check for visual abnormalities, such as strabismus, nystagmus, cataracts, refractive errors, and blepharitis.
- Document recurrent serous otitis media. It is estimated that 40% to 60% of children with trisomy 21 have significant conductive hearing loss and 20% to 30% have some degree of neurosensory loss.
- Examine the oropharynx carefully for delayed dentition, malocclusion, and caries.
- Perform a thorough cardiac examination and note any evidence of previously unrecognized congenital heart disease.
- Palpate the abdomen for distention or organomegaly. Children with trisomy 21 have a slightly increased risk of developing acute non-lymphoblastic or acute lymphoblastic leukemia.
- Perform a rectal examination in infants or children with a history of constipation.
- Evaluate any musculoskeletal abnormalities such as overall hypotonia and joint laxity (most commonly in the knees and hips) that might contribute to overall gross motor delay.

are easily collapsed, making the tympanic membrane difficult to visualize. In some cases, an otolaryngology referral may be necessary for an adequate otoscopic examination. A complete neurologic examination should be performed at each visit, including an assessment of the degree of hypotonia.

Laboratory Tests

Hearing evaluation should be performed annually, starting with the newborn hearing screen. Developmentally appropriate gross visual screening should be performed in infants between 6 and 12 months of age at each visit, and a formal ophthalmology examination is recommended at 6 months and every 2 years thereafter. Thyroid screening tests should be repeated at 6 and 12 months and then annually.

Children with congenital heart disease should be given antibiotic endocarditis prophylaxis for dental or other procedures. In addition, these children should be considered for monoclonal antibody therapy against respiratory syncytial virus in the winter.

Children with Down syndrome have an increased risk for autoimmune disorders such as celiac disease, Grave disease, and type 1 diabetes. Because the signs of celiac disease may be subtle, most pediatric gastroenterologists recommend measuring tissue transglutaminase immunoglobulin (Ig) A antibodies, as well as an IgA level, at 2 to 3 years of age. Rescreening for celiac disease is currently a topic of debate, but several experts suggest that retesting approximately every 5 years during childhood may be appropriate.

Children with Down syndrome have an increased incidence of atlantoaxial instability when screened with routine lateral cervical

radiographs with flexion and extension views. Any patient with signs or symptoms of cord compression should be evaluated by computed tomography or magnetic resonance imaging and referred to an orthopedic surgeon or neurosurgeon. Symptomatic children should be kept out of any sports that involve contact or neck extension, such as swimming, gymnastics, and soccer. Experts have debated the value of routine radiographs, and most agree that careful neurologic screening at health supervision visits is a much better predictor of serious injury. However, at this time routine radiographs are still recommended at age 3 to 5 years and are required prior to participation in events such as the Special Olympics.

Management

Infants with trisomy 21 should have all routine screening tests and immunizations. Growth and developmental progress should be reviewed with parents at the end of each visit, and any concerns or unmet expectations should be addressed at this time. Often the developmental delay associated with trisomy 21 is not apparent to families until infants are 4 to 6 months of age and not achieving the expected milestones of rolling over or sitting. It should also be emphasized to families that the degree of mental retardation in trisomy 21 is quite variable, ranging from mild to severe. However, social function is not necessarily related to IQ. If the child is not already enrolled in an early intervention program, the positive role of such an experience should be addressed. The availability of support groups for parents and other family members should also be discussed.

In the early childhood years, plans for preschool attendance and future educational opportunities should be reviewed with families. The role of discipline and the presence of common behavioral problems such as temper tantrums and biting should be assessed in preparation for school entry and socialization. Nutrition should be reviewed because children with Down syndrome have a reduced metabolic rate and are at increased risk for obesity. Nutritional supplements and other alternative medicines have not been proven to have any efficacy in the treatment of Down syndrome patients.

A dental referral should be made by the age of 1 year in accordance with the latest recommendation for all children.

Older Childhood and Adolescence

History

School-aged children with Down syndrome should continue to visit their primary care physician at least annually. Educational issues should be discussed, including individual education plans and the transition from school. Specific medical issues to address during the history include visual or hearing deficits, evidence for hypothyroidism (decreased activity, coarse and dry hair, and constipation), skin problems including eczema, and dental problems. A careful nutritional history should also be taken because of the propensity for obesity, and the children should be closely monitored for signs of obstructive sleep apnea.

Physical Examination

Height and weight should continue to be plotted. The skin should be examined closely for xerosis, acne, or syringomas (multiple papules often present on the eyelids and upper cheeks) during adolescence. A cardiac examination is important because of an increased risk of mitral valve prolapse and valvular dysfunction. The sexual maturity rating (Tanner stage) of both males and females should be noted and discussed with the parents. A pelvic examination is not indicated as a part of the routine visit unless there is concern about sexual abuse or a sexually transmitted infection, but a testicular examination is important due to the increased risk of testicular cancer. A complete neurologic examination should also be performed in the patient participating in sports activities to look for signs indicating impending atlantoaxial dislocation.

Laboratory Tests

Annual thyroid screening (thyroid-stimulating hormone, thyroxine) is recommended for all school-aged children and adolescents with trisomy 21, in addition to other routine screening tests. An audiological evaluation should also occur at least once in older children and then annually thereafter. Because of the risk of keratoconus, an annual ophthalmology consultation should be arranged after the age of 10 years. In addition, children with trisomy 21 should be encouraged to continue biannual dental visits because gingivitis, periodontal disease, and bruxism (teeth grinding) are common in these individuals.

Management

The major part of the visit with school-aged and adolescent children should be spent on developmental, educational, and vocational anticipatory guidance. Educational placement and future goals should be both developmentally appropriate for the child and acceptable for the parent. Activities requiring socialization and the development of responsibility should continue to be encouraged; however, these events can be very stressful for parents and other family members. Injury prevention should be highlighted as well, especially because older children are becoming more independent. In early adolescence, prevocational and vocational training within the school curriculum should be reviewed. In addition, brief discussions regarding independent living, group homes, transition of medical care, and financial resources (eg, community-supported employment for young adults) should begin during adolescence.

Puberty, fertility, and contraception are extremely important to address with adolescents and their parents. The patient's psychosocial development and physical sexual maturation should be discussed, including menstrual hygiene and any foreseeable problems with its management. Contraception and the potential for victimization must be addressed as well, particularly with female patients. Males with trisomy 21 are usually sterile, but females have an approximately 50% chance of having children with Down syndrome.

Prognosis

Individuals with trisomy 21 can often live well past the age of 50 unless they are born with a congenital heart lesion, which may limit life expectancy. One major cause of morbidity and mortality is the development of symptomatic Alzheimer disease, which occurs in approximately 15% of adults after the fourth decade. Fortunately, most adults with Down syndrome remain asymptomatic, despite histopathologic evidence of the disease.

CASE RESOLUTION

In the case described at the beginning of the chapter, the family should be encouraged by the healthy progress of their daughter. For this visit, anticipatory guidance should consist of a review of early intervention services, available resources, and general support services for the patient and her family. The increased risk for both upper respiratory infections and otitis media should be reviewed. Medical screening should include thyroid screening, subjective hearing screening, and a formal evaluation by a pediatric ophthalmologist. If the results are normal, the next visit should take place in 3 months.

Well-Child Care for Preterm Infants

Lynne M. Smith, MD

CASE STUDY

A 2½-month-old infant girl was discharged from the neonatal intensive care unit 2 weeks ago, where she had been since birth. She was the 780-g product of a 26-week gestation born via spontaneous vaginal delivery to a 32-year-old primigravida. The perinatal course was complicated by premature rupture of membranes and maternal amnionitis. Several aspects of the neonatal course were significant, including respiratory distress that required surfactant therapy and 2 weeks of endotracheal intubation; a grade II intraventricular hemorrhage on head ultrasound at 1 week of life; hyperbilirubinemia, which was treated with phototherapy; several episodes of apnea, presumably associated with the prematurity; and a history of poor oral intake with slow weight gain.

The infant's parents have a few questions about her feeding schedule and discontinuing the apnea monitor, but they feel relatively comfortable caring for their daughter at home. She is feeding well (2 oz of 22 cal/oz post-discharge formula for premature newborns every 2–3 hours)

and is becoming progressively more alert according to the family. She sleeps on her back in a crib.

The infant's weight gain has averaged 25 g/day. The rest of the physical examination is normal, except for dolichocephaly and a left esotropia.

Questions

1. What constitutes well-child care in preterm infants?
2. What are the nutritional requirements of preterm infants in the months following discharge from the hospital?
3. What information must be considered in the developmental screening of preterm infants?
4. What immunization schedule is appropriate for preterm infants? Do they require any special immunizations?
5. What specific conditions or illnesses are more likely to affect preterm infants than term infants?

Premature infants are born at less than 37 completed weeks' gestation and often weigh less than 2,500 g. Providing primary care for these infants is an important and challenging task and often requires coordination of medical, developmental, and social services for multiple chronic conditions. Because preterm infants are at increased risk for both impaired growth and developmental delay, longer visits may be necessary to evaluate the infants' nutritional and developmental progress and to assess how families have adjusted to caring for them at home. Primary care physicians must learn to manage these and many other complex issues while providing families with comprehensive anticipatory guidance.

Epidemiology

In the United States, 1 in 8 newborns is born prematurely, a 30% increase since 1981. The preterm delivery rate is highest for African American women (17.5%) and lowest for white (11.1%) and Asian and Pacific Islander (10.7%) women. Reasons for the increased premature delivery rates include an increased use of artificial reproductive technologies (see Chapter 21) and increased maternal age.

Though most preterm newborns are delivered between 34 and 36 weeks' gestation, these neonates are at increased risk for morbidity and mortality relative to infants born at term. In addition, many neonatologists routinely resuscitate neonates born at 23 weeks' gestation, a gestation that has a survival rate of approximately 25%. Very low birth weight (VLBW, <1,500 g) and extremely low birth weight (ELBW, <1,000 g) newborns are at risk for cerebral palsy, hearing and vision problems, and mental retardation. Further, learning disabilities, attention-deficit disorder, borderline to low IQ scores, and abnormalities in executive function and visuomotor integration occur in more than 50% of VLBW infants, complicating the posthospital care for these children. In 2006 the Institute of Medicine estimated the annual societal cost of prematurity at \$26 billion.

Evaluation

The purpose of the health maintenance visit for preterm infants is the same as for other healthy children: to provide consistent preventive health care and education for patients and their parents. Prematurity,

however, places children at risk for additional medical and neurodevelopmental conditions.

History

At the initial visit, it is imperative to review the entire medical history and hospital course with the family. Ideally, the neonatal intensive care unit (NICU) should provide a discharge summary that includes the following information:

1. Birth weight, gestational age, and significant prenatal and perinatal information
2. An overview of the hospital course, including significant illnesses, events, surgical procedures, and pertinent radiographic studies
3. Nutrition information and present feeding regimen
4. A list of current medications, including dosing intervals and, if appropriate, serum drug levels
5. Immunizations given during the hospitalization
6. Pertinent laboratory data, such as most recent hemoglobin, newborn screening results, ophthalmologic and hearing screening information, neurosonogram and magnetic resonance imaging (MRI) results, and highest serum bilirubin level
7. Discharge physical examination, including most recent height, weight, and head circumference
8. Problems remaining at discharge
9. Follow-up appointments

Any significant complications or concerns should be discussed with the parents as soon as possible to assess their understanding of these issues as well as expectations for improvement.

Specifically, growth, nutrition, and developmental issues should be addressed at each visit (Questions Box). Adequate or desirable weight gain should be explained to the caregivers in terms of the

infant's current weight versus the discharge weight. Infants younger than 6 months should gain, on average, 20 to 40 g/day. To ensure continued weight gain, many preterm infants are discharged from the NICU on a 24-hour feeding schedule, which requires that parents feed infants at least every 3 hours. The necessity for this practice should be reevaluated during the first few weeks following discharge after infants have demonstrated adequate weight gain.

A critical component of the health maintenance visit is the developmental history. Parental expectations and observations should be noted, and any developmental concerns should be evaluated. The adjusted developmental age should be calculated by subtracting the number of weeks the infant was born prematurely from the current chronological age in weeks. The adjusted age should then be used for all formal and informal developmental assessments. The importance of correcting for prematurity until children are 2 years of age must be emphasized when discussing developmental progress and giving anticipatory guidance to parents.

Physical Examination

A complete physical examination should be performed at each visit to monitor the status of associated medical conditions. All growth parameters (weight, height, and head circumference) should be plotted on the growth chart for premature newborns until approximately 50 weeks' postmenstrual age and adjusted for prematurity on standard growth charts until age 2. Because catch-up head growth generally precedes catch-up weight and length, preterm infants may appear to have disproportionately large heads. The onset of accelerated head growth may begin within a few weeks after birth (36 weeks' postconception) or as late as 8 months adjusted age. Average daily weight gain in grams per day should also be calculated.

The size and shape of the head must be evaluated, especially if the infant has a history of intraventricular or intracranial hemorrhage or hydrocephalus. An increase in head circumference of more than 2 cm per week should be cause for concern in these infants. In infants who have been treated neurosurgically for hydrocephalus, ventriculoperitoneal shunt and tubing may be palpated. Visual abnormalities such as strabismus must be carefully ruled out by examination as well as by history because up to 20% of preterm infants may have an ophthalmologic problem (see Chapter 76). Oropharyngeal abnormalities, such as a palatal groove, high-arched palate, or abnormal tooth formation, may occur as a result of prolonged endotracheal intubation. Baseline intercostal, substernal, or subcostal retractions; wheezing; stridor; and tachypnea in former premature babies with moderate-to-severe bronchopulmonary dysplasia (BPD) should be documented.

Chest scars secondary to the placement of chest tubes should be noted. Adult female breasts may be affected if scarring occurs on or close to breast tissue. The umbilicus may appear hypoplastic as a result of umbilical catheter placement and suturing. Multiple scars on the heels from blood sampling or on the distal extremities from intravenous catheters and cutdowns may be evident.

The genitalia of both male and female preterm infants should be examined closely for inguinal hernias. The incidence of inguinal hernias in preterm newborns is up to 30% with incarceration rates of up

Questions

Well-Child Care for Preterm Infants

- How much did the infant weigh when discharged from the hospital?
- Is the infant breastfed or formula-fed? Is the infant on any special formula?
- How often and how much does the infant feed? How long do feedings take?
- Does the infant have any feeding problems (eg, pain, vomiting, gastroesophageal reflux)?
- Does the infant take dietary supplementation of vitamins and minerals?
- What developmental milestones has the infant reached? Does the infant roll over? Smile? Sit up?
- Does the infant seem to hear and see?
- Who cares for the infant?
- Where and in what position does the child sleep?
- Do the parents have any concerns regarding growth, development, or nutrition?
- Is the infant on an apnea monitor? Have there been any apneic episodes?

to 31%. If hernias are surgically repaired under general anesthesia, infants should be monitored for apnea for up to 24 hours postoperatively. The male scrotum should be examined for cryptorchidism because only 25% of testes are in the scrotum of prematurely delivered males at term gestation. By 1 year of age, more than 90% of testes are intrascrotal. A careful evaluation for developmental dysplasia of the hip should be performed until children are ambulatory, and a hip ultrasound should be performed at 6 weeks of age for all breech deliveries (see Chapter 100).

A thorough neuromuscular examination is essential in these children. Increased muscular tone, asymmetry, and decreased bulk should be noted along with the presence of any clonus or asymmetry of deep tendon reflexes. Inappropriate reflexes, such as a persistent Moro or fisting beyond 4 months of age, should also be documented. Other abnormalities (eg, scissoring or sustained clonus) in the neurologic examination may become more apparent as infants become older. The detection of subtle early findings is important so appropriate intervention services can begin as soon as possible.

Laboratory Tests

In addition to the standard screening tests performed on all healthy infants and children during health maintenance visits, several laboratory studies are important in preterm infants. Such tests include a complete blood cell count and reticulocyte count to check for anemia; electrolytes in infants with BPD on diuretics to detect abnormalities; and serum calcium, phosphorus, and alkaline phosphatase levels in infants with documented rickets.

Pulse oximetry is indicated for oxygen-dependent infants as well as those presenting with respiratory symptoms greater than baseline. Results from newborn screening tests, including auditory and ophthalmologic examinations, should be reviewed and repeated as indicated. Cranial ultrasound studies should be reviewed with caution because nearly 30% of infants born weighing less than 1,000 g with normal head ultrasound findings develop cerebral palsy or developmental delay. In addition, infants with a grade I or II intracranial hemorrhage have an increased risk for developmental delay. Brain MRI scans should be considered in infants born less than 30 weeks' gestation, or in any infant with a concerning abnormal neurologic examination or abnormal rate of head growth.

Management

Well-child care in relatively healthy preterm infants has 2 components. One is the provision of routine health care maintenance for infants and appropriate developmental anticipatory guidance for parents. The other component involves the incorporation of treatment for chronic conditions into each visit. Health care maintenance should include nutrition counseling, developmental surveillance, immunizations, and assessment of vision and hearing in addition to standard screening tests discussed previously. Outside resources concerning developmental delay can be reviewed with parents (Box 38-1). Care related to chronic conditions includes adjusting medication doses, such as diuretic therapy; weaning from supplemental oxygen; and discontinuing the apnea monitor.

Box 38-1. Physician Support and Education of Parents With Preterm Infants

- Understand parental expectations.
- Legitimize parental fears.
- Be a source of support and encouragement.
- Provide consistent, honest information.
- Assume the role of the overall coordinator of care.
- Provide referrals to outside resources, including respite care.

Parents should be given anticipatory guidance prior to discharge that caring for a NICU graduate is challenging. Premature newborns have poorly organized sleep-wake cycles resulting in more frequent awakening than term newborns. In addition, premature newborns have immature suck-swallow coordination, causing them to feed more frequently and for longer periods. Colic is reported twice as frequently in VLBW infants relative to term newborns, and many are described as having difficult temperament until past their first birthdays.

The medical costs associated with the care of premature newborns often strain the family finances at a time when many women decrease their work schedules. Additional stressors include uncertainty about the long-term outcome of the child, guilt many women feel after delivering prematurely, and anxiety about future pregnancies. The difficulty of caring for these complicated, challenging children results in significant parental stress and can interfere with their ability to properly bond to their newborn.

Nutrition

According to the American Academy of Pediatrics (AAP) Committee on Nutrition, the average daily energy requirement for most hospitalized healthy preterm infants is 105 to 130 kcal/kg/day to achieve adequate growth. Energy requirements vary with individual infants depending on associated chronic conditions, such as BPD or malabsorption. Growth is considered adequate in the newborn weighing more than 2,000 g if weight gain is more than 20 g/day and length and head circumference increase 0.7 to 1.0 cm/week.

At 40 weeks' corrected age, preterm newborns are usually smaller than term newborns. Adequate nutrition in the first year of life is critical because catch-up weight gain is unlikely to occur after age 3. Because breast milk is insufficient for providing adequate protein and micronutrients to preterm newborns, human milk fortifier is added to breast milk.

If not receiving breast milk, children born at 34 weeks or less and/or weighing less than 1,500 g are usually discharged home on a nutritionally enhanced transitional formula (Similac NeoSure Advance, Enfamil EnfaCare LIPIL). The calcium, phosphorous, and caloric content of these 22 cal/oz transitional formulas are between levels found in standard preterm and term formulas. Use of preterm enriched formulas is usually continued until the child reaches the 5th to 10th percentile on the growth chart or is 1 year adjusted age. A meta-analysis, however, failed to demonstrate nutrient-enriched

formulas improve growth rates or developmental outcome after discharge relative to standard term formula.

Formula-fed infants require multivitamin supplementation until 750 mL/day of formula is consumed. Breastfed premature newborns may benefit from continuing multivitamin solution as long as human milk is the predominant source of nutrition. Vitamin D supplementation is recommended for all breastfed infants. Because premature newborns are at increased risk for osteopenia of prematurity, soy formulas are to be avoided because of the low phosphate content.

The introduction of solid foods is appropriate once infants have developed acceptable oral–motor skills for swallowing solids. Cow's milk should not be introduced until 12 months' adjusted age.

Developmental Assessment

Both informal and formal developmental surveillance should include referral to an early intervention program, particularly in ELBW infants because routine screening tests are not sensitive enough to pick up subtle neurodevelopmental abnormalities (Box 38-2; see Chapter 27). The Individuals with Disabilities Education Act, Part C guarantees early intervention programs for infants and toddlers with disabilities up to age 3. Children born weighing less than 1,200 g are automatically eligible, but any child suspected of a developmental delay is entitled to an evaluation to determine eligibility for services regardless of a family's ability to pay. Because many developmental issues do not manifest until school age, frequent developmental assessments and enrollment in preschool are especially important for infants born prematurely.

Immunizations

Routine immunization schedules recommended by the AAP Committee on Immunization Practices should be followed. The administration of any vaccine is determined by the chronological or postnatal age, not the gestational age. Standard doses and intervals should also be used (see Chapter 32). Several studies have shown an adequate serologic response despite a history of prematurity. Absolute and relative contraindications to specific vaccine components or to live vaccines for preterm infants are identical to published guidelines for term infants and children. In addition to following the recommendation that all infants 6 months and older be vaccinated against influenza, all household contacts of premature newborns should also be strongly urged to be vaccinated. Two doses of influenza vaccine are administered 1 month apart, with subsequent immunization the following year only requiring one dose. Rotavirus vaccination is recommended for clinically stable premature newborns if they are 6 to 14 weeks' chronological age at discharge or have already been discharged from the NICU.

If adequate weight gain has been established, it is safe to administer hepatitis B vaccine to medically stable neonates weighing less than 2,000 g as early as 30 days of age or at discharge, whichever comes first. All neonates born to mothers who are hepatitis B surface antigen (HBsAg) positive should receive hepatitis B vaccine and hepatitis B immune globulin (HBIG) within 12 hours of delivery. When maternal HBsAg status is unknown, neonates weighing less

Box 38-2. Typical Speech, Play, and Physical Development^a

In addition to standardized tests, the following guidelines provide development milestones useful for early detection:

By 3 months' adjusted age, the infant

- Coos or vocalizes other than crying
- Visually tracks a moving toy from side to side
- Attempts to reach for a rattle held above their chest
- Pushes up on arms
- Lifts and holds head up

At 6 months' adjusted age, the infant

- Begins to use consonant sounds in babbling and uses to get attention
- Reaches for a nearby toy while on their tummy
- Transfers a toy from one hand to the other while lying on back
- Reaches both hands to play with feet while lying on back
- Uses hands to support self in sitting
- While standing with support, accepts entire weight with legs

At 9 months' adjusted age, the infant

- Increases variety of sounds and syllable combinations in babbling
- Looks at familiar objects and people when named
- Explores and examines an object using both hands
- Turns several pages of a chunky book at once
- Imitates others in simple play
- Sits and reaches for toys without falling

At 12 months' adjusted age, the child

- Meaningfully uses "mama" or "dada"
- Responds to simple commands (eg, "come here")
- Produces long strings of gibberish in social communication
- Finger feeds self
- Uses thumb and pointer finger to pick up tiny objects
- Pulls to stand and cruise along furniture
- Stands alone and takes several independent steps

At 15 months' adjusted age, the child

- Has a vocabulary consisting of 5–10 words
- Helps with getting undressed
- Walks independently and seldom falls
- Squats to pick up toy

At 24 months' adjusted age, the child

- Uses 2- to 4-word sentences
- Walks up and down stairs holding on for support
- Builds a tower of 4 blocks or more
- Can identify basic body parts

than 2,000 g should receive HBIG within 12 hours, neonates weighing more than 2,000 g should receive HBIG within 7 days, and all should be vaccinated for hepatitis B within 12 hours.

Because respiratory syncytial virus (RSV) causes an increased morbidity and mortality in NICU graduates and infants with

congenital heart disease, administration of RSV-specific immunoglobulin, palivizumab (Synagis), is recommended every month from November to March (Box 38-3). A documented infection with RSV is not an indication to discontinue passive immunization as multiple strains may circulate during the RSV season.

Assessment of Vision and Hearing

Follow-up visits for visual and auditory sequelae of prematurity must be arranged at the health maintenance visit. An initial ophthalmologic screening examination should have been performed between 4 and 9 weeks of age in infants weighing less than 1,500 g or less than 32 weeks' gestation, irrespective of oxygen exposure. Infants between 1,500 g and 2,000 g or greater than 32 weeks' gestation with an unstable clinical course should also be screened. The frequency and need for repeat examinations are determined based on the initial findings. Preterm infants, regardless of the presence of retinopathy of prematurity, are at increased risk for the development of strabismus, myopia, amblyopia, and glaucoma and need an ophthalmologic examination beginning at 6 months of age.

The AAP recommends universal hearing screening for all newborns. Neonatal intensive care unit graduates account for approximately 50% of all newborn hearing screening failures, and severe sensorineural hearing loss occurs in up to 10% of ELBW infants. Screening is recommended immediately prior to discharge, and repeat testing is recommended if speech delays develop.

Other Possible Problems

Preterm infants with chronic lung disease are at increased risk for respiratory illness, especially during the winter. Parents should be informed of this risk and counseled about symptoms such as tachypnea and wheezing associated with a simple upper respiratory infection. Practitioners should have a low threshold for considering a diagnosis of pneumonia in these infants in the appropriate clinical setting.

Primary care providers should also keep in mind that preterm infants are at increased risk for sudden infant death syndrome (Chapter 59). The AAP recommends that all infants sleep in the supine position. In the NICU, neonates are often placed on their stomachs if they have respiratory difficulties and on their sides if they have symptomatic gastroesophageal reflux. Neonatal intensive care unit personnel need to begin placing these babies on their backs in anticipation of discharge. Parents should also be reminded that cosleeping is not recommended and is highly associated with sudden infant death from accidental asphyxia.

Home apnea monitors are not associated with the prevention of SIDS and should be reserved for infants who are considered to have extreme cardiorespiratory instability. Discontinuation of home monitoring may be considered at 42 weeks' postmenstrual age and when significant apneic events have ceased, whichever comes later.

Preterm survivors who were critically ill can be particularly at risk for developing **vulnerable child syndrome** because their parents often perceive them as fragile and vulnerable. Features of this syndrome include abnormal separation difficulties for both the

mother and child, sleep difficulties, parental overprotectiveness and overindulgence, lack of appropriate discipline, tolerance of physical abusiveness by the child toward the parent, and excessive preoccupation with the infant's health. Serious behavioral problems may arise as a result of such parent–child interactions. Primary care providers must be cognizant of early signs of this syndrome and should try to prevent its occurrence by reassuring parents about the infant's well-being. Once vulnerable child syndrome is suspected, connecting the child's history of critical illness with ongoing parent concerns is important as many parents are unaware that current concerns may stem from their unresolved anxiety. Every effort should be made to normalize the family's schedule once the infant is stable and to encourage parent–infant interactions unrelated to health care.

Prognosis

Neurodevelopmental impairment is a concern for physicians who care for preterm infants. Risk factors for developmental delay include postnatal steroid exposure, necrotizing enterocolitis, BPD, and small for gestational age. Chorioamnionitis is a risk factor for cerebral palsy in term infants and possibly in infants born prematurely. Extremely low birth weight infants and those born between 20 to 25 weeks' gestation have significant risk for developmental issues. Surviving infants born at less than 26 weeks' gestation in the United Kingdom in 1995 had median Bayley mental and psychomotor scores at 30 months of age of 80, with comparable cognitive score deficits at age 6.

During adolescence, 50% of former VLBW infants will have an IQ in an abnormally low range, and 30% will have attention-deficit/hyperactivity disorder. Though former premature newborns report more health-related and learning difficulties in adolescence relative to their normal birth weight peers, the VLBW teens rated their

quality of life higher than their peers. In addition, increased systolic blood pressure, insulin resistance, and impaired glucose tolerance has also been reported in VLBW adults. Parents should also understand that long-term follow-up information may not accurately reflect the outcome for their child because these adolescents were managed prior to advances in prenatal and neonatal care.

CASE RESOLUTION

In the case presented at the beginning of the chapter, the infant's current feeding schedule should be continued because appropriate weight gain has occurred. Iron and multivitamin supplementation is recommended until 750 mL/day of formula is consumed. Discontinuation of the apnea monitor can be considered after the infant reaches term gestation and has been event-free. The first set of immunizations should be administered at this visit, and any questions that the family has should be answered. A follow-up visit should be scheduled in 3 to 4 weeks. Formal developmental testing should be arranged in 1 to 2 months, and the parents should be encouraged to continue having the child sleep on her back.

Care of Children With Special Health Care Needs

Julie E. Noble, MD

CASE STUDY

A 5-year-old physically disabled girl is brought to your office for her first visit for a routine physical examination for school entrance. The girl was the full-term product of a pregnancy complicated by an elevated screening α -fetoprotein and a subsequent fetal ultrasound that demonstrated a lumbar myelomeningocele and no hydrocephalus. Delivery was elective cesarean section with Apgar scores of 9 at 1 minute and 9 at 5 minutes to a 25-year-old gravida I para 0–I female. The mother used no illicit drugs, alcohol, or any other medications during pregnancy, but was not on vitamins or folate supplementation at the time of conception. At delivery, a low lumbar spinal malformation was noted without other malformations. The quadriceps muscles were strong but the feet demonstrated a rocker bottom deformity.

Shortly after birth the myelomeningocele malformation was closed by neurosurgery. She has had orthopedic surgical release of Achilles tendon contractions and is ambulatory with ankle–foot orthotics. She has a neurogenic bladder and requires intermittent catheterization.

She has chronic constipation treated with a bowel regimen. Her cognitive function is age-appropriate.

She will be entering a school program for the first time since moving to this community and has not established care with any specialists.

Questions

1. Why is early identification and intervention important for infants and children with special health care needs (SHCN)?
2. What are the unique needs of infants and children with SHCN?
3. What role do primary care practitioners play in the care of children with SHCN?
4. What are the appropriate referrals and resources for families of children with SHCN?
5. What specific psychosocial issues should be addressed whenever children with SHCN visit their primary care practitioners?

Children and youth with SHCN have disabilities that are defined as abnormalities in body function or structure that interfere with the activities of normal daily life. These disabilities can include physical, sensory, developmental, behavioral, or emotional conditions. They can range from mild to severe, depending on the nature and extent of the condition and its impact on daily living. Frequently the care requirements of both families and medical providers for children diagnosed with a disability are dramatically increased. For parents, the diagnosis of a disability in their child can be initially overwhelming and disappointing. Support of the parents is essential as they transition from disappointment to acceptance and assume the role of facilitator of their child's treatment plans.

Early identification of a disabling condition by physicians can lead to appropriate, definitive treatment for many disabilities. Early intervention can sometimes even prevent secondary conditions (eg, early management of hearing loss with hearing aids may minimize speech abnormalities). Even when such corrective treatment is not available, prompt identification improves children's long-term outcome

and allows families to obtain appropriate resources for their children. Through early intervention, infants and children with irreversible conditions can be introduced to medical, educational, and psychosocial services available in the community that serve to help each child maximize and reach full potential.

Epidemiology

The prevalence of children in the United States with SHCN is difficult to assess. Studies report that approximately 17% of children younger than 17 years have at least one disability, including deafness or hearing loss, blindness, cerebral palsy, physical malformations, speech impediments, developmental delay, and other learning problems. Comorbid conditions, such as epilepsy, and secondary conditions, such as behavior problems, have a very high incidence. An estimated 30% of disabled children have more than one disability. A single sensory disability, such as deafness, affects approximately 3.5% of children, and blindness occurs in 1% of children. The prevalence of cerebral palsy is 1.5 to 2 per 1,000 live births. Advances in

medical technology, as well as improved survival of low birth weight infants and children with malformations, have increased the number of children living with such disabilities. Environmental exposures have also increased the incidence of chronic medical conditions, such as asthma, which also produces SHCN.

The presence of SHCN has a profound impact on the health and education of affected children. Studies show that children with disabilities have 1.5 times more doctor visits and spend 3.5 more days in the hospital than children without these conditions. Children with disabilities miss twice the number of school days and are twice as likely to repeat a grade compared with children without disabilities.

In addition, numerous associated conditions occur more commonly in children with disabilities. These include mental retardation, growth failure, and nutrition problems. Problems with dentition, respiratory infections, and bowel and bladder continence may also develop. Significant emotional disturbances may occur as the child adapts to his condition.

Clinical Presentation

Children with disabilities can present in a variety of ways depending on their diagnosis. Many physical disabilities may be readily apparent at birth on the newborn examination or through newborn screening. Some diagnoses, such as cerebral palsy, may be detected later, as the motor impairment becomes more evident. Following development at routine health maintenance visits is essential for early detection of developmental delay. Children with disabilities can also present with chronic illness, such as asthma, and diabetes, or with specific complaints, such as poor vision or hearing. Their presentation may be for a more general concern, such as growth failure (Dx Box). Behavioral problems or difficulties in school may precipitate the initial visit.

Dx

Children With Physical and Sensory Disabilities^a

- Growth failure
- Microcephaly
- Abnormal neurologic examination, including hypertonicity, spastic diplegia or quadriplegia, and brisk deep tendon reflexes
- Developmental delay
- Speech or hearing deficit
- Visual deficit
- Physical malformations

^aMay not be present in all children.

Pathophysiology

The pathophysiology of disabilities is totally dependent on the disabling condition. Conditions may be secondary to an embryological defect, such as myelomeningocele, or an infection, such as congenital cytomegalovirus (CMV), which interferes with cochlear

development and leads to hearing loss. Etiologies are often multifactorial. For some conditions, autism being an example, the pathophysiology is unknown.

Disabilities may be classified as acquired or congenital, and static or progressive. **Cerebral palsy**, for example, is a group of nonprogressive neuromotor disorders resulting from a central nervous system insult prenatally or in the first 2 years of life. It is characterized by abnormal motor movements and posturing and may be accompanied by other problems. Causes of cerebral palsy include prematurity, low birth weight, asphyxia, prenatal abnormalities (eg, placental insufficiency), congenital infections (eg, toxoplasmosis, CMV), and biochemical abnormalities (eg, severe hyperbilirubinemia). Other causes are environmental (eg, alcohol [maternal alcoholism]) and genetic (eg, inborn errors of metabolism). Severe postnatal injuries or infections can also lead to cerebral palsy (eg, shaken baby syndrome and meningitis). However, an estimated 25% to 50% of cases of cerebral palsy have no discernible cause.

Diagnosis

The term **special health care needs** is used in a broad sense to include conditions that require additional medical care and supervision. The term was defined by the US Department of Health and Human Services Maternal and Child Health Bureau. Children may have significant physical, sensory, or developmental disabilities that may result from prematurity, congenital infections such as CMV, or exposure in utero to alcohol or illicit substances. Some children are born with inborn errors of metabolism that mandate special diets and occupational or physical therapy. Other children with SHCN include those with chronic medical conditions such as asthma and sickle cell anemia. All of these medical conditions alter lifestyle, require increased medical care including subspecialty care, increase medication usage, and use community services beyond the general pediatric population.

Evaluation

History

When initially evaluating children with newly diagnosed disabilities, practitioners should first determine any specific parental concerns. A complete medical history should then be obtained, including information about the pregnancy and birth. The history should also include any possible exposures as well as significant infections. General screening questions about development are also important to ask (Questions Box) so that the child's developmental progress can be assessed. Specific questioning is warranted if parents are concerned about delayed development or if any of their responses indicate that their children are not attaining age-appropriate developmental milestones.

In cases of children with known sensory or physical disabilities, families should be asked directly at each visit about daily activities and the child's ability for self-help skills. Because many children with

Questions

Children With Special Health Care Needs

- Were there any perinatal complications, such as premature rupture of membranes or fetal distress?
- Was the infant born prematurely? If so, how long did the infant remain in the hospital and for what reasons?
- Was the infant exposed to any toxins (eg, alcohol, illicit drugs) in utero?
- Is there any history of infection during the perinatal period or infancy?
- What developmental milestones has the infant or child mastered?
- Is the child attending school or some type of early intervention program?
- How does the child get there?
- What does the child do on returning from school?
- Who feeds and bathes the child?
- Can the older child use the toilet without assistance?
- How is the child sleeping? Does the child take naps at school and at home?
- Has respite care been arranged for the family?
- Does the caregiver seem overwhelmed or excessively tired, especially one who is caring for a child with multiple disabilities?
- Do other family members help care for the child?
- Is the extended family available to help with the siblings?
- Are there any other disabled people in the family?
- Does the family receive any financial assistance for care of the child?

disabilities are also on daily medication for either seizures or other chronic conditions, it is also important to ask about the presence of any side effects of drugs.

Behavioral or emotional problems that the child might be having should be identified. In addition, an overall assessment of family dynamics should be made. It is important to inquire about the relationships between children with disabilities and their siblings, as well as the impact these children have on the parents' marriage.

Physical Examination

In general, a complete physical examination, including a neurologic assessment and neuromotor examination, should be performed at each visit. The height, weight, and head circumference should be plotted on the growth chart and compared with previous measurements. A failure of adequate growth as measured by any of these parameters should be examined closely. For example, microcephaly, nutritional problems, and growth failure are not uncommon in children with cerebral palsy. Depending on the disability, the examination should then focus on physical findings associated with the particular condition. For children with physical disabilities such as congenital or acquired amputations, for instance, assessment of the skin that comes in contact with prosthetic devices is a pertinent aspect of the physical examination. Pressure sores may be found in

non-ambulatory children with cerebral palsy. In children with sensory disabilities such as unilateral hearing loss, the evaluation of a middle ear effusion or infection in the unaffected ear should be a priority. If a child has a tracheostomy or gastrostomy tube, inspection of the site is essential at each visit to look for erosions or skin infections.

Overall, for most children with disabilities, the neurologic examination is extremely important. The following questions should be addressed: Are normal primitive reflexes such as the Moro and rooting reflexes present in neonates? Have all primitive reflexes been extinguished in older children? Do infants appear to visualize and track objects appropriately? Are there any abnormal movements of the trunk or extremities at rest? Is the muscle tone normal? Is any hypertonicity or hypotonicity evident? Is any asymmetry of the upper and lower extremities apparent? Are the deep tendon reflexes normal and symmetrical? Is the gait appropriate for age?

An age-appropriate developmental assessment is also an essential part of the examination at all health maintenance visits.

Laboratory Tests

The laboratory evaluation of infants or children with physical or sensory disabilities depends on the specific condition. Not all patients need a costly array of diagnostic procedures. A **chromosomal karyotype** using peripheral blood is helpful in children with suspected genetic disorders (eg, abnormal facies or a major anomaly and developmental delay). Routine testing for fragile X syndrome in all mentally retarded boys and in girls with a family history should be strongly considered. Other testing should be specific, relating to the suspected diagnosis (see Chapter 69).

Metabolic screening for inborn errors of metabolism should be performed on children with mental retardation and any of the following symptoms: intermittent vomiting or lethargy, loss of developmental milestones, or seizures. Such screening is not needed in the routine evaluation of children with developmental delay and no other symptoms.

A screening test for visual acuity (Snellen test) and hearing (audiogram) should be performed in all children suspected of having sensory deficits, even mild ones. For infants or toddlers, a brain stem auditory evoked response or behavioral audiogram is a more appropriate screening test for hearing. A visual evoked response can be performed to test vision.

Psychometric testing may be helpful in certain school-aged children to assess intellectual function.

An electroencephalogram is indicated in all patients who have a history of seizures or seizure-like episodes.

Imaging Studies

Brain imaging studies, such as magnetic resonance imaging scans of the head, can be informative when intrauterine infection, intraventricular hemorrhage, or genetic disorders with associated developmental delay and even isolated global developmental delay are suspected. An electromyogram can be used to differentiate cerebral palsy from a congenital myopathy.

Management

Caring for children with either a single disability or multiple disabilities can be both a rewarding and challenging task for primary care pediatricians. The pediatrician should be cognizant that the patients will take increased practice time and paperwork to ensure that they receive all services necessary. Case management services are an essential aid to their management. The primary care provider needs to supervise both acute and chronic medical care, provide anticipatory guidance, monitor growth and development, coordinate subspecialty involvement, and offer community services. Sometimes a subspecialist will provide comprehensive care. Although all cases should be handled individually, general guidelines have been developed for the provision of pediatric services for infants and children with SHCN. They include recommendations for establishing a medical home with the primary care provider, medical services, suggestions for parental involvement, assistance from community agencies, and fulfillment of specific federal requirements for educational opportunities for children with disabilities. Pediatricians who care for children with SHCN should be familiar with the principles of care, published by the American Academy of Pediatrics (AAP), and should incorporate these principles into the overall treatment plan. Pediatricians should also be knowledgeable about the rights of such individuals as established by various legislation, including the Americans with Disabilities Act. Coordination of intervention services and the use of adaptive or assistive technology are essential components of management.

General Considerations

The major role of primary care pediatricians who care for children with disabilities is 4-fold: (1) provide primary medical care, (2) serve as the patient and family advocate in evaluating therapeutic options, (3) inform families of available community resources and, most importantly, (4) serve as a proactive coordinator of care. The first task of the pediatrician is to establish the diagnosis and recognize comorbid conditions. Whether the diagnosis is an obvious physical malformation or one that is not readily apparent, physicians are placed in the challenging position of breaking the news to families. Parents should be informed of the diagnosis as soon as possible, but care should be taken to refrain from discussing the prognosis, especially if it is still unknown. The cause of any disability and the possible complications of the condition should be reviewed with the parents. *The primary goal is to help children with disabilities reach their full potential.*

Health care providers are in a unique position to establish a treatment plan with families that includes medical, psychosocial, and educational services. A multidisciplinary team that includes the pediatrician, a member of the school system, a social worker, and a representative of an early intervention program should be identified. Federally funded, nonprofit, regional centers can provide an organized treatment plan and entry into an early intervention program to some children with disabilities. To qualify, children must be diagnosed with an eligible condition, such as cerebral palsy, epilepsy,

autism, or global developmental delay. In addition, infants considered at risk for developing disabilities qualify for assistance (eg, premature infants with bronchopulmonary dysplasia and intraventricular hemorrhage). For children who do not qualify, similar services can be coordinated on an individual basis by the physician's office or the school district.

Children with severe physical and sensory disabilities are often cared for by many medical subspecialists in addition to primary care pediatricians. Referrals to pediatric orthopedic surgeons, plastic surgeons, geneticists, ophthalmologists, otolaryngologists, child neurologists, and psychologists may be necessary. Special comprehensive clinics, such as craniofacial or spina bifida, are established in some children's referral centers to facilitate care of patients, with multiple subspecialists forming a multidisciplinary team in the same clinic setting. In addition, speech and language therapists, occupational therapists, and physical therapists are often an integral part of the medical team. Initial and ongoing therapeutic services provided by each of these individuals must be monitored periodically to assess the progress and overall effectiveness of the treatment plan. Ideally, services should be coordinated so that children as well as parents miss a minimum number of school days and workdays (eg, Saturday and after-school appointments, visits to several providers on 1 day). All information from diagnostic studies and initial evaluations should be shared among each of the health care providers. The AAP has published a Care Coordination Toolkit, which can be very helpful to the primary provider.

The primary care physician should also offer counseling to parents regarding ethical issues as they pertain to the child's condition. These issues include palliative care decisions, decision-making in critical care situations, limiting non-beneficial interventions at the end of life, and advance directives. Because of the pediatrician's relationship with the family, he may be in the best position to engage parents in conversations concerning these topics.

The family has a vital role in caring for the disabled child, and the care can frequently be stressful and emotionally draining. Family support and counseling should be readily available. The sociocultural context of the family and the needs of the other children in the family should be considered when the care of the child with SHCN is addressed.

With improved medical care and services 90% of children with SHCN reach adulthood. The transition into adult services can be challenging. Preparation for this transition should begin as early as 11 years of age to ensure success. The goal should be independence to the degree that is possible. The individual should be prepared for a work environment if possible and financial independence. The family and child should be evaluated to determine whether the child is capable of independent living, a group home, an institution, or remaining with the family. If necessary, guardianship issues must be addressed. A successful transition to adult health care providers must be ensured, and insurance coverage must be arranged. The Affordable Care Act of 2009 addressed a number of insurance concerns including extending the age of coverage for dependent children until 26 years, preventing exclusion from coverage

based on preexisting conditions, and prohibiting lifetime caps on medical expenses.

Economic Concerns

The cost of care for children with disabilities places a significant financial burden for as many as 40% of these families in the United States. Families with an affected child are more likely to have a single income, have a single parent, live in poverty, and have poor-quality housing. Economic evaluation should be performed by the caseworker to determine the eligibility of children with SHCN for financial support through Supplemental Security Income and medical insurance under Medicaid. The caseworker can then assist families to apply for the appropriate assistance or to other programs such as food stamps and the Low Income Home Energy Assistance Program, which can help extend a family's resources.

It is apparent that children with SHCN from low income families have decreased access to health, educational, and social services. Recent studies have been undertaken to determine the best strategy to improve access to services and availability of services for underserved communities.

Specific Medical Conditions

A number of medical conditions commonly occur in children with moderate to severe disabilities. While providing children with comprehensive well-child care, general pediatricians can also address and treat these conditions.

Problems with adequate nutrition, which usually result from insufficient caloric intake, are manifested by growth failure. Depending on the degree of disability and amount of oropharyngeal dysfunction, the placement of a nasogastric or gastrostomy tube may be necessary. Caloric needs may be 10% to 50% higher than normal basal needs to ensure growth.

Respiratory illness is not uncommon among these children. Close observation and conservative treatment of viral illnesses are often necessary. Aspiration pneumonia is likely to occur, especially in children with severe developmental delay because of poor handling of oral secretions or severe oral dyspraxia. To help minimize respiratory infections, influenza vaccine should also be administered during the winter months.

Maintaining good oral hygiene is another challenge because some children with disabilities do not clear oral secretions well and retain food in their mouths, predisposing to cavity development. In addition, many children are treated with anticonvulsants and antibiotics that can cause gingival and enamel dysplasias. Abnormal oromotor coordination, tone, and posturing also contribute to the development of oropharyngeal deformities, such as high-arched palate and overcrowded teeth. As with other children, fluoride supplementation and consistent preventive dental care are recommended.

Bowel and bladder continence is important to attain for several reasons. It allows children to function in a socially acceptable fashion; provides independence; and prevents the development of complications such as recurrent urinary tract infections, diaper dermatitis, and decubitus pressure sores. Behavior modification

techniques coupled with positive reinforcement are associated with complete or partial success for bowel training.

Community Resources

Optimal care for children with developmental disabilities depends on maximum use of community agencies and resources. An assessment of parental and patient needs should first be performed and prioritized. The appropriate resources should then be identified for individual children. Early intervention services should be used. Primary care physicians may need to help determine the appropriateness of specific services for patients and families. Emphasis should be placed on integrating each child into support services. Parent-to-parent support and support groups can be very helpful in relieving stress, helping parents to understand the disability, and avoiding feelings of isolation. Support groups for siblings as well as parents are available. Respite care to give parents a break from caregiving and in-home health service programs should also be investigated. Hospice care in the home is now available for children near the end of life. It can be an excellent support for the patient and family. Physicians should act as liaisons between all agencies. Case conferences are occasionally necessary to review the progress of individual children with each member of the health care team.

Education

By federal law, every child with a disability is entitled to an education. Every effort should be made to enroll children with disabilities in conventional schools and to provide opportunities for socialization at an early age. The concept of structured independence and mainstreaming, the placement of disabled children in classes with nondisabled children, can be a very productive setting for the child as well as their schoolmates.

Mainstreaming may not be available in some areas, and the severity of some disabilities may not allow attendance on a regular school campus. Then several other educational possibilities can be considered, and each case should be evaluated on an individual basis. Options include special education classes in designated schools (full- or part-time), special education classes in regular schools (full- or part-time), part-time special education classes and part-time regular classes, or home education. The decision can be facilitated through the development of an Individualized Education Plan by a multidisciplinary team at the school. Parents and primary physicians are encouraged to participate in this evaluation (see Chapter 31).

Prognosis

The prognosis for children with SHCN is dependent on the diagnosis, the severity and extent of any disability, medical and supportive intervention, and the environment of the child. It may be impossible to establish a prognosis at the time of diagnosis. Children can adapt differently to the same disability. It is important to establish realistic goals to determine the best intervention. Most affected children are able to lead productive, independent lives when they receive adequate early intervention and education.

CASE RESOLUTION

Although the girl's medical condition of low lumbar spina bifida seems stable, the physician should inquire about any ongoing problems or concerns. A complete examination should be done. Routine screening laboratory tests and immunizations required for school entry should be performed. The family should be evaluated for financial stability and support services. The mother should be placed on folate supplementation for prevention of recurrence in future children. The patient should be referred to the local spina bifida clinic for comprehensive specialist care by orthopedics, urology, and physical therapy. Integration into the regular classroom should be recommended. The school should be contacted to arrange for adaptive physical education and for intermittent catheterization by school nursing personnel. A follow-up visit is scheduled with the primary care physician in 2 months to review the child's integration into services.

Reproductive Health¹

Monica Sifuentes, MD

CASE STUDY

An 18-year-old female college student in good health comes in for a routine health maintenance visit during her spring break. She is unaccompanied by her parents and has no complaints, stating that she just needs a checkup. She enjoys college, passed all of her fall and winter classes, and has some new friends. She denies tobacco use but says most of her friends smoke. She occasionally drinks alcohol and has tried marijuana once. Although she is not sexually active, she is interested in discussing oral contraception. Her last menstrual period, which occurred 2 weeks ago, was normal. She is taking no medications. Her physical examination is entirely normal.

Questions

1. What issues are important to discuss with adolescents at reproductive health maintenance visits?
2. What are the indications for a complete pelvic examination?
3. When is a Pap smear indicated as a part of the reproductive health visit?
4. What methods of contraception are most successful in adolescent patients? What factors regarding each method should be considered?
5. What are the legal issues involved in prescribing contraception to minors in the absence of parental consent?

Adolescent visits to primary care physicians are relatively infrequent by the time teenagers reach puberty. At most, healthy adolescent patients are seen once or twice during high school for preparticipation sports or camp physicals. If adolescents are not involved in athletics or if their schools do not require periodic assessments, these teenagers will probably never visit their health care providers again while in high school. Therefore, it is extremely important to use any interaction with an adolescent as a unique opportunity for anticipatory guidance and health education, particularly reproductive health education.

Reproductive health can be defined as sexuality-related services, screening, and counseling. Such services should be included as a part of the routine health maintenance examination for both male and female adolescents for several reasons. The high incidence of sexually transmitted infections (STIs) in this age group, the risk of acquiring HIV, and the reality of an unplanned pregnancy make reproductive health issues increasingly important for teenagers. In addition, adolescents rarely schedule appointments with health care providers prior to the initiation of coitus. Experimentation with drugs and alcohol at this time in their lives also contributes to early, unplanned sexual experiences (Box 40-1).

Aside from issues of sexual activity, adolescents also may have questions about their progression through puberty. Normal variants

in body habitus or certain physical characteristics can be a source of unnecessary anxiety for uninformed teenagers. Health education to alleviate these fears is ideal. Adolescents who come for physical examinations should be allotted extra time so that topics such as puberty, abstinence, sexual activity, STIs, and contraception can be discussed. In addition, during more acute, problem-oriented visits, adolescents should be encouraged to voice any other concerns they may have. Depending on the nature of these issues, follow-up appointments can be scheduled.

Normal Secondary Sexual Development

Puberty begins during early adolescence with the development of secondary sexual characteristics. Because there can be tremendous variation with regard to the age, duration between pubertal stages, and somatic growth of adolescents, a sexual maturity rating (SMR) scale (Tanner staging) is used to describe breast and pubic hair development in females and genital development and pubic hair growth in males (Figures 40-1, 40-2, and 40-3). The average age of menarche in the United States is 12.5 years and for most females occurs during SMR 3 and 4. In contrast, spermarche occurs early in pubertal development in boys, at approximately 13 years of age, with little to no pubic hair development. Full fertility is generally achieved by age 15 years, or mid-adolescence, in most boys and girls.

¹This chapter is largely devoted to a discussion of the reproductive health of adolescent females. However, Evaluation is divided into 2 sections—one for females and one for males. The reader is referred to Chapter 97 for more information regarding male reproductive health.

Box 40-1. Reproductive Health: Sexual Activity

Statistics regarding sexual activity among adolescents in the United States have changed over the last decade. Previously it was reported that 1 in 4 females and 1 in 3 males had had sexual intercourse by 15 years of age. Currently only 13% of teens have ever had vaginal intercourse by age 15 according to the Guttmacher Institute. Most adolescents are now waiting until later to initiate sexual activity; by their 19th birthday, 7 in 10 teens of both sexes have had sexual intercourse. Contraceptive use at first premarital sexual encounter has increased to almost 80% in adolescent females and 87% in adolescent males; however, unintended pregnancy and sexually transmitted infections (STIs) continue to be a major public health concern for this age group. While the pregnancy rate among teenagers has dropped steadily over the past 10 years, each year almost 850,000 adolescent females younger than 20 years become pregnant. Most of these pregnancies are unintended and occur premaritally, especially among certain racial and ethnic minority groups. The outcome of these pregnancies in 15- to 19-year-olds varies. An estimated 50% to 60% of these pregnancies result in live births, 30% end in abortion, and 10% to 15% are miscarried or stillborn.

Unprotected sexual activity among adolescents has several adverse health consequences, the most obvious being teenage pregnancy. Of the adolescents who continue their pregnancies, prematurity (<37 weeks' gestation) and low birth weight (<2,500 g) are 2 of the most frequently reported neonatal complications. Long-term maternal psychosocial sequelae of adolescent pregnancy include undereducation/school failure, limited vocational training and skills, economic dependency on public assistance, subsequent unwanted births, social isolation, depression, and high rates of separation and divorce among teenaged couples.

In addition to unintended pregnancy, the risk of contracting an STI, such as chlamydia, human papillomavirus, herpes, and HIV, is increased. In cases of pelvic inflammatory disease from gonorrhea or chlamydia, future problems with fertility and an increased risk of ectopic pregnancy can occur. Human papillomavirus, which is associated with the development of genital warts, cervical dysplasia, and cancer, accounts for about half of STIs diagnosed in adolescents and young adults. The prevalence rates of other STIs, such as chlamydia and gonorrhea, are still highest among 15- to 19-year-old females compared with older age groups in the United States. More alarming, however, is the relationship between AIDs in young adults aged 20 to 29 and probable exposure to HIV during adolescence.

Many factors have been associated with the initiation of early coitus in adolescents. They include male gender; race/ethnicity; poverty; a large, single-parent family; previous teen pregnancy in the household (either mother or sibling); poor academic achievement; discrepancy between the onset of physical puberty and cognitive development; peer group encouragement; and problem behaviors such as drug use. In addition, religious affiliation and cultural norms probably influence this decision. The role of hormonal changes during puberty and their influence on behavior is yet to be determined.

An estimated 10% to 20% of adolescents have limited typical functioning because of a disability or chronic illness by the age of 20 years. However, most of these adolescents experience normal pubertal development and fertility because of advances in medical treatment for conditions such as diabetes and sickle cell disease. Like their healthy peers, many of these adolescents begin sexual intercourse at an early age. Pregnancy and childbirth can exacerbate some illnesses and increase risks significantly for both adolescents and fetuses. The genetic implications and specific patterns of inheritance of certain chronic conditions must also be considered. For this reason, attention to sexual issues is essential for adolescents with chronic medical illness.

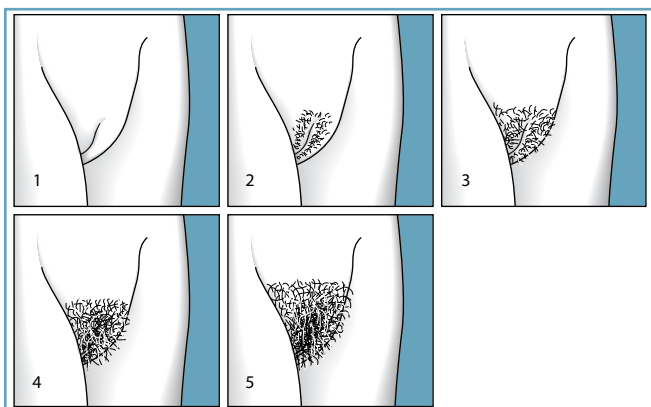

Figure 40-1. Female pubic hair development. Sexual maturity rating 1: prepubertal, no pubic hair. Sexual maturity rating 2: straight hair is extending along the labia and between ratings 2 and 3, begins on the symphysis pubis. Sexual maturity rating 3: pubic hair is increased in quantity; is darker, coarser, and curlier; and is present in the typical female triangle. Sexual maturity rating 4: pubic hair is more dense, curled, and adult in distribution but is less abundant. Sexual maturity rating 5: abundant, adult-type pattern; hair may extend on the medial aspect of the thighs.

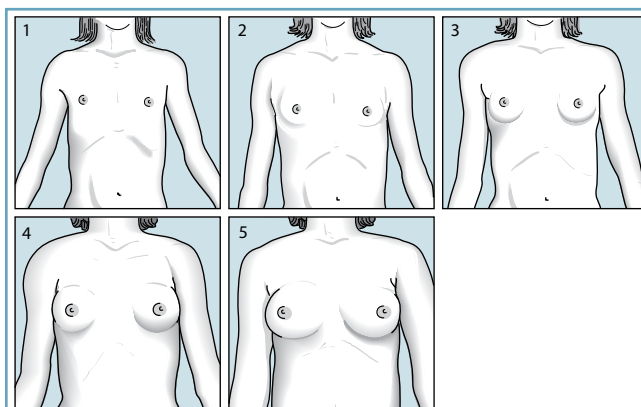

Figure 40-2. Female breast development. Sexual maturity rating 1: prepubertal, elevations of papilla only. Sexual maturity rating 2: breast buds appear, areola is slightly widened and projects as small mound. Sexual maturity rating 3: enlargement of the entire breast with no protrusion of the papilla or of the nipple. Sexual maturity rating 4: enlargement of the breast and projection of areola and papilla as a secondary mound. Sexual maturity rating 5: adult configuration of the breast with protrusion of the nipple, areola no longer projects separately from remainder of breast.

Figure 40-3. Male genital and pubic hair development. Sexual maturity rating 1: prepubertal, no pubic hair, genitalia unchanged from early childhood. Sexual maturity rating 2: light, downy hair develops laterally and later becomes dark, penis and testes may be slightly larger, scrotum becomes more textured. Sexual maturity rating 3: pubic hair is extended across pubis, testes and scrotum are further enlarged; penis is larger, especially in length. Sexual maturity rating 4: more abundant pubic hair with curling, genitalia resemble those of an adult, glans has become darker. Sexual maturity rating 5: adult quantity and pattern of pubic hair, with hair present along the inner borders of the thighs. The testes and scrotum are adult in size.

Evaluation

History

The history obtained at a reproductive health visit should include 2 parts: the medical history, which focuses primarily on the gynecologic history in females, and the psychosocial interview. Regardless of the type of visit scheduled, practitioners should take a few moments at the beginning of the interview to address routine health maintenance issues with the adolescent (Questions Box: Reproductive Health). The provider should find out whether the female adolescent has ever had a genital or pelvic examination. In addition, current methods of contraceptive use, if any, should be reviewed (Questions Box: Contraceptive Use). If the adolescent female takes oral contraceptives, a review of the more emergent complications of birth control pills is warranted, especially at an initial visit. **ACHES** (*abdominal pain, chest pain, headaches, eye problems, severe leg pain*) is a useful acronym to remember life-threatening reactions that can be associated with hormonal contraceptive use (Box 40-2), although they occur uncommonly in otherwise healthy adolescent girls.

The rest of the psychosocial history, otherwise known as the **HEADSSS** interview (*home environment, employment and education, activities, diet, drugs, sexual activity/sexuality, suicide/depression, safety*), should be completed whether or not the adolescent is currently sexually active (see Chapter 6). Risk factors for an unplanned pregnancy or unintentional exposures to STIs should be kept in mind when formulating health care plans with the teenager.

Questions

Reproductive Health

For males and females

- How is the adolescent feeling overall?
- Has the adolescent had any recent illnesses or conditions that the health care provider should know about?
- When was the last physical examination performed? Did it include a genital or pelvic examination?
- Is the adolescent sexually active?
 - If so, when was the last episode of vaginal intercourse?
 - Was the last episode of sexual intercourse protected or unprotected?
 - Does the adolescent have anal or oral sex?
 - How old was the adolescent when he or she initiated coitus? Was it consensual?
 - How many sexual partners does the patient have currently? How many sexual partners have they had in their lifetime? What gender are they (all contacts may not be heterosexual)?
- Is there any history of physical or sexual abuse?
- Has the adolescent or any of his or her partners ever been treated for a sexually transmitted infection or tested for HIV?

For females only

- What was the age at menarche?
- What was the date of the last menstrual period and the duration and amount of flow?
 - Are any symptoms such as cramping, bloating, or vomiting associated with menses?
 - Are any of these symptoms incapacitating? Do they cause the adolescent to miss school or work?
 - Does the mother or siblings have similar problems? If so, how do they manage them, if at all?

Questions

Contraceptive Use

- Does the adolescent use condoms: never, sometimes, or always?
- Is any other method, such as spermicidal foam or jelly, also used?
- Is the adolescent female currently using oral contraceptives?
 - If so, what particular type is she taking, and how long has she been using this method of contraception?
 - How often does she forget to take the pill? or What does she do when she forgets to take the pill?
 - Does she experience common minor side effects such as breakthrough bleeding or nausea?
- Is the adolescent female using a long-acting progestin, such as Depo-Provera? If so, has she experienced irregular bleeding, weight gain, hair loss, headache, or acne?
- Is there another method of contraception that the adolescent has used or might be interested in discussing and/or starting?
- What does the adolescent know about emergency contraception?

Box 40-2. Danger Signs Associated With Oral Contraceptive Use

- A** Abdominal pain (severe)
- C** Chest pain (severe), shortness of breath
- H** Headaches
- E** Eye problems (visual loss or blur)
- S** Severe leg pain (calf/thigh)

Physical Examination

A complete physical examination should be performed on all adolescents, with particular attention paid to their SMR. Chaperones are strongly encouraged, with the permission of the patient, even when the patient and examiner are the same gender, particularly during the breast and genital examination.

Males

The genitalia should be examined closely for penile and testicular size; distribution of pubic hair; and presence of any ulcerative, vesicular, or wart-like lesions. Any urethral erythema or discharge should be noted. Testicular masses require further evaluation. Ideally, clinicians should use this opportunity to teach male adolescents how to perform a testicular self-examination.

Females

Prior to performing the physical examination, the physician should determine whether a full-speculum examination is indicated (Box 40-3). This decision should be based on the details of the individual case and not solely on the basis of sexual activity. With the advent of noninvasive screening methods for STIs, a routine pelvic examination is often unnecessary. Most experts now recommend the use of urine-based nucleic-acid amplification tests (NAATs) to screen for gonorrhea or chlamydia instead of endocervical swabs. However, if a speculum examination is indicated, proper preparation of the adolescent is imperative. This should include an explanation of the procedure and the physical sensations felt while the endocervical specimen is being obtained. The choice of who should be present during the examination (eg, parent or friend who may have accompanied the patient), and a discussion of the desired positioning (ie, supine vs semisitting) are also important points to review. In addition, the speculum, specimen swabs, and other equipment should be shown to the adolescent before she is draped. The goal is to minimize the adolescent's fears, anxieties, misconceptions, and discomfort regarding the examination.

A breast examination should be performed on female adolescents, and any breast tenderness, nodularity, or masses should be noted. Again, this portion of the examination can be used to educate patients about the purpose and importance of breast self-examinations and to document breast SMR.

The external genitalia should be examined in all adolescent females whether or not they are sexually active. The SMR and any congenital anomalies, such as an imperforate hymen, should be identified. In sexually active adolescents, the external genitalia should be carefully

Box 40-3. Indications for a Complete Pelvic Examination

- Pregnancy
- Request by the adolescent
- Unexplained lower abdominal pain
- Persistent abnormal vaginal discharge
- Unexplained vaginal bleeding
- Dysmenorrhea, unresponsive to nonsteroidal anti-inflammatory medications
- Suspected or reported sexual assault
- Perform a Pap test

examined for warts, ulcers, and vesicular lesions. Any urethral erythema, edema, or discharge that may indicate an otherwise asymptomatic chlamydial infection should be noted. If a pelvic examination is indicated, a vaginal discharge may be appreciated prior to inserting the speculum but, ideally, the cervix should be examined for cervical ectopy, friability, and any lesions or discharge from the os. The vaginal mucosa should also be inspected as the speculum is withdrawn.

During the bimanual examination, the cervix should be palpated for any cervical motion tenderness. Uterine size and position should be appreciated, and adnexal tenderness or masses should be noted. Because normal ovaries are approximately the size of almonds, they are often not palpated by many clinicians. A rectovaginal examination is necessary to rule out fistulas, especially in postpartum adolescents. If the practitioner is unable to perform a vaginal bimanual examination, a rectoabdominal examination can be done to assess uterine size and position and the presence of adnexal masses.

Laboratory Tests

Because most *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections in adolescents are asymptomatic, screening noninvasive urine-based NAATs should be sent annually in all sexually active adolescents, and more frequently in those who have a history of unprotected intercourse and/or a new sexual partner. If the adolescent has vaginal discharge or cervical friability noted on speculum examination, the specimen should be obtained directly from the cervix and sent for NAAT. A saline and KOH wet mount should also be collected in symptomatic patients. A Pap smear should be performed in sexually active females who are 21 years of age. The Pap smear can also help detect *Trichomonas vaginalis* or the cytological changes associated with human papillomavirus (HPV). A NAAT (eg, polymerase chain reaction) for herpes simplex virus (HSV) should be performed if painful vesicles are noted on examination.

Other laboratory tests include a rapid plasma reagin test for syphilis and an HIV screening test (after appropriate pretest counseling). Baseline complete blood cell count, liver function tests, cholesterol, and fasting glucose may be indicated as part of the health maintenance visit but are not required before starting contraception. A pregnancy test is warranted in sexually active females if the practitioner chooses to begin oral contraceptives or another method of hormonal contraception mid-cycle.

Management

Reproductive Health Education

All management plans during reproductive health visits should include a frank **discussion of puberty, sexuality, and STIs** regardless of current sexual activity. The adolescent should be counseled about abstinence as an acceptable choice. Ideally, preventive health care measures such as **breast and testicular self-examinations** have been reviewed during the physical examination. It is hoped that by encouraging adolescents' familiarity with these self-examinations, they will continue to perform them throughout their adult lives. The use of posters, plastic models, and electronic or written materials to support the discussion is greatly encouraged. The goal of education should be to assist adolescents in identifying and communicating their thoughts and feelings about sexual abstinence as well as sexual activity and to aid in the prevention of unintended pregnancy, parenthood, and STIs. Prevention programs offered by schools must be supplemented by open parental communication in the home about sexuality.

Legal Issues

The issue of **confidentiality** is important to consider when providing reproductive health care for adolescents. Parental involvement should be strongly encouraged, but health care practitioners are not required to disclose any information to parents except in cases of suicidal ideation, harmful intent to others, and sexual or physical abuse. In most states, contraceptive services can be provided to adolescents of any age without specific parental knowledge or consent. The complex issue of parental consent and pregnancy termination varies from state to state and should be reviewed by the individual health care provider. Of note, all 50 states including the District of Columbia explicitly allow minors to consent for their own health services for STIs and do not require parental consent for STI care. Providing confidential care for adolescents enrolled in private health insurance plans, however, continues to be a difficult issue because many states mandate that health plans provide a written statement to the beneficiary regarding the services covered and received, including clinical services provided confidentially to teens.

Pap Smear

The 2009 recommendation of the American College of Obstetricians and Gynecologists (ACOG) is that cervical cancer screening should begin at 21 years of age in young women. However, the American Cancer Society continues to recommend that young women start cervical screening with Pap tests 3 years after the onset of vaginal intercourse, and no later than age 21 years. After the initiation of screening, a Pap smear for average-risk women aged 21 through 29 years should be performed every 2 years, and every 3 years for women 30 years and older with 3 consecutive normal cervical cytology test results. The rationale for the most recent changes in cervical cancer screening by ACOG is that there seems to be little risk in not treating abnormal cervical cytology in adolescents since 90% to 95%

of low-grade lesions, as well as many high-grade lesions, in this age group regress to normal without treatment. Screening prematurely can lead to an overdiagnosis of cervical dysplasia and an overtreatment of lesions with potentially harmful procedures such as excision or ablation of the cervix. Since the incidence of cervical cancer is very low among adolescents, the benefits of Pap screening are offset by the potential harm of unnecessary treatments in this age group.

Contraceptive Methods

The appropriate method of contraception should be individualized. Barrier methods include condoms (male and female), diaphragms, and cervical caps. Vaginal spermicides such as nonoxynol 9 are available in a variety of forms (foams, gels, films, and suppositories) and should be used with a barrier method since there are general concerns that these products in high doses can increase the risk of genital ulceration and irritation, thereby facilitating STI acquisition. Hormonal contraceptive methods include oral contraceptives, long-acting progestin agents, transdermal methods, and the intrauterine device. Although previously not recommended for teens, a levonorgestrel intrauterine device may be indicated in postpartum teenagers as well as for the treatment of severe dysfunctional uterine bleeding. The withdrawal method, or coitus interruptus, and natural family planning are ineffective methods for adolescents for protection against pregnancy.

Hormonal Contraception

Combined low-dose oral contraceptives are an effective means of birth control for adolescents, with most pills containing 20 µg to 35 µg of ethinyl estradiol (estrogen) and a progestin. Monophasic pills contain a fixed dose of estrogen and progestin throughout the 21-day pill cycle. Biphasic preparations contain a lower dose of the progestin component during the first 10 days of the cycle, but are rarely used in teens. In triphasic pills, the doses of both estrogen and progestin or the progestin component alone are varied 3 times throughout the cycle. This contraceptive was created to decrease the overall progestin-related side effects, such as hypertension, acne, and lipid abnormalities. Most recently, lower-dose estrogen (20 µg) pills have been developed to minimize estrogen-related side effects and decrease discontinuation rates. Although 20 µg estrogen pills are now considered the "first-line" therapy for most teens, their lower efficacy must be taken into account in patients concurrently receiving medications that increase the metabolism of synthetic steroids, such as anticonvulsants. Other combined oral contraceptive regimens include 3-month continuous hormonal therapy followed by 1 week of withdrawal bleeding for young women who prefer to menstruate only 4 times a year (an extended-cycle pill). To lessen the frequency of breakthrough bleeding often experienced by users of the extended-cycle pill, another product is now available that replaced the placebo pills with 7 days of low-dose estrogen. Progestin-only pills, referred to as the "minipill," also are available and particularly useful in postpartum and lactating teen mothers. Clear benefits associated with oral contraceptive use include prevention of pregnancy,

protection against ovarian and endometrial cancers, decreased risk of functional ovarian cysts, and decreased menstrual symptoms, such as dysmenorrhea. The potential risks, which include thromboembolic phenomena, hypertension, and changes in the lipid profile, are minimal in most healthy adolescents compared with the morbidity and mortality associated with teenage pregnancy and childbirth.

The long-acting progestin depot medroxyprogesterone acetate (DMPA) (Depo-Provera) is given intramuscularly every 11 to 13 weeks to inhibit ovulation; a subcutaneous formulation is also available and should be repeated every 12 to 14 weeks. The most common side effect is irregular menstrual bleeding, especially in the first few months, and eventual amenorrhea with prolonged use. Weight gain remains a significant issue for some patients and clinicians, particularly in obese adolescents where exaggerated increases in weight can be seen. Breast tenderness and mood disturbances also can occur, but less frequently. In 2004 the US Food and Drug Administration (FDA) issued a black box warning for DMPA regarding possible irreversible bone loss in women with long-term use of DMPA and a potential reduction in overall bone mineral density (BMD) in teenagers that may contribute to the development of osteoporosis later in life. The FDA therefore recommends that DMPA should not be used in adolescents for longer than 2 years; however, many experts believe that the risk for pregnancy using an inferior method of birth control far outweighs the risk for the development of osteoporosis in a healthy teenager. Ongoing studies suggest that although adolescents may not increase their BMD while receiving DMPA and do experience bone loss, the effects appear to be temporary and reversible with the discontinuation of DMPA.

A subdermal implant (Implanon) received approval by the FDA in 2006 and is available for young women. It is designed to deliver a low, steady dose of continuous progestin for 3 years via a single plastic polymer rod placed below the skin. Formal instruction for insertion and removal is required for the health care professional interested in providing this form of contraception. The subdermal implant is highly effective but, as with other long-acting progestin-only contraceptives, it is associated with bleeding abnormalities, especially during the first year of use.

Other combined hormonal contraceptive methods for the adolescent include the vaginal ring (NuvaRing) and the transdermal patch (Ortho Evra). Approved in 2001, the vaginal contraceptive ring is a soft, flexible device that contains both estrogen and progestin, which is released directly into the vaginal wall. The ring is inserted into the vagina for 3 weeks, and then removed for 1 week to allow for a withdrawal bleed. Systemic side effects are similar to other low-dose combined hormonal methods (headache, breast tenderness, nausea, breakthrough bleeding/spotting); specific local effects include vaginal discharge and discomfort.

The transdermal adhesive patch is a thin, beige, 3-layered plastic patch that contains both estrogen and progestin and is applied weekly to specific areas of the body (lower abdomen, upper torso, upper arm, or buttocks) followed by 1 week off. Although well tolerated, high detachment rates in teens have been documented. In addition, adolescents may have concerns regarding the visibility of

the patch. Side effects are similar to other combined hormonal methods of contraception; local effects include skin irritation and rash at the site of application. Recent concerns have been cited by the FDA regarding the risk of venous thromboembolic events associated with the patch, although conflicting data have been reported. The reader is referred to the article by Trenor et al in Selected References for a comprehensive review of this topic.

Emergency Postcoital Contraception

Emergency contraception (EC), or the “morning-after pill,” is an effective way to prevent unintended pregnancy in adolescents. It requires, however, that the physician educate teens about its availability and usage and that teens feel comfortable contacting their health care provider within 72 to 120 hours of unprotected or inadequately protected intercourse. Although not meant to be used repeatedly as the sole method of contraception, EC is useful for the “unplanned” sexual encounter, which is often the case with adolescents. The morning-after pill contains a high dose of hormone that is thought to inhibit ovulation, disrupt follicular development, and/or interfere with the maturation of the corpus luteum. Emergency contraception does not interrupt or disrupt an already-established pregnancy and is not an abortifacient.

The original regimen was a combination of high-dose estrogen and progestin, known as the Yuzpe method; however, nausea and vomiting occurred in about 25% to 30% of patients. Plan B is the progestin-only method of EC that is currently available by prescription for adolescents younger than 17 years. It consists of 2 doses of 0.75 mg of levonorgestrel, which should be taken 12 hours apart within 3 days of unprotected intercourse. Based on data reported by the World Health Organization, this regimen has been modified to *take both pills at once up to 5 days after unprotected or inadequately protected intercourse*. Plan B is most highly effective when used within the first 24 hours after unprotected coitus. Although less common than with the Yuzpe method, side effects of Plan B include nausea, vomiting, breast tenderness, and irregular bleeding patterns such as spotting; shortened interval to menses; and lighter or heavier menses. Because EC is both safe and highly effective in preventing pregnancy, physicians should consider providing the sexually active teen with a prescription or advance supply of Plan B at the health maintenance visit.

The patient should be given a follow-up office or clinic appointment 2 to 3 weeks after using EC so that a pregnancy test can be performed, treatment failures can be identified early, STI screening can occur, and issues of contraception can be discussed.

Nonhormonal Contraception

Numerous studies and clinical experience have shown that nonhormonal methods are less effective in adolescents. However, latex condoms in conjunction with a spermicide have become crucial as a method of contraception since the emergence of AIDS. Although they help prevent transmission of some STIs, such as gonorrhea, chlamydia, trichomonas, and HIV, condoms do not protect against HPV and HSV infection overall because the genital area is not

completely covered. A few moments, therefore, should be taken during the visit to explain these details and demonstrate proper use of condoms. Risks of condom use are minimal, except for allergic reactions to the spermicide, latex, or lubricants. Although available, the female condom is not widely used by adolescents but may be helpful in situations where a male partner refuses to wear a condom. The inner ring is inserted into the vagina up to 8 hours prior to intercourse, and a prescription or physician visit is not necessary to obtain a female condom. Some teenagers, however, may be uncomfortable with its insertion and the fact that the outer ring remains on the vulva during vaginal intercourse. Similar issues are encountered when considering the diaphragm as a contraceptive method for teens; therefore, it is not recommended as a first-line contraceptive method for most adolescents. Other nonhormonal methods should be reviewed with adolescents as they become available.

Sexually Transmitted Infections

All STIs should be treated according to specific guidelines published by the Centers for Disease Control and Prevention based on current epidemiology. See Chapter 97 for details regarding the diagnosis and management of STIs in adolescents.

CASE RESOLUTION

In the case scenario presented at the beginning of the chapter, a more detailed history should be obtained regarding the adolescent's menstrual history and daily activities (eg, With whom does she spend most of her time? What does she like to do in her spare time?). In addition, the indications for a pelvic examination should be reviewed since most teens are not familiar with the new recommendations to delay the Pap smear until 21 years of age. Since the new indications do not apply in this case, the pelvic examination can be deferred. A discussion should then follow regarding both barrier and hormonal methods of contraception and their role in the prevention of pregnancy and STIs. Emergency contraception should also be reviewed with the teen. Written information as well as useful Web site addresses also should be given to the adolescent.

Providing Culturally Competent Care to Diverse Populations: Sexual Orientation and Gender Expression

Lynn Hunt, MD

CASE STUDY

The mother of an 11-year-old boy makes an appointment with you to discuss her son's "behavior problems." He is the youngest of 4 children and is doing well in fifth grade, but she is concerned that her son does not like typical "male" activities. He dropped out of Little League, won't join other sports teams, and prefers riding his bike. In addition he still likes dressing up in costumes and prefers playing with girls rather than boys. She finally mentions that she is worried that he will be gay and is wondering what she can do to help her son develop "normally."

Questions

1. What is meant by gender expression, sexual orientation, and gender identity?
2. What is the role of the pediatrician in counseling parents and patients about gender expression, sexual orientation, and gender identity?
3. What are some of the consequences of discrimination of sexual minority populations?
4. Are there programs that can change sexual orientation?

Every pediatrician and health professional needs a basic understanding of lesbian, gay, bisexual, transgender, and questioning (LGBTQ) populations. Each of us has contact with sexual minority individuals. They are among our teen patients and parents of our patients. Every day we encounter family members of someone who is LGBTQ—whether we are aware of it or not. Furthermore, the Joint Commission on Accreditation of Healthcare Organizations and the American Association of Medical Colleges, among other organizations, call for nondiscrimination and proactive cultural competence as markers of quality, appropriate patient care, and key content for professional education.

Incidence

The US census and other large-scale surveys indicate that approximately 5% of the adult population identifies as LGBTQ or reports same-sex relationships. The prevalence of sexual minority persons is impressively consistent across all ethnic and socioeconomic groups.

The number of adolescents who identify as LGBTQ tends to increase with age. However, in one survey, over twice as many youth reported same-sex sexual experiences as those who eventually identify as gay. These data reinforce the important distinction between sexual orientation and sexual behavior. There is a wide range of sexual behavior in teens, and sexual identity formation is a dynamic developmental process. Teens who eventually identify as gay may have had heterosexual sexual contact and those who identify as straight may have had same-sex partners.

LGBTQ Youth

Despite an increase in public dialogue and a perceptible boost to societal acceptance in recent years, LGBTQ youth continue to suffer stigmatization and its consequences. All too often LGBTQ youth are the objects of bullying, isolation, and family rejection. Additionally, sexual minorities are by far the group most targeted for violent hate crimes in America. According to the Southern Poverty Law Center, gay people are twice as likely to be attacked as Jews or blacks, 4 times as likely as Muslims, and 14 times as likely as Latinos.

Health Consequences of Discrimination

There are data documenting increased suicide attempts, substance use, and risky sexual behavior among LGBTQ youth overall. While it is helpful with all teens to identify those at increased risk, understanding key mediators of risk is also crucial. Youth who have been victimized or who perceive discrimination are more vulnerable to engaging in high-risk behaviors.

Families are particularly important. In one study of family support, LGBTQ young adults who experienced higher levels of family rejection during adolescence were 8 times more likely to report suicide attempts, 6 times more likely to report significant depression, and 3 times more likely to use illegal drugs or report unprotected sexual intercourse compared with those that did not experience family rejection. Conversely, families that are highly supportive are more likely to have children who are resilient and well adjusted. Family acceptance during adolescence is associated with better general health, self-esteem, and social support in LGBTQ young adults.

LGBTQ youth are also significantly overrepresented among homeless youth. Studies estimate that up to 40% of homeless youth identify as sexual minorities. Youth become homeless usually as a result of family conflict regarding their sexual orientation or gender expression. Sexual minority youth are more likely to suffer negative outcomes associated with living on the streets. Physical assault, sexual victimization, substance abuse, and high-risk sexual behavior are all more common for LGBTQ than heterosexual homeless youth.

Important Role of Pediatricians

Pediatric health care providers have a unique opportunity to model acceptance of each patient (Box 41-1) and to provide appropriate risk-reduction counseling, yet studies have shown that many adolescents are reluctant to share information about their sexuality with their health care provider. They are hesitant for various reasons. LGBTQ adolescents want just the same attributes in their health care providers as studies document for other groups of teens: confidentiality, cleanliness, honesty, respect, competence, and a nonjudgmental approach to history taking and guidance.

“Reparative” or Conversion Therapy

Some religiously and politically motivated groups use outdated and discredited medical theories to justify trying to “cure” the natural sexual orientation or gender identity of those who are lesbian, gay, bisexual, and transgender. Reparative therapy does not work and the process can severely damage self-esteem, leading to depression and self-destructive and suicidal behaviors. In 2001 the US Surgeon General’s Call to Action to Promote Sexual Health and Responsible Sexual Behavior asserted that homosexuality is not “a reversible lifestyle choice.” Reparative therapy is considered inappropriate and dangerous by several professional organizations, including

Box 41-1. Ways for Clinicians to Indicate Support for Lesbian, Gay, Bisexual, Transgender, and Questioning (LGBTQ) Youth

Waiting Room or Exam Room Environment

- Signal a welcoming environment with LGBTQ Safe Zone or rainbow stickers.
- Assess the images and literature available in your office. Much available information for teens assumes that the consumer is heterosexual. Consider including some posters or brochures that are not exclusively heterosexual in character.

Office Forms

- Review standard intake and history forms for assumptions that every patient (or parent) is heterosexual and consider modifying them to be more inclusive. Instead of only “single,” “married,” and “divorced,” consider “partnered” and “other.” Instead of “mother’s name” or “father’s name,” consider simply using “parent’s name.”

Patient Interview

- Stress the importance of privacy and confidentiality. Concerns over possible disclosure of sexual orientation or behavior are often reasons mentioned by LGBTQ youth as a reason to avoid seeking health care.
- Use gender-neutral language. Questions like “Are you dating?” or “Are you currently in a relationship?” are more inclusive than “Do you have a boyfriend/girlfriend?” Other approaches, such as “What types of sexual experiences have you had?” or “Have you been attracted to/had sex with boys, girls, or both?” are useful no matter what the self-identified orientation of the patient may be. Discuss “protection” rather than just “birth control.”
- As with any adolescent, a nonjudgmental attitude from the provider will help elicit honest and relevant information.

Physical Exam

- General primary care for LGBTQ youth, including examination and laboratory evaluation, should follow the recommendations for all adolescent health care as outlined by the American Academy of Pediatrics *Bright Futures* health supervision guidelines.

Children With LGBTQ Parents

LGBTQ parents are raising millions of children across the United States. According to the 2000 census, 33% of female same-sex couple households and 22% of male same-sex couple households reported at least one child younger than 18 living in their home. Children join families with same-sex parents in a variety of ways: adoption, assisted reproductive technologies, and from previous heterosexual contact as step/blended families. It is surprising to some that the “typical” same-sex parent families are not all upper or middle class. Parents in same-sex couples are more likely to be racial minorities;

their children are more likely to have disabilities and to be adopted. And same-sex parents tend to have lower household incomes than opposite-sex couples.

Child Outcomes

Well-crafted longitudinal and cross-sectional studies indicate that children with same-sex parents do well in domains of social, academic, and total competence. In study after study, children in same-sex parent families turn out remarkably similar to children in heterosexual families. The AAP in a 2002 technical report stated, “A growing body of scientific literature demonstrates that children who grow up with one or two gay and/or lesbian parents fare as well in emotional, cognitive, social, and sexual functioning as do children whose parents are heterosexual.” That report was reaffirmed in 2010. A meta-analysis of many of the studies found that the sexual orientation of a parent is irrelevant to the development of a child’s mental health and social development and to the quality of a parent–child relationship. In spite of the available data, organized opposition to these families remains the law in many states and several myths persist.

Myth #1: Gays are likely to molest children.

Fact: One of the most common arguments against LGBTQ individuals and adoption is that gays are more likely to molest children. The American Psychological Association finds, however, there is no evidence that gays are more likely to molest children than heterosexuals. In fact, when examining percentages, straight men as a group are the most likely to molest children; however, nobody would seriously suggest preventing heterosexual men from adopting children.

Myth #2: Gays recruit young people—or—Children raised by gays will be gay.

Fact: The truth is that being raised in a gay household does not make a child any more or less likely to become gay. In fact, most studies suggest that sexual orientation is biologically determined in a multifactorial way. The percentage of LGBTQ individuals who were raised in heterosexual families would seem to contradict the central role of environmental exposure in influencing sexual orientation.

Myth #3: Children raised in same-sex families are poorly adjusted.

Fact: According to the AAP, the APA, and the National Association of Social Workers, there is no evidence that the sexual orientation of a child’s parents or adoptive parents interferes with the child’s social adjustment. Children raised in gay households function just as well cognitively, socially, and emotionally as children of heterosexual parents.

How to Be an Ally

An ally is someone straight (or gay) who acknowledges and supports sexual diversity, acts accordingly to challenge homophobic or transphobic remarks and behaviors, and works to understand these forms of bias within oneself.

Following are some concrete next steps providers can take:

- Register as an ally provider in the Gay and Lesbian Medical Association online Provider Directory (www.glma.org). Joining the directory is a great way to signal your support in health care. This is an easy way to let LGBTQ people in your community who are looking for health care providers to know that you’re a supportive ally.
- Visit the Parents and Friends of Lesbians and Gays (PFLAG) Web site (www.pflag.org) and review their program for health providers: Straight for Equality in Healthcare.
- Learn more at any of the resources listed at the end of this chapter.

CASE RESOLUTION

This child is displaying behaviors that do not meet his parent’s expectation for male gender expression. The pediatrician should let the mother know that gender expression, sexual orientation, and gender identity are separate and distinct, and that there is a broad range of normal for all of these. There is no way to predict sexual orientation or gender identity from the behaviors described.

Many adolescents go through a period of questioning their sexuality. The child’s mother should be informed that whether her son grows up gay, straight, transgender, or typically male, a major risk factor for him engaging in unsafe behaviors as an adolescent would be parental rejection. Programs designed to change a person’s sexual orientation don’t work and are actually dangerous; they are associated with significant depression and thoughts of suicide. For her son to develop normally, he will need supportive adults in his life who accept and love him, ideally his parents.

It would be important to determine if her son has been a victim of bullying at school or on the sports teams. Schedule an appointment for the son. You will have the opportunity to evaluate the child’s strengths and note if he is displaying any signs of anxiety or depression. Questions about sexuality would be those appropriate for all children his age and stage of development. An ongoing dialogue with the mother will also help to know if/when referrals to PFLAG or other support and educational groups are appropriate.

Online Resources

For LGBTQ Youth

It Gets Better

www.itgetsbetter.org

See hundreds of videos of encouragement. The Web site is a place where young people who are LGBTQ can see how love and happiness can be a reality in their future. It’s a place where straight allies can visit and support their friends and family members.

Glossary

Sexual orientation	Permanent emotional, romantic, or sexual feelings toward other people. Straight individuals experience these feelings primarily for people of the opposite sex. Gay or lesbian individuals experience these feelings primarily for people of the same sex. Bisexual individuals can experience these feelings for people regardless of sex.
Gender identity	Knowledge of oneself being male or female.
Gender expression	Outward expression of maleness or femaleness.
Gender nonconforming	A person who either by nature or by choice does not conform to gender-based expectations of society. These children and adolescents are among the most vulnerable to bullying and violence.
Sexual behavior	Refers to the way one chooses to express one's sexual feelings. Sexual behavior does not necessarily correlate with sexual orientation. Heterosexually identified individuals may have same-gender sexual experiences and homosexually identified youth may have opposite-gender sexual experiences.
Gay	The adjective used to describe people whose enduring romantic, physical, and emotional attractions are to people of the same sex. Often refers to men, but also used more generically as well.
Lesbian	A woman whose enduring romantic, physical, and emotional attraction is to other women.
Bisexual	A person who develops romantic, physical, and emotional attraction regardless of the other's sex.
Transgender	A term describing a person whose gender identity does not necessarily match his/her assigned gender at birth or, more generally, who experiences or expresses gender differently from what people expect.
Homosexual	An outdated clinical term sometimes considered derogatory or offensive by many gay people.
Queer	Traditionally a pejorative term, queer currently is used by some LGBTQs, particularly among younger people, to describe themselves. Some value the term for its defiance and because it can be inclusive of the entire LGBTQ community, and others find it to be an appropriate term to describe their identities in a less categorical way. Straight health providers should generally avoid using the term.
Intersex	Also known as <i>disorders of sex development</i> or <i>differences of sex development</i> . A general term used for the variety of conditions in which a person has atypical external or internal genitalia. These conditions may be apparent at birth and can cause difficulty assigning gender or they may be diagnosed later, due to infertility or other pubertal clues.
Ally	A friend or supporter of the LGBTQ communities.
Partner/spouse	A way to talk about someone's boyfriend, girlfriend, husband, or wife without mentioning gender. Using these words instead of gendered words allows you to be more inclusive, putting LGBTQ patients or parents at ease.

Injury Prevention

Sarah Atunah-Jay, MD, and Iris Wagman Borowsky, MD, PhD

CASE STUDY

A 16-year-old girl was brought to the emergency department (ED) after being rescued from her submerged vehicle. The girl was texting a friend while driving and crashed into a pond. After several weeks in the intensive care unit, she was transferred out for rehabilitative care from her drowning injury.

Questions

1. How extensive is the injury problem in children?
2. What are the different methods for injury prevention? How could this particular injury have been prevented?
3. What injury prevention program has been developed by the American Academy of Pediatrics (AAP)?
4. What are some general guidelines for effective injury prevention counseling?

Traditionally, unintentional injuries have been called accidents. The problem with the term accident, however, is that it implies unpredictability, carrying with it connotations of chance, fate, and unexpectedness. The perception that injuries are chance occurrences that cannot be predicted or prevented has been a major barrier to progress in injury prevention and the study and control of injury as a scientific discipline. According to the modern view of injury, accidents must be anticipated in order to be prevented. Specialists in injury prevention have tried to replace the word *accident* with *injury* and have developed the idea of “reducing injury risk.” Thus injuries are not random events at all; rather, they occur in predictable patterns determined by identifiable risk factors. For example, if a 16-year-old girl is texting while driving, which has been shown to be a dangerous driving distraction, the resulting injury can hardly be called an accident. On the contrary, the injury is entirely predictable.

Epidemiology

Unintentional injuries are the leading cause of death among people aged 1 to 44 in the United States. In 2007 unintentional injuries claimed the lives of more than 20,000 Americans younger than 24 years. Motor vehicle crashes are the leading cause of unintentional injury-related deaths in people aged 5 to 34. Suffocation and drowning are the leading cause of unintentional injury-related deaths for infants and ages 1 to 4, respectively. Other major causes of unintentional injury death in young people include burns and poisonings.

Intentional injuries are also a major cause of mortality in young people. Homicide ranks second among all causes of death for ages 15 to 24 and third for ages 1 to 4 and 10 to 14. Suicide ranks third for ages 15 to 24 and fourth for ages 10 to 14.

In addition to deaths, in 2009 nonfatal unintentional injuries led to more than 11 million hospital ED visits in persons younger than 24 in this country. In the same year, almost 1 million young

people visited EDs due to a violence-related injury. The most common causes of nonfatal unintentional injuries in people aged 1 to 24 are falls, being struck by or against something, bites, cuttings/piercings, overexertion, and motor vehicle occupancy.

Several epidemiological factors are associated with higher rates of pediatric injuries. These include male gender, low income, and family stressors (eg, death in the family, new residence, birth of a sibling). There is a bimodal age distribution of injuries, with infants and adolescents at greatest risk. Females are most likely to experience rape or assault. American Indian/Alaska Native and black children have higher rates of total injury-related deaths than other racial/ethnic age-matched populations. Geography influences injury rates: Drowning deaths tend to be higher in coastline states (Alaska and California) or states with a higher number of swimming pools (Texas); injury-related deaths are higher in rural areas and may be related to decreased access to emergency medical care; and homicide occurs more frequently in urban areas.

Strategies for Injury Prevention

During this century, efforts to prevent injuries have shifted from changing the behavior of individuals to modifying the environments in which injuries occur. William Haddon, a medical epidemiologist, devised 2 useful frameworks for developing injury prevention strategies.

Haddon Matrix

This matrix relates 3 factors (host, vector, and environment) to the 3 phases of an injury-producing event (pre-event, event, and post-event). The 3 factors interact over time to produce injury. Table 42-1 shows a Haddon matrix of motor vehicle crash injuries. The pre-crash phase describes elements that determine whether a crash will occur, the crash phase describes the variables that influence the nature and

Table 42-1. The Haddon Matrix^a

Phase	Host (Human)	Vector (Vehicle)	Environment
Pre-crash	Driver vision Alcohol consumption	Brakes Tires Speed	Speed limit Road curvature Road signs
Crash	Use of safety belts Osteoporosis	Vehicle size	Median barriers Laws about use of car seats and safety belts
Post-crash	Age Physical condition	Fuel system integrity	EMS personnel training

Abbreviation: EMS, emergency medical service.

^aAdapted from the National Committee for Injury Prevention. Injury prevention: meeting the challenge. *Am J Prev Med.* 1989;5(3 suppl):1–303

severity of the resultant injury, and the post-crash phase describes the factors that determine the degree to which the injury is limited and repaired after the crash occurs. By describing the “anatomy” of an injury, the Haddon matrix illustrates the numerous characteristics that determine an injury and the many corresponding strategies for interfering with the production of an injury.

Haddon also developed a list of **10 countermeasures to prevent injuries** or reduce the severity of their effects.

1. Prevent creation of the hazard (eg, stop producing poisons, toys with small parts, and non-powder firearms; do not participate in dangerous sports; support community centers that engage children in safe after-school activities).
2. Reduce the amount of the hazard (eg, package drugs in nonlethal amounts; reduce speed limits).
3. Prevent the release of the hazard (eg, use child-resistant caps for medications, toilet locks, and safety latches on cabinets and drawers; pass and enforce distracted driving laws; implement restrictions on handgun purchases).
4. Modify the rate or spatial distribution of release of the hazard (eg, require air bags in cars; use child safety seats and seat belts; make poisons taste bad).
5. Separate people from the hazard in space or time (eg, make sidewalks for pedestrians, bikeways for bicyclists, and recreation areas separated from vehicles).
6. Separate people from hazards with material barriers (eg, use bicycle helmets and protective equipment for athletes; install fences around swimming pools; build window guards).
7. Modify relevant basic qualities of the hazard (eg, place padded carpets under cribs; require guns to have safety locks; develop inter-vehicle communication systems).
8. Increase resistance to damage from the hazard (eg, train and condition athletes; make structures more earthquake-proof; use flame-retardant sleepwear).
9. Limit the damage that has already begun (eg, use fire extinguisher; begin cardiopulmonary resuscitation).

10. Stabilize, repair, and rehabilitate injured individuals (eg, develop pediatric trauma centers and physical rehabilitation programs; improve emergency medical services).

Haddon’s work serves as a practical guide for thinking about ways to prevent injury. It emphasizes the importance of considering injuries as a result of a sequence of events, with many opportunities for prevention. The shift of emphasis away from changing human behavior to preventing injury is particularly appropriate with regard to injuries in children because inhibiting children’s curiosity is impractical as well as undesirable.

Passive and Active Interventions

Interventions to prevent injuries can also be categorized as passive or active. **Passive, or automatic, strategies** protect whenever they are needed, **without the action of parents or children**. An example is the automobile air bag that automatically inflates to cushion the occupants during a crash. Other examples of automatic strategies are water heater temperatures set to 120°F or lower, not having guns in the home, and energy-absorbing surfaces under playground equipment. In contrast, **active interventions require action to become effective**. For example, nonautomatic safety belts are active strategies; every time protection is needed, individuals must “buckle up.” Watching children continuously is another example of an injury prevention strategy that requires constant activity.

Some strategies are partially automatic, requiring some action by individuals. Smoke detectors can be very effective in preventing injury and death in house fires, but roughly one-third of smoke detectors do not have working batteries. Batteries should be changed once a year and, ideally, tested once a month. As might be expected, the greater the effort required for children to be protected, the smaller the chance that protection occurs. Therefore, whenever possible, passive measures are preferable because they are the most effective.

Several approaches have been used successfully to prevent childhood injuries, including engineering, education, legislation, and enforcement. An engineering intervention, the car safety seat, is extremely effective (Table 42-2). When used correctly, child safety seats in passenger cars reduce the risk of death by 71% for infants and 54% for toddlers aged 1 to 4 years. Booster seats reduce injury

Table 42-2. Pediatric Car Seat Guidelines^a

Age Group	Type of Car Seat	General Guidelines
Term infant	Rear-facing	Until at least 1 year <i>and</i> at least 20 lbs.
Toddlers/preschoolers	Rear-facing and forward-facing	Should ride rear-facing as long as possible. A full harness should be used as long as they fit.
School-aged children	Booster seat	Usually start at 4 years and 40 lbs. Use until adult belt fits correctly (usually at 4’9”).

^aFrom American Academy of Pediatrics. *Car Safety Seats: A Guide for Families*. Available at: <http://www.aap.org/healthtopics/carseatsafety.cfm>.

risk by 59% for children aged 4 to 7 years compared with safety belts alone. Unfortunately, studies indicate that between one-third and two-thirds of car safety seats are used incorrectly. To address this, newborn care units often have car safety seat education programs, and some require possession of an infant car safety seat prior to hospital discharge. Police departments and private motor companies hold free public events to teach and manually check appropriate car seat use. In addition to engineering and education, passage and strict enforcement of child restraint laws are essential to compliance. All 50 states and the District of Columbia have child restraint laws (<http://www.iihs.org/laws/restraintoverview.aspx>). Nevertheless, loopholes still exist, such as exemptions in some states for seat belt use if older children are riding in rear seats; for car safety seat use in school buses, taxis, or police vehicles; and if all safety belts are already in use. Such exemptions reinforce parental misconceptions, particularly that the lap of an occupant (the “child crusher” position) is a safe position.

Counseling by Pediatricians

Although the existence of significant gaps in parental knowledge about injury prevention has been clearly established, studies have shown that pediatricians spend surprisingly little time counseling parents about childhood safety. One survey found that only 42% of caregivers of children younger than 15 years who had a medical visit in the past year recalled receiving injury prevention information. Another survey found that while 55% of pediatricians responded that they provided injury prevention information, only 19% of their patients recalled receiving this information. Reasons for limited discussion of safety issues may include lack of emphasis on preventive medical care in medical schools and pediatric training programs, inadequate time or reimbursement, and lack of perceived self-efficacy or effectiveness. Research, however, has shown that injury prevention counseling in primary care settings is effective, resulting in increased knowledge and improved safety practices. Parents report that they would listen to physicians much more than any other group regarding child safety.

The Injury Prevention Program (TIPP) was developed in 1983 by the AAP to firmly establish injury prevention as a cost-effective standard of care for pediatricians. The AAP suggests that providers focus their safety counseling on a few topics targeted to individual risk factors (eg, age, gender, location, season of the year, socioeconomic status of family). Table 42-3 shows the age-specific counseling schedule of TIPP, which indicates the minimum topics to cover at each visit. Topics are scheduled for discussion before children reach a particular developmental milestone. For example, a discussion of falls is scheduled for the 2- or 4-week visit, before infants normally begin to roll over, and a discussion of choking is scheduled for 4 months, before they can grasp and put things in their mouths. Specific preventive measures should be reinforced at each visit. Areas of injury prevention guidance recommended for adolescents include (1) traffic safety (eg, seat belts, alcohol use, motorcycle and bicycle helmets), (2) water safety (eg, alcohol use and diving

injuries), (3) sports safety, and (4) firearm safety.

Connected Kids: Safe, Strong, Secure is a violence prevention tool introduced by the AAP in 2006 to augment TIPP. Acknowledging that injury and violence prevention are intertwined, it uses an assets-based approach to engage parents in understanding and fostering healthy child development. An emphasis is put on support and open communication to promote emotional and physical safety.

Health care professionals should involve parents and patients in educational efforts (eg, have a bicycle helmet in the office for children to try on). Safety counseling is most effective if limited to 2 or 3 topics per visit. Advice should be well defined and practical rather than general information (eg, write the poison control center number on the phone; never leave children unattended in a bathtub). Advice should be tailored to each family after exploring their individual situation through open-ended questions (eg, “Where does your baby spend awake time during the day?” “What do you think is the biggest safety risk for your child?”). Providers should be aware of different levels of health literacy and should confirm understanding rather than rushing through a prepared statement. Access to interventions should be considered, such as cost and accessibility of helmets and child safety seats. Whenever possible, pediatricians should coordinate their educational efforts with current community injury prevention efforts (eg, bicycle helmet campaigns; handgun regulation).

Recent Recommendations

The AAP has multiple safety recommendations. The following are a few of the newer and revised recommendations.

Motor vehicle crashes are the leading cause of death for children age 5 and older. Comprehensive legislation and education promoting 3-stage graduated driver’s license programs should be encouraged. The AAP recommends that pediatricians know their state laws regarding teenage drivers, encourage seat belt use, discourage distractions when driving, encourage restrictions on nighttime driving and limits on the number of passengers, and counsel teenagers about the dangers of driving while impaired (2006). Pedestrian injuries are a significant traffic-related cause of morbidity and mortality. An emphasis should be given to community and school-based strategies to reduce exposure to high-speed and high-volume traffic, to improvements in car engineering, and to driver education to reduce pediatric pedestrian injury (2009). Children between 12 and 24 months should ride in a rear-facing car safety seat until age 2, based on injury statistics showing that they are 5 times safer in rear-facing than in forward-facing seats. Increased efforts should be made to prevent food-related choking among children through federal agency surveillance and regulation, food manufacturer design, and health care provider counseling efforts (2010). Pediatricians should provide general and targeted office-based water-safety counseling, including maintaining 4-sided fences around swimming pools. Body entrapment and hair entanglement in pool and spa drains are potential dangers to children; thus, drain covers and filter-pump equipment should be installed to prevent injuries (2010). Shopping carts with child seats should provide restraints (seat belts)

Table 42-3. The Injury Prevention Program (TIPP) Safety Counseling Schedule for Early and Middle Childhood^a

<i>Visit</i>	<i>Introduce</i>	<i>Reinforce</i>
Prenatal/newborn	Infant car seat, smoke detector, crib safety	
2 d–4 wk	Falls	Car safety seat
2 mo	Burns—hot liquids, choking/suffocation	Car safety seat, falls
4 mo	Water safety—bathtubs	Car safety seat, falls, burns, choking/suffocation
6 mo	Poisonings, burns—hot surfaces	Falls, burns, choking
9 mo	Water/pool safety, toddler car safety seat, firearms	Poisonings, falls, burns
1 y		Water/pool safety, falls, burns
15 mo		Car safety seat, poisonings, falls, burns
18 mo		Car safety seat, poisonings, falls, burns, firearm hazards
2 y	Falls—play equipment, tricycles, pedestrian safety	Car safety seat, water/pool safety, burns, firearm hazards
3 y		Car safety seat, pedestrian safety, falls, burns, firearm hazards
4 y	Booster seat use	Pedestrian safety, falls—play equipment, firearm hazards
5 y	Water/pool safety, bicycle safety	Firearm hazards, pedestrian safety, booster seat
6 y	Fire safety	Bicycle, booster seat, pedestrian, and firearm hazards
8 y	Sports safety, seat belt use	Bicycle
10 y	Firearm hazards	Sports, seat belt use, bicycle safety

and children should be supervised while in them. Alternatives to shopping carts include strollers, wagons, front/backpack child carriers, or having the child walk (2006). Sports-related concussions are common yet underreported; any pediatric or adolescent athlete who sustains a concussion should be evaluated by a health care professional and receive medical clearance before returning to play (2010). Health care equity is fundamental to child health; children should be protected from injury within the built environment and with access to quality, patient-centered, and culturally effective medical care (2010). Improving pediatric trauma services will decrease injury-related morbidity and mortality. The AAP recommends an integrated public health approach to trauma, starting at preventive care and continuing through long-term follow-up (2008). Additional guidelines can be found at <http://aappolicy.aappublications.org/> using keywords “injury prevention.”

Pediatricians as Advocates

As advocates for child safety, pediatricians can play a major role in injury prevention outside of the clinical setting. Pediatricians have started community programs or provided support to ongoing programs. Safe Kids (www.safekids.org) is a worldwide organization made up of safety experts, educators, corporations, foundations, governments, and volunteers whose mission is to prevent childhood injury through education and advocacy. Safe Kids and other issue-specific organizations, such as the Children’s Defense Fund (www.childrensdefense.org) and Farm Safety 4 Just Kids (www.fs4jk.org), can provide resources to support pediatricians in local or national projects and provide avenues for legislative participation. Through their Community Pediatrics grants programs (www.aap.org/commpeps/), the AAP provides grants to pediatricians and pediatric residents who want to create innovative community projects promoting child health.

Legislative advocacy is an exciting opportunity for health care professionals to effect wide-reaching change. States have enacted laws covering many aspects of injury prevention, including car safety seats, poison control centers, cribs, playgrounds, amusement parks, protective gear for sports, swimming pools, and school buses. Dramatic reductions in injuries often follow safety legislation. For example, infant walker-related injuries have decreased by 76% since the introduction of the American Society for Testing and Materials F977 voluntary infant walker standard in 1997 and the introduction of stationary activity centers as alternatives to mobile infant walkers. Other examples of product-related legislation include federal crib standards of 1974 mandating close spacing of vertical slats to reduce the risk of entrapment, the Child Safety Protection Act of 1995 requiring toy safety labels on any balls with a diameter less than 1¼ inches (4.44 cm), window blinds manufactured with tassels instead of loops and children's clothing without drawstrings to prevent strangulation, and toy boxes manufactured with safer lids and air holes in case of a trapped child. Similarly, in December 2010 the Consumer Product Safety Commission voted to ban drop-side cribs, citing the recall of more than 9 million cribs over the previous 5 years and the entrapment and death of 30 babies over the previous 10 years. The ban went into effect in June 2011 and prohibits the sale of such cribs even at garage sales.

Pediatric practitioners can heighten awareness about the magnitude of childhood injuries through calls or letters to legislators, testifying about the benefits of specific safety legislation, or partnering to introduce new legislation. Pediatrician legislative involvement is critical to ensuring evidence-guided local and national injury prevention.

CASE RESOLUTION

Some of the factors that influenced the injury suffered by the girl in the case history are the age of driver's licensure, the passage and enforcement of laws pertaining to cell phone use in cars, the design of the car, road conditions, and the availability of emergency rescue services and specialized pediatric care. Health care professionals have the opportunity to teach injury prevention to children and their parents as well as to influence the individuals who manufacture the products and pass the laws that affect children's risk of injury.

Fostering Self-esteem

Rick Goldstein, MD

CASE STUDY

A 4-year-old girl is brought to the office for her annual physical examination. She has been healthy. Her mother expresses concern that her daughter is shy and does not always play well with other children. She has never participated in a child care program or group activities out of the home. She spends most of her time with her mother, grandmother, and 7-year-old sister, with whom she gets along fairly well. Both parents work outside the home, her father full-time and her mother part-time.

The girl's medical history is unremarkable except for an episode of bronchiolitis at 8 months of age. She has reached all of her developmental milestones at appropriate ages, currently speaks well in sentences, is able to dress herself without supervision, and can balance on one foot with no difficulty.

The physical examination is entirely normal. However, numerous times during the visit, the mother tells her

daughter to “sit up straight,” “stop fidgeting,” and “act your age.” The mother rolls her eyes as she tells you “she doesn't know how to act.”

Questions

1. What is self-esteem?
2. How do parents or other caregivers affect the development of their children's self-esteem both positively and negatively?
3. What role does discipline play in the development of self-esteem?
4. How does illness affect self-esteem?
5. What suggestions can primary practitioners give parents and other caregivers to help foster positive self-esteem in children?

Self-esteem is a concept that resonates deeply in contemporary American culture. In its casual usage, the term is often used to mean contentment or a sense of agency. Agency is considered the capacity to act in the world, the notion that what the individual thinks, wants, and does matters. Alternatively, poor self-esteem may be used to describe an overly self-critical child with limited confidence. Fundamentally, self-esteem is based on the confidence a child has for success and also the confidence that difficulties, failures, and disappointments are tolerable and can be met while still feeling whole and supported. Self-esteem is grounded in the fact that success with other people is fundamental to a sense of who we are. It is essential to children's health and well-being, and influences the development of relationships and identity during both childhood and adulthood.

Researchers have developed an informative model for understanding self-esteem. In self-determination theory, a child's general self-concept is understood as an organization of complex, hierarchically inter-related components. Self-esteem is the evaluative aspect of self-concept, and is linked to and rests on intrinsic motivation. Research has demonstrated that (1) optimal challenges, effectance-promoting feedback, and freedom from demeaning critique; (2) parenting that promotes autonomy rather than control; and (3) a secure interpersonal environment of relatedness are all essential contributions to intrinsic motivation and, by extension, self-esteem.

While self-esteem is a concept in action throughout our lives, it first comes into clear view in the developing internal self-concept of

the 4-year-old. In the language of a 4-year-old, the pediatrician or allied health professional can find a child who is learning to know herself and appreciate her abilities. The joy of autonomy and initiative are suffused with a need to live up to expectations—part of feeling she is a big girl is feeling she is a good girl. The first stirrings of conscience and the confidence to manage measured responsibility can be seen. The complex interaction of temperament, developmental stage, the family's security, the parental style of discipline, sibling and peer interactions, and school experiences coalesce in the experience of a uniquely competent child. For her caregivers, the desire to encourage a kind of fearlessness is balanced by the very real need to keep the child safe and appropriate. All of these aspects of her life contribute to the development of her competence, autonomy, and relatedness, and animate her self-esteem.

All parents hope that their children will develop a positive self-concept that will aid them throughout their lives. Unfortunately, discussions related to self-esteem are usually held as a result of a crisis or an observation by worried parents or teachers. Primary care practitioners should bring the parents' focus to this important aspect of the child as a normal part of anticipatory guidance. Pediatricians and child health practitioners are in a unique position to offer specific recommendations for fostering self-esteem that may have a major impact on their patients' lives. During health maintenance visits with the child, they should model respect for the child's self-concept and the fostering of the child's self-esteem in their interactions.

Self-esteem and Growth and Development

While the appearance of what is understood as self-esteem requires the development of certain cognitive abilities, it springs from an accumulated experience with parents and other caregivers. Beginning with the responsiveness of the newborn's environment and continuing onward, distressed infants quickly adapt to the calming influence of a maternal figure. Infants who are 3 to 4 months of age often smile at all individuals for social interaction and protest being left alone. As infants become more verbal and develop more advanced motor skills, they begin to respond consistently to verbal and nonverbal cues from parents (eg, laugh with parents, follow simple commands, are taken aback by a stern voice). If parental figures are warm and loving as well as supportive and consistent, infants learn to trust and enjoy these interactions.

By the time children are toddlers, they have developed a specific relationship with their caregivers and the rest of their environment. As a goal, they are learning to live within consistently set limits and are corrected when they go beyond them in their attempts at exploration. All children, regardless of temperament, exhibit negative behaviors such as temper tantrums and selfish behavior, which elicit some type of response from parents.

Preschool children become much more independent, and they spend more time away from primary caregivers. This newly acquired independence, however, does not remove the need for attention, interest, and approval from their parents. Agency must be nurtured, and not simply controlled, to feed self-esteem. Opportunities to demonstrate the competence of children can be seen in the autonomy that appropriate parenting affords, and heard as a source of pride in parents taking note of it. Preschoolers also enjoy playing alongside other children, although not necessarily in cooperative play (eg, helping each other in addition to playing together).

Much of a child's self-concept is established and reinforced by those around them, especially their primary caregivers. While important activities occur when the child is alone and engaged in individual pursuits, much of a child's self-concept develops in a context of relatedness. This continues into the school years, with peers and teachers eventually assuming a more influential role in the continued development and reinforcement of self-esteem. The development of self-esteem is transactional, built by the responses children receive to their increasing initiative and abilities, resting on a foundation of security.

Optimal Challenges: Encouragement Versus Pressure

Parenting should help promote autonomy, competence, and relatedness. Parents should understand the difference between encouragement and pressure, and should be introduced to the concept of positive communication. To build positive self-esteem, children need encouragement at all levels of their development (Box 43-1). This is communicated both verbally and nonverbally and should be distinguished from overt pressure. For example, a first-grader learning to spell should be praised for his early, if flawed, application of

Box 43-1. Encouraging Self-esteem

Don'ts

- Have negative expectations.
- Focus on mistakes.
- Expect perfection.
- Overly protect children.

Dos

- Show confidence in children's abilities.
- Build on children's strengths.
- Value children as they are.
- Stimulate independence.

phonemes when he spells "winter" as "wntur," and may not need criticism at that point. In general, children should be allowed to develop at their own rate and be neither coaxed into activities before they are ready nor judged too harshly for earnest, early attempts.

Successful parenting creates opportunities for the child to safely extend their boundaries while ensuring the child's feeling of personal control. An overly critical or controlling style of parenting constrains the emergence of a child's young sense of competence and, by extension, affects their self-esteem. Being handed a scribble drawing by a preschooler and told what it represents is emblematic. An appreciative, interested, positive response to the disordered marks is sustaining; disinterest or criticism undermines.

When pressure occurs, it is often from parents' having unrealistic expectations of how the child learns and develops, or an improper sense that lack of success is due to laziness or a character flaw. Inadvertent pressure can be detrimental and cause tremendous frustration when, for example, parents try to lead a toddler into toilet training when the child has shown few signs of readiness, even if most of the children in his preschool class are out of diapers. Pressuring young children to give up pacifiers or another security object without giving thought to the child's readiness may also be quite anxiety provoking to them.

While children may not know what is best for their ultimate development, well-intentioned pressure may be equally harmful later in childhood. Forcing children to participate in rigid, structured play, and sometimes classes or lessons, does not foster individual creativity or independence. Children are merely doing what the parents have arranged. Ideally, children should be encouraged to explore and occasionally take risks. They should be helped to build on their "islands of competence." Mistakes should be put into the context of a sincere effort and seen in terms of what can be learned rather than as a humiliation. Pressuring children to do things "right" or "perfectly" discourages normal, healthy, risk-taking behavior and interferes with future efforts by children to participate in activities unless they are certain they can succeed.

A variation on this theme is overprotection, where the parent controls the child's environment so as to reduce any risk of failure or discomfort to the child. This generally comes at the cost of sacrificing the experience of novel achievement and developing the competence

to work through frustrations and disappointments. This also has a negative impact on self-esteem.

Communication That Builds Self-esteem

Specific ways to communicate that build self-esteem include active listening, use of positive language, discarding “labels,” use of encouragement rather than pressure, and the use of the “I” method of communication (Box 43-2). The pediatrician should coach parents that this is not a rigid code to be followed at all times and at great hazard, but rather that the goal is a “good enough” environment where well-intended parents put up a fairly consistent effort to be mindful of how they deal with their children. A useful way to set the correct tone with parents and caregivers is the use of strength-based counseling, where advice grows out of a focus on what parents are doing right.

The purpose of active listening is to hear the child’s message and understand its meaning. Its success rests on a centered approach to important parenting moments: Parents should strive to be attentive and present at these moments. They should stop what they are doing, and look directly at children. They should be aware of non-verbal cues, such as body posture and facial expression. If children are having trouble understanding their feelings, the parent should repeat what they hear them saying (“It sounds like...”).

A nonjudgmental response, validating and non-dismissive, should be the goal of communication between primary caregivers and children. The basic message should be stated simply, clearly, and at a level that respects the maturity of the child. Words should be easily understood and spoken in a moderate tone, especially when discipline is necessary. Facial expression and body language should also be consistent with the message parents or caregivers are trying to convey.

The importance of positive language should be emphasized, even when disciplining children (see Chapter 47). For instance, when children are playing kick ball in the house, it is understandable that a parent might yell, “Don’t play ball in the house!” or “Haven’t I told you before? No ball playing inside!” While emotionally honest parenting in a loving context is the best parenting, practically speaking this rarely occurs 100% of the time and parents need to be aware of when they are speaking in a reprimanding and negative fashion. Parents or other adults should tell children clearly what they can do, what the limits are, and the reason for these rules. For example, they could state: “You have to stop playing ball right now. If you kick the ball inside, you may break a window or hurt yourself or someone else. You may kick the ball outside in the backyard.” Communicating

in a clear manner changes the tone of the interaction from a reprimand for being bad to one where rules are clarified to a child who wants to do the right thing.

Parents should praise their children for successes and achievements. Failures should be put into context whenever possible, although the acknowledgment of mistakes can be important. A forgotten jacket or a careless job with homework can be frustrating but are not worthy of demeaning critique. Negative labels have no helpful role. If children hear themselves referred to pejoratively by their primary caregivers, not only is an undesirable behavior modeled, but they will feel undermined and wonder about the truth of such statements, no matter how innocuous they may initially seem to parents.

At the other extreme, parents should be cautioned against always speaking in the superlative to their child and staying blind to any shortcomings. Children are adept at seeing the world as it is. A failure to see themselves reflected realistically by parents or caregivers may feed a kind of insecurity where despite the glowing language of the parents, the child feels uncertain of their actual worth.

Talents and abilities should be recognized and highlighted. Children should know that parents have confidence in their abilities and that any display of effort is appreciated. Even small successes should be noted and not overshadowed by the large ones or the failures. Children thrive on the joy and pride they see in the eyes of their parents. Lack of encouragement can limit their optimism for continued success.

Many parenting courses teach primary caregivers to use the “I” method of communication, which requires that parents explain their feelings to children rather than blame them for their actions. This approach is believed to be less threatening and demeaning for children, especially in situations requiring discipline. The “I” method has 4 recommended steps.

1. Statement of behavior or situation to be addressed (eg, “When you...”)
2. Statement in specific terms of how one feels about the effect of the situation on oneself (eg, “I feel...”)
3. Statement of reason (eg, “because...”)
4. Statement of expectations (eg, “I would like...” or “I want...”)

Using this approach, a parent’s statement might be: “When you speak so unkindly, I feel upset because I would never speak with you in that way. It makes you seem like the kind of person that you are not. I would like you to speak with me in the way we all try to speak with you, no matter how angry you feel.”

Vulnerable Times in a Child’s Life

There are instances when a child’s self-esteem can be particularly vulnerable. The primary care provider should be cognizant of circumstances where a child may feel shame, confusion, or guilt for problems occurring in them or their family. Negative experiences in school and at home can predispose a child to feelings of shame and worthlessness. Marital conflict, divorce, or the abuse of a parent may negatively influence the self-esteem of children who may feel responsible for the problem. In such circumstances, parents are often

Box 43-2. Communication That Builds Self-esteem

Active listening
Use of positive language
Discarding “labels”
Use of encouragement
Use of the “I” method of communication

concerned about the impact on the child, which provides an opportunity to work together to minimize negative effects. Honest, open communication with parents can reinforce the need for sensitive support of the child and help them set priorities or rehearse how they will talk with the child about the matters at hand (see Chapter 136).

Physical and psychiatric illness can challenge a child's sense of competence, autonomy, and relatedness. They can be left uncertain of their standing, expecting failure or feeling they stand apart. It is worth mentioning the challenge of supporting self-esteem that enters the pediatrician's office often when dealing with "new morbidities." The diagnoses of obesity, attention-deficit/hyperactivity disorder, and learning disabilities can have in common the taint of personal judgment and the threat of undermining self-worth. This aspect of a child's care is present in disclosure of diagnosis, the response of the parent and the child, determining a realistic treatment plan, following what can be a frustrating lack of progress, and ultimate outcomes. Parents and patients will benefit from careful modeling when representing the problem and how to talk about it by the pediatrician.

Discipline and Self-esteem

Parents should consider their understanding of the complex relationship between discipline and self-esteem, and they should be questioned about their impressions of their child's independence and competence. Promoting the growth of healthy autonomy should be a goal for all parents. As children grow, so does their ability to act responsibly and their ability to maintain greater self-control. This central insight is an important way to help parents see beyond discipline in simply punitive terms. Children do best when they are provided with clear, consistent guidelines for their behavior while at the same time being encouraged to do well, pursue their interests, and increase their abilities.

They do this even better when they see this modeled in the adults around them. Parents and other caregivers should remember that certain methods of discipline, particularly if harsh or shame provoking, can be very destructive to a child's self-esteem. For instance, making an enuretic child sleep in wet bed sheets or reprimanding a child with physical punishment (eg, spanking) in public places can be demeaning. Several different approaches to discipline have been adapted by various ethnic, cultural, religious, and socioeconomic groups. While a discussion of each of these methods is beyond the scope of this chapter (see Chapter 47), it is important to explore strategies with parents and caregivers.

CASE RESOLUTION

In the case history, the health maintenance visit provides the perfect opportunity for promoting parental support of their child's self-esteem. The shy child should be approached by giving sincere general compliments (eg, "My goodness, you are so big." Or to a carefully dressed girl, "What a beautiful pink outfit!") and, in the interview, inviting her to tell you some things about herself (eg, "What are your favorite things?" "What is your favorite color?"), while employing humor and enthusiasm to engage her in some details. This models interactions, which allows the child to demonstrate her autonomy, with the hope that this approach will be repeated by the parent at home. The health care provider can reassure the girl and her mother that the child's overall health and development are normal. In addition, once the careful, protective experience the parents have managed for their child is appreciated, the practitioner should attempt to normalize the child's behavior for the parent. While it may be important to directly discuss shyness in a developmental context, whether she is shy is not certain and the parent's sense of deficiencies should be challenged by a view of developing competencies. Concrete suggestions should be offered for positive communication, such as minimizing "don't" and "no" phrases and being cognizant of how one speaks about the daughter. The parents should be encouraged to think about the child's temperament when considering involvement in multiple school activities but reminded that they have not yet seen her in an independent setting, where she may negotiate very well and show sociability not yet evident at home.

Sibling Rivalry

Carol D. Berkowitz, MD

CASE STUDY

An 8-year-old boy is brought to the office for an annual checkup. During the course of the evaluation, his mother complains that her son and his 6-year-old sister are always fighting. She says her son hits his sister and pulls her hair, and nothing she does prevents them from fighting. The boy is a B+ student and has no behavior problems in school. The medical history and the physical examination are completely normal.

Questions

1. What is sibling rivalry?
2. What is the physician's role in counseling a family about sibling rivalry?
3. What is the role of anticipatory guidance in preparing older children for the birth of a new sister or brother?
4. What are some practical suggestions to share with parents about sibling rivalry?

Sibling relationships are important in helping children shape peer and later adult interactions. Siblings educate and socialize together, and mediate parental demands. Siblings often spend more time interacting with each other than with either parent. The sibling relationship is characterized by continuity and permanence, but the relationship is not without turmoil.

Sibling rivalry refers to the competitiveness between siblings based on the need for **parental love** and **esteem**. The rivalry is often characterized by jealousy, teasing, and bickering. The term was introduced in 1941 by David Levy who described it as “a common feature of family life.” Historical examples of sibling rivalry include relationships between the biblical figures Cain and Abel, Joseph and his brothers, and Jacob and Esau. Sibling rivalry is also noteworthy in pairs of celebrities, such as actresses Joan Fontaine (Academy Award winner for *Suspicion*) and her older sister, Olivia de Havilland (Academy Award winner for *To Each His Own* and *The Heiress*). Their relationship was termed one of the most dysfunctional sibling relationships in Hollywood, and may have had its roots in their simultaneous nomination for an Academy Award in 1942. By 1975 the sisters were no longer in communication with each other.

Sibling rivalry is a **universal phenomenon** occurring even in the animal kingdom. For instance, the firstborn eaglet pushes the other eaglets out of the nest as soon as they are hatched as a way of ensuring an adequate food supply. In humans, the fear of displacement, dethronement, and loss of love occurs with the birth of a new brother or sister, leading to sibling rivalry. Older children fear they are not good enough and need to be replaced. Such feelings lead to a **fear of abandonment**. Jealousy also plays a role, and older children may be angry with younger siblings for displacing them within the family.

Sibling rivalry frequently has a negative effect on parents because it is hard for them to see one of their children hurt, even if it is by a sister or a brother. The challenge for parents is to know when, and

when not, to intervene and what strategies to use to minimize conflicts. Physicians can help by offering **anticipatory guidance** to all parents and specific recommendations to parents who are experiencing such individual problems.

Epidemiology

Sibling rivalry is a universal phenomenon, and a number of factors influence its development. Time interval between children affects the degree of rivalry, as does the age of the older children. Toddlers who are entering the “**terrible twos**” may have a particularly hard time mastering independence and tolerating the presence of their younger sibling. Close spacing results in more problems, particularly when the children are fewer than 2 years apart. In such situations, older children still have dependency needs, often feel less secure, and experience a need for maternal attention. They stay closer to mothers, are less playful, and are tenser. Closely spaced children engage in less spontaneous play, seem angrier, and issue sterner commands to their playmates.

Position in the family also influences sibling rivalry. Middle children experience what is referred to as “**middle-child syndrome**”; they lack the prestige of older children or the privileges of younger ones. These children are often least secure and strive hardest to gain affection. Special difficulties may develop if middle children are the same gender as older ones. Middle children grow up to be flexible, adaptable, and good negotiators. In myths and folklore, youngest children are “favorites.” They are often the ones defended by parents when there are bouts of fighting.

Twins rarely present a problem of sibling rivalry; instead they have a problem maintaining their individuality. However, sets of twins create problems for older siblings because they are not as unique as the pair of twins.

Step-siblings also present a unique problem in sibling rivalry. Children of divorce frequently feel abandoned by one parent and in competition for the time and love of the custodial parent (see Chapter 136). Competition with step-siblings is especially difficult if the step-siblings are in the same home.

There are also unique considerations when one child has a chronic or potentially terminal illness or long-term disability. Similarly, being the sibling of a gifted child (see chapter 30) places unique challenges on sibling relationships. The unique strengths of each child need to be acknowledged.

Issues of sibling conflict change over time. Toddlers are protective of their toys and belongings and are particularly upset when a younger sibling touches their possessions. Sharing is a challenging theme of the toddler years. Children during their school-aged years are concerned about equity and fairness. They may be upset by what they construe as preferential treatment, for instance when a 1-year-old sibling is not expected to put their toys away. Sibling competitiveness is said to peak between the ages of 10 and 15 years. Adolescents with their additional responsibilities, including minding younger siblings, may resent the siblings for imposing on their time. Sibling rivalry can persist into adulthood, and one-third of adults describe their relationship with a sibling as distant or rivalrous. After age 60 years, 80% of siblings report being close.

Clinical Presentation

Parental complaints related to sibling rivalry consist of fighting between siblings, including physical violence and verbal abuse, bickering, and regression to immature behavioral patterns. Although such immature behavior occurs most often following the birth of a new baby, it may also be apparent if one sibling is receiving more attention, such as during an illness or after a major accomplishment. Regressive behavior includes bedwetting, drinking from a bottle, and wanting to be carried to bed. Substitution behavior, such as nail-biting, in place of biting the new sibling, may occur after the birth of a new baby.

Before the birth of a new baby, parents may complain that their children exhibit temper tantrums, irritability, and solemnness. They may mimic the pregnancy by eating a lot and putting a pillow under their clothes. In addition, children may have psychosomatic complaints such as stomachaches or headaches. Risk factors for maladjustment following the addition of a sibling include family discord, physical or emotional exhaustion in parents, and housing insecurity. Conversely, a good marital relationship and family support facilitates the adjustment to new siblings.

Differential Diagnosis

Dilemmas concerning the correct diagnosis of sibling rivalry most often relate to the appearance of behavioral changes, such as regressive or aggressive patterns after the birth of a new sibling. For example, a child who was previously toilet trained may become incontinent of urine. Although urinary tract infection may be considered in the

diagnosis, a careful history concerning the birth of the sibling reveals the correct etiology.

Evaluation

The evaluation of children with suspected sibling rivalry involves a history of the problem and parental strategies for dealing with the difficulties. The parent should be particularly queried about one-on-one opportunities between parents and individual children. The physical examination and laboratory assessment are noncontributory.

Management

The focus of management is to allow the parents to recognize the normalcy of sibling rivalry while helping them define the behaviors that are acceptable and not acceptable within the family context. Children fight more often in families when parents condone fighting and aggression between siblings as normal behavior. Likewise, children of parents who are angry may interact with their siblings through anger. Parents should be counseled about this. Parents may not appreciate their child's fear of loss of parental love as the basis of the sibling conflicts. They should be reminded that many children think, "If I am so good, why do I have to be replaced?" Parents should be asked to empathize by imagining how they would feel if their spouse brought home another mate, even if they were reassured about being loved. Physicians can also help parents deal with sibling rivalry by having them consider their treatment of children in terms of uniqueness versus uniformity and quality versus inequality. In general, parents should be advised to set the ground rules for acceptable behavior. Such rules include no hitting, punching, hair pulling, name-calling, cursing, or door slamming. There may be a neutral area in the home that can be set aside for arbitration should disagreements arise. Moving to a neutral area also allows for some time to cool off. Parents should also be reminded that children who are hungry, tired, or bored are more easily frustrated and may start fights more readily.

Birth of New Siblings

Parents may notice the behavioral changes in their children before the birth of the new sibling. These changes depend on the age of the children and the presence of other siblings. Children should be told about the upcoming birth. The timing depends on the children's age; younger children do not need much lead time. Some studies have evaluated the inclusion of older children in the birthing process. The results of these studies vary, but they suggest that children younger than 4 years need their mother for emotional support and are concerned about her physical exertion during the birthing process. Some older children may also want to distance themselves from the actual events.

Physicians should suggest that older children be involved in planning for the arrival of the new baby as a means of minimizing their feelings of exclusion. For example, they can help purchase clothes or prepare the baby's room. Physicians should also suggest that parents

purchase a gift for older children that represents a present from the new baby, such as tee shirts that announce the older sibling's new status, such as "big sister" or "big brother." In addition, older siblings may be given a doll to serve as a baby they can care for. Parents should point out the advantages of being older with comments such as, "You can stay up later" or "You can walk and play with all these toys." Frequently, the birth of a new baby is met with regressive behavior in older siblings. Regressive behavior should be handled with tolerance and a realization that symptoms resolve with time.

Once the mother goes to the hospital, she should be advised to maintain contact with older children by telephoning. Many hospitals now allow for visitation by siblings. At present, hospital stays are so brief that this period of separation is much shorter than previously. Household changes that may be necessitated by the birth of the new baby, such as room changes, the substitution of a bed for a crib, and entrance into nursery school, should be made before the arrival of the new baby.

Rivalry Between Older Children

Physicians need to consider individual parenting techniques when counseling parents of older children. Parents who compare one child with the other may foster contentious behavior, and those who strive to treat all children equally may inadvertently perpetuate rivalry. Children need to feel that they are unique rather than ordinary. For example, parents who buy both children the same presents may think they are preventing rivalry from developing, but they are actually depriving each child of a sense of uniqueness. The harder parents try to be uniform, the more vigilantly the children may look for inequality. Each child needs a parent's undivided attention, time alone together. Siblings also need time apart from each other, and they should be encouraged to hold separate play dates and individual activities. Not all children in a family need piano lessons and soccer practice. Individuality and uniqueness are important. The more agreeable a parent-child relationship is, the more agreeable a sibling-sibling relationship is, because each child has good self-esteem. Practitioners should recommend uniqueness and quality in each parent-child relationship.

Parents sometimes have to deal with sibling rivalry between older children. Physicians should reassure parents that these older children should be allowed to vent their negative feelings toward each other. For example, if a girl refers to her brother by saying "I hate him," the parents should respond by validating these emotions and saying something like, "It sounds as if he's done something to really annoy you." Parents should also be advised not to take sides. They should examine how they usually respond to squabbling between siblings. Is one child's name always called first during a fight? Do they perpetuate sibling rivalry by using certain nicknames (eg, "turkey brain") or other derogatory terms? Parents should assume that both parties are at least partially guilty and should not allow themselves to be drawn into the fight as referees. Parents can respond to a request for arbitration with a statement such as, "I wasn't here when

things started, so I don't know who is right or wrong." The parents should also advise siblings that they do not have to be friends with one another, but they should not hurt each other's feelings.

Anticipatory guidance helps parents anticipate conflictual situations, such as who sits where during long car rides and who holds the remote control device. Family meetings can be held to determine the ground rules that may avoid such battles. If conflicts arise, children should be allowed to work out a solution by themselves, with the stipulation that the parents will solve the problem if the children do not reach an agreement. If fights between siblings have recurrent themes (eg, which television shows to watch [who controls the remote] or video games to play), parents can devise a weekly schedule. Failure to abide by the schedule means both children forfeit the activity. If borrowing is the source of disputes, children who borrow from their siblings should leave "collateral," which gets given back when the borrowed item is returned. Box 44-1 lists suggestions for parents who are seeking advice about fighting between children.

Siblings of Children With Special Health Care Needs

Nearly 1 in 5 children in the United States is a child with special health care needs (see Chapter 39). Caring for such children places increased demands on parents and their resources, and there is less parental attention or time available for siblings. Integrating the unaffected sibling into the families' care plan and activities can be empowering for the child and positively influence their self-esteem. As with all children, time alone between the unaffected child and parent should be strongly encouraged. Support groups for siblings of children with special health care needs have been demonstrated to help youngsters cope and to deal with their often conflicted feelings of anger at the special attention their brother or sister receives and their guilt about being healthy.

Box 44-1. Coping With Rivalry Between Siblings: Physicians' Advice to Parents

Dos

- Allow children to vent negative feelings.
- Encourage children to develop solutions.
- Anticipate problem situations.
- Foster individuality in each child.
- Spend time with children individually.
- Compliment children when they are playing together.
- Tell children about the conflicts you had with your siblings when you were children.
- Define acceptable and unacceptable behavior.

Don'ts

- Take sides.
- Serve as a referee.
- Foster rivalry.
- Use derogatory names.
- Permit physical or verbal abuse between siblings.

Prognosis

Although sibling rivalry may last for years, most siblings become good friends as adults. Rarely, mental health services are needed, especially if the sibling conflict has led to marital discord, there is concern about physical or severe emotional harm, or there is evidence of another psychiatric disorder such as depression. Learning how to negotiate with one's siblings enables children to develop skills to collaborate with peers and colleagues as adolescents and adults.

CASE RESOLUTION

In the case history presented at the beginning of the chapter, the mother should be advised not to serve as a referee. She should learn how to validate each child's feelings about the other. The physician can help her by talking to her son about his feelings. She should be advised to have a discussion with her children during which each child has the opportunity to define areas of conflict and the means to resolve them. The mother has the right and responsibility to prohibit physical fighting and encourage verbal dialogue.

Toilet Training

Sabrina D. Diaz, MA, and Lynne M. Smith, MD

CASE STUDY

A 2-year-old boy is brought to the office for a well-child visit. His mother, who is about to begin toilet training her son, asks your advice. The mother says that by the time her daughter was 2 she was already toilet trained, and she wants to know if training her son will be any different. The boy was the product of a full-term pregnancy and a normal delivery. He has been in good health, and his immunizations are up to date. He is developmentally normal, uses some 2-word phrases, and has been walking since the age of 13 months. His physical examination is normal.

Questions

1. When should physicians begin discussing toilet training with parents?
2. What factors help determine children's readiness to begin toilet training?
3. Is toilet training in boys different from toilet training in girls?
4. What are some of the methods used to toilet train children?

The age at which toilet training is carried out is culturally determined. Some cultures train children at a very early age. For example, in the East African Digo culture, some children between 2 to 3 months of age are conditioned to urinate or defecate when placed in certain positions. Similar conditioning practices are carried out in China. Chinese children are kept without diapers, and when caregivers who are holding them sense a change in their bodies in response to a need to eliminate, they place their children in an appropriate position. In addition, children are dressed in clothing that facilitates toileting. Split pants, with the back and bottom portion missing, are used so that children can squat and eliminate without removing complicated clothing.

American culture has emphasized the learning aspects of toilet training as opposed to the conditioning aspects. This training focuses on the cognitive development of children and children's readiness to learn the complexity of the task. It has been demonstrated that infants as young as 6 months can be trained to signal the need to urinate or defecate and suppress emptying for brief periods.

Toilet training is potentially both a rewarding and frustrating experience for children and parents. Parents may have unrealistic expectations of their children's capability or may be very intolerant of normal accidents that occur in the training process. It is important for physicians to introduce the topic of toilet training early on to prevent these unrealistic expectations. Children's refusal to toilet train or accidents related to toilet training are often cited as a precipitating event for child physical abuse. It is recommended that the issue of toilet training be introduced and anticipatory guidance provided by the age of 18 to 24 months to help parents develop reasonable expectations.

Epidemiology

The age at which children are toilet trained varies depending on social considerations and social pressures. Prior to the 1920s, the American approach to toilet training was permissive. This attitude then changed, and the methods became more rigorous, requiring that children be trained at an earlier age. In 1947 only 5% of children were not trained by 33 months of age, but by 1975, this figure had increased to 42%. Currently approximately 25% of typically developing American children are daytime toilet trained at 24 months and 98% by 48 months, although many parents expect their child to be trained by 18 months. Cultural and socioeconomic factors also influence parental beliefs about toilet training. Horn and colleagues found that white race and higher family income were associated with parents favoring later initiation of toilet training. There has been a renewed interest in earlier toilet training in the United States. This has been attributed to 3 societal factors: the lower cost and increased options for child care and schooling associated with children once toilet trained, concerns about contagious illnesses such as hepatitis and infectious diarrhea in child care facilities where diapers are changed, and the adverse environmental effects of nonbiodegradable disposable diapers. There may be some reversal in these trends related to the development of highly absorbent, biodegradable disposable diapers that are also flushable, and the marketing of nighttime pull-ups to children as old as 4 years.

As a general rule, girls are trained a bit earlier than boys, but only by a matter of a few months. Most children (80%) are trained simultaneously for bladder and bowel control. Approximately 12% are trained first for bowel control and about 8% for bladder control. Girls achieve nighttime continence at a younger age than boys.

Pathophysiology

Toilet training involves the ability both to inhibit a normal reflex release action and then relax the inhibition of the involved muscles. For the process to be successful, a certain degree of neurologic and biological development is essential. Myelination of the pyramidal tracts and conditioned reflex sphincter control are necessary. Voluntary control is evidenced by myelination of the pyramidal tracts by the age of 12 to 18 months. Conditioned reflex sphincter control occurs by 9 months of age and voluntary cooperation between 12 to 15 months of age. In assessing the neurologic development of children, walking is viewed as one of the milestones that indicate motor readiness for toilet training.

Toilet training depends on both physiological and psychological readiness. Cognitive development is assessed by a child's ability to follow certain instructions. Two years of age has been suggested as the appropriate age to initiate toilet training in most children. Toilet training usually takes 2 weeks to 2 months to learn, although training may occur in less time using more intense conditioning methods.

Differential Diagnosis

The differential diagnosis of toilet-training difficulties focuses on factors that contribute to a delay in acquisition of skills. Physicians should look for associated symptoms such as dysuria, a weak urinary stream, constantly wet underwear, or fecal soiling when assessing children who continue to manifest signs of either urinary or stool incontinence. In addition, it is important to determine if children are essentially toilet trained but are having intermittent accidents.

Voiding dysfunctions involve an abnormal voiding pattern stemming from a problem with the bladder filling or emptying. They are characterized by urine leakage, an increase in urgency, and an increase in frequency, and often result in frequent urinary tract infections (UTIs). The most common cause of isolated daytime wetting in previously trained children is **UTI** (see Chapter 52). **Chemical urethritis** may also be associated with urinary incontinence. **Stress incontinence**, which has also been called *giggle incontinence*, may result in wetting. **Urgency incontinence** occurs when children delay going to the bathroom and then are unable to hold urine any longer. Some children have ectopic ureters, which can empty into the lower portion of the bladder, vagina, or urethra and cause a constant dribble of urine. **Labial fusion** with **vaginal reflux of urine** may also be associated with daytime wetting. Urine pools behind the fused labia or labia that do not separate sufficiently to allow natural egress during voiding, and when children stand up the urine exits. Children with **neurogenic bladders** may also have symptoms of daytime enuresis.

Stooling accidents may be associated with chronic **constipation** and overflow incontinence or with Hirschsprung disease (see Chapter 53). Stool toileting refusal occurs when a child is trained to urinate in the toilet but refuses to defecate in the toilet for at least 1 month. While many parents view stool toileting refusal as insignificant, it is often associated with developing encopresis, constipation, painful bowel movements, and delayed completion of toilet training.

Children who prefer to stand in a corner to defecate should be commended for recognizing their physiological urge. However, parents should be aware that children who hide while stooling in their diaper are more likely to exhibit stool toileting refusal and be constipated. Successful treatment of constipation may decrease the incidence of toileting refusal.

Evaluation

History

Typically developing toddlers should be assessed for both their physiological and psychological readiness to initiate toilet training, as well as any underlying medical conditions that may affect their ability to learn toileting skills at the customary age. Physicians should provide anticipatory guidance to parents about toileting readiness. Affirmative answers should be obtained to the following 3 questions:

1. Do children exhibit bladder control as evidenced by (1) periods of dryness that last up to 2 hours and (2) facial expressions that show their physiological response to the elimination process?
2. Do children have the motor skills necessary to get around? This essentially involves the children's ability to walk and remove their clothing.
3. Do children have the cognitive ability to understand the task at hand?

Cognitive ability can be assessed by giving children 10 one-step tasks and seeing if they are able to carry out at least 8 of the 10 tasks (Box 45-1). The ability to carry out these tasks does not ensure a willingness to be toilet trained.

Stress in the home may negatively affect a toddler's ability to master the task of toilet training. The physician might counsel a family to delay toilet training if the family has moved recently; the birth of a new baby is expected; or there has been a major family crisis, such as a death or serious illness.

Children who have had difficulties with toilet training need to undergo a similar assessment.

Physical Examination

A physical examination to rule out underlying problems such as spina bifida occulta, which may be associated with a neurogenic bladder, should be performed. A neurologic examination may reveal nerve damage impeding muscles from relaxing or tightening at the right time. A careful examination of the genitalia is important in children who are having urinary incontinence to determine if conditions such as labial fusion, meatal stenosis, or posterior urethral valves are

Box 45-1. Requests or Imperatives Used to Help Assess Toilet-Training Readiness

Sit on the chair.	Put the doll on the floor.
Pick up the doll.	Take off your shoes.
Open the door.	Open the book.

evident. In children who are having stooling problems, physicians should check for an abdomen with feces-filled intestines, a sign of obstipation. In addition, a rectal examination should be considered to determine the presence of hard or impacted stools or any other abnormalities in the anal area.

Laboratory Tests

Although a laboratory assessment is not indicated in normal toddlers who are being toilet trained, diagnostic studies may be appropriate in children who are having problems with training. In older children, urinalysis may show evidence of a UTI.

Management

Physicians should help parents understand the appropriate approach to the toilet-training process. Unfortunately, most parents do not obtain the necessary advice from physicians. In one report, no parents attending a clinic and only 7% of parents in a private practice received advice about toilet training from their physicians. Therefore, it is important for physicians to initiate the discussion early enough to prevent the development of any problems.

There are 2 main contrasting styles of toilet training, although reliable efficacy studies are lacking. The first method described by Azrin and Foxx is parent-oriented and uses intense operant conditioning methods and a potty doll to assist with learning. The 5 components of the method include increasing the amount of fluids consumed; regularly scheduled times for toileting starting with 15-minute intervals; positive reinforcement for asking about, approaching, or sitting on the potty chair; grasping pants and successful urinating or defecating in the potty chair; time-out from positive reinforcement/cleanliness training following accidents; and teaching the child to differentiate between wet and dry pants, checking for dry pants every 5 minutes. Though this method has been effective in training children, including those individuals with mental disabilities, it is not recommended for training typically developing children.

The second method, endorsed by the American Academy of Pediatrics (AAP), is a child-oriented approach that stresses the child's physiological and psychological readiness to toilet train. There are 3 versions of this approach: Brazelton, AAP guidelines, and Dr Spock's approach. All versions use the same components, with only minor deviations. This method involves gradual training and emphasizes the use of **rewards**, not punishments. Children with autism who do not understand the social reward system advocated by this method may benefit from the intense conditioning methods described by Azrin and Foxx.

When toilet training typically developing children, parents should be advised to take the following approach:

1. Teach children the **appropriate vocabulary** related to the toilet-training process. This could include words such as “pee,” “poop,” “urine,” “stool,” “dry,” “wet,” “clean,” “messy,” and “potty.”
2. Tell children what the **purpose of the potty** is. Placing the contents of a soiled diaper into the toilet can educate them on the purpose of the potty. In general, a child potty chair should be purchased. The potty chair has a number of advantages over

the toilet. Parents can encourage children to decorate the potty and put their names on it. The potty can be kept in a place where children spend much of their time, not necessarily in the bathroom. Children can sit on the potty and have their feet on the floor, which is more physiologically sound and gives them a greater sense of security. Parents should suggest that children stand fully clothed in the bathroom as an initial step in encouraging their use of a potty. Children should be allowed to sit on the potty with their clothes on for about a week before the process of toilet training begins. Then children should sit on the potty without their clothes on, but no attempt to catch either stool or urine should be made. Boys should learn to urinate in the seated position because they may otherwise resist sitting for defecation.

When away from home, the potty chair should be packed to maintain the established routine. It is important that all individuals caring for the child (grandparents, babysitters) understand the parents' plans for toilet training.

Toilet adapter rings can be used if the family is resistant to using a potty chair, or if the transition from a potty chair to the toilet is likely to be stressful, as is true for many children with autism. Adapter rings fit directly onto the toilet and do not require emptying, as do separate potty chairs. They require that the toddler climb up on the toilet, and they need to be removed for others to use the toilet. A stool should be used to aid in climbing onto the toilet as well as to provide more leverage while defecating.

3. Encourage cleanliness and dryness by **changing children frequently**. Parents should ask their children whether they need to be changed using the appropriate vocabulary. This phase is important to continue as the toilet-training process proceeds. Some parents mistakenly do not change their soiled children as a means of punishing them for having accidents. This gives children a confusing message about the need for cleanliness.
4. Explain the **connection between dry pants and going to the potty** to children. Children should understand that dry pants feel good and that they can keep their pants dry by going to the potty.
5. Help children understand the **physiological signals** for using the toilet. Parents can facilitate this by observing children's behavior around the time of elimination and making comments such as, “When you jump up and down like that, Mommy knows you have to go to the bathroom.”
6. Children must have the physiological ability to postpone the “urge to go.” This usually occurs when children have the ability to delay voiding for at least 2 hours. Parents then can initiate toilet training by taking children to the bathroom at 2-hour intervals. In addition, children should sit on the toilet immediately after naps and 20 minutes after meals. Children should not be left on the toilet for more than 5 minutes and should be permitted to get up if they want. While sitting on the potty, they can be entertained with reading a story or playing games. It is helpful to have designated toys or books enjoyed only when the child is sitting on the potty. Parents are encouraged to rotate the toys so potty training continues to be interesting to the child.

Additional suggestions involve allowing children to have their clothes off and keeping the potty chair near them during play. This facilitates using the potty and is reminiscent of the practice of using split pants in China.

Children who use the potty successfully should be rewarded. Rewards can be in the form of verbal comments such as “Mommy is so proud of you,” hand clapping, or the use of star charts that can be redeemed for rewards. Children can be consulted about what rewards they like. The AAP recommends using praise rather than treats for reinforcement. Punishment should not be used, particularly physical punishment. One report indicates that 15% of parents of clinic patients believe that spanking their children for accidents is acceptable. Parental disapproval of accidents can be articulated; however, parents should understand that accidents may continue to occur for months. Regression in a toilet-trained child may also occur with stressors such as a recent move, new sibling, or divorce.

There are 2 additional conditioning methods less commonly used in North America. The first is assisted infant toilet training and begins when the infant is 2 to 3 weeks of age. The infant is placed over a toilet after feeding or if showing signs of elimination, and is rewarded with food or affection for voiding or stooling. The second method focuses on elimination communication and begins at birth. The parent learns infant body language, noises, and elimination patterns. The parent also makes noises, such as the sound of running water, to associate with voiding while the infant is placed in positions to facilitate elimination. Interest in these conditioning methods has increased over the past few years.

If children are trained on a potty chair, they can generally begin using a toilet between 2½ to 3½ years of age. Children should wash their hands following sessions sitting on the toilet. Children can also use training pants, which are thickened underwear, or pull-ups, which are diaper-like underwear, rather than diapers. Pull-ups are now marketed to children as old as 4 to 5 years, and there is anecdotal evidence to suggest that the age of completion of toilet training may be delayed by the use of pull-ups. Regular underwear is promoted as advantageous because it feels different from diapers and encourages the use of the potty. Using a bigger size or snipping the waistband facilitates children’s ability to remove their underpants and can be recommended.

If children demonstrate resistance to toilet training, the process should be delayed for 1 to 2 months. Children who learn how to withhold need additional time to learn how to relax their sphincter when sitting on a potty. It is important for parents to avoid an aggressiveness/resistance struggle, because this then may become the source of future bowel problems, including constipation. Children who are regular, particularly those who have a bowel movement at the same time every day, are more easily toilet trained.

Some children seem fearful of certain aspects of the toilet-training process. These include fear of falling into the toilet (this is circumvented with the use of a potty or toilet adapter rings) or fear of the loud noise of the flush. Allowing the child to flush the toilet without using it may dispel the fear. Toilet phobias can cause a child to hold

their urine until the last moment, resulting in wetting, or can cause a child to hurry and not fully empty their bladder, resulting in possible infections. Some children become fascinated with flushing or unrolling toilet paper, and parents should discourage children from wasting water or paper.

One of the major components of toilet training children is **modeling**. Children should be allowed to enter the bathroom with the parents and even sit on the potty chair as one or the other parent sits on the toilet. Some children who are very strong-willed and independent, coupled with perfectionist parents, may have problems with toilet training.

Special considerations have to be made for children attending child care. Their teachers should be advised about the toilet training. Children should have “open bathroom privileges,” which means that they should be permitted to leave the room to go to the bathroom without raising their hands or other reminders. Child care offers the advantage of peer modeling and peer pressure during the toilet-training process. Potty chairs should not be used in child care settings because of the risk of infectious diseases.

Children with special needs generally encounter more obstacles when mastering toileting. Communication delays, decreased motor skills, sensitivity to stimulation, and preference for routine are just a few of the additional challenges that make it difficult to ascertain whether the child is ready to toilet train. Although incontinence was once thought to be inevitable for children with special needs, it is important for parents to understand that continence can be achieved but that expectations need to be modified (may take until age 5 to achieve and standard toilet training methods rarely are successful).

Medications have a limited role in toilet training. Some physicians recommend the use of drugs to increase bladder capacity. Although tolterodine and oxybutynin (Ditropan) increase bladder capacity and decrease the frequency of bladder contraction, they should not be used because they do not assist children with the toilet-training process. However, children who are constipated may require stool softeners, such as mineral oil, or the addition of fiber bulk to their diet and increased fluid consumption to facilitate the stooling process. Physicians should see children who seem to have particularly challenging toilet-training problems on a weekly or biweekly basis until they show improvement.

Parents can also be referred to the many books on toilet training, particularly if problems develop. Many books are geared for children to help them understand their body and the elimination process. Videotapes are also available to help children with toilet training. Children may also have the opportunity to practice with dolls designed to wet or poop after being fed.

Prognosis

All typically developing children are eventually toilet trained. The age when this occurs varies and is significant only if it restricts children from participating in school.

CASE RESOLUTION

The mother in the case history should be advised that this is a good time to initiate the toilet-training process. She should be told that boys, as a group, are successfully toilet trained at a later age than girls. Her son can be assessed to see if he can follow at least 8 out of 10 instructions (see Box 45-1). If he can, the mother should be given the stepwise approach to initiating the toilet-training process. The mother should be informed that nighttime continence can take months to years after daytime continence is achieved.

Crying and Colic

Geeta Grover, MD

CASE STUDY

The parents of a 2-week-old infant bring their son to the emergency department because he has been crying persistently for the past 4 hours. He has no history of fever, vomiting, diarrhea, upper respiratory tract infection, or change in feeding. The infant is breastfed.

On physical examination, the infant appears well developed and well nourished. His weight is 7 lb, 7 oz—7 oz more than when he was born. Although he is fussy and crying, he is afebrile with normal vital signs. The remainder of the physical examination is within normal limits.

Questions

1. What is the normal crying pattern in young infants?
2. What is colic?
3. What conditions are associated with prolonged crying in young infants?
4. What are key factors in the history of crying infants?
5. What laboratory tests are indicated in crying infants?
6. What are a few of the management strategies that can be used by parents to soothe their crying or colicky infants?

Crying, an important method of communication between infants and caregivers, is nonspecific, and many stimuli can produce the same response (eg, hunger, fatigue, pain). Parents report that they can discriminate among various types of cries in their infants. Crying can be divided into 3 categories: (1) normal or physiological crying, (2) excessive crying secondary to distress (eg, hunger) or disease, and (3) excessive crying without an apparent cause.

The difference between normal and excessive crying may be more qualitative than quantitative. Some investigators have used the mnemonic **PURPLE** to characterize crying during early infancy focusing on the qualities that make the crying particularly frustrating to caregivers: **P**: peak pattern (increases weekly until 2 months of age), **U**: unexpected bouts of crying, **R**: resistance to soothing measures, **P**: pain-like facial grimacing, **L**: long periods of crying, **E**: evening clustering. Deciding whether crying is excessive varies with parents' expectations and thresholds. Expressed parental concern about extreme crying or fussiness requires attention. If parents complain that infants cry inconsolably or continuously as well as excessively, the crying may have an underlying organic etiology.

Colic, a poorly understood, benign, self-limited condition, falls into the third category. It manifests as unexplained crying or fussing in infants that usually occurs in the late afternoon or evening. During an episode of colic, infants cry and may either draw the knees up to the chest or rigidly stiffen the legs, flex the elbows, clench the fists, and turn red (Figure 46-1). Although infants may appear to be totally miserable during an episode of colic, they are otherwise healthy, eat well, and demonstrate good weight gain.

Figure 46-1. Colicky infant.

Epidemiology

Qualitatively, **excessive crying** is any amount of crying that concerns or worries parents. Quantitatively, definitions of excessive crying have been based on the results of Brazelton's study of normal infants. Excessive crying begins at 2 weeks of age (median daily crying time about 2 hours per day), peaks at 6 weeks of age (median daily crying time about 3 hours per day), and then decreases to less than 1 hour

per day by 12 weeks of age. Apparently, more crying occurs during the evening hours, especially between the ages of 3 and 6 weeks.

Although many infants exhibit a fairly similar pattern of fussiness that peaks at about 6 weeks of age, infants with colic tend to be inconsolable for longer periods and cry with more intensity. Colic affects 10% to 20% of infants younger than 3 months. There is no seasonal variation in its occurrence, and breastfed and formula-fed infants are affected equally. Colic usually begins at 2 to 3 weeks, peaks at 6 to 8 weeks, and resolves by 3 to 4 months of age. In studies of infant colic, the definition of colic that is cited most frequently is the Wessel definition, which describes colicky infants as having unexplained paroxysmal bouts of fussing and crying that last for more than 3 hours a day, for more than 3 days a week, and for more than 3 weeks' duration ("rule of threes").

Clinical Presentation

Colicky infants are otherwise healthy infants younger than 3 months who cry or fuss inconsolably for extended periods, usually during the afternoon or evening. The crying usually resolves within a few hours.

Pathophysiology

Crying is a complex vocalization that changes during the first year of life as infants develop. In the first few weeks of life, crying is a signal that infants are experiencing a disturbance in homeostatic regulation (eg, hunger, discomfort). As infants mature and begin to differentiate internal from external stimuli, crying may also be an indication of too little or too much environmental stimulation. During the second half of the first year, as infants mature neurologically and gain voluntary control over vocalizations, crying can be an expression of different affects (eg, frustration, fear).

A variety of explanations for the etiology of **colic** have been proposed. Some authorities believe that colic may not be a pathologic entity but simply an extreme variant of normal crying. The condition may result from an allergy, cow's milk intolerance, abnormal intestinal peristalsis, or increased intestinal gas, which are some of the more frequently associated factors. Others have proposed that colic is caused by problems in the interaction between infants and their environment, specifically their parents. This interactional theory requires not only excessive crying on the part of the infant, but also an inability of the parents to soothe the crying infant. The "missing fourth trimester" theory of colic posits that infants cry because they are born "3 months too soon" (ie, human gestation should last 3 months longer). There is no scientific evidence to support this hypothesis. Whether maternal anxiety has any role in colic remains a controversial issue. More than one of these factors may contribute to the pathogenesis of colic.

Differential Diagnosis

An acute episode of excessive crying may be secondary to disease (eg, fever, otitis media). An organic etiology should be suspected in infants who present with inconsolable crying of acute onset. Box 46-1 lists the most common causes. Some conditions occur in

- Persistent night awakening

Drug Reactions

- Immunization reactions (previously common: with diphtheria-tetanus-pertussis vaccine)
- Neonatal drug withdrawal (narcotics)

Child Abuse

- Long bone fractures
- Retinal hemorrhage
- Intracranial hemorrhage

Hematologic^a

- Sickle cell crisis

Cardiovascular

- Arrhythmia (supraventricular tachycardia)
- Congestive heart failure
- Anomalous left coronary artery

^aMay present as acute or recurrent episodes of excessive crying.

a more chronic or recurrent pattern, particularly if the condition is not treated.

The differential diagnosis of infants who experience recurrent episodes of excessive crying or recurrent night awakenings associated with crying focuses more on behavior and temperament. Colic, neonatal drug withdrawal, or difficult infant temperament (eg, extreme fussiness) may cause recurrent crying. Recurrent night awakening and difficult infant temperament are discussed in Chapters 25 and 48, respectively.

Evaluation

A thorough history and physical examination usually provide clues to the diagnosis in instances of acute onset of crying.

History

The focus of the history should be on determining the presence of any associated symptoms. In addition, the circumstances surrounding the crying (eg, occurrence during day or night) should be ascertained (Questions Box).

Physical Examination

A thorough physical examination is required for accurate diagnosis. Particular attention should be given to the following aspects of the examination:

1. Careful inspection of the skin after all clothing has been removed to look for any suspicious bruises or marks
2. Palpation of all long bones to detect fractures
3. Examination of all digits and the penis to check for hair tourniquets (single strands of hair wrapped around digits or the penis)
4. Examination of the retina to look for retinal hemorrhages (a sign of intracranial hemorrhage)
5. Eversion of the eyelids to check for foreign bodies
6. Fluorescein staining of the cornea to look for corneal abrasion

Laboratory Tests

Except for urinalysis, most screening laboratory tests are probably not useful. Test selection can be guided by the history and physical examination (eg, infants with fever without an apparent cause should have a septic workup, with an examination of blood, urine, and cerebrospinal fluid). Urinalysis, which may provide clues to an underlying metabolic deficiency, is sometimes helpful. Even when the initial history and physical examination are non-diagnostic, infants who persist in crying inconsolably should be suspected of having a serious underlying condition (eg, intracranial hemorrhage, drug ingestion). Such infants may warrant an extended period of observation or a more extensive workup that includes laboratory assessment.

Imaging Studies

Roentgenographic studies such as long bone radiographs may be necessary in some situations (eg, infants with long bone pain on palpation, suspicion of child abuse). Infants with retinal hemorrhages should have a computed tomography scan.

Management

Management and treatment depend on identification of the cause of the crying. Underlying organic conditions (eg, urinary tract infection, fractures) should be treated. Management of colic depends on presumptions regarding its etiology. It is important for practitioners to **reassure** parents regarding the benign nature of colic and its resolution over time. Physicians should provide a caring and supportive environment in which the parents may express their concerns and frustrations. Reassurance along with practical suggestions regarding infant feeding and handling techniques (eg, cuddling, swaddling, or rocking) may often suffice.

Some management strategies have specifically been developed to reduce the risk that an infant will be injured by a frustrated caregiver.

Questions

Crying and Colic

- Is this the first time the infant has cried inconsolably or does this happen on a recurring basis?
- Has the infant had a fever?
- Does the infant have any cold symptoms, vomiting, or diarrhea?
- Is the infant having any difficulty feeding? Is the infant formula-fed or breastfed?
- Has the infant had a recent fall or accident?
- What do you do when your infant cries?

Educational materials in the form of booklets and instructive DVDs have been used to prevent the risk of abusive head trauma.

Management suggestions for colic should be customized for infants and families. The more common management techniques are listed in Box 46-2. Complementary and alternative medicine therapies have been used historically to treat colic. Evidence from recent small clinical trials and pilot studies have shown that some natural health products, nutritional modulation, cranial osteopathy, infant massage, and parental behavioral training have some promise in the treatment of infantile colic, but larger confirmatory trials are needed to address concerns regarding both safety and efficacy.

Changes in sensory input (eg, soothing sounds or motions) may resolve crying and soothe colicky infants. According to the “missing fourth trimester” theory of colic, re-creating the sensory environment of the womb calms infants by triggering a soothing response—the calming reflex—and promotes relaxation. Five maneuvers (swaddling, side or stomach position, shushing, swinging, and sucking—“the 5 Ss”) that mimic uterine sensations are noted to activate this calming reflex. It is further recommended by proponents of this theory that 3 to 5 of these maneuvers should be performed simultaneously and vigorously to activate the calming reflex.

Prophylactic measures to prevent the passage of swallowed air through the pylorus can also be useful. Such techniques include feeding in an upright position and limiting the period of sucking at the breast or bottle to about 10 minutes (after this time, greater amounts of air are swallowed relative to the amount of milk ingested). Some infants eat very fast and swallow a lot of air. Burping these infants every 5 to 10 minutes during feeds may help alleviate

Box 46-2. Management of Colic

- Parental reassurance
- Parental education
- Alteration in techniques of infant feeding and handling
- Alteration of sensory input to infant
- Prevention of swallowed air from passing through pylorus
- Dietary alterations
- Medication
- Complementary and alternative medicine therapies
- Increased carrying
- Responding quickly to crying

discomfort due to excessive air swallowing (aerophagia). Decreasing the size of the opening of a nipple in a bottle-fed infant may reduce the amount of air-swallowing.

Methods to decrease intestinal spasm (eg, abdominal massage, warm baths, avoidance of overfeeding) may be helpful. The use of suppositories or rectal thermometers to break up rectal spasm and thereby release retained gas should be discouraged.

Data regarding **dietary changes**, such as the use of hypoallergenic diets by breastfeeding mothers, have been inconclusive but suggest that there may be some therapeutic benefits. Similarly, the use of soy-based or hypoallergenic infant formulas also seem to have beneficial effects on the symptoms of colic. Generally, these dietary modifications should be reserved for infants with additional symptoms of allergy (eg, wheezing, rash) or intolerance (eg, vomiting, diarrhea, hematochezia, or weight loss).

Various drugs, including anticholinergics, motility-enhancing agents, barbiturates, laxatives, and anti-flatulents, have limited success and are best avoided. Currently, anti-flatulents (eg, simethicone) are prescribed most commonly. Despite lack of scientific evidence to support their efficacy, parents indicate that they are effective.

As long as no adverse effects are evident, limited amounts (eg, 1–2 oz per day) of **herbal remedies** (eg, chamomile tea) can be supported if parents report satisfaction. Over-the-counter homeopathic preparations are also innocuous and have no scientifically demonstrated efficacy, but may be advocated as helpful by some parents.

Finally, the practitioner should encourage parents to respond to the infant's cries quickly and carry the infant as much as possible (eg, at least 3–4 hours daily). Parents should be advised that they cannot “spoil” infants younger than 4 months and that they might actually improve behavior by their own increased responsiveness.

Presently, the best evidence-based approaches to the management of colic include holding, swaddling, and comforting an infant; a trial of dietary modifications; limited amounts of herbal teas; and attempting to minimize environmental stimulation levels.

Prognosis

Fortunately, the natural history of persistent crying during infancy is resolution over time. Long-term sequelae of infant colic that have been identified include possible relationships with irritable bowel syndrome and increased levels of externalizing behavior problems (eg, hyperactivity, conduct concerns, and decreased adaptability) in childhood.

CASE RESOLUTION

The infant described in the case history is experiencing an acute episode of unexplained crying. Despite a normal physical examination, he was observed for 1 hour in the emergency department because his crying persisted. Subsequently, a septic workup was initiated, which revealed that a urinary tract infection was the source of the irritability.

Discipline

Carol D. Berkowitz, MD

CASE STUDY

A 3-year-old boy is being threatened with expulsion from preschool because he is biting the other children. His mother states that he is very active and aggressive toward other children. In addition, his language development is delayed. She is at her wit's end about what to do. The birth history is normal, and the mother denies the use of drugs or cigarettes, but she drank socially before she realized she was pregnant. The medical and family histories are non-contributory, and the physical examination is normal.

Questions

1. What is the definition of discipline?
2. What are the 3 key components of discipline?
3. What strategies can parents use to discipline children?
4. What are the guidelines for using time-out?
5. What is meant by parental monitoring?
6. What is the relationship between corporal punishment and child abuse?

Discipline can be defined as an educational process in which children learn how to behave in a socially acceptable manner. The word is derived from *disciplinare*, meaning to teach or instruct. It involves a complex set of interactions of attitudes, models, instructions, rewards, and punishments. Discipline is not synonymous with punishment. The goal is to help children gain self-control and respect for others and to learn behavior that is appropriate for given situations. It is also to ensure a child's safety in the environment. Proactive discipline is action taken by parents to encourage good behavior, and reactive discipline is parental action following misbehavior. To be effective, child discipline must have 3 components: a learning environment with a positive supportive parent-child relationship, a refined strategy for teaching and reinforcing desired behaviors, and a defined strategy for decreasing or extinguishing undesired behaviors. Children thrive in a supportive environment in which they are praised for socially appropriate behavior and are able to participate in the responsibilities and activities of the household. Parents, however, are more often interested in eliminating unwanted behaviors and may bring these specific concerns to their pediatrician.

Parental monitoring relates to the oversight of children's activities at home, in school, and in the community. The extent and form of parental monitoring varies with the age of the child. Parental monitoring occurs when parents ask their children: "With whom are you going to be? Where are you going? What will you be doing?" Parental oversight involves children's access to and use of the Internet and social media (Chapter 9). Inadequate parental monitoring has long-term sequelae, including a greater incidence of risk-related behaviors. Parental monitoring must be coupled with parental discipline to promote desirable behaviors and eliminate undesirable ones.

Physician-Parent Interactions Concerning Discipline

Practitioners can assist parents by giving them guidelines for appropriate childhood discipline related to both routine and problem development and to counsel about the scope of monitoring. The age and temperament of the child are important factors to consider. In addition, pediatricians can discourage corporal punishment as the major method of discipline. Pediatricians may also have a role in advising against corporal punishment in schools. While most states have banned corporal punishment in the school setting, 21 states still permit it.

It is important to encourage parents to establish a positive interactive environment with verbal communication, monitoring children's behavior and commending desirable behavior, ignoring trivial problems, and consistently applying predetermined consequences for misbehavior. Psychologist Marshall B. Rosenberg promotes the concept of compassionate communication using the analogy of the language of the giraffe, which is a language of requests, versus the language of the jackal, one of demands. Identifying feelings is integral to the language of giraffes. Rules should be simple, clear, and established ahead of time. Frequently physicians fail to inquire about children's behavior. Unless parents bring up the topic, it is not discussed during the physician visit. On average, physicians spend only 90 seconds per visit on anticipatory guidance and counseling. However, one survey of mothers in a physician waiting room showed that up to 90% were concerned about one aspect of behavior. Sixty percent of mothers surveyed found physician intervention quite helpful. The American Academy of Pediatrics recommends anticipatory guidance about discipline at each health maintenance visit between

9 months and 5 years. Such counseling is especially important to help parents understand the value of appropriate discipline in shaping their children's self-esteem. Information about discipline in the media may be confusing and contradictory, and often supports the unfounded approaches of nonprofessionals. Starting when a child is 5 years old, physician–parent discussions should include the notion of monitoring.

Early in the physician–parent relationship, physicians may express their interest in behavioral problems by saying, “I am interested not only in your child's physical well-being, but also in his (or her) growth and development and how he (or she) gets along with friends and family.” They may then question parents about how children spend their days. During subsequent visits, pediatricians may say, “Parents of children of (child's name)'s age frequently worry about discipline. I wonder if you have any concerns.” In making these inquiries, the physician may establish what factors, such as religious or ethnic beliefs, or family influences are shaping parents' decisions about discipline.

Problem Behaviors

Behavioral problems can be placed in 5 major categories.

- 1. Problems of daily routine.** Such problems refer to the refusal of children to go about their daily activities, such as eating, going to bed, awakening at a certain time, and toilet training.
- 2. Aggressive-resistant behavior.** This behavior is characterized by negativism and includes temper tantrums and aggressive responses to siblings and peers. Some undesirable behavior can place children or those around them in danger or at risk for injury.
- 3. Overdependent or withdrawal behavior.** Such behavior is typical of children who are very attached to their mothers. These clingy children find separation difficult, especially in a preschool setting.
- 4. Hyperactivity or excessive restlessness.**
- 5. Undesirable habits,** which include thumb sucking, nail biting, throat clearing, and playing with genitals (see Chapter 51).

Some of the behaviors listed above are age-appropriate, and physicians can help parents by counseling them about stage-related behavior, such as oppositional behavior in a 2-year-old and independence-dependence problems in a 3- to 5-year-old. Parents may be more tolerant of a particular behavior if they understand what is normal at a given age. Just because something is normal, however, does not mean that it should be tolerated. Physicians can suggest to the parents ways of dealing with age-appropriate behavior (eg, placing breakable objects out of reach of toddlers).

Certain behavioral problems reflect differences in childhood temperaments. Temperament is the biological predisposition to a style of behavior. Carey has compiled a series of temperament scales

to assess children and adolescents of different ages. For example, some children are shy and have a hard time adjusting to new situations. If parents anticipate such problems, they are often less angry when difficulties arise. Parental expectations can vary with a child's gender. Boys may be permitted to act a certain way (“He's all boy!”) that would be disapproved of in girls. Physicians can discuss such expectations at health maintenance visits.

Physicians can also be particularly helpful in detecting and advising parents about disparities in the achievement of different developmental skills. Some children acquire motor skills before verbal skills, yet parents expect their children to be equally versatile in speech and movement.

Psychophysiology

All behaviors are modified by the responses and reactions of other individuals. The basic premise of discipline is to discourage unwanted behavior and to encourage desired behavior. This is accomplished by using techniques that are based on conditioning modalities.

Several factors contribute to an increased incidence of behavioral problems in children. Ten percent to 15% of all preschool children are raised in grossly disrupted family situations. These homes are impacted by divorce, death, separation, violence, parental substance abuse, mental illness, or extreme poverty. Parental insecurity may also be a factor. In addition, families may have fewer social contacts than they once did because of greater mobility within society. As a result, families face greater social isolation.

Differential Diagnosis

In addition to providing anticipatory guidance about discipline, physicians must make 2 diagnostic decisions. First, they must determine whether a specific behavioral problem represents normal childhood behavior or an abnormality in behavior that warrants more specific intervention. Between 8% and 18% of behavioral disturbances may deserve physician intervention. More intensive management may be necessary for problems related to aggressive-resistant behavior and hyperactivity. Hyperactive behavior, which may exist as part of attention-deficit/hyperactivity disorder (ADHD), may be a sign of a significant underlying problem that warrants one-on-one intervention or the use of neuropharmacologic agents (see Chapter 125).

Second, physicians must differentiate between legally permitted corporal punishment and child abuse. Some individuals feel that any form of physical punishment is unacceptable and note studies that suggest that violence in the form of physical punishment is prone to escalate. Despite this, the use of physical punishment remains widely accepted in our society, and is legally condoned in the home setting though there may be guidelines about what exceeds the legal limits. Fractures and bruises are not acceptable, and physical abuse should be suspected in children who present with such injuries.

Evaluation

History

The key component in the evaluation process is the assessment of the means parents use to discipline children (Questions Box). To obtain this information, physicians may simply ask parents, “How do you get your child to mind you?” This question is designed to lead to a discussion of how parents interact with their children. If parents have specific complaints, such as oppositional behavior, they should be questioned about the strategies they have used in their effort to discipline their children.

Physical Examination

Children’s behavior should be assessed during the office visit. A general physical examination is useful to check for any signs of physical abuse as well as to evaluate children’s well-being. A developmental assessment is also helpful because it may delineate disparities in the achievement of certain skills. Some hyperactive children may warrant a more extensive psychodevelopmental assessment to look for findings consistent with ADHD. Behavioral checklists may be used to evaluate children’s temperament.

Laboratory Tests

No specific laboratory or imaging studies are indicated for children with discipline problems. Such studies are indicated if child abuse is suspected (see Chapter 127).

Management

Physicians should assist parents in establishing appropriate guidelines for disciplining their children and reinforce the role of parents as the source of authority (Box 47-1). It is important for parents to realize that total freedom results in uncontrollable anxiety. Children mimic behavior, and **parents should act as role models**. If parents have temper tantrums when they are frustrated, their children may act in a similar manner. **Consistency** is also important. A system with a limited number of enforced rules is better than one with many different rules. In families where both parents are working, especially if they have overlapping time schedules, consistency is sometimes difficult to attain, especially if children are supervised by non-parental caregivers.

Physicians should emphasize to parents that it is best to **avoid power struggles**. Children engaged in a struggle often win because they have final control (eg, refusing to eat). Children should always be given the opportunity to graciously back out of a situation and save face. It is easier to avoid situations that lead to head-on confrontations than to get out of them once the confrontation has occurred. Parents should be the source of information for physicians. This helps strengthen parents’ egos and validates their ability to handle their children appropriately.

In the past, specific methods of dealing with children with discipline problems concerned the issues of permissiveness versus over-permissiveness and accommodation versus strict punishment.

Questions

Discipline

- What does the child do that the parents wish he or she would not do?
- What do the parents do to stop unwanted behavior?
- Does the child usually obey the parents?
- When and where does most of the unwanted behavior occur?
Does it occur mainly if a child is tired?
- Which parent is responsible for disciplining the child?

Box 47-1. Advice for Parents About Discipline

Set rules.
Set limits.
Define consequences.
Be consistent.
Ignore trivial problems.
Compliment desirable behavior.
Take time out when angry.

Over-permissiveness refers to the allowing of undesirable acts and may exacerbate anxiety and increase demands for privilege.

Physicians should remind parents that preventing many behavioral disorders is easier than treating them. Reasoning is a useful modality, but it is unrealistic to expect infants and toddlers to have the cognitive skills to understand adult reasoning or to consistently respond to verbal commands or reprimands. Discipline should not only discourage bad behavior but also reinforce good behavior. Following are 5 examples of reactive discipline.

Redirection

Redirection is a simple and effective method in which the parent removes the problem and distracts the child with an alternative. This technique is frequently used to remove some object (such as a valued knickknack) from the hands of an infant, replacing it with a toy. Parental patience, ingenuity, and enthusiasm facilitate this approach. This approach is also important in teaching children what is acceptable behavior. For instance, one cannot draw on the wall but can draw on a piece of paper. Children also respond to making tedious routines into a game. For instance, children can be challenged to see who can get their clothes on faster or who can brush their teeth first. Parental creativity and energy often avert confrontations.

Spanking

Spanking involves inflicting physical pain, which is usually successful in bringing about the immediate cessation or a decrease in problem behavior. Spanking is highly prevalent as a form of discipline, with between 70% and 94% of parents reporting using the practice. Spanking is used more often for younger children and for boys and correlates with parental attributes such as age, education, socioeconomic status, and religious orientation. Spanking is often employed when other methods of discipline have failed to abort the unwanted behavior. Spanking tends to clear the air and get the punishment

over with rather than producing a lingering guilt. To be truly effective, however, physical punishment must immediately follow the act. The “wait until Daddy comes home” approach is less effective because of the lack of temporal association. In addition, spanking tends to become situation-specific so that children associate a particular action with being spanked. This learning does not generalize to other situations. Spanking can teach children to be afraid of adults rather than to respect them.

Spanking may actually be damaging to the parent–child relationship and have a long-term effect on a child’s self-esteem. Many parents feel remorseful after having spanked a child, and some acknowledge that they spank out of anger and frustration and question the efficacy of this modality. Most pediatricians discourage spanking as a means of disciplining children. Differentiation of physical punishment from child abuse is often difficult. In general, punishment with the hands is acceptable, but punishment with objects and spanking on parts of the body other than the buttocks or thighs is unacceptable. Spanking may be an early precursor of later physical violence and subsequent abuse. Again, parents act as role models. Children should never be allowed to hit their parents. This makes children feel extremely insecure.

Devices that are marketed for child discipline and inflict physical pain on a child, such as a sudden sting (modified stun gun), are never appropriate.

Scolding

Scolding involves the excess use of reasoning and explanations and is used by most parents as part of the discipline process. In families where communication or interaction is minimal, scolding or verbal reprimands may result in an initial increase in inappropriate behavior because this is the only way children receive any attention. Verbal reprimands are more effective if used infrequently. Verbal reprimands should not be used during time-outs because they reinforce undesirable behavior.

Scolding, because of its negative focus, can be damaging to children’s self-esteem. Scolding would be categorized as “jackal language.”

Ignoring

Ignoring represents the opposite of explaining and reasoning. This form of discipline is difficult to use successfully because parents must totally ignore children’s behavior. If even the least flicker of recognition occurs, then activity increases. A brief initial increase in unwanted behavior, a so-called response burst, may occur with ignoring. This disciplinary method works better in younger children.

Time-out and Removal of Privileges

Time-out, the form of discipline most recommended, refers to time out from positive reinforcement. In sports, teams call a time-out to rethink what they are doing and to replan their strategies. Children are placed in a neutral or boring environment whenever they engage in inappropriate behavior. The time-out technique can be used to discourage undesired habits. For example, parents may say, “You can suck your thumb, but you may only do it in such and such a room.”

This type of discipline is better than ignoring, especially if “ignored” children are receiving attention from siblings and peers. Children should understand the rules ahead of time and why the behavior is unacceptable. Once this is accomplished, time-out may occur without any warning.

A timer should be used, and children should stay in the time-out area for 1 minute per 1 year of age. An appropriate area must be selected. This area should be fairly boring, so children’s rooms are often not appropriate. A laundry room, a corner, or a specific chair may be better. If children act unacceptably during the time-out, the timer should be reset. If children have to go to the bathroom during the time-out, they are allowed one trip. After they return from the bathroom, the timer is reset.

The use of the time-out method is sometimes difficult. If the inappropriate behavior occurs in the morning when children are getting ready for school, time-out just encourages children’s desire to delay. “Beat the buzzer” is another idea that may be used in such situations. With “beat the buzzer,” the timer is set. If children are dressed before the timer goes off, they may be rewarded for the behavior by being allowed to go to bed half an hour later. If the buzzer “beats” them, then they have to go to bed half an hour earlier.

Inappropriate behavior away from home presents the greatest difficulty. These situations can be dealt with in numerous ways, particularly if the behavior problem involves temper tantrums. When children are crying or screaming uncontrollably, it is best to remove them from the embarrassment of the situation. This “manual guidance” often occurs in a supermarket, where children select something that parents do not wish to buy. Parents can often circumvent this problem easily by walking into the supermarket and saying, “If you are a good boy (or girl) during the whole trip, then I will get you something at the checkout counter.” If children still have temper tantrums, then they should be removed from the area and brought to a neutral place, such as the automobile or a restroom, and allowed to finish their crying and screaming. It has been said that a glass of cold water splashed in a child’s face is sometimes beneficial because it rapidly aborts the behavior. If the inappropriate behavior does not develop into a temper tantrum, then “marking” time-out is helpful. This consists of putting a mark with a colored water-soluble marker on the child’s wrist every time he or she engages in an inappropriate behavior. When the child returns home, the marks are totaled, and the time-out method is used.

Removal of privileges is a strategy applied in older children. Classically this involves grounding a child, prohibiting television or video games, or loss of driving privileges. The privilege must be something of value to the child for this method to be effective.

Parents who complain about inappropriate behavior should be asked to keep a record of children’s behavior for 1 to 2 weeks. This helps determine if the behavior is really inappropriate and what is motivating it. Parents should be encouraged to talk to their children in a reasonable manner and to verbalize what they think children are feeling. They might say something like this, “It’s terrible to be three years old and get so upset. You feel that you can’t get the things you want, but some day you will grow up and then you will be in charge.”

I am really sorry it is so hard for you right now.” Physicians should tell parents that it is important to set limits for children and to avoid threatening, judging, and constantly criticizing children. Frequent threats such as, “If you don’t stop hitting your sister, you’ll get a time-out” that are not carried out undermine the entire discipline process. To help foster compassionate communication, parents should ask themselves, “If someone said this to me, how would I feel?” Many parents have themselves been disciplined only with spanking and know no other means, and the advice that physicians offer is valuable.

Prognosis

Children raised in a supportive environment that teaches respect for others and self-control grow up as caring adults. Children who have been exposed to excessive physical punishment show aggressive behavior later.

CASE RESOLUTION

In the case presented at the beginning of the chapter, further history should be elicited about the mother’s disciplining techniques. It is also significant that the child’s speech is delayed. The boy’s ability to articulate his feelings may be limited, and a formal speech and hearing assessment is warranted. The preschool should be advised that the evaluation is underway. A report from the preschool concerning the boy’s behavior would be appreciated.

Temper Tantrums

Geeta Grover, MD

CASE STUDY

During a routine office visit, the parents of a 3-year-old boy express concern about his recent behavior. They report that whenever he is asked to do something he does not want to do, he throws a “fit.” He cries fiercely, falls to the floor, bangs his hands, and kicks his feet until his parents give in. He often displays such behavior at bedtime or mealtime if he is asked to turn off the television or eat foods that he does not want. He has 2 to 3 such episodes per week. The parents state that their home life has not changed, and the boy’s teacher reports that he displays no such behaviors at preschool.

Questions

1. At what age are temper tantrums common in children?
2. How do parents’ reactions encourage or discourage temper tantrums?
3. What appropriate management strategies may help control such oppositional behavior?
4. What factors or aspects of such oppositional behavior indicate underlying pathology?

Temper tantrums are common, normal, age-related behaviors in young children. To a certain degree, oppositional behaviors such as negativism, defiance, and tantrums are part of the normal progression toward self-reliance and independence. Toddlers need to assert their freedom and explore their environment, which often puts them at odds with the limitations imposed by society and well-meaning parents. Young children cannot appreciate that rules and limitations have been established in the interest of their own safety and well-being. They see only that their own desires have been thwarted, and they may react to this disappointment with intense emotions. Children are not simply upset because they cannot have their way. They are angry and frustrated, and they lose control over their emotions. During tantrums children cry and scream uncontrollably. They may fall to the floor, bang their heads, kick their feet, pound their hands, and thrash about wildly. Some children may throw things, try to hit one another, or destroy property.

Such intense displays of anger may be a terrifying experience for both children and parents. Some children use tantrums to gain attention, whereas others use them to achieve something or to avoid doing something. Recurrent temper tantrums may strain relationships among parents, children, and other family members.

Epidemiology

Temper tantrums are noted most often in children who are 2 to 3 years of age, but they may occur any time between the ages of 12 months and 5 years. Parental surveys reveal that about 20% of 2-year-olds, 18% of 3-year-olds, and 10% of 4-year-olds have at least one tantrum per day. Most children are able to express their feeling verbally by 3 to 4 years of age, so temper tantrums begin to taper off. Children who are not able to express their feelings well with words

(eg, children with developmental delays—especially children with speech and language delays or children with autism spectrum disorders [ASDs]) are more likely to continue to have tantrums. Boys and girls are affected equally. Although temper tantrums are unusual in school-aged children, they often reappear in the form of verbal tantrums during adolescence, when autonomy and independence once again become developmental issues.

Pathophysiology

Appreciation of children’s level of maturity and the developmental tasks normally associated with the toddler and preschool years, when temper tantrums occur most often, facilitates an understanding of tantrum behavior. Young children who are exploring the world and developing a sense of autonomy think primarily in egocentric terms. They view reality from their own perspective and are unable to appreciate the perspective of other individuals. Only as they mature and enter school do they learn to recognize the position of others and begin to develop a sense of morality, of right and wrong. Toddlers may become frustrated or angry because of their lack of control over the world, inability to communicate, or limitations of their cognitive and motor abilities, which do not allow them to accomplish desired tasks. Unlike adults, who have the ability to verbalize frustrations or simply walk away from unpleasant situations, young children have neither the sophisticated ability to articulate their feelings nor the freedom to walk away. Therefore, they may react to disappointments with temper tantrums.

Temper tantrums may be classified as normal or problematic based on their cause, frequency, and characteristics. Normal tantrums can simply be demands for attention or signs of frustration, anger, or protest. In the interval between tantrums, the child’s

disposition and mood are normal. The well-behaved 3-year-old boy who has an occasional tantrum following the birth of a sibling, the 2½-year-old girl who throws a tantrum to express frustration because no one understands what she is trying to say, and the 2-year-old boy who cries uncontrollably because he cannot complete the puzzle he has started or run fast enough to keep up with his 4-year-old brother are all examples of normal tantrums. A typical reason for an avoidance-type tantrum is not wanting to go to bed at bedtime. All types of tantrums are more common when children are tired, ill, or hungry, because their ability to cope with disappointment and frustration is limited under these circumstances.

Frequent tantrums (>5 per day) or tantrums that result in destruction of property or physical harm to the child or others are signs of problematic tantrums (Box 48-1). These tantrums result from factors that are beyond the child's control, such as parental problems, school difficulties, or health-related conditions (Box 48-2). For example, the child with unrecognized hearing loss may be performing poorly at school and resort to tantrum behavior in frustration. Marital discord or domestic violence may create anxiety for a child, which may manifest as frequent or destructive tantrums.

Differential Diagnosis

Temper tantrums are readily recognizable because of their classic pattern where a toddler-aged child becomes frustrated, reacts physically, and cries or screams. Sometimes temper tantrums are indicative of more significant problems, such as speech or language delays or ASDs (see Chapter 124).

Evaluation

History

Thorough history taking is essential (Questions Box). The frequency of the temper tantrums, circumstances that provoke them, a description of actual tantrums, and parental reaction must be ascertained. In some instances, this reaction may provide insight as to why the tantrums recur. In addition, parental expectations should be assessed. Expectations that are inappropriate for children's age and developmental maturity may create unnecessary tensions between parents and children and lead to tantrum behavior. Factors associated with problematic tantrums should also be assessed (see Box 48-2).

Tantrums that are frequent (>5 per day), severe, or persist after the age of 5 years may be a sign of underlying conditions, such as depression or low self-esteem. Frequent tantrums may also be associated with attention-deficit/hyperactivity disorder (ADHD). Children with a history of impulsivity, hyperactivity, and inattention that are inappropriate for age should be evaluated for ADHD. Children who hurt themselves or others or destroy property during tantrums may have significant emotional problems. Peer pressure may inhibit tantrum behavior; if tantrums occur frequently at school, the presence of learning disabilities or speech and hearing deficits should be considered.

Box 48-1. Features of Problematic Tantrums

- Tantrums that persist or get worse beyond 5 years of age
- Frequent tantrums (>5 per day)
- Persistent negative mood or behavior in intervals between tantrums
- Recurrent tantrums at school
- Destruction of property during tantrums
- Harm to self or others during tantrums
- Other behavioral problems (eg, sleep disorders, aggressive behaviors, enuresis)

Box 48-2. Underlying Causes of Problematic Tantrums

Parent-Related Factors

- Marital discord
- Abusive behavior toward children
- Domestic violence
- Substance abuse
- Depression
- Inappropriate parental expectations

Child-Related Factors

- Developmental and/or learning disabilities
 - Hearing loss
 - Speech and language delays
 - Autism spectrum disorders
- Mood disorders (eg, depression)
- Attention-deficit/hyperactivity disorder
- Temperament (eg, high persistence and intensity of response and slow adaptability)
- Illness
 - Unrecognized illness (eg, otitis media, sinusitis)
 - Chronic or recurrent illness

Questions

Temper Tantrums

- How often does the child have temper tantrums?
- What circumstances provoke the tantrums?
- How does the child behave during the tantrums? What does the child do?
- How does the child behave in the interval between tantrums?
- How do the parents react to the child during the tantrums? What do they do or say?
- Are parental expectations consistent with the child's developmental stage?
- Have there been any changes at home or school (eg, birth of a sibling, new school)?
- Is the child having any other behavioral or development-related problems (eg, enuresis, sleep difficulties)?

It is important to remember that physicians usually see children whose tantrums are frequent, severe, or cannot be controlled by parents. First, pediatricians must determine whether any underlying pathology may be contributing to the behavior and, if so, what parental or child factors may be provoking it. Second, they must differentiate between normal tantrums and problematic tantrums. Identification and remediation of the cause of problematic tantrums are the first steps toward cure. Children with suspected underlying conditions such as ADHD or mood disturbances should be referred to the appropriate specialist for further evaluation.

Physical Examination

A thorough physical examination is appropriate, as is a developmental assessment to determine if there are findings such as speech delay or behavioral signs consistent with ASDs. Most often, the physical examination is normal.

Laboratory Tests

There are no laboratory tests indicated in the assessment of the child with temper tantrums. Routine tests that are age-appropriate and suggested as part of health maintenance are appropriate.

Management

Punishment is not the solution to temper tantrums (see Chapter 47). Health maintenance visits are an ideal time to provide **anticipatory guidance** regarding tantrums and discuss strategies to prevent or minimize this behavior. Parents typically report that their children become defiant and difficult to manage during the “terrible twos.” At the 12- and 15-month visits, physicians should alert parents that this period is approaching and remind them that it is a normal part of development. Preventive strategies, such as **childproofing** the home to minimize unnecessary conflicts, should be discussed. In addition, parents can give young children **frequent opportunities to make choices** (eg, which color shirt to wear or which of 2 foods to have for lunch). These opportunities allow children to exercise independence and autonomy in a positive rather than a negative manner. Physicians can provide **reassurance** that this unpleasant stage will pass; children will eventually become more cooperative and agreeable.

Parents should be told that helping children learn self-control and how to handle anger are keys to management. To expect that children will never get angry is unrealistic. Children should be taught how to **vent their anger and frustration in an acceptable manner** (eg, articulating their feelings or hitting a designated punching bag or pillow). As children mature, their ability to verbalize their feelings increases, but even young toddlers can say “me angry.” Physicians should emphasize that it is **important for parents to remain calm** during children’s temper tantrums. Shouting and spanking indicate to children that parents are also out of control. Children feel more secure if the adults around them are calm and in control.

Different types of temper tantrums may require specific treatment and management strategies. Parents should **be supportive** of children who are having tantrums resulting from frustration or fatigue by letting the children know that they understand. Children’s energy should be redirected into activities they can do well. Parents should be encouraged to **praise positive behavior** (eg, completing tasks properly, handling anger in an acceptable fashion). They should **ignore some tantrums**, such as those for purposes of attention seeking or wanting something. If children have no audience, they have no need to perform. **Time-outs** may also be used in such situations (see Chapter 47). Parents should not give in to children’s wishes; this may reinforce tantrum behavior. **Physical movement** of children to where they belong may be necessary if they are refusing to do something (eg, bed for the child who is refusing to go to sleep at bedtime) or in danger of hurting themselves. **Holding children** who are raging may give them a sense of security and help calm them. If temper tantrums occur outside the home, it may be necessary to accompany children to a **quiet, private place**, such as an automobile, until they calm down. Distracting children by suggesting another activity or pointing out something of interest in the environment may also interrupt the unwanted behavior.

CASE RESOLUTION

The child in the case scenario seems to be having normal, age-appropriate tantrums. The boy’s tantrums occur when he is asked to do something that he does not want to do. In these situations the parents should try to ignore the tantrums as much as possible and not give in to the child’s wishes.

Breath-Holding Spells

Geeta Grover, MD

CASE STUDY

A 15-month-old girl is brought to the office because of parental concern about seizures. In the last month she has passed out momentarily 3 times. Each episode seems to be precipitated by anger or frustration on her part. Typically she cries, holds her breath, turns blue, and passes out. Each time she awakens within a few seconds and seems fine. The medical history and family history are unremarkable, and the physical examination is entirely within normal limits.

Questions

1. What are breath-holding spells (BHS)?
2. What is the differential diagnosis of BHS?
3. What, if any, laboratory studies are indicated in the evaluation of BHS?
4. What measures can be taken to prevent BHS? Are anticonvulsants necessary?
5. What, if any, are the long-term sequelae of BHS?

Breath-holding spells are a benign, recurring condition of childhood in which anger or pain produce crying that culminates in noiseless expiration and apnea. The frequency of BHS, an involuntary phenomenon, is variable and ranges from several episodes a day to only several episodes per year. Although the spells are innocuous, they usually provoke parental fear and anxiety because children often turn blue and become limp. The diagnosis can usually be made on the basis of a characteristic history and description of the episode, but the possibility of seizures should be considered.

Epidemiology

Breath-holding spells occur in about 5% of all children between the ages of 6 months and 6 years, but they are most common in children between 12 and 18 months of age. Most children have experienced their first episode by 18 months and virtually all by 2 years of age. Although BHS have been described in children younger than 6 months, occurrence in such young infants is uncommon. Boys and girls are affected equally. A positive family history is found in about 25% of cases.

Clinical Presentation

The typical clinical sequence of the major types of BHS is described later in the chapter (see Pathophysiology and Dx Box). After the spells, children may experience a short period of drowsiness.

Pathophysiology

Breath-holding spells may be classified as one of the non-epileptic paroxysmal disorders of childhood. These recurrent conditions, which have a sudden onset and no epileptiform focus, resolve spontaneously. Other disorders in this heterogeneous group include

Dx

Breath-Holding Spells

- Identifiable precipitating event or emotion
- Brief duration
- Color change, if present, prior to loss of consciousness and rhythmic jerking of extremities
- Rapid restoration of full activity
- Normal neurologic examination

syncope, migraine, cyclic vomiting, benign paroxysmal vertigo, paroxysmal torticollis, sleep disorders (narcolepsy, night terrors, somnambulism), and shudder attacks.

Types of BHS

The 2 major types of BHS are **cyanotic** and **pallid**. The cyanotic type is more common. Approximately 60% of children with BHS have cyanotic spells, 20% have pallid spells, and 20% of affected children have both types. Most commonly, affected children experience several spells per week. Approximately 15% of children with BHS have complicated features. Complicated BHS are defined as typical BHS followed by seizure-like activity or rigid posturing of the body. Unlike the postictal period of epileptic seizures, prolonged periods of lethargy or drowsiness following spells are uncommon.

Pallid spells are similar to cyanotic BHS with some exceptions. Pallid episodes are more commonly provoked by minor injury, pain, or fear rather than frustration or anger; the initial cry is minimal prior to apnea and loss of consciousness; and children become pale rather than cyanotic. In pallid BHS, children often lose consciousness or tone after only a single gasp or cry, whereas in the cyanotic form, the period of apnea prior to loss of consciousness is much longer.

Etiology

Although the spells are triggered by identifiable stimuli, they are involuntary phenomena. It is believed that loss of consciousness in both the cyanotic and pallid forms is caused by cerebral anoxia. The actual mechanisms of the 2 types of BHS are different. The processes involved in cyanotic BHS are not clear. Proposed mechanisms include centrally mediated inhibition of respiratory effort and altered lung mechanics, which may inappropriately stimulate pulmonary reflexes, thus resulting in apnea and hypoxia. In the pallid form, the pale coloration and loss of tone are thought to result from vagally mediated severe bradycardia or asystole. Pallid spells have been spontaneously induced in the electroencephalogram (EEG) laboratory using ocular compression to trigger the oculocardiac reflex. Vagally mediated bradycardia or asystole lasting more than 2 seconds has been produced by this maneuver.

An association between iron deficiency anemia and BHS has been recognized for many years but is poorly understood. It may be related to iron's importance in the function of various enzymes and neurotransmitters in the central nervous system, or may be because children with anemia have decreased cerebral oxygenation making them more susceptible to BHS.

Differential Diagnosis

The differential diagnosis primarily includes seizures and syncope secondary to cardiac arrhythmia or a vasovagal episode. Although vasovagal syncope, like BHS, may be provoked by fear or pain, it is uncommon in children younger than 12 years. Three factors may help differentiate BHS from true epileptic seizure activity. First, spells are usually provoked by some upsetting event or emotion, unlike seizures, which generally do not have a recognizable precipitating event. Second, episodes are brief in duration and followed by rapid restoration of full activity. Third, color change precedes loss of consciousness and rhythmic jerking of the extremities, whereas in the typical epileptic seizure, convulsive activity and loss of muscular tone usually precede change in color. See Box 49-1 for the differential diagnosis of BHS.

Evaluation

History

The history alone may be diagnostic (Questions Box). A family history of BHS should be obtained. It is essential to record a detailed history of the suspected breath-holding episode. The sequence in which the events occurred may help differentiate BHS from epileptic seizures.

Physical Examination

Children should have a complete physical examination, including a thorough neurologic evaluation. Focal neurologic signs or evidence of structural lesions such as meningomyelocele or hydrocephalus may lead the physician away from a diagnosis of BHS.

Box 49-1. Differential Diagnosis of Breath-Holding Spells

Central Nervous System

Seizures (epilepsy)
Occult or overt brain stem lesions (causing dysfunction within the pontomedullary area)
Benign paroxysmal vertigo

Cardiovascular

Cardiac arrhythmia (eg, prolonged QT syndrome)
Syncope (orthostatic or vasovagal)

Miscellaneous

Gastroesophageal reflux/Sandifer syndrome
Cataplexy (transient loss of muscle tone associated with narcolepsy; rare before adolescence)
Central or obstructive apnea
Munchausen syndrome by proxy

Questions

Breath-Holding Spells

- What happened before the episode?
- Was the child crying?
- What was the child's color before and during the episode?
- Was the child lethargic after the episode?
- Does the family have a history of breath-holding spells?

Laboratory Tests

If the history is consistent with BHS and the physical examination is normal, laboratory evaluation is usually unnecessary. Because of the association of BHS with iron deficiency anemia in some children, it is appropriate to determine a hemoglobin level. An EEG may be performed if the physician is concerned about the possibility of epileptic seizures. In both forms of BHS, the EEG shows generalized slowing followed by flattening (a pattern characteristic of cerebral anoxia) during attacks, although it is unusual to record the EEG during BHS. Simultaneous EEG and video recordings can be very useful in helping to distinguish BHS from seizures, especially in children having frequent episodes. The interictal EEG is normal in children with BHS, whereas it may often be abnormal in children with epilepsy. An electrocardiogram may be obtained if there is any question about cardiac arrhythmia (eg, prolonged QT syndrome).

Management

Management of BHS includes **parental support and reassurance**. Breath-holding spells may be extremely frightening for parents to witness, especially if the episodes are routinely associated with loss of consciousness or seizure-like activity. Parents should be told about the involuntary nature of the attacks and be cautioned against

reinforcing the spells by giving in to the child's wishes. They should be advised to avoid unnecessary confrontations with the child. Similarly, it is impossible to ensure that the child will never be frustrated or injured. Instead, parents should be encouraged to handle the episodes in a "matter-of-fact" manner and continue age-appropriate discipline. They should be reassured that the long-term prognosis is excellent.

Pharmacologic therapy is usually not necessary, but atropine sulfate may be considered in the management of children with frequent pallid BHS because of atropine's anticholinergic action. Anticonvulsants are not effective. A recent clinical trial showed that iron therapy was effective in the treatment of both cyanotic and pallid BHS, especially in children who were iron deficient. Referral to a neurologist or psychiatrist may be considered at the family's request if the episodes are frequent and associated with loss of consciousness or if there is uncertainty regarding the diagnosis or management.

Prognosis

Breath-holding spells resolve spontaneously in most children by 5 to 6 years of age. About 50% of cases resolve by 4 years of age, and 90% resolve by 6 years of age. Neither pallid nor cyanotic BHS are associated with an increased risk of development of epilepsy, although children with pallid BHS do have an increased incidence of developing syncopal attacks during adulthood.

CASE RESOLUTION

The child presented in the opening case scenario has a history and physical examination suggestive of BHS. The girl's episodes are consistent with cyanotic BHS. The episodes are preceded by an identifiable emotion, are brief in duration, and are followed by a rapid recovery of normal consciousness and activity. Assessment of the hemoglobin level revealed mild iron deficiency anemia. The child received iron therapy, and the parents were reassured about the benign nature of BHS.

Fears, Phobias, and Anxiety

Carol D. Berkowitz, MD

CASE STUDY

A 5-year-old girl is brought into the office by her mother, who complains that her daughter has been frightened of sleeping alone since the occurrence of an earthquake. The house did not sustain any significant damage, but the entire family was awakened. The mother says that the girl has become more timid. As nighttime approaches, she becomes particularly fearful. She will not stay in her bed, and she is comforted only by sleeping with her parents. In addition, the girl has begun bedwetting since the earthquake, and the mother wonders whether she should put her daughter in diapers. The physical examination, including the vital signs, is normal, except for the observation that the child is very clingy and whiny.

Questions

1. What are normal childhood fears?
2. When do these fears commonly occur?
3. What strategies are used to deal with these fears?
4. What are simple phobias? What are social phobias?
5. What is school phobia, and how is it best handled?
6. What are common anxiety disorders in children and adolescents?
7. How can families deal with childhood disturbances that emerge after natural and man-made disasters?

Fears are normal feelings that cause emotional, behavioral, and physiological changes that are essential for survival. Fears are associated with psychological discomforts, such as a negative, unpleasant feeling. Children may develop fears in response to actual events (eg, earthquakes) or as a result of the temporal association of 2 events (eg, seeing a scary movie on a rainy day and then becoming afraid of rain). Some fears seem to be innate, and others seem to be developmental. Children fear different things at different ages. For example, school phobia is sometimes particularly problematic in young, school-aged children.

Phobias are overwhelming, intense, highly specific, and often irrational fears. The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* defines a phobia as excessive anxiety accompanied by worry occurring more often than not, for at least 6 months and associated with one or more of the following: restlessness, easy fatigability, difficulty concentrating, irritability, tense muscles, and disturbed sleep. Childhood phobias can be divided into 5 categories: animals (spiders, snakes, dogs), natural environment (heights), medical related (doctors, dentists, injections), situations (flying), other (loud noises, rain, thunder). Social phobias are specific to social situations that arouse intense concerns about humiliation or embarrassment. Fear of speaking in public may represent a social phobia. Selective mutism involves children who are able to speak but are unable to do so in certain settings, such as school. This probably represents one form of a social phobia. When these fears are combined with avoidance behavior, they may be incapacitating. Anxiety refers to fear without a definable source. It is a vague feeling of uneasiness, apprehension, and foreboding of impending doom. A child may experience an anxiety **problem** where

there is significant but not severe distress and an anxiety **disorder** when the distress is excessive or functioning is impaired. Up to 8% of children and adolescents have anxiety disorders. These may be referred to as generalized anxiety disorders.

Different strategies are useful for dealing with different fears. It is important for parents not to trivialize these fears, nor to reinforce them, but to empower children to deal with them.

It is also important to realize that parents sometimes foster fears by using threats with children such as “the doctor will give you a shot unless you eat your spinach” or “the boogie man will get you.” By fostering fears, the parents are also fostering dependency. Parents lack the imagination that children have and find it difficult to understand the degree of fear that children experience.

The opportunities for primary care providers to counsel families about childhood fears has increased over the past 10 years related to a number of catastrophic events, such as the terrorist attacks of 9/11, the tsunami in Asia, hurricane Katrina, and the earthquake in Haiti. Acts of violence such as the shootings at Columbine High School and Virginia Tech also create fear and anxiety in children who witness these events on the television. It is important to recognize the pervasiveness of mental health sequelae following disasters and the factors that influence the prevalence of these disturbances. One percent of children in New York City lost a relative on 9/11. There is a greater risk of mental health sequelae if there are poor social supports, a prior history of psychopathology, or the child is fearful or shy by nature. Natural disasters have less of an impact than intentional ones. While many of the recent disasters have been acute and unexpected, there are children who are continuously exposed to what has been called “process trauma” in the form of war and child abuse.

Epidemiology

Fears follow a developmental pattern. Neonates are believed to have no fear, although young infants whose faces are covered with a blanket struggle to toss off the blanket. Infants who are 6 months of age exhibit what is known as **stranger anxiety** in response to unfamiliar persons, places, or objects. To combat this anxiety, infants seek refuge with a parent. Stranger anxiety becomes equated with separation anxiety and reaches a peak at 2 years of age. Children between 6 months and 2 years of age are also frightened by loud noises and falling or quickly moving objects.

Children between the ages of 2 and 5 years are in what is termed the **age of anxiety**. They fear many things, including animals, abandonment, loud noises, and darkness. Children in this age group are particularly fearful of physicians, hospitals, and getting hurt. Young children are afraid of the physically disabled, who represent bodily injury, and monsters and scary movies. They sometimes displace their anger onto monsters and witches and attribute to these imaginary characters the bad feelings they are experiencing. Children in this age group have strong imaginations, which makes it difficult for them to differentiate fantasy from reality.

School-aged children between 6 years of age and adolescence tend to have more abstract thoughts, and their fears are less relevant to physical immediacy. These children are afraid of the death of their parents or the burning of their home. They also fear war, growing up (expressed as “How will I know what to do?”), going into the next grade, being alone or being kidnapped, and the divorce of their parents. Children in this age group are often reluctant to bother their parents with their fears, and they can easily misinterpret parental concerns when they overhear parental conversations. Childhood anxiety disorders are reported in 6% to 20% of children.

Separation anxiety, which may manifest as school phobia and may be referred to as separation anxiety disorder, may occur in school-aged children. The prevalence is estimated at 3.2% to 4.1%, though up to 50% of third graders report separation anxiety symptoms. Separation anxiety disorder is defined as developmentally inappropriate, excessive anxiety precipitated by actual or anticipated separation from home or family. Affected children develop physical complaints (eg, stomachaches) on school days. The mother–child relationship is often disturbed, and the child is fearful of leaving the parent alone. Childhood school phobia and parental history of panic attacks and agoraphobia may be associated.

Fears during adolescence relate to social functioning, such as public speaking or talking to members of the opposite sex. Older children are also concerned about school failure and physical injury. They have many of the same fears expressed by younger school-aged children, although phobias are uncommon. Phobias, which occur in less than 1.7% of the general population, are reported in 13% of disturbed children.

Anxiety disorders are rare in childhood, but more common during adolescence. They may include panic attacks, which involve the sudden onset of intense fear or discomfort associated with physiological symptoms such as palpitations and shortness of breath.

Fear about a panic attack may lead to agoraphobia, the avoidance of going away from home. Post-traumatic stress disorder (PTSD) involves a set of symptoms that recurs after a person has experienced a traumatic event. Symptoms include intense fear, helplessness, or a sense of horror. The person reexperiences the trauma, avoids circumstances that are reminiscent of the trauma, and is in a state of hyperarousal. It is estimated that 5% of men and 10% of women have a lifetime prevalence of PTSD.

Pathophysiology

Fear has its basis in a series of psychophysiological reactions, which are mediated through a series of neurotransmitters. Elevated levels of certain transmitters, such as γ -aminobutyric acid and norepinephrine, are associated with feelings of anxiety. Excess serotonin has also been related to anxiety disorders. Patients with panic attacks and anxiety disorders have disturbances in neurotransmitter regulation.

Differential Diagnosis

The challenge for physicians is to assess the etiology of the fear and to differentiate normal fears from those that may be signs of unusual stresses or signs of psychopathology. Appropriate fears represent a real reaction to a real danger. As a rule, children are more resilient than adults and recover more rapidly from traumatic events. On the other hand, children are prone to inappropriate fears, which may develop for a number of reasons.

Inappropriate fears may occur because of operant conditioning, in which a conditioned stimulus becomes associated with another object. Fear of the other object becomes reinforced through this association. Inappropriate fears may also develop in a child whose parent has the fear (modeling) or through witnessing a fearful event in the media (informational). True phobias represent neuroses and may occur in more than one family member.

School phobia, also called school refusal, may occur under 3 distinct conditions. Not uncommonly, young children who are entering school for the first time are frightened. This fear is a normal component of separation anxiety, which usually resolves within a few days of starting school. In contrast, older children may experience school phobia because they are truly afraid of a school situation. They may fear a teacher, violence, or a bully. To avoid the problem, children may actually request to change classrooms or schools. It is important to talk to children to find out what is behind their fear of school.

On the other hand, some children who seem fearful of school are actually concerned about parental separation (ie, separation anxiety). Frequently these children enjoy school and miss it when they are absent. Absences occur when feelings of separation from parents are so intense that they do not allow children to function well in school settings. This separation anxiety disorder may result from parental illness or parents' fostering dependency in children. Children then see parents as vulnerable and are uncomfortable about leaving them alone.

School refusal is the third leading cause of school absenteeism after transient illness and truancy. Fifty percent of children with

school refusal have other problems, including depression (28%), tantrums (18%), sleep disturbances (17%), obsessive-compulsive behavior (11%), other fears (10%), enuresis (3%), and learning disabilities (3%). Overall, school refusal has a good prognosis, although adolescents do not do as well as younger children, and individuals with a higher IQ have a poorer outcome. Twenty percent of parents of children with school refusal have a diagnosable psychiatric disorder. Issues of mother–child dependency are often a concern.

Another type of childhood fear concerns physicians and hospitals. Children have many concerns about what happens to them at the doctor's office. They are particularly fearful of needles. To children, needles represent possible mutilation. When asked to represent needles in drawings, children often portray needles as larger than themselves and very pointed. They comment that needles are sharp (eg, "Needles can make you pop, just like a balloon." "Needles can also take out all your blood until you die."). In addition, children are preoccupied with what happens to their blood. One youngster commented, "They check out your blood to see if it's good or bad, and if your blood is bad, then it means that you need to have more tests." Another youngster thought that physicians were doing a "blood taste" rather than a blood test.

Hospitalization raises other issues concerning parental separation as well as painful procedures. As children adjust to hospitalization, they progress through 3 stages: protest, during which they complain about the hospital and cry; despair, during which they have given up hope that their parents will return; and detachment, during which they seem to be adjusting but actually have distanced themselves from their parents.

Evaluation

Physicians should explore the area of childhood fears and phobias at routine health maintenance visits, even if parents do not have specific concerns. Sometimes parents are embarrassed by children's fears (eg, the fear of an older child to sleep without a night-light or the fear of dogs, which may preclude the child from visiting certain friends). Parents may not report children's fears unless these fears seem to be unusually intense. Practitioners may ask children, "What is the scariest thing you can think of?" If children are having difficulty providing details, physicians may ask them to name things that other children fear or to complete the sentence, "I feel afraid when...." Alternatively, practitioners may suggest things that other children may fear: "Do the kids you know seem to be worried about kidnapping?"

There are a number of instruments that have been used to assess the level of anxiety in children. These include the Multidimensional Anxiety Scale for Children, Spence Children's Anxiety Scale, and Screen for Child Anxiety Related Disorders. The latter instrument is in the public domain and readily available.

History

The evaluation of children with specific fears demands a careful history that provides information about situations in which children are fearful (Questions Box). Physicians should consider fears within a

Fears and Phobias

Questions

- What fear does the child have? Exactly what does the child fear?
- Under what circumstances was the fear originally expressed? Did any changes in the child's life occur around the time that the fear appeared?
- Under what conditions is the fear currently expressed?
- How long has the child had the fear?
- How does the fear affect the daily living of the child and family?

developmental context because many childhood fears are normal and experienced by all children. It is also important to look at changes in the family situation. Children sometimes develop what seem to be fears but in fact are behaviors designed to manipulate other family members. For instance, young children who sense marital discord may insist on sleeping with their parents as a way of ensuring that the parents are together rather than separate.

Physical Examination

A routine examination is warranted, but findings are usually normal. Such an evaluation, however, is particularly important if presenting complaints include symptoms such as abdominal pain, headache, or palpitations.

Laboratory Tests

As a rule, laboratory tests are not required unless the symptoms suggest an organic etiology, such as hyperthyroidism, as the cause of palpitations.

Management

The management of the fear or phobia is determined by the degree to which children are incapacitated. As a general rule, **children should be empowered to conquer their fears**. Children's books that address the issues of certain fears can help achieve this empowerment. Books such as *The Berenstain Bears in the Dark* (Random House, 1982) discuss specific worries such as fear of lightning and thunder. These books often explain the basis of such natural phenomena in easy-to-understand terms. The books also normalize particular fears and show how one character is fearful. Parents can also re-create some of the sounds that children fear. For example, children who are afraid of the noise the wind makes are shown a teakettle where the hot steam blows through the whistle, creating the same noise as the wind. For fears about nuclear war, empowering children to become active, such as joining a nuclear protest group, may be useful.

Parents may feel helpless because they do not know how to deal with children's fears. Physicians should give them the necessary information. Children's fears should not be trivialized. Even if the **fears** are unfounded, they **should be validated**. In general, children should be questioned about whether they are fearful about a situation. The following 2 examples illustrate the proper handling of fears in children.

If children are visiting the dentist for the first time, it is appropriate for parents to ask, "Are you afraid?" If children reply, "Yes, a

little bit,” parents can say, “Almost everybody is afraid. Tell me what it is you’re afraid of. Fear is a normal emotion, and I’m glad you told me about it.”

Parents of children who express fear of imaginary characters can reassure children that they do not exist. In addition, parents can tell children what the parents would do if such characters did exist. For instance, the father of a little girl who was afraid of witches told her, “There are no such things as witches. But if there were, and they came into your room, I would punch them in the nose and punch them in the stomach and beat them up, and then there would be no more witches to hurt you.” For those who would opt for a less violent approach, the parent could state: “I would tell any witch who came into your room, ‘STOP! Go away. No witches allowed in here.’ And the witch would run away and I would slam the door!” By doing this, parents establish the reality of the situation and then also create a plan to deal with the problem should it actually happen.

Parents can also help to limit or reduce children’s fears by **minimizing their exposure to fear-provoking situations** such as television shows or scary movies. These programs can be particularly frightening for some children, who should not watch them without adult supervision. Minimizing exposure to television is particularly important following a disastrous event. The recurrent images of planes flying into buildings on 9/11 were interpreted by children as repeated different attacks.

When dealing with children who have school phobia because of problems in school, it is important to determine if a change in school would be appropriate to facilitate their school attendance. This may be particularly appropriate in children whose schools are plagued with violence.

Cognitive-behavioral therapy (CBT) is reported to have the highest rate of success for dealing with anxiety-related conditions. Cognitive-behavioral therapy includes psychoeducation, somatic management (eg, relaxation techniques), cognitive restructuring (modifying negative thoughts), and exposure methods including desensitization. The goal of the therapist is to teach the child alternative ways of viewing the feared object and of coping with the fear itself. Medications such as antidepressants, anxiolytics, sedatives, and β -blockers have an unsubstantiated role in managing phobic disorders in children.

When school refusal is linked to separation anxiety, then a program of **desensitization or habituation (graded exposure)** is recommended. Desensitization may involve the participation of mothers in the classroom for a time. When children acclimate and can tolerate some separation, mothers move to another area in the school, such as the principal’s office. Next they go outside the school grounds. As children reestablish a sense of well-being in spite of the separation, the mothers gradually move farther and farther away. This solution is somewhat problematic for mothers who work outside the home. There is some research to suggest that children adjust more readily

if they resume school immediately without the gradual withdrawal of their parent. Children with significant school refusal may need the assistance of child psychologists or psychiatrists.

Phobias may be treated using the concept of **flooding**, which consists of rapid, prolonged exposure to the feared item. For example, a child who is afraid of dogs is exposed to a friendly, docile, small dog while in the company of his or her parents. Alternatively, systematic desensitization, during which children are exposed to the feared objects over a series of weeks, coupled with relaxation techniques, is also used. Phobias usually require the help of mental health specialists. Selective serotonin reuptake inhibitors (see Chapter 126) have been found to be beneficial in the management of certain anxiety disorders in children and adolescents. They are noted to be effective for panic disorders, social phobia, generalized anxiety disorder, obsessive-compulsive disorder, and PTSD. Benzodiazepines are safe and generally used on a short-term basis. Sedation is a frequent side effect, and there is the potential for abuse, tolerance, and drug dependence. Propranolol lessens the peripheral autonomic nervous system symptoms of social phobias and may be used for specific instances. Combined therapy involving CBT and medication is beneficial in some patients.

Children who must undergo hospitalization benefit from a pre-hospital visit, when possible. This visit familiarizes the child with the facilities and explains proposed procedures. Many hospitals have child life specialists who ease the adjustment of children as well as their parents to the hospital stay.

Prognosis

Most childhood fears resolve with time, nurturing, and reassurance. Most fears last only several weeks, and then new fears develop. As a rule, specific fears should not last longer than 2 years, and the younger the child, the shorter the duration of the fear.

Prognosis is good for children with true phobias, with 100% resolution of monosymptomatic phobias. More significant anxiety disorders may persist into adulthood, where similar management involving CBT and medications may be indicated.

CASE RESOLUTION

In the case scenario, the girl’s fear of sleeping in her bed was triggered by a significant environmental event. Although earthquakes are uncontrollable, the girl can be empowered to deal with manageable aspects of an earthquake as much as possible. She should be assured that in the same situation, many adults probably would also fear sleeping alone. The parents should stock a box with shoes, flashlight, radio, and water and place the box under the child’s bed. In addition, they may also have their daughter get into her bed and then shake it, simulating the jiggling that she would experience during an earthquake. The girl should also practice getting out of bed and standing in the doorway. To combat the child’s fear of separation during times of natural disaster, the parents should reassure their daughter that they will all be together.

Thumb Sucking and Other Habits

Carol D. Berkowitz, MD

CASE STUDY

A 5-year-old boy is brought to the office because of thumb sucking. His mother claims that she has tried nearly everything, including tying his hands at night and using aversive treatments on his thumbs, but nothing has worked. She reports that her son has been teased at school and has few friends. He is in good general health, and his immunizations are up to date.

His growth parameters are at the 50th percentile. Except for a callus on the right thumb, the physical examination is normal.

Questions

1. What are common habits in children?
2. What is the significance of transitional objects?
3. What are the consequences of the common habits in children?
4. What are strategies used to break children of habits?
5. How does one differentiate benign habits from self-injurious behaviors?

Habits are defined as somewhat complicated, repetitive behaviors that become automatized, fixed, and carried out easily and effortlessly. They are different from tics, which are rapid, repetitive muscle twitches involving the head, face, or shoulders. Tics are also referred to as habit spasms (see Chapter 117). Children have many socially unacceptable habits, including thumb sucking, nail biting, skin picking, nose picking, hair pulling (trichotillomania), rocking, biting other children, and teeth grinding (bruxism). Some habits, such as pica, are potentially harmful. Children engage in most of these habits because of their soothing potential. In recent years, “cutting,” a form of self-injury in adolescents, has received attention. While not a habit in a traditional sense, cutting is described by teens as a way of dealing with stress and alleviating anxiety. One-third of children use transitional objects for comfort. Blankets or favorite toys are traditional transitional objects that represent an age-appropriate coping strategy. Most transitional objects are strokable, and the stroking often occurs in association with thumb sucking. Transitional objects sometimes present a problem because children experience distress if these objects are lost, misplaced, or need cleaning.

Epidemiology

Thumb sucking probably represents the most common habit of children. A reported 50% to 87% of children engage in this habit. The median age for the onset of hand sucking is 54 minutes of life, and 90% of newborns show hand-sucking behavior by the age of 2 hours. Forty percent of children between the ages of 1 and 3 years, 33% of children between the ages of 3 and 5 years, and 25% of children

at the age of 5 years still suck their thumbs. Some children suck their fingers rather than thumbs. Other oral behavior may involve lip sucking, lip biting, and toe sucking. Lip sucking and biting begin at about 5 to 6 months of age and occur in about 90% of infants. It is unusual for these actions to persist as habits. Toe sucking is noted in infants who are 6 to 7 months of age, and it is reported in 80% of normal infants.

Trichotillomania is a disorder once believed to be uncommon but now thought to affect 8 million Americans (about 5 in 1,000). The term, first coined in 1889 by French dermatologist Hallopeau, is derived from the Greek *thrix* (hair), *tillein* (pull), and *mania* (madness). The condition is an impulse control disorder in which alopecia develops from compulsive hair pulling. Hair pulling may involve hair from the head, eyebrows, eyelashes, or pubic area. Although trichotillomania seems to peak during early childhood and adolescence, the disorder is reported from infancy to adolescence. In young children, boys and girls are equally affected, but in older children and adolescents, females outnumber males. The disorder is not associated with comorbid psychopathology, but there may be some association with mood disorders or attention-deficit/hyperactivity disorder. There is a condition in infants, called baby trichs, in which infants pull their mother’s hair when they are being held or nursed. This is considered normal exploratory behavior.

Rhythmic habits are stereotypical, repetitive behaviors that usually occur in infants younger than 1 year. These habits are reported in 15% to 20% of the population. Rhythmic habits include rocking (about 19% of infants), when infants rock back and forth; jouncing

(5%–10%), when they move up-and-down on their hands and knees so that the whole crib rocks; head rolling (8%); and head banging (5%). Rhythmic habits are seen more commonly in boys; the male–female ratio is 3:1. These habits usually occur with a frequency of 60 to 80 movements per minute, often when infants are tired, and last for less than 15 minutes before they fall sleep.

Rhythmic movements have been equated with **sleep tics**. These tics are reported in 20% of children, most often between the ages of 6 and 10 years. As a rule, tics are 3 times more common in boys than in girls. They tend to be noted with increased frequency in children who are shy, are overly self-conscious, or have obsessive-compulsive tendencies. Tics usually occur when children are under stress.

Biting, an aggressive habit noted in toddlers, may be related to teething. It occurs more often in children with slow verbal skills.

Nail biting (onychophagia) is usually believed to be a sign of internal tension. The disorder affects 10% to 40% of children. Nail biting begins between the ages of 3 and 6 years, and the peak age is 13 years. One-third of adolescents bite their nails, but 50% of these adolescents break the habit by the time they reach adulthood. Nail biting in adults is regarded as a sign of emotional and social immaturity and regression. The family history for nail biting is often positive. Identical twins are concordant for the condition in 66% of cases. In contrast, the incidence in dizygotic twins is 34%.

Nose picking, noted in children and adults, is reported in more than 90% of individuals. In general, adults and older children limit nose picking to when they are unobserved, but younger children will pick their noses in public. There are no gender-based differences in the incidence of nose picking. Epistaxis is the most common complication of nose picking.

Pica, which is not a normal behavior, is defined as the ingestion of nonfood products. The peak incidence of pica is between the ages of 1 and 3 years. The incidence is increased in children from lower socioeconomic levels, and the behavior occurs in 10% of children who present with lead poisoning.

Teeth grinding (bruxism) is reported in 5% to 15% of children. Boys are more commonly affected than girls, and the disorder seems to regress later in life. It is reported with increased incidence among developmentally delayed children including those with autism spectrum disorder. The cause is unknown, although it may be associated with malocclusion in some children. The disorder may contribute to temporomandibular joint dysfunction and pain.

Self-injury has been reported in up to 20% of mentally retarded adults. Autism and the absence of speech are the highest associated risk factors. Nail biting, head banging, and self-biting are frequently described associated behaviors. Severe self-injury related to biting is seen in Lesch-Nyhan syndrome.

Clinical Presentation

Children with common habits, such as thumb sucking or rhythmic movements, may be brought to the physician with these particular complaints because the parent wants advice about stopping the behavior. Other children may present with consequences of habits,

such as alopecia (trichotillomania), paronychia (nail biting), or lead intoxication (pica). Trichobezoars that can complicate trichotillomania may present with gastric outlet or bowel obstruction. Symptoms then include abdominal pain, anorexia, early satiety, nausea, vomiting, halitosis, and weight loss (Dx Box).

Dx Childhood Habits

- History of a habit
- Callus on thumb or fingers
- Short, chewed nails
- Alopecia
- Lead intoxication
- Iron deficiency anemia

Pathophysiology

Children engage in habits to reduce stress and provide comfort. Thumb sucking is related to nonnutritive sucking. Although the initial purpose of sucking is nutritional, the pleasure associated with sucking reinforces the behavior. Infants who are served from a cup from birth develop no interest in sucking. Humans and other primates spend more time in nonnutritive than in nutritive sucking. Monkeys use a 5-point hold, with 2 hands, 2 feet, and mouth (holding on to their mother's nipple) for attachment. Universal thumb sucking is noted even in orphan monkeys, and sucking is thought to be an important aspect of environmental adaptation. Nonnutritive sucking occurs even in the absence of fatigue, hunger, or discomfort, and has a purpose in itself—to provide comfort and be self-soothing. The maximum intensity of sucking occurs at 7 months. For older children (>3 years), sucking is also a way of dealing with boredom.

In bottle-fed infants, thumb sucking seems to commence when feeding stops. Some infants, described as “type A,” seem to be satisfied only when their thumb is in their mouth. As infants spend more time engaged in motor activity, they spend less time thumb sucking. Placid infants who cry less also do less sucking. Some studies have shown that thumb sucking is less common in breastfed infants, and that thumb suckers as a group feed less frequently (every 4 hours rather than 3 and for 10 minutes rather than 20).

Nail biting is related to thumb sucking, a form of oral gratification, and children may progress from thumb sucking to nail biting. The pattern of nail biting usually involves placement of the hand in the vicinity of the mouth, tapping of the fingers along the teeth, quick spasmodic bites with the fingers around the central incisors, and the removal and inspection of the hands. Other oral habits, such as pencil gnawing, gum chewing, lip biting, and nail picking, are related activities, as is nose picking. The cause of teeth grinding is unclear.

Rocking habits are believed to be kinesthetically pleasing and soothing and a means of autostimulation. The etiology of hair pulling is less apparent. The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* defines trichotillomania as

chronic hair pulling often associated with hair ingestion. In recent years, investigators have linked trichotillomania to disorders of serotonin reuptake and placed it in the category of obsessive-compulsive behavior. Some individuals who engage in trichotillomania have abnormal head positron emission tomography. Although the etiology of trichotillomania is unclear, affected children share certain features, which have been characterized as fiddling SHEEP (sensation, hands, emotion, environment, perfectionism). The overriding factor is a need for tactile stimulation. Pica, which is also considered abnormal, may be associated with mental retardation, environmental deprivation, or inadequate nutrition, particularly iron deficiency.

Differential Diagnosis

The differential diagnosis of most habits is not difficult. Tics or habit spasms should be differentiated from Tourette disorder. This syndrome, which is reported in 1 in 3,000 children, is a neurologic disorder characterized by severe, frequent, and multiple tics. These tics are also often vocal and consist of sounds such as hissing, barking, grunting, or coprolalia (repeating profanities). Some of the rhythmic habits may be mistaken for seizures but can be easily distinguished because of the stereotypical, repetitive nature of the behavior.

Trichotillomania usually has a classic physical appearance that has been referred to as *tonsure Friar Tuck* pattern baldness, with baldness around the vertex of the head. Unilateral temporal baldness is also a consequence of trichotillomania. The differential diagnosis of trichotillomania includes alopecia areata, tinea capitis, syphilitic alopecia, and androgenic alopecia (see Chapter 119). Broken hairs of variable length usually characterize alopecia secondary to trichotillomania. Other disorders in the differential diagnosis include traction alopecia, related to tight braids or hair brushing; atopic eczema; seborrheic dermatitis; hypothyroidism; systemic lupus erythematosus; and dermatomyositis. When trichotillomania is associated with a trichobezoar and signs of gastric outlet obstruction, the differential diagnosis includes neuroblastoma, lymphoma, and gastric carcinoma.

Cutting is not a benign habit, but it can provide stress relief, a feature of many benign childhood habits. It is usually associated with a wide range of psychopathology, including depression; anxiety; eating disorders, especially bulimia nervosa; a history of prior sexual abuse; and obsessive-compulsive symptoms. The mechanism by which cutting alleviates stress and anxiety has not been elucidated, but the role of endogenous endorphins has been suggested. Cutting is felt not to represent suicidal behavior, but some studies differentiate the site of cutting as predictive of suicidality: Wrist cutters as opposed to arm cutters have a higher rate of suicide ideation and attempts. All cutters are at greater risk for suicide than the general population. Management generally involves referral to a mental health specialist and the use of psychotherapy. Other forms of self-injury are reported with increased frequency among children with developmental disabilities, including autism spectrum disorder (see Chapter 124).

Evaluation

History

Children who present with thumb sucking, nail biting, and teeth grinding usually do not require an assessment other than a routine health maintenance history and physical examination. The history should determine the specific circumstances when the habit is manifest. Is the habit more likely to emerge when the child is tired or stressed? Habits must also be evaluated in the context of the child's developmental level and home situation. Understanding the impact of the habit on the child and the family is important. Children who present with movements that resemble tics should be carefully questioned about the frequency and duration of the tics, the effect of the tics on their behavior, and whether coughing is associated with the tics (sign of Tourette disorder). The occurrence of obsessive-compulsive mannerisms should also be noted (Questions Box).

Questions

Childhood Habits

- What about your child's habit concerns you?
- Is your child experiencing any adverse consequences (eg, being teased at school) as a result of the habit?
- Does the habit interfere with your child's routine activities?
- Can you identify stressors in your child's life?
- Is your child comforted by the habit?

Physical Examination

A routine physical examination should be performed. The physical examination may reveal the sequelae of the habit, such as thumb calluses, candidal infection of the nails, or evidence of malocclusion with an overbite (Figure 51-1). Children with suspected trichotillomania should have a thorough assessment of their scalp in an effort to differentiate other causes of alopecia (see Chapter 119). A careful neurologic examination should be performed in children with tics, and referral to a child neurologist may be indicated in children with suspected neurologic disorders.

Laboratory Studies

Routine laboratory studies are not needed in children diagnosed with habit disorders.

Children with trichotillomania should be evaluated for the disorders listed previously. An easy evaluation process for trichotillomania involves shaving the hair in the middle of the area of baldness. The growth of these small hairs is uniform because children are unable to pull them out. Head shaving may not be acceptable, however, to the parent or the child. Disorders such as syphilis and collagen vascular diseases can be ruled out using appropriate laboratory studies. Fungal infections can be differentiated by the use of appropriate cultures. A Wood light examination may reveal fluorescence noted with certain fungal infections.

Figure 51-1. Anterior open bite associated with thumb sucking.

Children who present with pica should be evaluated for the presence of iron deficiency anemia and lead poisoning.

Management

The management of childhood habits should be directed at the specific symptoms. For older children, self-monitoring and relaxation training may be helpful as alternative means for dealing with stress. The issue of thumb sucking versus the use of pacifiers can be addressed by anticipatory guidance. **Pacifiers**, which were previously discouraged, are now believed to have some advantages over thumb sucking. A report from the American Academy of Pediatrics noted a decrease in the incidence of sudden infant death syndrome in infants who used a pacifier. With pacifiers, the risk for dental disturbances is lower because the pacifiers are softer and are accompanied by a plastic shield that puts counter pressure on the teeth. Pacifiers are also detachable and cleanable.

Pacifiers can be lost, however. Parents should be advised not to attach a pacifier to the child's shirt with a string because of risk of strangulation. For children who are pacifier-dependent and are unable to go back to sleep if they lose their pacifier at night, multiple pacifiers can be placed in the crib to make finding one easier. For infants who desire pacifiers because they complete their feeding in less than 20 minutes, a nipple with a smaller hole can be used or the cap can be screwed on the bottle more tightly to prolong the time spent in nutritive sucking. Dental problems may develop when pacifiers are used upside down, all day long, or after the eruption of permanent dentition.

It is suggested that parents do not try to stop thumb-sucking behavior until children have reached the age of 4 years. Dental problems in late thumb suckers include anterior open bite, increased overjet (protruding upper incisors), intruded and flared upper

incisors, lingually flipped lower incisors, and warped alveolar ridge. When thumb sucking persists to school age, tongue thrust is noted, as are articulation problems, specifically with consonants s, t, d, n, z, l, and r. The physician should reassure parents that children who stop sucking their thumbs prior to the onset of the secondary dentition are not at risk for poor dentition.

Numerous devices have been proposed to help with the cessation of thumb sucking, but reported success has been variable. The use of arm restraints, particularly at night, is not recommended and may result in rumination. Bitter paints such as Stop Zit seek to reduce thumb sucking by subjecting children to a bitter, aversive taste. This medication consists of 49% toluene, 19% isopropyl alcohol, 18% butyl acetate, 11% ethylcellulose, and 0.3% denatonium benzoate. A three-quarter-ounce bottle is toxic if ingested in its entirety. Nocturnal application is needed if children suck their thumbs during the night. The principle of retraining, where thumb sucking becomes a duty and children are required to suck all 10 fingers one at a time, has also been recommended. Some recommend that elastic bandages be put on the hand of nocturnal thumb suckers. Problems associated with thumb sucking include sore thumbs, calluses, and candidal infections. Dentists may fashion a reminder appliance, called a palatal crib or rake, making it difficult for children to suck their thumbs. Such devices are usually applied for a minimum of 3 months. A fixed appliance is preferable to a removable one and treatment should be initiated in spring or summer when children are engaged in numerous physical activities. Some dental devices are available commercially or online. They may consist of a plastic covering for the thumb and hand. This covering eliminates the pleasurable sensation created by the interaction of thumb, saliva, and mouth. Such devices cost about \$80 and success is variable.

Encouragement works better than nagging, as a rule, and a **reward system** is particularly useful in children who are 5 to 6 years of age. Parents may be referred to books such as *Danny and His Thumb* (Ernst KF. Englewood Cliffs, NJ: Prentice-Hall; 1973) and encouraged to talk to their children about how good it feels not to suck their thumbs. A star chart and diary are also useful. Sometimes telling children something like, "Mommy would be so proud of you if you didn't suck your thumb now that you're such a big girl or a big boy" is effective. In addition, the pressure to stop thumb sucking becomes greater during the school years. Children who suck their thumbs are regarded by their peers in first grade as less intelligent, less happy, less likable, and less desirable as friends.

In children who suck their thumbs and twirl their hair at the same time, the hair twirling stops once the thumb sucking ends. The phenomenon is referred to as *habit covariance*. Hair pulling in young children seems to often resolve spontaneously but is more problematic in adolescents and adults. Management of trichotillomania usually involves non-pharmacologic treatments. In children, behavior modification, including putting socks on the hands and the use of time-out for hair pulling, in addition to extra attention for not pulling the hair, is recommended. Substituting behavior is also encouraged. For instance, children should be advised to sit on their hands, wear gloves, pull rubber bands, or squeeze a ball whenever they have

an urge to pull their hair. In older individuals, hair pulling may be related to obsessive-compulsive disorders. Trichotillomania may lead to the presence of bezoars (hairballs) from swallowed hair. Sometimes hairballs can extend through the gastric outlet into the small intestine, a phenomenon referred to as Rapunzel syndrome. Gastric hairballs can be dissolved enzymatically or with the installation of Coca Cola through a nasogastric tube. If such maneuvers fail, they are removed endoscopically or through surgery. Pharmacologic therapy for trichotillomania is not routinely recommended for the management of affected children. In adults, selective serotonin reuptake inhibitors, bupropion, and risperidone have been used. Children whose symptoms have not improved with behavioral interventions should be referred to a mental health worker for additional management.

Nail biting also often responds to behavior modification. Olive oil may be put on the nails to make them soft so there are fewer jagged edges to bite. In the children's book, *The Berenstain Bears and the Bad Habit*, collecting pennies is suggested as a habit substitution for nail biting.

Rhythmic habits are less easy to modify. For the most part, reassurance is all that is available. The use of metronome-like devices has had no demonstrable effect. Children older than 3 years who disturb the family's sleep with their rhythmic habits may be given mild sedatives, such as diphenhydramine or hydroxyzine. Medications to reduce head banging include transdermal clonidine and thioridazine (Mellaril). Other maneuvers involve placing the crib or bed on carpeting or bolting the crib to the wall to decrease the amount of noise from movement.

Children who engage in biting behavior should be managed with behavior modification, including praising of good behavior and time-out for inappropriate behavior. Aversive conditioning involves the placement of some non-palatable food, such as a lemon or onion on a necklace, and having the child bite on that object rather than biting another child. Biting behavior is reported to be extinguished with this technique. Another option is the placement of a whistle. The child blows the whistle rather than biting the other child.

Nose picking is a common habit in both children and adults. One suggestion to extinguish or minimize this habit involves letting children look in a mirror and pick their nose or videotaping the child while nose picking. Their reaction is that nose picking looks "gross" and the habit may decrease in frequency.

Iron deficiency related to pica requires iron supplementation. Lead intoxication should be managed with chelation and environmental manipulation.

Prognosis

Most habits are not harmful to children's health. The major problem is social acceptability. Parents should be encouraged to stop a habit before it becomes ingrained. This can often be done by praising good behavior and encouraging activities during which the unwanted behavior does not appear. Habits that do not respond to parental influence often resolve spontaneously under peer pressure.

CASE RESOLUTION

In the case history presented at the beginning of the chapter, it is important for the physician and the mother to empower the boy to stop thumb sucking before he finds himself ridiculed by his classmates. He might be allowed to suck his thumb at certain times and in certain places (eg, "You can suck in your room after school for fifteen minutes."). Books geared at children and parents to help stop the thumb sucking are recommended, and the boy is rewarded for times when he is not sucking his thumb.

Enuresis

Carol D. Berkowitz, MD

CASE STUDY

A 9-year-old boy who is in good general health is evaluated for a history of bedwetting. He is the product of a normal pregnancy and delivery, and he achieved his developmental milestones at the appropriate time. The boy was toilet trained by the age of 3 years, but he has never been dry at night for more than several days at a time. Enuresis occurs at least 3 to 4 times a week even if he is fluid-restricted after 6:00 pm. The boy never wets himself during the day, has normal stools, and is an average student. His father had enuresis that resolved by the time he was 12 years old.

The boy's physical examination is entirely normal.

Questions

1. What conditions account for the symptoms of enuresis?
2. What is the appropriate evaluation of children with enuresis?
3. What is the relationship between enuresis and emotional stresses or psychosocial disorders?
4. What management plans are available for enuresis?
5. How do physicians decide which management technique is appropriate for which patients?

Enuresis is defined as involuntary or intentional urination in children whose age and development suggest achievement of bladder control. Voiding into the bed or clothing occurs repeatedly (at least twice a week for at least 3 consecutive months). Urinary continence is reached earlier in girls than in boys, and the diagnosis of enuresis is reserved for girls older than 5 years and boys older than 6 years. The term diurnal enuresis, wetting that occurs during the day, has been replaced by daytime incontinence. The International Children's Continence Society promotes a new standardization for enuresis-related terminology. They prefer the use of the term incontinence to denote uncontrollable leakage of urine, either intermittent or continuous, which occurs after continence should have been achieved. Nocturnal or sleep enuresis refers to involuntary urination or incontinence that occurs during the night. The term **primary nocturnal enuresis (PNE)** is used when children have never achieved sustained dryness, and **secondary enuresis** is used when urinary incontinence recurs after 3 to 6 months of dryness. Monosymptomatic nocturnal enuresis means that nighttime wetting is the only complaint. Children who experience urgency, frequency, dribbling, or other symptoms have polysymptomatic enuresis. Such symptoms may be related to inappropriate muscle contraction, are usually associated with constipation, and are termed dysfunctional elimination syndrome.

Physicians can be particularly helpful by routinely questioning parents about bedwetting during health maintenance visits. Many families are otherwise reluctant to bring up this embarrassing complaint because enuresis is viewed as socially unacceptable. It poses particular difficulties if children wish to sleep away from

home. In addition, enuresis may be a marker for other behavioral or developmental problems.

Epidemiology

Enuresis affects 5 to 7 million patients in the United States. It is one of the most common conditions of childhood, affecting 10% to 20% of first-grade boys and 8% to 17% of first-grade girls. By age 10 years, 5% to 10% of boys have enuresis (1% of army recruits are enuretic). Seventy-four percent of affected children have nocturnal enuresis, 10% daytime incontinence, and 16% both. Primary enuresis affects the majority (75%–80%) of children with enuresis, and 80% to 85% of these children have monosymptomatic nocturnal enuresis. Although the overall incidence of secondary enuresis is lower (20%–25%), it increases with age; secondary enuresis makes up 50% of cases of enuresis in children 12 years of age.

Several epidemiological factors have been associated with enuresis, including low socioeconomic level, large family size, single-parent family, low birth weight, short height at 11 to 15 years of age, immature behavior, relatively low IQ, poor speech and coordination, and encopresis (fecal incontinence; 5%–15% of cases). Enuresis has been associated with obstructive sleep apnea where an increased level of atrial natriuretic factor has been reported. Atrial natriuretic factor inhibits the renin-angiotensin-aldosterone pathway, causing diuresis. Correcting the obstructive sleep apnea with tonsillectomy and/or adenoidectomy leads to an elimination of the enuresis. Enuresis occurs more often in institutionalized children. Enuresis has a familial basis, with 44% being enuretic if one parent was enuretic and as many as 77% of children are enuretic if both parents were

similarly affected. Concordance for enuresis is reported in up to 68% of monozygotic twins and between 36% and 48% of dizygotic twins.

Clinical Presentation

A history of enuresis may be obtained as a presenting complaint or elicited by physicians during a health maintenance visit. Medical complaints such as encopresis, obstructive sleep apnea (nighttime snoring), or attention-deficit/hyperactivity disorder (ADHD) may be associated with the enuresis (Dx Box). Children with ADHD have a 30% greater risk of being enuretic. The physical examination is usually normal.

Dx Enuresis

- Bedwetting
- Old enough to be toilet trained
- Precipitating problem such as diabetes or urinary tract infection
- Encopresis
- Attention-deficit/hyperactivity disorder
- Family history of enuresis

Pathophysiology

Delayed control of micturition has several possible causes (Box 52-1).

1. Faulty toilet training. Faulty toilet training may perpetuate both diurnal and nocturnal enuresis but is not expected to selectively perpetuate the latter. Parental expectations are believed to play a role in the toilet training experience. Parents who allow children to sleep in diapers may be delaying the achievement of nighttime dryness, but it is unlikely that the use of diapers causes nocturnal enuresis. Poor toilet habits, particularly infrequent voiding

or constipation, may be associated with urinary tract infections (UTIs).

2. Maturation delay. The development of the inhibitory reflex of voiding may be delayed in some children, which may contribute to enuresis until the age of 5 years. This is similar to the range with which children achieve other developmental milestones. It is unlikely that maturational delay persists as a cause of enuresis beyond this age. Experts believe that maturational delay is not a reasonable explanation if children can achieve dryness in the daytime but not at night.

3. Small bladder capacity. Evidence suggests that some children with enuresis have smaller bladder capacities. Bladder capacity in ounces is estimated as the age in years plus 2. For example, 5-year-old children have a bladder capacity of 7 ounces (210 mL). Adult bladder capacity is 12 to 16 ounces (360–480 mL). Small bladder capacity is associated with diurnal frequency or incontinence.

4. Sleep disorder/impaired arousal. It has been suggested that children with enuresis are in “deep sleep” and do not sense a full bladder. This is often the parent’s perception of their child’s sleep pattern. However, studies have shown that enuresis occurs during all stages of sleep, particularly in the first one-third of sleep and in transition from non-rapid eye movement stage 4 to rapid eye movement sleep. During this period body tone, respiratory rate, and heart rate increase, and erection and micturition occur. Studies suggest that the arousal center in the brain fails to respond (ie, the child does not awaken) to full bladder sensation. Children with enuresis do not seem to sleep more deeply than other children. However, enuretic children may have diminished arousal during sleep. In one study, 40% of enuretic children, compared with only 8.5% of non-enuretic children, failed to awaken to an 80-decibel noise.

5. Allergens. No evidence confirms the notion that exposure to certain foods (eg, food additives, sugar) contributes to enuresis. However, some parents believe that bedwetting is decreased if certain foods such as sodas and sweets are eliminated from the diet. The ingestion of caffeine-containing beverages may exacerbate nocturnal enuresis.

6. Nocturnal polyuria/relative vasopressin deficiency. Research has shown that although non-enuretic children exhibit a diurnal variation in vasopressin secretion, this rhythm is disturbed in some children with enuresis, resulting in nocturnal polyuria.

7. Dysfunctional bladder contraction. In cases of daytime incontinence, contractile disturbances of the bladder affect normal voiding. Children with an “ uninhibited bladder ” have not learned to inhibit bladder contraction. They may assume a certain posture, called Vincent curtsy, in an effort to prevent micturition. Some children exhibit discoordinated, incomplete voiding and the urine exits the urethra in a staccato stream. Trabeculations or bladder wall thickening may be noted on imaging studies.

Daytime incontinence can be related to problems with bladder filling and storage or to bladder emptying. Each of these functions is under different neurologic control, with filling and storage under

Box 52-1. Causes of Enuresis

Primary Enuresis

- Faulty toilet training
- Maturation delay
- Small bladder capacity
- Sleep disorder/impaired arousal
- Allergens
- Nocturnal polyuria/relative vasopressin deficiency
- Dysfunctional bladder contraction

Secondary Enuresis

- Urinary tract infection
- Diabetes mellitus
- Diabetes insipidus
- Nocturnal seizures
- Genitourinary anomalies
- Sickle cell anemia
- Medication use
- Emotional stress

the sympathetic nervous system and bladder emptying related to the action of acetylcholine and the parasympathetic system. Effective voiding requires the coordinated effort of these 2 phases. Management of daytime incontinence is dependent of which phase is malfunctioning.

Differential Diagnosis

Primary nocturnal enuresis is usually related to the conditions discussed in Pathophysiology. An organic problem is rarely the cause. However, secondary enuresis may result from an organic problem, such as UTI, diabetes mellitus, diabetes insipidus, nocturnal seizures, genitourinary anomalies (eg, ectopic ureter), sickle cell anemia, medication (eg, diuretics, theophylline), or emotional stress. When primary enuresis is both diurnal and nocturnal, some of these conditions should also be considered. Additional diagnoses include neurogenic bladder, which may occur in association with cerebral palsy; sacral agenesis; or myelomeningocele. Some children experience pollakiuria, a benign self-limited condition characterized by the sudden need to urinate very frequently, often 25 to 30 times a day. Rarely there is nocturia without other urinary symptoms. The condition occurs most often in children between 3 and 8 years, is self-limited, and felt to be stress-related. A urinary diary, noting time and amount of voiding, is sometimes helpful in diagnosing the condition.

Evaluation

History

A thorough history should be obtained when evaluating children with enuresis (Questions Box).

Physical Examination

A general physical examination should be performed, with particular attention to certain areas. The pattern of growth should be plotted. Blood pressure should be obtained. The abdomen should be assessed for evidence of organomegaly, bladder size, and fecal impaction. An anal examination should be performed to evaluate rectal tone.

If possible, physicians should watch children void. Practitioners should determine whether children can start and stop micturition and whether the stream is forceful. Dribbling in girls may indicate an ectopic ureter. A more sophisticated approach involves the uroflow test where the patient voids into an apparatus that electrically senses the rate of flow. A graph is generated that notes the flow rate and quantity. This study is most useful in children with diurnal incontinence. The appearance of the genitalia should be assessed. A rash in the genital area may be secondary to wetness from urinary incontinence. The skin may be macerated, erythematous, or hyperpigmented secondary to persistent moisture and irritation.

Labial fusion in girls may trap urine, allow reflux into the vagina, and lead to dribbling. Meatal stenosis, epispadias, hypospadias, or cryptorchidism may be present in boys. Any of these conditions suggests a possible underlying genitourinary anomaly.

Questions

Enuresis

- Is the enuresis primary or secondary?
- Is the enuresis diurnal, nocturnal, or both?
- How old was the child when he or she was toilet trained?
- How old was the child when he or she achieved daytime and nighttime dryness?
- How often does the child urinate and defecate during the average day?
- Is the child's urinary stream forceful or dribbling?
- Does the child dribble before or after voiding?
- Does the child experience symptoms such as polydipsia, polyuria, dysuria, urgency, frequency, or problems with stooling?
- Who changes the bed and who washes the bedclothes after bedwetting occurs?
- Does the child wear diapers or pull-ups, or use incontinence pads?
- Does the child seem to delay using the toilet?
- Does the child assume any unusual or distinct postures to avoid being incontinent?
- What is the attitude of the family toward the child with enuresis? Are family members accepting or ashamed?
- Has the family tried any treatments yet?
- Is there a family history of enuresis?
- Does the child have other symptoms such as encopresis, attention-deficit/hyperactivity disorder, or obstructive sleep apnea?

The neuromuscular integrity of the lower extremities should be evaluated. This may provide a clue to a disorder such as spina bifida occulta. The presence of some anomaly in the sacral area, such as a sacral dimple or a tuft of hair, may also be a sign of this condition.

Laboratory Tests

Only a minimal laboratory evaluation is indicated in most children with primary enuresis. Urinalysis, including specific gravity, is usually indicated. A complete blood cell count, hemoglobin electrophoresis, serum electrolytes, and blood urea nitrogen should also be considered. Studies such as urine culture and blood glucose are more often indicated in cases of secondary enuresis.

Imaging Studies

In cases in which the urinalysis is abnormal, the culture is positive, or genitourinary anomalies are apparent on physical examination, a renal ultrasound and vesicoureterogram may be warranted. Vertebral radiographs or magnetic resonance imaging is appropriate in the diagnosis of spina bifida. Magnetic resonance urography is helpful in girls suspected of having an ectopic ureter. An electroencephalogram is indicated if nocturnal epilepsy is suspected. Urodynamic studies to evaluate bladder contractility are controversial but are recommended by some urologists. They are recommended in children who do not respond to traditional therapy or are suspected of having spina bifida occulta.

Management

Primary Enuresis

Family counseling about enuresis should be part of all management plans. Issues related to psychosocial stress should be explored, particularly in cases of secondary enuresis. Families should be advised that the wetting is not intentional and that punishing children for accidents is inappropriate. However, children may take some responsibility for the consequences of their actions, such as removing soiled bedding or helping with the laundry. They should be rewarded for dry nights. Star charts, in which a sticker or gold star is applied to a calendar for each dry night, have traditionally been used. The exclusive use of these charts without other interventions has limited success, however, and suggests that the enuresis may have a volitional component. Star charts should be used in conjunction with other management strategies.

Two treatment modalities are acceptable for managing enuresis. Most studies do not support the use of fluid restriction as a reliable isolated means of controlling enuresis.

Conditioning therapy involves the use of an alarm that is triggered when children void during the night. Children are awakened by the sounding of the alarm, and further urination is inhibited. Eventually bladder distention is associated with inhibition of the urge to urinate. When conditioning therapy is used for 4 to 6 months, it is associated with a success rate of 70%. If the alarm is used for 4 more weeks with sustained dryness, relapses are uncommon.

Because patient cooperation is needed with the alarm system, its use is reserved for children older than 7 years. A newer system is a transistorized version of the original device that contains a small sensor in the underwear and an alarm on the wrist or collar. Some systems use vibrations so other family members are not disturbed by loud alarms.

Overall, conditioning devices have a cure rate of 70% to 85%, and a relapse rate of 10% to 15%. They incur a one-time cost of \$50 to \$75. Conditioning devices may be covered by insurance companies if the alarm is prescribed by a physician as a medical device. Conditioning without the use of auxiliary alarms may also be undertaken. One proposed method involves instituting a self-awakening program. Older school-aged children practice lying in bed during the daytime and simulating the experience of awakening, sensing a full bladder, and going to the toilet. Another dry bed training program involves parents' awakening their children first hourly, and then at longer intervals over the period of about 1 week. Children eventually learn to self-awaken. A 92% success rate with a relapse rate of 20% is reported with this program.

Pharmacologic agents include tricyclic antidepressants and desmopressin. Tricyclic antidepressants, especially imipramine, have been successfully used to treat nocturnal enuresis, although the mechanism of action is uncertain. The antidepressant action of the drug, its effect on sleep and arousal, and its anticholinergic

properties may all play a role. There is also some evidence that imipramine increases concentrations of antidiuretic hormone. The bladder capacity of individuals with enuresis treated with imipramine may be increased by 34%, which indicates that the anticholinergic effects of the drug may be the most significant.

Imipramine should not be prescribed for children younger than 6 or 7 years because of potential adverse effects. The recommended dosage is 0.9 to 1.5 mg/kg/day. In general, children younger than 8 years are given 25 mg 1 to 2 hours before bedtime, and older children are given 50 to 75 mg. Beneficial results usually occur within the first few weeks of therapy. Medication is usually continued for 3 to 6 months to prevent relapses, which are reported in up to 75% of cases. The drug should be tapered by reducing the dose or using an alternate-night regimen. Side effects are rare and include insomnia, nightmares, and personality changes. Acute overdoses are potentially fatal secondary to cardiac complications. The initial cure rate is 10% to 60% with a relapse rate of 90%. The monthly cost of imipramine is about \$5.

Desmopressin, an analog of vasopressin, the antidiuretic hormone, is another pharmacologic agent used for enuresis. Desmopressin probably works to decrease nocturnal urine production. Most patients respond rapidly to desmopressin and become dry within 1 to 2 weeks of the initiation of therapy. The medication is taken orally as 0.2 mg/tablet 1 hour before bedtime. The dose may be increased by 1 tablet at weekly intervals (maximum dose: 0.6 mg). Desmopressin in nasal spray is no longer recommended for the treatment of enuresis because of the risk of severe hyponatremia, seizures, and even death. Hyponatremia has also been reported with oral desmopressin in the face of high fluid intake sometimes associated with habit polydipsia. Fluid restriction is recommended from 1 hour before until 8 hours after desmopressin administration. While some recommend a 6-month course of the medication, others suggest a shorter trial period. If patients achieve a 2-week period of dryness, the dose can be tapered at 2-week intervals. The cure rate is 40% to 50% with a relapse rate of 90% off medication. Desmopressin is expensive, with an average monthly cost of \$150 to \$250.

Oxybutynin is an antispasmodic, anticholinergic agent used in the management of daytime incontinence or polysymptomatic nocturnal enuresis. The dosage is 5 mg at bedtime for children 6 to 12 years and 10 mg at bedtime for children older than 12 years. The response rate is 33%, and the major side effects include drowsiness, flushing, dry mouth, constipation, and hyperthermia. Hyoscyamine sulfate and flavoxate hydrochloride are 2 other medications used for daytime incontinence.

Treatment of enuresis in children with small bladder capacities includes bladder retention training. Such children are fluid loaded and asked to delay voiding for 5 to 10 minutes. This strategy is generally reserved for children with daytime incontinence.

Associated symptoms, particularly constipation and encopresis should be adequately addressed.

Secondary Enuresis

The management of secondary enuresis should focus on the treatment of the causal disorder, such as a UTI or diabetes mellitus.

Prognosis

The prognosis for children with enuresis is good. The spontaneous cure rate is 15% per year. Medical management results in a reduction in symptoms in more than 70% of affected children.

CASE RESOLUTION

The boy in the case scenario has PNE. The history of childhood enuresis in the father is significant. Two management options, behavior modification and treatment with desmopressin or imipramine, can be discussed with the family. The child's symptoms will probably spontaneously improve over time.

Encopresis

Carol D. Berkowitz, MD

CASE STUDY

A 7-year-old boy presents with the complaint of soiling his underpants. His mother states that he has never been completely toilet trained, and that stooling accidents occur at least 2 to 3 times a week, mainly during the day. The boy rarely has a spontaneous bowel movement without assistance. He sits on the toilet for just a few minutes and passes small, pellet-like stools. His mother has never sought medical care before for this problem.

The boy is very fidgety during the physical examination. The vital signs are normal and the child's height and weight are at the 25th percentile. His abdomen is soft but distended, with palpable loops of stool-filled bowel.

A small amount of stool is present around the anus and in the boy's underpants. Digital examination of the rectum reveals hard stool. The rectal tone is normal as is the rest of the physical examination.

Questions

1. What is the definition of encopresis?
2. What is the difference between retentive and non-retentive encopresis?
3. What are some physiological conditions that contribute to encopresis?
4. What conditions may be mistaken for encopresis?

Encopresis is the repeated passage of stool into inappropriate places (eg, clothing), either voluntary or involuntary, in children who should be toilet trained on the basis of age (usually at least 4 years, the age at which 95% of children have achieved stool continence) and developmental level and who have no primary organic pathology. One such encopretic event occurs each month for at least 3 months. The term *encopresis*, coined in 1926 by Weissenberg and originally used for children with psychogenic soiling, is similar to enuresis. Unlike enuresis, encopresis rarely occurs at night. Now encopresis is used in a broader sense to refer to all types of fecal incontinence.

Retentive encopresis, also referred to as functional fecal retention with encopresis, occurs in the face of constipation (obstipation), in which chronic rectal distention leads to the seepage of liquid stool around hard, retained feces. Sometimes this is called overflow or fecal soiling. The onset of symptoms is usually about 4 years of age. Approximately 95% of cases of encopresis are retentive. **Non-retentive encopresis** is characterized by the passage of soft stool without colonic distention or retention of stool. Some have recognized 2 categories of children with non-retentive encopresis: those who can control defecation but stool in inappropriate places, and those who have true failure to achieve bowel control. Primary encopresis occurs when children have never been completely toilet trained. Secondary encopresis occurs in children who have had a period of complete continence of stool. Most encopretic children have secondary encopresis.

Epidemiology

Encopresis is reported in approximately 1.5% of school-aged children, and boys are reported to be affected 2 to 6 times more often

than girls. This gender ratio reverses in the elderly, in which the prevalence of encopresis is twice as high in females as in males. An association between encopresis, enuresis, and attention-deficit/hyperactivity disorder (ADHD) is sometimes present. About 15% of children with enuresis also have encopresis. Family history for encopresis may also be positive; 16% of affected children have one affected parent, usually the father. An association between encopresis and child sexual abuse has been reported in a small number of children. There is no reported relationship between socioeconomic status, parental age, child's birth order, or family size.

Clinical Presentation

Children with encopresis have a history of staining of the underpants, which may be hidden in drawers or under beds by embarrassed children. Occasionally parents are unaware of the problem. Stooling accidents occur more frequently at home than in school. Some children have a history of constipation. Other children may initially be misdiagnosed as having diarrhea and are inappropriately placed on anti-diarrheal medications, which then exacerbate their problem. Parents may complain that their children exude a fecal odor, but children are unaware they are malodorous (Dx Box).

Pathophysiology

A history of constipation, often with painful defecation, is associated with retentive encopresis. With time, the colon distends and liquid feces seep around impacted stool (Figure 53-1). In 30% to 50% of children, anal spasm, referred to as *animus*, occurs and contraction rather than relaxation occurs during evacuation of feces. In another 40%, rectal hyposensitivity is apparent so that the children

Dx Encopresis

- Incontinence of stool
- Constipation
- Hyperactivity
- Distended abdomen
- Stool-filled loops of bowel
- Lax rectal tone
- Soiled clothing or bedding
- Fecal odor

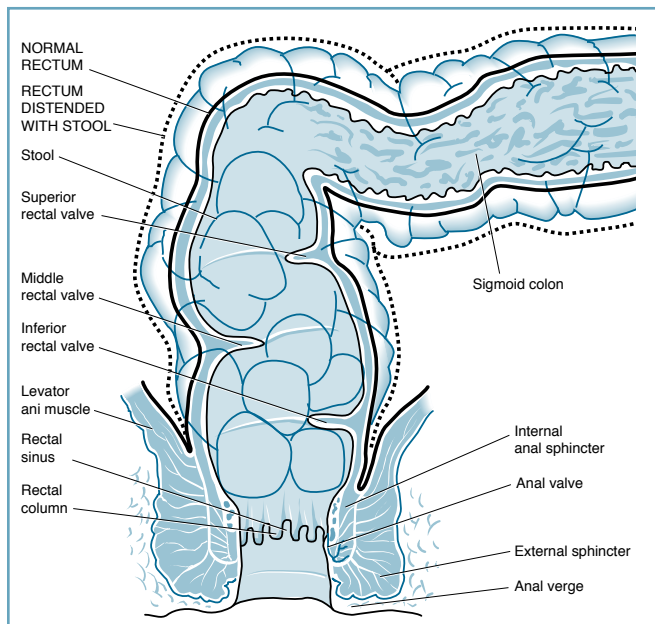

Figure 53-1. Diagram of the rectum, anal canal, and sigmoid colon distended with stool.

are unaware of the presence of the stool. Some children have an evacuation release disorder, in which the presence of the stool does not result in relaxation and stool evacuation. In such cases, the rectum is chronically distended by stool. Water is absorbed and the stool becomes harder and drier. The distended rectum fails to sense the presence of the stool. When evacuation is attempted, the process is painful, leading to further retention (see Chapter 111).

Encopresis has been associated with a short attention span and a high level of motor activity. Affected children are unable to sit on a toilet for more than a few minutes and do not adequately attend to the task of stool evacuation. As a result, they get off the toilet after the incomplete evacuation of only small amounts of stool. In some toddlers, constipation is related to the struggle of toilet training and an unwillingness to sit on the toilet (see Chapter 45).

The pathophysiology of non-retentive encopresis seems to be psychogenic. Some children who have been chronically sexually abused have lax anal tone, which may contribute to the fecal incontinence. Animus, abnormal anal sphincter contraction, has been reported in up to 30% of children with constipation.

Differential Diagnosis

The differential diagnosis of encopresis focuses on organic conditions associated with chronic constipation. Organic conditions account for 5% to 10% of fecal incontinence. These conditions include Hirschsprung disease, disorders of intestinal motility (eg, pseudo-obstruction), disorders of anal tone and anal anatomy (eg, imperforate anus with fistula), disorders of the lumbosacral spine (eg, meningomyelocele), and previous surgeries (eg, repair of imperforate anus). Neurofibromatosis, lead poisoning, and hypothyroidism are also associated with constipation. Congenital anorectal anomalies, which are reported in 1 in 5,000 live births, are rare.

Most of these conditions can be ruled out on the basis of a careful history and physical examination. In some cases, specific testing, such as anal manometry or rectal biopsy, may be necessary to exclude a particular disorder.

Evaluation

History

The age of onset of the problem, as well as the age of initiation of toilet training, should be determined. In general, affected children are 4 years of age and older. A detailed history of the stooling pattern should be obtained (Questions Box). The frequency and consistency of stools as well as quantity of stools should also be noted. In addition, the presence of nocturnal episodes of encopresis should be determined. In cases of secondary encopresis, the duration of fecal continence and the occurrence of any events, such as the birth of a sibling or the start of school, that may have precipitated the

Questions

Encopresis

- At what age was the child toilet trained?
- Does the child have spontaneous bowel movements (without enemas or suppositories)? If so, how frequently?
- Does the child have large, dry, hard stools that clog the toilet?
- Does the child pass blood with the stool?
- Did the child pass meconium within the first 24 hours after birth?
- Has the child had any surgery in the ano-genital area, spine, or bowel?
- Is the child taking any medications, such as aspirin, iron, Ritalin, imipramine, calcium channel blockers, or anticholinergics?
- Does the child seem to resist the urge to defecate (eg, squeeze legs together and rock back and forth)?
- Does the child have a history of enuresis or attention-deficit/hyperactivity disorder?
- What is the pattern of encopresis (ie, is the encopresis primary or secondary)?
- When and where does the child soil (eg, nocturnal, at home)?
- Have there been changes or stresses in the home or family?
- What happens to the child's stained underwear?
- What has the family done to manage the problem?

episodes of encopresis should be noted. Some children experience the onset of encopresis when they start school. Because of “toilet phobia,” they are unwilling to use the public toilet in the school setting.

Physical Examination

The next step involves the performance of a comprehensive physical examination, paying particular attention to the abdomen to check for the presence of distended, stool-filled loops of bowel. The rectal area should be assessed for rectal tone, an anal wink, and the presence of hard stool. Rectal prolapse, if present, may be indicative of chronic constipation or another condition, such as cystic fibrosis. Perianal fissures may reflect passage of large, hard stools. Hemorrhoids are unusual in children and can indicate chronic constipation. Location of the anus should also be noted, and anterior displacement may suggest incomplete forms of imperforate anus. Children with retentive encopresis have normal or tight anal tone on rectal examination because they are frequently contracting their external anal sphincter to prevent the seepage of the liquid stool.

Dysmorphic features should be noted and may suggest a syndrome in which constipation is a feature. Abnormalities around the anus, such as fistulas, should also be noted. Fistulas are found in Crohn disease. The underpants should be evaluated for the presence of stool, mucus, or pus. A sensory and motor examination of the lower extremities helps determine if any signs of spinal cord dysfunction are evident. An evaluation of the skin over the spinal area may reveal abnormalities such as sacral dimples or tufts of hair.

Children who do not exhibit abdominal distention may have soft stool on rectal examination, which indicates non-retentive encopresis. If patulous anal tone is noted, spinal cord abnormalities or prior child sexual abuse should be suspected.

Laboratory Tests

Most children with encopresis require few laboratory studies. Studies focus on eliminating organic causes of encopresis, such as Hirschsprung disease or spinal cord anomalies. Urinalysis and urine culture are recommended in children with fecal impactions to exclude urinary tract infection. Encopresis is reported to be an independent risk factor for urinary tract infections. Anorectal manometry, which may be used to measure the pressure generated by the anal sphincter, may also reveal abnormalities of anal tone or evidence of aganglionosis. The Child Behavioral Checklist is useful to determine if certain behavior problems exist. Such problems may either potentiate the encopresis or result from it.

Imaging Studies

In most encopretic children, imaging studies are not necessary. If radiographs of the abdomen are taken in children with retentive encopresis, distended, stool-filled bowel may be noted. A barium enema is useful if Hirschsprung disease is to be ruled out. Strictures, which may occur following necrotizing enterocolitis, will also be detected. Electromyogram to determine whether the innervation of the external anal sphincter is intact is recommended for children with encopresis who fail to respond to routine treatment.

Management

The management of encopresis focuses on complete rectal evacuation and patient and parent education and counseling. Regaining muscle tone of the anal canal usually requires 2 to 6 months.

Rectal evacuation requires **pharmacologic management** to ensure an adequate clean-out of retained stools. The decision about which laxatives to use depends on the degree of constipation. If the degree of fecal retention is mild, a high-fiber diet and stool-bulking agents or oral laxatives, such as senna derivatives, bisacodyl, or lactulose syrup, may be used in association with stool softeners or lubricants, such as mineral oil. The amount of mineral oil may be titrated up to ensure success. Some practitioners recommend that mineral oil be given until it oozes from the rectum. The amount may then be titrated back to a lower level. Magnesium sulfate is also recommended to relieve constipation. Magnesium citrate can be used, but should be administered cautiously and with the admonition to drink plenty of fluids to prevent dehydration. Polyethylene glycol 3350 has a very high success rate in the management of constipation and encopresis.

If the degree of retention is more severe, suppositories or enemas may be needed. Occasionally, children have to be disimpacted manually. Alternative methods to manual disimpaction include 2 to 3 sodium phosphate enemas over 1 to 2 days or 8 oz of mineral oil a day for 4 days. Pulsed irrigation–enhanced evacuation involves the insertion of a rectal tube and the installation of pulses of warm irrigating solution, simultaneously draining rectal contents. If the above modalities are not successful, children may need to be admitted to the hospital for oral lavage using polyethylene glycol-electrolyte solution at 30 to 40 mL/kg/hour until successful evacuation has occurred. This procedure often requires insertion of a nasogastric tube and 6 to 8 hours of treatment. Once the fecal accumulation has been relieved, every effort should be made to keep children regular. This can be accomplished with the combined use of toilet retraining, stool softeners or laxatives, and enemas or suppositories. Prokinetic agents such as metoclopramide may also be used.

Dietary manipulation is important to ensure sustained regular stooling. Parents should be told that children require a high-fiber diet with fruit juices, such as pear or peach juice, and decreased milk (≤ 16 oz/day). It has been suggested that a “team and coach” approach is the most successful route, and that bowel training be likened to fitness training.

The toilet retraining process, sometimes referred to as enhanced toilet training, requires that children sit on the toilet at least 2 or 3 times a day, usually after meals, for about 10 minutes or until they have had a bowel movement. Some practitioners recommend the use of an egg timer to ensure that children spend the appropriate amount of time on the toilet. Children should be requested to maintain a diary of their evacuation, which may take the form of a star chart. Stars or other rewards are given for successful bowel movements in the toilet.

If children skip a day between bowel movements, they may be treated with a suppository, such as a glycerin or bisacodyl suppository.

If they still have not succeeded in having a bowel movement, then an enema may be appropriate. This sequence should be maintained until children are having bowel movements in the toilet and not soiling for at least 1 month. In general, stool softeners are required for at least 3 to 6 months. The regimen may have to be modified, particularly in younger children.

Behavior modification and biofeedback, such as using external anal sphincter electromyography, are 2 other modalities that can be used to help manage encopresis. Consultation with specialists such as pediatric gastroenterologists may be required.

Thirty percent of children with encopresis may need psychological consultation. Psychological intervention in the form of interactive parent–child family guidance has been reported successful when standard gastroenterologic intervention has failed. Children with evidence of child sexual abuse or non-retentive encopresis should be referred to a psychologist early in the course of therapy. The underlying psychosocial problems of children with non-retentive encopresis must be adequately addressed before their condition can improve.

Prognosis

The prognosis for children with retentive encopresis is reportedly good with appropriate intervention. In one study, children who were able to defecate a rectal balloon filled with 100 mL of water within 5 minutes were twice as likely to recover from constipation and encopresis. It is estimated that about 30% to 50% of affected children experience long-lasting remission after 1 year and up to 75% are in remission by 5 years.

The prognosis for children with non-retentive encopresis is less predictable and highly dependent on the underlying psychopathology.

CASE RESOLUTION

In the case scenario, the boy exhibits typical manifestations of retentive encopresis. His condition should be managed with the use of laxatives, stool softeners, and toilet retraining with a star chart. The possible ADHD should be addressed separately but may be contributing to his inability to attend to the task of toileting.

Fever and Bacteremia

Paul Bryan, MD

CASE STUDY

An 8-month-old girl is brought to the emergency department (ED) with a 2-day history of fever and increased fussiness. She is irritable but consolable by parents. Her parents believe that her immunizations are up to date, but they do not have the immunization record with them. On examination, she has a rectal temperature of 39.5°C (103.1°F). The rest of the physical examination is within normal limits, and no source for the fever is apparent.

Questions

1. What are serious bacterial infections in young febrile infants?
2. What has been the impact of conjugated vaccines against *Haemophilus influenzae* and *Streptococcus pneumoniae* on the incidence of bacteremia and meningitis in febrile infants?
3. What are the challenges in differentiating between serious and benign febrile illnesses in young children?
4. What diagnostic studies are recommended in the evaluation of febrile infants and children?
5. When should febrile infants be hospitalized?

Fever is one of the most common chief complaints among pediatric patients seeking medical attention in physician offices, urgent care centers, and EDs and accounts for up to 20% to 30% of these visits. Most of these patients will have a benign, self-limited viral illness. Some patients, however, will have a **serious bacterial infection** (SBI), defined as meningitis, urinary tract infection (UTI)/pyelonephritis, bacteremia, septic arthritis, osteomyelitis, cellulitis, or deep tissue infection. **Bacteremia** is a bacterial infection within the bloodstream. **Occult bacteremia** occurs when there is a bacterial infection in the blood without any apparent source of infection after a thorough physical examination in an otherwise healthy-appearing child.

Epidemiology

Historically, management decisions regarding febrile children have been largely dictated by age. Children have been broken down into age-defined categories: (1) young infants less than 90 days, (2) infants and young children 3 to 36 months, and (3) children older than 3 years. Young febrile infants (ie, <90 days) have higher rates of SBIs than older children and often represent a diagnostic challenge. They have relatively immature immune systems rendering them particularly susceptible to bacterial infections, have not yet received most of their immunizations, and often have limited responses in the face of bacterial infections and, therefore, exhibit relatively nonspecific signs and symptoms. In addition, young infants have different bacterial pathogens that can cause these serious infections, including *Escherichia coli*, *Streptococcus agalactiae* (group B streptococci or GBS), *Listeria monocytogenes*, and other gram-negative organisms (Box 54-1). The prevalence of an SBI among young febrile infants with a fever of 38.0°C (100.4°F) is about 10%, with UTIs being by far

the most common source. A smaller percentage has bacteremia and/or meningitis. Recent studies have demonstrated that young febrile infants with diagnosed viral infections have lower rates of SBI than those without viral infections (4% vs 12%). None of the young febrile infants with viral infections by diagnostic testing had meningitis, but some did have UTIs and, rarely, bacteremia.

Febrile children aged 3 to 36 months are at a higher risk for bacteremia than older children, but less so than young febrile infants. The physical examination, while more reliable than in younger infants, can often be normal without any localizing source of infection. These individuals may in turn have occult bacteremia. Vaccine development and widespread immunization programs have dramatically

Infants Younger Than 3 Months

- Group B streptococcus
- *Escherichia coli*
- *Listeria monocytogenes*
- *Salmonella* species (infants >1 month)
- *Haemophilus influenzae* type b (Hib)^a (infants >1 month).

Children Between 3 and 36 Months of Age

- *Streptococcus pneumoniae*
- *Neisseria meningitidis*
- *Salmonella* species
- *Staphylococcus aureus*
- Hib^a

^a Hib disease has been virtually eliminated with the routine use of Hib conjugate vaccines.

changed the epidemiology and clinical course of bacteremia among this population within the United States over the last several decades. Prior to the introduction of the *Haemophilus influenzae* type b (Hib) and pneumococcal vaccines, the prevalence rates of bacteremia were around 3%. During this time, *Haemophilus* was considered the most significant organism causing bacteremia because of its invasive ability to cause localized infection, particularly meningitis. In the mid-1980s, the Hib vaccine was introduced, which has now virtually eliminated this particularly invasive organism. In the post-Hib but pre-pneumococcal conjugate vaccine era, the rates of occult bacteremia ranged from 1.6% to 1.9% in children with a temperature of 39.0°C (102.1°F) or higher and no obvious source of infection. More than 90% of the cases of occult bacteremia in this age group were caused by *Streptococcus pneumoniae*, with the remainder being caused by *Salmonella*, *Neisseria meningitidis*, *Staphylococcus aureus*, and a few other rare organisms. Pneumococcus is not as virulent a microorganism as some other bacteria. Most cases of occult pneumococcal bacteremia resolved spontaneously without any intervention. If untreated, a small percentage (3%–5%) went on to develop pneumococcal meningitis, which has the most serious complication and fatality rate. In 2000 the heptavalent pneumococcal conjugate vaccine was licensed by the US Food and Drug Administration for use within the United States. This vaccine provided coverage against the 7 main serotypes of *S pneumoniae* responsible for approximately 80% of the cases of invasive pneumococcal disease in the United States and Canada at the time. Following the introduction of this vaccine, the rate of invasive pneumococcal disease (including bacteremia) and carriage for the serotypes covered by the vaccine dropped considerably. In addition, there was evidence suggestive of herd immunity in that there was a decline in invasive pneumococcal disease among older individuals who had not received the vaccine. Consequently, there has been a selective pressure that has increased the prevalence of invasive pneumococcal disease caused by strains not covered by the heptavalent vaccine, although the overall magnitude of this effect appears to be relatively small. In addition, other bacteria, such as *E coli*, *Salmonella*, and *S aureus*, appear to have increased in relative frequency as a source of bacteremia. In 2010 a new 13-valent pneumococcal conjugate vaccine was licensed and is manufactured in the same way as the heptavalent vaccine. This vaccine expanded coverage to include 6 different serotypes that have emerged with increasing frequency as a cause of invasive pneumococcal disease following the introduction of the heptavalent vaccine. The American Academy of Pediatrics and the Advisory Committee on Immunization Practices currently recommends the pneumococcal conjugate vaccine for all infants in a 4-dose regimen to be given at 2, 4, 6, and 12 to 15 months of age. Continued surveillance of invasive disease will be necessary to ascertain what impact the changes in epidemiology of these newer vaccines may have on the diagnosis and management of bacteremia in young febrile children.

Clinical Presentation

In many febrile children, fever is the only complaint or manifestation of disease. These children may look fine and behave normally.

Young children, especially infants younger than 3 months, have fewer and subtler behavioral signs with bacterial infections. Physicians must, therefore, maintain a high index of suspicion for the presence of an SBI even in the absence of localizing signs (Dx Box). Occult bacteremia, by definition, has no abnormal physical manifestations aside from fever.

Dx

Serious Bacterial Illness

- Lethargy, irritability, or change in mental status
- Tachycardia disproportionate to the degree of temperature elevation
- Tachypnea or labored respirations
- Bulging or depressed anterior fontanelle
- Nuchal rigidity
- Petechiae
- Localized erythema, pain, or swelling
- Abdominal or flank pain
- Fever

Pathophysiology

Fever is an elevation in the thermoregulatory set point of the body. The thermoregulatory center is located in the preoptic region of the anterior hypothalamus, and an elevation in the hypothalamic set point above the normal body temperature initiates the physiological changes that lead to fever. Exogenous pyrogens (eg, bacteria, viruses, antigen-antibody complexes) stimulate host inflammatory cells (eg, macrophages, polymorphonuclear cells) to produce endogenous pyrogens (EPs). Interleukin-1 is currently regarded as the prototypical EP. Endogenous pyrogens cause the hypothalamic endothelium to increase intermediary substances, such as prostaglandins and neurotransmitters, which then act on the preoptic neurons of the anterior hypothalamus to produce an elevated set point. The body uses physiological mechanisms (eg, peripheral vasoconstriction, shivering) and behavioral actions (eg, bundling up, drinking hot tea) to increase body temperature to reach and maintain this higher set point, thus producing fever (Figure 54-1).

In contrast, the thermoregulatory set point of the body is normal in hyperthermia. Due to abnormal physiological processes, heat gain exceeds heat loss, and the body temperature rises in spite of efforts to return to the control set point.

Differential Diagnosis

In most cases, the duration of fever in children is short, and signs and symptoms are localized. Fever without a source involves an acute episode of fever that lasts 1 week or less in children in whom history, physical examination, and preliminary laboratory tests fail to reveal a source. Most affected children are eventually diagnosed with an acute, generally self-limited, infectious illness. Occult bacteremia has been a major concern in young children, primarily in infants younger than 36 months. High risk factors for occult bacteremia are presented in Box 54-2. Fever of unknown origin (FUO) is fever of at least 8

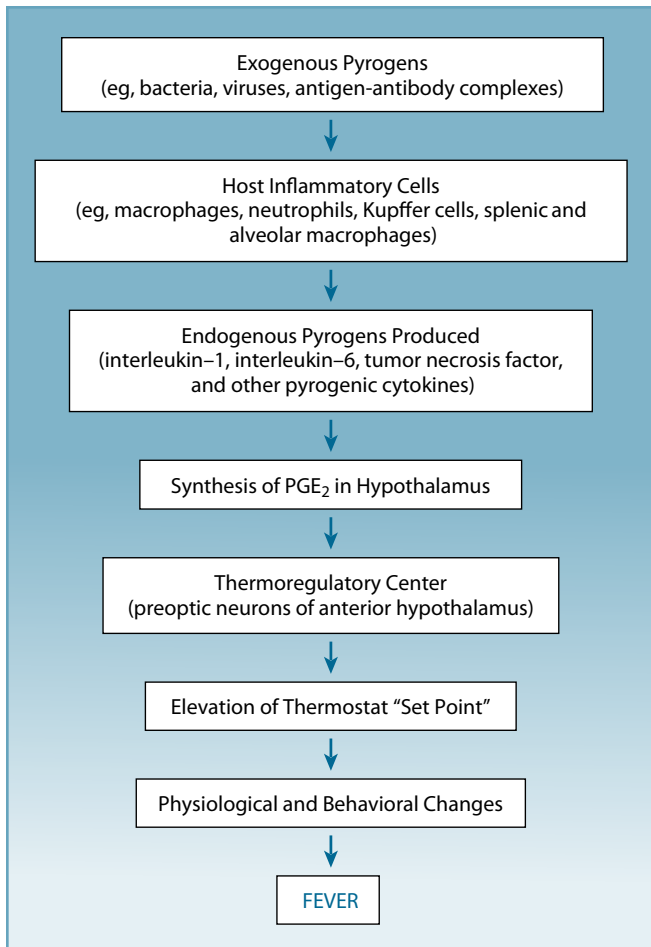

Figure 54-1. Pathophysiology of fever production. Antipyretics work by blocking the synthesis of prostaglandin E_2 (PGE_2).

days' duration in infants or children in whom routine history, physical examination, and laboratory assessment fail to reveal a source.

The differential diagnosis of children with an acute febrile illness is primarily infectious (Box 54-3), including both benign, generally self-limited illnesses such as upper respiratory infections, and less common, more serious illnesses such as meningitis and osteomyelitis. Occasionally a child with a fever without a source turns out to have a noninfectious illness such as a collagen vascular disease or neoplasia. By comparison, the differential diagnosis of children with FUO is quite broad (Box 54-4) and contains both infectious and noninfectious disorders.

Evaluation

History

The medical history can provide a great deal of valuable information in the evaluation of children with fever (Questions Box). The history should focus on the duration and severity of the fever. The presence of associated symptoms that may be signs of specific organ system involvement should also be noted.

Box 54-2. Risk Factors for Occult Bacteremia

- Age 36 months or younger
- Temperature 103.1°F (39.5°C) or higher
- White blood cell count 15,000/ μ L or higher or 5,000/ μ L or lower
- Total band cells 1,500/ μ L or higher
- Erythrocyte sedimentation rate 30 mm/hour or higher
- Underlying chronic disease (malignancy, immunodeficiency, sickle cell disease, malnutrition)
- Clinical appearance (irritability, lethargy, toxic appearance)

Box 54-3. Common Infectious Causes of an Acute Episode of Fever in Children

Upper Respiratory Tract

- Upper respiratory infection (common cold)
- Otitis media
- Sinusitis

Pulmonary

- Bronchiolitis
- Pneumonia

Oral Cavity

- Gingivostomatitis
- Pharyngitis
- Dental abscess

Gastrointestinal Tract

- Acute gastroenteritis (bacterial or viral)
- Appendicitis

Genitourinary Tract

- Urinary tract infection
- Pyelonephritis

Musculoskeletal

- Septic arthritis
- Osteomyelitis

Central Nervous System

- Meningitis

Miscellaneous (including noninfectious causes)

- Bacteremia
- Immunization reaction
- Viral exanthems (eg, chickenpox, measles)
- Neoplasia
- Collagen vascular disease

Physical Examination

Rectal temperatures should be performed in all young infants and children. An elevation in rectal temperature in an infant should not be attributed to overbundling. Vital signs in addition to temperature may provide important diagnostic clues. Tachycardia disproportionate to the degree of temperature elevation may suggest dehydration or sepsis. Tachypnea, which is often the only sign of a respiratory

Box 54-4. Common Causes of Fever of Unknown Origin in Children^a

Infectious Diseases

Bacterial

- Localized infection: mastoiditis, sinusitis, pneumonia, osteomyelitis, pyelonephritis, abscess (eg, abdominal, pelvic)
- Systemic disease: tuberculosis, brucellosis, salmonellosis, leptospirosis, tularemia

Viral

- Hepatitis viruses
- Cytomegalovirus
- Epstein-Barr virus (infectious mononucleosis)
- HIV

Fungal

- Disseminated coccidioidomycosis
- Disseminated histoplasmosis

Miscellaneous

- Malaria
- Rocky Mountain spotted fever
- Syphilis
- Lyme disease

Neoplasia

- Leukemia
- Lymphoma
- Hodgkin disease
- Neuroblastoma

Collagen Vascular Diseases

- Juvenile rheumatoid arthritis
- Systemic lupus erythematosus
- Rheumatic fever

Miscellaneous

- Inflammatory bowel diseases
- Kawasaki disease
- Thyroiditis
- Drugs
- Factitious fever

^a For a complete discussion of fever of unknown origin, the reader is referred to Lorin MI, Feigin RD. Fever without localizing signs and fever of unknown origin. In: Feigin RD, Cherry JD, eds. *Textbook of Pediatric Infectious Diseases*. 4th ed. Philadelphia, PA: W.B. Saunders; 1998:820–830.

infection, also occurs in response to metabolic acidosis secondary to sepsis or shock. These changes may suggest an occult focus of infection. Response of the temperature and other vital signs to antipyretics should be noted. The physician must remain cautious because a clinical improvement in response to antipyretics can be seen in younger children and infants even in the face of an SBI. Young infants with recorded fevers at home, but who are afebrile on physician evaluation, should be managed as if they have a fever present.

Observation of the overall hydration and activity of infants and children is extremely important. An attempt should be made to

Questions

Fever and Bacteremia

- How long has the child had fever? How high has the temperature been?
- Does the child have any other symptoms, such as rash, vomiting, diarrhea, abdominal pain, or dysuria; cough, rhinorrhea, or other respiratory symptoms; or lethargy, irritability, or change in mental status?
- Is anyone sick at home?
- Has the child's activity level changed (eg, more sleepy than usual) or is the child more irritable?
- What immunizations has the child received?
- Is the child taking any medications?
- Do any pets live in the house?
- Has there been any history of recent travel, especially outside the country?
- Has the child ever been hospitalized for an infectious illness?
- Does the child have any medical problems, especially asthma, sickle cell anemia, congenital heart disease, or immunodeficiency?

determine whether they are behaving and responding in an age-appropriate fashion. Physicians should look for eye contact, spontaneous motor movements, negative responses to adverse stimuli, and positive responses to pleasant stimuli.

All febrile children should receive a complete physical examination. This is important even when the history may suggest involvement of one organ system. For example, in young children, vomiting and fever may be the only signs of viral illness, or possibly a more serious infection, such as a UTI or central nervous system (CNS) infection. The underlying condition may go undiagnosed unless a thorough examination and diagnostic evaluation are performed.

The anterior fontanelle should be palpated. It may be normal, bulging as a result of CNS infection, or depressed secondary to dehydration. The ears should be examined carefully and pneumatic otoscopy performed. Careful inspection may reveal otitis media as the source of fever, especially in children younger than 3 years. The occurrence of otitis media should not preclude further workup for invasive bacterial disease in children who do not appear well (see Chapter 72). The oropharynx should also be examined carefully. Dry mucous membranes may indicate dehydration. Enlarged, inflamed, or exudative tonsils may signal the presence of a viral infection or group A streptococcal infection in older children. Respiratory symptoms such as retractions, nasal flaring, grunting, stridor, rales, rhonchi, or wheezing may all be clues to respiratory tract infections. Enanthems on the buccal mucosa, or exanthems on the skin, are often signs of viral infections. The presence of petechiae in association with fever may indicate serious underlying infection, such as meningococemia. The capillary refill time, quality of peripheral pulses, and the general temperature of the extremities assess perfusion. Localized areas of pain, erythema, swelling, induration, or fluctuance may point to cellulitis, septic arthritis, osteomyelitis, or the

presence of an abscess. Nuchal rigidity can be an important clue to the presence of meningitis. This is rarely present in infants younger than 15 to 18 months, however, and physicians must maintain an index of suspicion for meningitis in febrile children of this age.

Laboratory Tests

Infants 90 Days or Younger

Because the physical examination alone cannot reliably identify an SBI in all febrile infants 90 days of age or younger with a temperature of 38.0°C (100.4°F) or higher, a thorough evaluation for a bacterial source of infection is required. This evaluation includes a complete blood cell count (CBC) with differential, urinalysis with microscopic evaluation, and blood and urine cultures. Cerebrospinal fluid (CSF) studies and CSF cultures should be performed on all infants younger than 6 weeks, and strongly considered between 6 to 8 weeks. Peripheral white blood cell (WBC) counts, while possibly helpful in older infants and children, do not reliably predict UTIs, bacteremia, or meningitis in young febrile infants. Decisions about whether to send blood and urine cultures, or to perform a lumbar puncture, should not be based solely on the screening peripheral WBC count in this age group. In addition, the standard urinalysis has a sensitivity of only around 85% in this age group and should not be used to determine the need for urine culture. Rapid viral diagnostic techniques that can reliably identify several of the more common viral pathogens (eg, respiratory syncytial virus, influenza, adenovirus, parainfluenza) are also available. The presence of a positive viral test result, however, does not preclude further diagnostic testing in this age group, specifically blood and urine cultures. If empiric antibiotics are to be dispensed, a lumbar puncture must be performed so as not to obscure the possibility of partially treated meningitis should pleocytosis be discovered on a subsequent CSF specimen. Stool analysis and culture should be reserved for those young febrile infants with diarrhea. Routine diagnostic radiographic studies (eg, chest radiographs) are not necessary, and should be reserved for infants with respiratory symptoms (eg, tachypnea, hypoxia, rales, wheezes, increased work of breathing).

Infants 3 to 36 Months

The diagnostic approach to older infants and young children has changed following the introduction of pneumococcal conjugate vaccines. Prior to widespread vaccine use, the standard of care involved an aggressive diagnostic approach looking for occult bacteremia in febrile children 3 to 24 months with temperature higher than 39.0°C (102.2°F), and in those 2 to 3 years with temperature higher than 39.5°C (103.1°F) without any apparent source of infection. The workup included a screening CBC, blood cultures, and empirically treating infants and children with an elevated WBC count greater than 15,000/mm³ or an absolute neutrophil count (ANC) greater than 10,000/mm³ because they were at higher risk for occult bacteremia. The ANC was generally considered to be the best predictor of risk for occult bacteremia. Acute phase reactants such as erythrocyte sedimentation rate and C-reactive protein, while commonly

elevated in serious infections, have not been shown to be better predictors for occult bacteremia than the peripheral WBC count or ANC. Other laboratory tests, including antigen testing, serum cytokine measurements, and polymerase chain reaction, are not particularly useful because of their limited availability, relatively high false-positive rates, and cost. Currently there is no single test that has been able to reliably identify all young febrile children with occult bacteremia.

With the declining prevalence of invasive pneumococcal disease post-licensure of the heptavalent conjugate vaccine, the need for routine screening, culturing, and selective antibiotic use for occult bacteremia has been challenged. The peripheral WBC count is no longer as useful a screening tool in the face of such low rates of invasive disease. In addition, the rates of contaminated blood cultures are now much higher than actual cases of bacteremia, which often results in unnecessary additional testing, hospitalization, antibiotic administration, and family stress. Infants and children who have received at least 2 doses of the vaccine can be safely managed without blood tests because this is no longer a cost-effective strategy. Individuals who are unimmunized, whose vaccine status is uncertain, or who have received only 1 dose of the vaccine may need screening evaluation with CBC, blood, and urine cultures, and expectant antibiotics if they are found to have an elevated WBC count or ANC. The change in epidemiology of bacteremia following the widespread use of the pneumococcal vaccine may warrant reconsideration of this in the future following long-term surveillance of invasive disease. Infants with fever higher than 39.0°C warrant urine testing, especially in girls younger than 2 years, uncircumcised boys younger than 12 months, and circumcised boys younger than 6 months. Chest radiograph should be considered in infants with significant respiratory symptoms or auscultatory findings suggestive of pneumonia. In infants with temperatures higher than 39.5°C and WBC counts greater than 20,000/mm³, chest radiographs should also be obtained to detect occult pneumonias, reported in up to 25% of these patients, even in the absence of significant respiratory symptoms or auscultatory findings.

Children Older Than 3 Years

The laboratory evaluation of children older than 3 years is individualized and influenced by the history and physical examination. Healthy children in this age group are not at high risk for occult bacteremia. In addition their physical examination is more reliable and they are better able to communicate their symptoms than younger children. Routine screening tests are not generally indicated in healthy individuals and should be reserved for those who look toxic or have an underlying disease that puts them at increased risk for bacterial infections (eg, sickle cell disease, cancer, immunodeficiency, nephrotic syndrome).

Imaging Studies

As noted previously, chest radiographs are the most common imaging study done in the routine evaluation of an infant or child with fever and symptoms consistent with lower respiratory infection or with fever and no apparent source. Other imaging studies, such as

bone scans, gallium scans, magnetic resonance imaging, and computed tomography scans, are indicated if there are suspected infections such as an occult abscess or osteomyelitis.

Management

Management of children with fever includes both controlling the fever and treating the underlying process causing the fever. There is no evidence that fever itself is harmful. To the contrary, animal studies have suggested that fever may have some survival advantage. Despite the possible beneficial effects of fever, febrile children may still feel uncomfortable. Fever should be reduced to relieve the associated discomfort and malaise. **Antipyretics** such as acetaminophen and ibuprofen can be used. Aspirin should be avoided in children because of the association with Reye syndrome and viral illnesses. **Sponging or bathing** with tepid water and **unbundling** children aid in fever reduction. Ice water or alcohol baths should be avoided.

All toxic-appearing febrile infants and children, regardless of age, require hospitalization and administration of broad-spectrum antibiotics. Hospitalization and the initiation of empiric intravenous (IV) antibiotics are recommended for all febrile infants 28 days or younger pending culture results. Ampicillin and gentamicin are the most commonly used initial antibiotics within this age group. Careful consideration must be made to resistance patterns within a particular region. With the onset of standard GBS surveillance during pregnancy and the use of intrapartum antibiotics, more gram-negative organisms and increased gentamicin resistance have been reported, necessitating the use of a third-generation cephalosporin, such as cefotaxime, for initial empiric coverage. Ceftriaxone is generally avoided in this age group, particularly among jaundiced newborns, because of its ability to displace bilirubin from albumin, thereby increasing the risk of kernicterus.

Well-appearing febrile infants aged 29 to 90 days can be managed safely as outpatients either with antibiotics (ceftriaxone 50 mg/kg intravenously or intramuscularly) or close observation alone provided they meet established low risk for SBI criteria (Box 54-5). In addition, parents must have a reliable means of communication and transportation in the event of a positive culture result so that they can be notified to return the infant for reevaluation and possible admission. All febrile infants aged 29 to 90 days need very close follow-up, typically within 24 hours. Most pathogens will be isolated from cultures within the first 24 hours, and hospitalization with IV antibiotics is generally warranted for any young infant with a culture result consistent with a pathogen and not a contaminant. The addition of vancomycin must be considered if resistant pneumococcus is a possibility.

The management of well-appearing febrile infants and children between 3 to 36 months of age is based on the results of any diagnostic studies. Antibiotics should be administered for any bacterial infection identified. Those well-appearing infants who are tolerating oral fluids well and have no significant respiratory distress or hypoxia can be managed as outpatients even if they have a UTI or pneumonia. Clinicians may administer a dose of ceftriaxone for the first 24 hours

Box 54-5. Low-Risk Criteria for Serious Bacterial Infection in Young Febrile Infants

1. Well-appearing
2. No focal bacterial infection on examination
3. Previously healthy term infant with unremarkable neonatal course
4. White blood cell (WBC) count between 5,000 to 15,000/mm³
5. Absolute band cell count less than 1,500/mm³ or a band-to-neutrophil ratio of less than or equal to 0.2
6. Normal cerebrospinal fluid examination with less than 8 WBCs per high-power field and negative Gram stain
7. Normal urinalysis with less than 10 WBCs per high-power field
8. Stool studies with less than 5 WBCs per high-power field (if diarrhea present)
9. Normal chest radiograph (if respiratory signs/symptoms present)

and transition to an oral antibiotic thereafter. Continued close follow-up is necessary, usually within 24 to 48 hours. Infants who have received one dose or less of the pneumococcal vaccine can receive a dose of ceftriaxone pending culture results if the WBC count is greater than 15,000/mm³ or the ANC is greater than 10,000/mm³.

Healthy well-appearing febrile children older than 3 years can be managed as outpatients if they are well hydrated and have no respiratory distress or hypoxia. Children with underlying medical conditions and at risk for bacterial infections may also need hospitalization and IV antibiotics regardless of age.

Children with occult pneumococcal bacteremia who are afebrile and well-appearing at follow-up can probably continue to be managed as outpatients. Additional dosing of ceftriaxone may be necessary or transition to an oral antibiotic can be considered if sensitivity testing has been performed. Repeat blood cultures are probably not necessary if the child is afebrile as the likelihood of persistent bacteremia is low. Those who are younger than 90 days, still febrile at follow-up, or who have clinically worsened warrant hospitalization and IV antibiotics. In addition, a lumbar puncture should be considered if not previously performed in a child with a positive blood culture. All individuals with occult *N meningitidis* bacteremia warrant hospitalization and IV antibiotics. A lumbar puncture should also strongly be considered if not previously performed given the substantial risk for meningitis with this particular microorganism. In general, most other cases of occult bacteremia warrant hospitalization and IV antibiotics. Consultation with an infectious disease specialist may be indicated to determine appropriate antibiotic selection and duration of therapy.

Prognosis

Occult bacteremia may resolve without therapy and have no sequelae, but it may persist or produce localized infections such as meningitis or septic arthritis. In children with bacteremia who do not receive antimicrobial therapy, the risk of persistent bacteremia is approximately 20% and the risk of meningitis is about 5% to 10%. These risks vary depending on which organism is isolated from the blood.

In general, the risk of developing serious sequelae is greater with bacteremia caused by *H influenzae* than by *S pneumoniae* (25% vs 5%). Concern about serious bacterial infection related to either of these organisms is now significantly diminished with the introduction of the conjugate vaccines.

CASE RESOLUTION

The infant presented in the case history is irritable and has a high fever of unknown source. Her vaccine status is uncertain. Her physical examination fails to reveal a source of her infection. Because her fever is 39.5°C, she is irritable, and her immune status is uncertain, a complete laboratory assessment, including a lumbar puncture, should be performed. Management should be determined after all laboratory data are available. If laboratory assessment reveals a focus of infection, such as a UTI, she should be managed with antibiotics. If laboratory assessment fails to reveal a source for the fever, and her WBC count is greater than 15,000/mm³ or her ANC is greater than 10,000/mm³, she can receive an intramuscular injection of ceftriaxone as expectant management for occult bacteremia and be reevaluated in 24 hours or be managed without antibiotics.

Emerging Infectious Diseases

Christian B. Ramers, MD, MPH, and Thomas R. Hawn, MD, PhD

CASE STUDY

A previously healthy 8-year-old boy is brought to his pediatrician's office in late August with 2 days of fever, fatigue, headache, myalgias, nausea, and gingival bleeding. On the morning of the visit his mother noted a rash on his legs. He lives with his family in the Northeastern United States but recently returned from a 1-week vacation in Key West, FL. He engaged in extensive outdoor activities, including snorkeling, hiking, and several evening boat trips, and sustained multiple mosquito bites during the trip. He received all routine childhood immunizations, denies any allergies, and takes no medications. No other family members are ill.

On physical examination, his temperature is 101.7°F (38.7°C) and he is generally ill-appearing. He has photophobia and mild meningismus, and a petechial rash is noted on his trunk and lower extremities. Laboratory studies sent from the office reveal microscopic hematuria, leukopenia (white blood cell count 2.8), and thrombocytopenia (platelets 85,000).

Questions

1. What is an emerging or reemerging infection?
2. What pathogens are associated with emerging infections?
3. What are some common or emerging infectious diseases that may cause the clinical syndrome in the case scenario?
4. What types of exposures should be considered when assessing acute febrile illnesses such as that described in the case scenario?
5. How does recent travel influence the differential diagnosis?
6. What are appropriate steps in initial management?
7. What resources can a primary care physician access to help in making a diagnosis?
8. When do isolation and reporting procedures need to be considered?

Introduction

Emerging and reemerging infectious diseases are defined as those whose incidence in human populations has increased in the past 2 decades or threaten to do so in the near future. They may represent the resurgence of an ancient human scourge, a novel zoonosis that has broadened its host range, a common pathogen that has acquired a new antimicrobial resistance profile or, in some cases, a previously unidentified or unknown microorganism. A startling diversity of organisms has met these criteria, including viral, fungal, parasitic, and bacterial pathogens. Likewise, a variety of factors has been implicated in the process of emergence and/or reemergence related to range and susceptibility of human hosts, evolution and antigenic shift of the pathogen, and ecological and environmental changes, such as vector amplification or breakdown of public health measures. Although a select few of these emerging pathogens represent malicious propagation or bioterrorism, most appear spontaneously at ambulatory or emergency health facilities, and are thus relevant to the practicing primary care physician. It has only been through astute clinical observation, targeted outbreak investigation, and a coordinated public health response that many emerging infectious diseases have been identified.

In this chapter we will review the factors involved in the emergence and reemergence of infectious diseases of public health

significance, discuss several specific examples that are likely to be most relevant to pediatric practice, summarize regional and global outbreaks of emerging infectious diseases, and provide practical steps for the primary care provider to access local diagnostic and public health support.

Contributing Factors

The spectrum of infectious diseases has always changed and evolved along with societal and environmental changes. Literature supports the supposition that throughout human history, several general driving forces influence the emergence or reemergence of certain infectious diseases. The most important factors are human migration, environmental and ecological changes, changing patterns of human host susceptibility and immunity and, more recently, the use and overuse of antimicrobial agents. Table 55-1 shows some of the mechanisms identified in recent emerging infectious diseases and provides illustrative examples from the United States and abroad. In reality, there are often many simultaneous contributing factors at play, and diseases may emerge or retreat within human populations without clear drivers. Common themes that lead to recognizable emergence events typically couple a vulnerable host population with a pathogen to which that population lacks immunity or prior exposure.

Table 55-1. Factors Contributing to Infectious Disease Emergence/Reemergence^a

<i>Contributing Factor</i>	<i>Examples</i>	<i>Illustrative Pathogen</i>
Societal change	<ul style="list-style-type: none"> • Economic impoverishment • Population growth or migration • Globalization of food distribution • Urban decay 	Cholera, malaria, salmonella
Advances in health care	<ul style="list-style-type: none"> • New medical devices • Organ transplantation • Drugs causing immunosuppression • Use of antimicrobial agents 	Aspergillosis, cytomegalovirus, methicillin-resistant <i>Staphylococcus aureus</i>
Human behavior	<ul style="list-style-type: none"> • Worldwide travel • Injection drug use • Sexual activity • Outdoor recreation activities 	HIV/AIDS, hepatitis C virus, histoplasmosis
Environmental changes	<ul style="list-style-type: none"> • Deforestation/reforestation • Flood/drought • Global warming 	<i>Cryptococcus gattii</i> , dengue, <i>Burkholderia pseudomallei</i>
Public health infrastructure and control	<ul style="list-style-type: none"> • Reduction of prevention programs • Inadequate surveillance • Waning immunization rates 	<i>Mycobacterium tuberculosis</i> (multidrug-resistant and extensively drug-resistant), measles, mumps, pertussis
Microbial adaptation and change	<ul style="list-style-type: none"> • Antigenic drift/shift • Changes in virulence factors • Development of drug resistance 	H1N1 and H5N1 influenza, chloroquine-resistant malaria, vancomycin-resistant enterococci

^a Adapted from Morens DM, Folkers GK, Fauci AS. The challenge of emerging and re-emerging infectious diseases. *Nature*. 2004;430:242–249

Pediatric populations are particularly susceptible to emerging and reemerging diseases in several of these categories. After immunity from acquired maternal antibody wanes, children develop adaptive immunity on their own and may experience up to 12 upper respiratory and/or diarrheal diseases per year. In some cases an unexplained increase in pediatric mortality from a typical clinical syndrome, such as upper respiratory or flu-like illness, may be the harbinger of an emerging pathogen. Large institutional settings, such as child care centers and schools, place children at high risk for exposure to infectious agents via close contact, respiratory, and droplet spread. Similarly, differing hygiene practices, such as hand washing, cough etiquette, sharing of fomites, and fecal/urinary incontinence, place infants and children at particular risk of exposure.

Antimicrobials are commonly prescribed in primary care settings for otitis media, pharyngitis, or respiratory infections, and overuse of antibiotics in these settings has been associated with a higher risk of colonization and infection with drug-resistant organisms. In many cases, what was once a first-line therapy for a particular clinical syndrome must be reconsidered due to the emergence of altered antibiotic susceptibility patterns. Advances in medical care have expanded the number of vulnerable hosts through increased survival of premature infants, cancer chemotherapy, organ transplantation, and the use of immunosuppressive or immunomodulatory agents. Lastly, due to access, parental belief systems, or personal choice, immunization rates in certain regions remain suboptimal, placing children at risk of acquiring vaccine-preventable disease.

Special Situations

Increasingly, primary care providers find themselves in settings that demand careful consideration of the risks of emerging or reemerging infectious diseases. The following is a collection of some unique clinical settings in which less common or emerging infectious diseases should warrant consideration.

Expanded International Travel

With the increasing accessibility of long-distance international travel, children are more frequently being included in tourist trips or, in the case of immigrant families, visits to friends or relatives back in their home country. Children are less likely to seek pretravel advice and consequently less likely to adhere to recommended travel guidelines. A report from the GeoSentinel Surveillance Network, a large group of worldwide travel clinics, found that only 32% of children visiting friends and relatives in developing countries received recommended travel vaccines or prophylactic medications yet they were more likely to present with illness and require hospital admission after travel. Primary care physicians evaluating returning travelers must consider detailed travel history, prophylaxis or protective measures taken (if any), risk profile of the region visited, and incubation period of the suspected pathogen. Although by far the most common travel-related illnesses are self-limited diarrheal disease, emerging infections, such as dengue, chikungunya, or H5N1 or H1N1 influenza,

must be considered along with other infectious diseases, such as malaria or tuberculosis.

Immigration and International Adoption

Increasing rates of international adoption or recent immigration may result in primary care providers evaluating children with unknown or unavailable birth, early childhood, or immunization histories (Chapter 34 and Chapter 36). Vaccine schedules vary by country of origin, including some vaccines that are no longer given in the United States (eg, bacille Calmette-Guérin, oral polio). There is a wide range of reliability among medical reporting in these situations, with some reaching or exceeding developed world standards, but most providing dubious quality. Many providers specializing in “adoption clinics” or working in settings with large immigrant populations obtain serologic evidence of prior immunization (eg, measles, mumps, varicella, polio, diphtheria, tetanus). Providers must also be aware of infections with clinically silent latent phases (viral hepatitis, latent tuberculosis, intestinal helminth infections, and even HIV). Several emerging or reemerging infectious diseases in the United States may be endemic in the countries of origin of adopted or recently arrived immigrant children.

Immune Suppression and Immunomodulation

Therapeutic advances in pediatric oncology, organ transplantation, rheumatology, and care of chronic congenital conditions have resulted in an increasing population of immunosuppressed children. Although typically under the care of specialists, these children may have a medical home in a primary care facility and thus can present with an opportunistic or emerging infectious disease to their primary care provider. The spectrum of risk for infectious diseases varies considerably depending on the type of immunosuppression. For example tumor necrosis factor- α inhibitors, now commonly used in the treatment of juvenile idiopathic arthritis, convey a particularly high risk of fungal and mycobacterial infection. Neutropenia from cytotoxic chemotherapy is associated with an increased risk of bloodstream bacterial infection among others. Similarly, lymphopenia related to solid organ transplantation portends a particular vulnerability to viral infections, ranging from widespread community respiratory viruses to reactivation of common agents such as varicella-zoster virus. Emerging infectious diseases such as human metapneumovirus or H1N1 influenza may have particularly severe clinical manifestations in immunosuppressed children when compared to the general population.

Unvaccinated or Under-Vaccinated Child

Despite the ongoing efforts of public health authorities, some regions have noted a worrisome downward trend in immunization rates. Although the most widely cited study linking autism to measles, mumps, rubella (MMR) vaccination was retracted by the *Lancet* in February 2010, several recent parental surveys indicate persistent beliefs surrounding a suspected vaccine-autism link. In 2004 the Institute of Medicine Immunization Safety Review Committee

published a comprehensive report that found no convincing evidence of a causal link between the MMR vaccine or any thimerosal-containing vaccine and autism. However, in a survey of 1,552 parents conducted in 2009, 25% agreed with the statement, “Some vaccines cause autism in healthy children” (see Freed et al). Decreasing vaccination rates have led to an increased risk for outbreaks of reemerging infectious diseases. In 2008 there were more cases of measles in the United States than any other year since 1997, with more than 90% of cases occurring in unvaccinated individuals or those with unknown vaccination status. Similarly, a 2010–2011 pertussis epidemic in California is the largest since 1955. It is thus crucial for clinicians to include vaccination status and exposure history when evaluating children with an infectious syndrome. Increasingly, the differential diagnosis and diagnostic workup must include emerging and reemerging diseases, some of which may be unfamiliar to the practitioner from their training or clinical experience.

Select Emerging Pathogens

Major emerging and reemerging infectious diseases (Figure 55-1) in the last 20 years are listed in Table 55-2. This table is not meant to be an exhaustive list, but rather a sampling of emerging pathogens most likely to present to a primary care office.

Viruses

Measles

Caused by a virus from the Paramyxoviridae family, measles began to decline as a major threat in the United States after a safe and effective vaccine was developed in 1963. However, a significant resurgence occurred between 1989 and 1991, due largely to a pool of vulnerable unvaccinated preschoolers. Nearly 55,000 cases and 130 deaths occurred in the United States, prompting a renewed effort at prevention through vaccination. A second dose of vaccine for school-aged children was also recommended after this outbreak. Since 2004 there has been another resurgence of new cases, but with new epidemiologic features; 90% of the cases were either directly imported from travelers or immigrants, or were associated with importation from outside the United States. Still, unvaccinated school-aged children make up a large pool of at-risk hosts.

Measles is known as a highly contagious pathogen passed via respiratory droplets. Secondary transmission is thought to be greater than 90% among susceptible household contacts. Roughly 10 days after exposure, clinical illness is characterized by a distinctive febrile prodrome (conjunctivitis, coryza, cough), followed by Koplik spots (blue-gray enanthem on buccal mucosa) and, ultimately, the classic maculopapular erythematous eruption. Diagnosis is usually ascertained on clinical grounds alone given the distinct clinical presentation; however, for confirmatory testing, the immunoglobulin (Ig) M serology is nearly 100% sensitive if performed after the onset of rash. Respiratory droplet isolation should occur until 4 days following appearance of the rash in immunocompetent patients and until the clinical illness resolves in those who are immunocompromised.

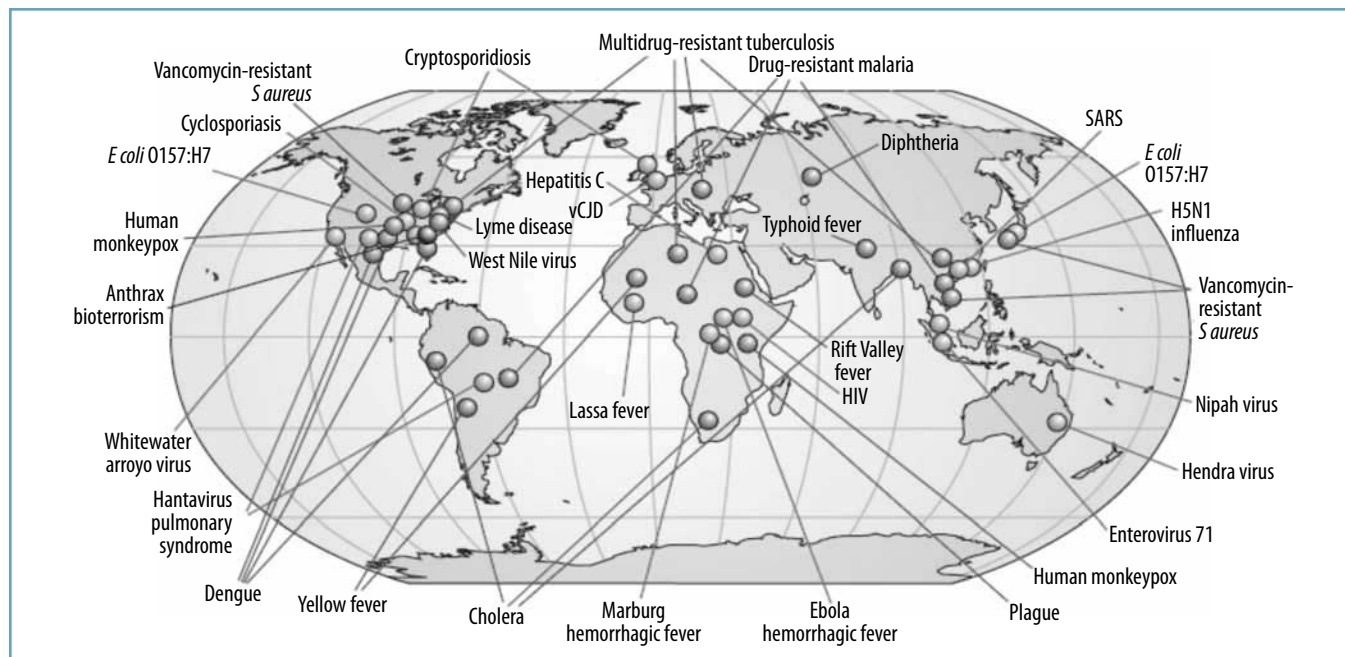

Figure 55-1. Global examples of recently emerging and reemerging infectious diseases. Does not demonstrate recently increased West Nile virus, methicillin-resistant *Staphylococcus aureus*, and measles. (Reprinted with permission from Fauci AS. Infectious diseases: considerations for the 21st century. *Clin Infect Dis*. 2001;32:675–685.)

Treatment is largely supportive; however, respiratory and neurologic complications can occur in 6% and 0.1% of patients, respectively. Further control of this reemerging infectious disease will likely depend on renewed attention to domestic vaccination efforts and the roll-out of vaccination worldwide.

Mumps

Although the clinical syndrome of the mumps virus is distinct from that of measles, the 2 members of the Paramyxoviridae family share a similar history of initial control and recent reemergence. A live, attenuated mumps vaccine was licensed in 1967 and incorporated into the Advisory Committee on Immunization Practices recommended schedule by 1977. Due to high vaccination rates, mumps had declined by more than 99% by 2005. However, there have been 2 major resurgences in the United States. In 2005–2006 a total of 6,584 cases were reported in a multistate outbreak in the Midwestern United States. Although numerically most of these cases occurred among college students who had been previously vaccinated, attack rates were considerably higher in unvaccinated individuals. In 2009–2010, an outbreak involving more than 1,500 reported cases occurred in New York and New Jersey.

The clinical presentation of mumps typically involves fever, malaise, and parotitis. Complications are rare, but in some studies up to 10% of patients had aseptic meningitis, of which hearing loss is an important sequela. Up to 37% of adolescent and adult males can present with orchitis, which may result in sterility. Diagnosis is typically made based on a compatible clinical syndrome with confirmation by isolation or polymerase chain reaction (PCR)-based detection of the virus from saliva, cerebrospinal fluid (CSF), urine, or seminal fluid. Immunoglobulin M serology is also a useful confirmatory method.

Treatment is generally supportive, with analgesics used for the pain of parotitis and/or orchitis. For severe cases, intravenous Ig has been used to mitigate immune-mediated post-infectious complications, and interferon- α -2b has been used to alleviate orchitis.

There has been much scrutiny of these outbreaks as indicators of vaccine effectiveness and community vaccination rates. Based on extensive analyses, MMR vaccine effectiveness is still considered 80% to 90% after 2 doses. This, however, leaves a significant portion of the population still vulnerable to sustain occasional outbreaks. No change was made to immunization schedules or interim recommendations after these outbreaks.

Dengue

Dengue fever virus is a member of the Flaviviridae family and is known to occur in 4 serotypes. It is transmitted via a vector, usually *Aedes aegypti*, and is present in more than 100 countries throughout the Americas, Asia, and Africa. Although historically confined to tropical and subtropical regions roughly overlapping with malarial zones, the range of dengue fever virus is expanding. In the United States, there were no cases of locally acquired dengue reported between 1946 and 1980. Since 1980, sporadic cases have been reported along the US–Mexico border, but more recently a small outbreak of locally acquired dengue occurred in Key West, FL, in 2009–2010. The worldwide incidence of dengue has increased at least 4-fold in the past 3 decades for unclear reasons.

Clinical manifestations occur over a wide spectrum, from asymptomatic seroconversion to severe, even fatal disease. Headache and petechial rash are commonly seen. Classically the disease is thought to occur in 3 forms: undifferentiated febrile illness, dengue fever, and dengue hemorrhagic fever. However, in reality clinical manifestations

Table 55-2. A Sampling of Recent Emerging Infectious Diseases

<i>Pathogen</i>	<i>Clinical Syndrome</i>	<i>Diagnosis</i>	<i>Management</i>
Measles virus	Measles Pneumonia Post-infectious encephalitis	Clinical Confirm with IgM	Supportive Consider antibiotics for bacterial superinfections
Mumps virus	Parotitis Orchitis Encephalopathy	Serology Culture PCR	Supportive NSAIDs
Dengue virus	Unspecified febrile illness Dengue fever Dengue hemorrhagic fever	Serology	Supportive Aggressive fluid management
Influenza virus	Fever, respiratory symptoms	PCR or antigen	Oseltamavir, zanamavir, amantadine, rimantadine
Chikungunya virus	Febrile syndrome with arthralgias, rash, conjunctivitis	Clinical Confirm with serology, viral culture, or PCR	Supportive, NSAIDs
WNV	Asymptomatic West Nile fever West Nile encephalitis (flaccid ascending paralysis)	Serology WNV antigen or PCR IgM in CSF	Supportive (ribavirin and interferon- α -2b are experimental)
MRSA	Skin and soft tissue infections, bacteremia, pneumonia	Culture and susceptibility	Antibiotics
Resistant gram-negatives	Pneumonia, UTI, bacteremia, sepsis	Culture and susceptibility	Antibiotics
Resistant <i>Streptococcus pneumoniae</i>	Pneumonia, meningitis, otitis media	Culture and susceptibility	Antibiotics
Ehrlichiosis/anaplasmosis	Fever, HA, myalgia, rash	PCR or peripheral blood smear	Doxycycline
<i>Cryptococcus gattii</i>	Pneumonia, meningitis	Culture or cryptococcal antigen	Amphotericin, 5-FC, fluconazole

Abbreviations: 5-FC, 5-fluorocytosine; CSF, cerebrospinal fluid; HA, headache; Ig, immunoglobulin; MRSA, methicillin-resistant *Staphylococcus aureus*; NSAIDs, nonsteroidal anti-inflammatory drugs; PCR, polymerase chain reaction; UTI, urinary tract infection; WNV, West Nile virus.

are diverse and may include hepatitis, myocarditis, pericarditis, and encephalopathy. Leukopenia and thrombocytopenia are common laboratory findings and, in severe cases, a coagulopathy and bleeding manifestations seem to be the most dangerous sequelae. Diagnosis can be made with a compatible clinical history and confirmed with serology. Unfortunately, there are no direct-acting antivirals, nor is a vaccine available. Care is generally supportive.

H1N1 Influenza

Although it seemed that bird flu or H5N1 influenza would be the greatest concern to public health in mid-2009, it was a different strain, an H1N1 swine flu, that led to a global pandemic. Influenza viruses have a segmented genome and thus are able to adapt and evolve quite rapidly to evade slower adaptive immune responses. Through antigenic drift, small changes occur in cell surface genes through time, resulting in subtle structural changes to the cell surface proteins (neuraminidase and hemagglutinin) and less recognition by the immune system. In antigenic shift, genome segments from diverse strains recombine in a single new virus particle, creating abrupt and substantial changes in antigenic variation. Typically,

shifts are more likely to cause pandemics because there are more nonimmune hosts in the population.

The clinical manifestations of H1N1 influenza seemed to be similar to prior influenza outbreaks; however, there were more severe cases and higher mortality in previously healthy young people than in typical influenza epidemics. Testing for H1N1 most commonly involves antigen-based PCR methods with variable sensitivities and specificities. Treatment for severe cases consists either of oral oseltamivir or inhaled zanamivir. Although there have been reports of oseltamivir resistance outside the United States, this currently remains the drug of choice. Of note, the circulating H1N1 strains identified in 2009 were mostly resistant to the older adamantanes (amantadine, rimantadine).

Chikungunya

Another vector-borne disease transmitted primarily by *Aedes* spp. mosquitoes, chikungunya was first described in Tanzania in 1953. It often occurs in epidemic outbreaks rather than steady endemic patterns and is most commonly seen in tropical Africa and Asia. More recently, outbreak ranges have expanded slightly, occurring

in Italy and Madagascar. In 2006 there were an unprecedented 37 cases diagnosed in the United States; however, all of these were determined to be imported. The clinical hallmark of chikungunya fever is the presence of intense arthralgias and occasionally frank arthritis after a febrile illness with rash and conjunctivitis. Whereas the clinical illness of malaise and fever may last days to weeks, the joint symptoms may last months to years. Other than the possibility of persistent and nagging arthralgias, severity is typically mild, and fatality is rare. Treatment of chikungunya is generally supportive, as there are no specific antivirals available.

Severe Acute Respiratory Syndrome (SARS) From Coronavirus

From 2002–2004, an epidemic of severe pneumonia due to a previously unrecognized coronavirus (SARS-CoV) caused considerable international concern due to its highly infectious nature and high mortality rate. Epidemiologic studies led to identification of palm civets as the main reservoir of transmission to humans from contact in the marketplace. Further studies suggested that horseshoe bats were the likely natural reservoir. The epidemic, which originated in China, eventually spread to 29 countries with an overall mortality rate of 9.6%, which included numerous health care workers. Clinical features included a mean incubation period of 4.6 days with a presentation of severe pneumonia with a high rate of respiratory failure. Additional clinical manifestations included watery diarrhea and hepatitis. Common laboratory features included lymphopenia, neutropenia, and disseminated intravascular coagulation. The cornerstone of treatment was supportive care. Although many subjects received ribavirin, there was no proven role for it or any antiviral agents during the outbreak. Despite the impressive nature of this epidemic, it subsided rapidly and there has not been evidence of ongoing SARS-CoV transmission. This epidemic highlighted an agent with high transmissibility, morbidity, and mortality, yet only a transient global impact.

Bacteria

Drug-Resistant Bacteria

Community-Acquired Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Methicillin-resistant *S aureus* strains were recognized shortly after the introduction of methicillin in the 1960s and have been a substantive problem in health care settings for several decades. Health-care associated MRSA (HA-MRSA) has well-established risk factors, which include exposure in the health care setting (eg, hospital, nursing facility) and the presence of comorbid medical conditions (eg, malignancy, chronic liver or lung disease, indwelling catheters). In the 1990s, a new strain of community-acquired MRSA (CA-MRSA) appeared that was not associated with these traditional risk factors, as it often was found in otherwise healthy individuals with no health care–related exposure. Furthermore, CA-MRSA carries the *mecA* resistance gene on a Type IV or V chromosomal

cassette in contrast to HA-MRSA, which belongs to Type I through III categories. Community-acquired MRSA is also more likely to contain the Panton–Valentine leukocidin genes, which may encode virulence factors that influence clinical symptoms. These genotypic differences have facilitated epidemiology studies that suggest that CA-MRSA is a distinct MRSA strain that has increased in frequency throughout the United States and is a bona fide emerging pathogen. In addition to genotypic differences, CA-MRSA is less likely to have a multi-drug–resistant susceptibility pattern. Treatment of CA-MRSA follows similar principles to HA-MRSA with the exception that more antibiotic choices are generally available. For an uncomplicated cutaneous abscess, incision and drainage without antibiotics is often sufficient. For deeper or more severe infections, empiric treatment with trimethoprim-sulfamethoxazole, clindamycin, a tetracycline (doxycycline or minocycline), or linezolid are empiric options while awaiting antibiotic susceptibilities. Although linezolid is an effective drug, it is far more expensive than the other choices. Tetracyclines should not be used in children younger than 8. For impetigo and other minor infections, topical mupirocin can be used.

Resistant Gram-Negative Bacteria and Streptococcus pneumoniae

Similar to CA-MRSA, there are other resistant bacteria that have established significant niches. For example, *S pneumoniae* was previously uniformly sensitive to penicillin. Currently, penicillin and ceftriaxone-resistant strains of *S pneumoniae* are now common and circulating in the community. Similarly, a number of gram-negative bacteria, such as *Escherichia coli* and *Klebsiella pneumoniae*, are highly resistant due to a variety of plasmid and chromosomally encoded mechanisms, such as β -lactamases, cephalosporinases, carbapenemases, porins, and efflux pumps. These strains are mostly seen in the nosocomial setting, although community circulation of these strains has also occurred. Although the emergence of these strains is not as extensive or as clearly delineated as CA-MRSA, each of these strains has similarly “emerged” to a prevalence level in the population that substantially impacts human health.

Ehrlichiosis and Anaplasmosis

Ehrlichia chaffeensis (agent of human monocytotropic ehrlichiosis [HME]) and *Anaplasma phagocytophilum* (agent of human granulocytotropic anaplasmosis [HGA]), formerly human granulocytotropic ehrlichiosis are examples of infections that emerged due to new diagnostic tests. Both infections were initially recognized as infections of the veterinary world until the application of molecular methods to humans with undiagnosed febrile illnesses. They have likely caused human disease for a long time, although the incidence may have increased with the recent resurgence of populations of some animal reservoirs, such as the white-tailed deer. In the early 1990s, *E chaffeensis* and *A phagocytophilum* were identified as human pathogens that are transmitted by ticks. *Ehrlichia chaffeensis* is transmitted by several ticks (*Amblyomma americanum*, *Dermacentor variabilis*, and *Ixodes pacificus*) and is found in the southeastern and south central United States as well as California. *Anaplasma*

phagocytophilum is transmitted by *Ixodes scapularis* and is found in the northern United States. Both agents cause a febrile illness with headache, myalgia, and malaise that is often accompanied by thrombocytopenia, leukopenia, and transaminitis. Rash, which is found in 90% of subjects with Rocky Mountain spotted fever (caused by *Rickettsia rickettsii*), is less often found with HME (31%) and rarely with HGA. Diagnosis of these infections can be made by PCR and less commonly with direct microscopy since the latter methods are insensitive (<10% for HME and 25%–75% for HGA). However, due to the potential severity of the illness, empiric treatment should be initiated if clinical suspicion is high while awaiting the diagnostic workup. The drug of choice for treatment of HGA and HME is doxycycline. Due to a lack of reliable alternative drugs, doxycycline is also recommended for children younger than 8 years.

Fungi

Cryptococcus gattii

Cryptococcus gattii (formerly *Cryptococcus neoformans* var *gattii*) and *C. neoformans* are yeast that cause pneumonia and central nervous system infections in immunocompetent and immunocompromised hosts. Although *C. neoformans* is present in most regions of the world, *C. gattii* has a restricted geographical distribution and previously had been identified in tropical and subtropical countries such as Australia, New Zealand, and Papua New Guinea. In the early 2000s, *C. gattii* was identified as a cause of meningoencephalitis for the first time on Vancouver Island in British Columbia. From 1999–2007, 218 cases were reported with a case-fatality rate of 8.7%. Subsequent studies identified its presence in the Pacific Northwest, including the states of Washington and Oregon. Similar to many emerging pathogens, the increased numbers of cases may be due to improved diagnostics and surveillance as opposed to the actual emergence of a new infection to a region. However, some molecular evidence suggests that the strain on Vancouver Island is novel. Clonal analysis suggests that it arose from an unusual type of sexual mating that generated a strain that is hypervirulent. This mechanism of emergence suggests that a species endemic to an original location (eg, tropics) can emerge in a new geographic region (Vancouver Island) in a clonal manner. The clinical presentation of *C. gattii* is similar to *C. neoformans*, although there may be an increased frequency of cryptococcoma in the lungs and central nervous system caused by *C. gattii*. Treatment principles are the same for both species and include initial treatment with amphotericin B and 5-fluorocytosine for meningitis followed by consolidation therapy with fluconazole. For uncomplicated pulmonary disease, fluconazole is the cornerstone of treatment. *Cryptococcus* spp., including *gattii*, infect children and treatment principles are similar to those for adults.

Summary

Contrary to myopic claims that public health would conquer infectious diseases in the 20th century, new pathogens have continued to emerge and old ones have reemerged time and time again, making for a challenging future of disease identification and control. The

tools employed by public health include surveillance and response, yet most of the major epidemics identified in the last 20 years began with astute clinical observation at the primary care level. It is thus essential for primary care providers and others caring for children to remain vigilant to the constant and unpredictable nature of emerging infectious diseases. With astute primary care clinicians, attentive scrutiny of new outbreaks and collaboration with regional and national public health laboratories and officials, the medical field will hopefully keep pace with emerging and reemerging pathogens.

CASE RESOLUTION

The patient was hospitalized and underwent an extensive diagnostic workup for infectious causes of fever and rash. A lumbar puncture revealed a mild lymphocytic pleocytosis. He received 2 days of empiric antibiotic therapy, which was discontinued when cultures were negative for 48 hours. The pediatrician notified the local health department, which facilitated laboratory testing performed by the state public health laboratory, and the Centers for Disease Control and Prevention (CDC).

Serologic testing at the state health department was positive for IgM antibodies against dengue virus. This was confirmed on samples sent to the CDC, and in addition, CSF sent to the CDC was positive by reverse-transcriptase PCR for dengue virus serotype 1. The patient recovered uneventfully over the following 2 weeks, but a public health investigation was launched that eventually resulted in the identification of 27 total cases of dengue fever acquired in Key West, FL. Subsequently, an adult serosurvey was conducted indicating recent exposure to dengue in 5.4% of adults.

This outbreak, which occurred in 2009–2010, represented the first reported cases of dengue fever acquired in Florida since 1934. Although dengue is the most common virus transmitted by mosquitoes in the world, no cases had been acquired in the continental United States between 1946 and 1980 and, subsequently, only sporadic cases were known along the Texas–Mexico border. Reported dengue cases have increased 4-fold in Latin America since 1980, and incidence has risen steadily among returning US travelers. Dengue represents a truly reemerging infectious disease and primary clinicians should be aware of its rising incidence.

Febrile Seizures

Kenneth R. Huff, MD

CASE STUDY

A 12-month-old girl is brought to the emergency department by paramedics because she is having a seizure. She is unresponsive and hypertonic, with arched trunk and extended arms and legs that are jerking rhythmically. Her eyes are open, but her gaze is directed upward. She has bubbles of saliva around her lips as well as circumoral cyanosis. Her vital signs are a respiratory rate of 60 breaths/min, heart rate of 125 beats/min, blood pressure of 130/78 mm Hg, and temperature of 105.8°F (41.0°C). An assessment of her respiratory status discloses that she is moving air in all lung fields, and there is no evidence of upper airway obstruction.

The paramedics inform you that the girl has been convulsing with varying intensity of tone and movements but remaining unresponsive for approximately 6 minutes. Glucometer testing reveals a normal serum glucose. Blood samples for other tests are sent to the laboratory, and urine is collected. An intravenous (IV) line is started, and the girl is given lorazepam by IV push. Within 2 minutes, the movements cease, and her respirations become slow and even. Her physical examination shows no signs of trauma. Her only abnormality other than her unresponsive mental status is an inflamed and bulging right tympanic membrane.

The girl's parents tell you that she has had a mildly stuffy nose for 2 days but has been afebrile and has seemed to be her usual self. While she was playing, she became cranky, and her parents put her in her crib for her nap. Thirty minutes later they heard grunting noises, found her in the midst of a seizure, and called the paramedics. The girl has never had a seizure before. Her father recalls that his mother once told him that he had several "fever seizures" as an infant.

Questions

1. What are the characteristics of simple febrile seizures?
2. What is the appropriate evaluation of children with febrile seizures, whether it is the first one or a recurrence?
3. What is the recurrence risk for febrile seizures and the risk of developing unprovoked seizures following a febrile seizure?
4. What are the treatment options for children with febrile seizures?

Febrile seizures are easily recognized, dramatic, generalized convulsions. These seizures are defined by the presence of a fever or an acute inflammatory illness (often sudden) from a source outside the nervous system; patient age of about 5 years or younger; absence of chronic brain pathology, including developmental delay; and absence of metabolic or structural abnormalities of the brain. Frequently, familial predisposition to similar seizures or a history of similar events in other family members is present. Despite the relatively uniform presentation of the seizure, genetic abnormalities in channels, neurotransmitter receptors, or hippocampal damage may influence prognosis, and individual clinical variables and social factors may play a part in the treatment.

Epidemiology

Febrile seizures occur in children between the ages of 6 months and approximately 5 years but are more common in those who are younger than 3 years. Some studies indicate that as many as 5% of all children experience at least one febrile seizure. The recurrence rate is 30% to 50% in children younger than 1 year, but drops to 25%

between 1 and 3 years, and is only 12% after 3 years. Seizures usually occur with the rise in temperature and often so suddenly that the febrile illness is not recognized by the family prior to the seizure. Frequently, the febrile illness is eventually diagnosed as an upper respiratory tract or influenza infection. Febrile seizures are seen often in children who have a first-degree relative who experienced the problem at the same age.

Clinical Presentation

Simple febrile seizures are characterized by a single episode of generalized, symmetrical, tonic posturing and clonic movements of a few minutes' duration that occur suddenly in children whose developmental progress is generally normal. Fever or an acute inflammatory illness is present, although it may not have been recognized before the seizure, and its source is outside the nervous system. A short time after the seizure (after usually 1–2 hours of postictal sleepiness), children become neurologically normal again (Dx Box).

Dx Febrile Seizures

- Sudden unresponsiveness, tonic posturing, and generalized rhythmic jerking
- Fever or acute inflammatory illness source outside nervous system
- Age 6 months to approximately 5 years
- Normal neurodevelopmental history

Recently described generalized epilepsy with febrile seizures plus (GEFS+) is characterized by the association of generalized febrile seizures beyond the age of 6 years and afebrile generalized convulsions, a positive family history of epilepsy with variable phenotypes, and a benign prognosis in most cases. The same families may have simple febrile seizures, febrile seizures beyond the age of 6 years, febrile seizures and absences, atonic or myoclonic seizures, and myoclonic-astatic epilepsy.

Pathophysiology

The susceptibility of young children to febrile seizures may be related to an increased incidence of sudden high fevers in this age group, a developmental genetic factor that may lower the seizure threshold, or both. Animal models indicate that the immature brain has a lower seizure threshold than the adult, and seizures in the immature brain are more likely to occur by a different mechanism than those in the adult. A sudden increase in temperature to a sufficiently high level can provoke seizures regardless of age. Seizures occur more frequently with fever in many seizure-prone patients who have seizures of different etiologies, including genetic epilepsies. Perhaps circulating pyrogens interact with a brain cellular circuitry mechanism or susceptible ion channels, causing hypersynchronous depolarization and a seizure. The multigenerational familial history that is often seen suggests a dominantly expressed genetic transmission.

Both the precise definition of the genetic markers and the mechanisms of generalized seizures in all cases are not yet fully understood. Recent work suggests a possible mechanism. Recently mutations in either γ -aminobutyric acid (GABA) A receptor or sodium channel genes have been found to be associated with febrile seizures and GEFS+ pedigrees. GABA A receptors receive inhibitory transmission and are composed of combinations of 5 subunits. The γ -2 subunit is critical for receptor trafficking, clustering, and synaptic maintenance, and mutations in this subunit have been associated with febrile seizure families. It has also been found that the trafficking of mutant receptors with γ -2 subunit mutations was more highly temperature dependent than mutations of other subunits, and impaired membrane insertion or accelerated receptor endocytosis with brief increases of 37 to 40 degrees occurred. In these families, the febrile seizures may be caused by a fever-induced change in the dynamic membrane state producing reduced numbers of available GABA A receptors.

In other families with GEFS+, it has been found that mutations in the *SCN1A* channel genes have occurred. Mutations in the same

gene occur in sequences that encode for the critical “pore” region of the subunit protein that participates in ion selectivity and results in a more severe phenotype with early prolonged resistant seizures, and later severe myoclonic epilepsy of infancy and mental retardation, the Dravet syndrome. The less severe GEFS+ phenotype is correlated with a less functionally critical position of the missense mutation in the *SCN1A* gene.

Differential Diagnosis

When a young child presents with a fever and a seizure, the possibility that the seizure is symptomatic of meningitis, encephalitis, or brain abscess must be considered. Signs of meningeal irritation may not be reliable in children younger than 18 months, and these and other signs of the illness may be obscured in the postictal period. If there is a history of lethargy or persistent vomiting, or the seizure was focal in onset, prolonged, or multiple, or the postictal depression in responsiveness is prolonged, an examination of the cerebrospinal fluid (CSF) should be done. In addition, if the patient is deficient in *Haemophilus influenzae* type B or *Streptococcus pneumoniae* immunizations, or the patient has been pretreated with antibiotics, which could mask meningeal signs or symptoms, a CSF examination should be considered. The fever also could be provocative or coincidental to a seizure of different etiology, such as trauma, toxic ingestion, metabolic derangement, degenerative or neurocutaneous disorder, or stroke.

A useful concept for the physician caring for a child with a seizure with fever has been the differentiation of simple febrile seizures from complex febrile seizures (Table 56-1). A question that has prognostic implications is whether children in the appropriate age range have had a true febrile seizure or a seizure with fever, which may be an early fever-provoked episode of a nonfebrile seizure disorder. The factors defining a complex febrile seizure also predict an increased likelihood of later unprovoked nonfebrile seizures. The length of a complex febrile seizure is longer than 15 minutes. Most febrile seizures last fewer than 90 seconds, although a significant number present in status epilepticus. More than one febrile seizure during

Table 56-1. Simple Versus Complex Febrile Seizures

Feature	Simple	Complex
Onset of clonic movements	Generalized	Focal
Length	<15 minutes (usually <90 seconds)	>15 minutes
Number of seizures per 24 h febrile illness	1	Recurrent
Neurodevelopmental history	Normal	Abnormal
Parent–sibling history of a febrile seizure	Often positive	Often negative

the same infectious illness or 24-hour period makes these recurrent seizures complex febrile seizures. The history of a focal or partial onset or the presence of postictal focal neurologic signs makes the febrile seizure complex. The presence of an abnormal neurodevelopmental history prior to the febrile seizure or abnormal neurologic examination or brain imaging study before or after the seizure also increases the likelihood of later unprovoked seizures.

Evaluation

History

After the seizure has been controlled and the child has been stabilized, a more detailed history relating to the circumstances of the seizure (the child's state leading up to the seizure; prenatal, birth, and developmental histories; and family seizure history) should be obtained (Questions Box).

Questions

Febrile Seizures

- What were the child's symptoms for the few days before the seizure?
- Where was the child and what was he or she doing immediately before the seizure?
- Were there any pregnancy-related or perinatal complications?
- Has the child's development been normal or similar to that of siblings?
- Have any other family members had seizures of any kind, including during infancy?

Physical Examination

Children should be examined completely after stabilization, noting the possibility that the fever may be coincidental and signs from an unrelated cause inciting the seizure could be present. Physicians should look for bruises, fractures, retinal hemorrhages, or other signs of trauma. The presence of dysmorphic features, enlarged organs, or bony changes should be noted. The skin should be examined for abnormal, pigmented, or textured spots. Lateralized signs of tone or strength should be assessed. An appropriate examination to determine the etiology of the fever should also be performed (see Chapter 54).

Laboratory Tests

If the seizure is prolonged, focal, or multiple; if there is a history of lethargy, stupor, or persistent vomiting before the seizure; or if the patient still appears ill after the postictal period, cultures should be obtained and metabolic and toxicological blood and urine studies sent. A spinal tap for CSF examination for meningitis or encephalitis should be done unless there are signs of increased intracranial pressure or a lateralized neurologic examination, in which case antibiotics should be given and an imaging study obtained prior to the spinal tap.

If the seizure is a simple febrile seizure, an electroencephalogram (EEG) has limited usefulness. The record is often abnormal in a nonspecific way, and not helpful in predicting either future simple febrile seizures or epilepsy. If the patient does not fully recover after the postictal period, the EEG may be useful to help define the nature of the encephalopathy.

Imaging Studies

Computed tomography and magnetic resonance imaging scans have a low yield of abnormal results in children with simple febrile seizures. Children who have had an abnormal neurodevelopmental history or who have had a focal or partial onset to their seizure should have an imaging study to detect a structural lesion that may be the source of the seizure or serve as a nidus for future seizures.

Management

If children are still convulsing on presentation and have been for at least 5 minutes, they should be managed as for status epilepticus (see Chapter 146). The airway must be secure, blood tests drawn and sent to the laboratory, an IV line started, and lorazepam administered in the appropriate dose to stop the seizure.

If children are not in status epilepticus, management decisions are made on a more long-term basis (Box 56-1). Whether to recommend **anticonvulsant prophylaxis** for children who have experienced febrile seizures is controversial. Factors that must be considered include (1) the benign, age-limited nature of the condition; (2) the morbidity of the anticonvulsant treatment; (3) the chance of recurrence of febrile or nonfebrile seizures; (4) the risk of overmedication during an acute recurrence; and (5) the family's reaction and social disruption caused by the seizures. Given the combination of these factors many physicians do not recommend antiepileptic drug prophylaxis for febrile seizures.

Box 56-1. Treatment Options for Febrile Seizures

- Cooling measures during febrile illness (antipyretics or bathing in tepid water)
- Family reassurance and education
- Diazepam, 0.3 mg/kg orally or 5–10 mg rectal gel (Diastat) every 8 h (during febrile illness only)
- Phenobarbital, 3–5 mg/kg orally daily, for prophylaxis
- Valproic acid (divalproex), 30 mg/kg orally divided twice daily, for prophylaxis

Daily doses of phenobarbital or valproic acid are effective prophylactic anticonvulsants. The most commonly used regimen is daily phenobarbital, but its potential side effects include hyperactive behavior disorder and depressed cognition and learning. Valproic acid can produce thrombocytopenia and may have the potential of provoking acute liver dysfunction in the patient younger than 2 years who is taking other medications. Fever control measures should be instituted to make the patient more comfortable but have not been

found effective as prevention for seizures. Intermittent anticonvulsant therapy with diazepam has the advantage of reducing side effects but relies on recognizing the fever prior to the seizure and mandates greater vigilance for compliance during each fever. Because prolonged febrile seizures tend to recur as repeated prolonged seizures, this group may benefit by having rectal diazepam or intranasal midazolam to administer at home as an abortive drug to stop the seizure earlier in its course while paramedics are being called.

Recommendations for prophylactic anticonvulsant treatment are often individualized. Anticonvulsants are usually not recommended unless the child has presented in status epilepticus, has experienced marked respiratory compromise (perhaps needing ventilatory support) during the seizure, or has had complex febrile seizures. There is no definitive evidence yet that anticonvulsant prophylaxis for simple febrile seizures prevents the development of unprovoked seizures. Children who have had frequently recurring seizures that are extremely disruptive for the family and deleterious to parent–child interactions despite educational efforts by the medical caretakers may also be candidates for prophylactic anticonvulsant treatment.

Prognosis

Febrile seizures are a common age-limited problem. The prognosis for children with simple febrile seizures is generally good; the incidence of seizure episodes later in life is 3 to 6 times higher than in the general population at the same age but is still low: 2% to 3%. Those who have a complex presentation have a higher likelihood of developing a nonfebrile seizure disorder, but this risk is only 6% if 2 of the first 3 factors (Table 56-1) are present or 17% if they are neurodevelopmentally abnormal. Overall, one-third of children with febrile seizures experience a recurrence. The risk of febrile seizure recurrence is most dependent on age: 50% of infants younger than 1 year at the time of their first seizure will have a recurrence, but only 20% of children older than 3 years will have a recurrence. Other factors that have a lesser influence on the recurrence risk include family history of seizures, temperature at the initial seizure, time since the previous seizure, and history of previous recurrences.

Animal models suggest that seizures, even status epilepticus episodes, in the immature brain are less often associated with neuronal death, but that seizures, particularly hyperthermic seizures, can modify brain development by altering the expression of ion channels regulating neuronal excitability, and epileptogenic mechanisms may be more robust than in the adult.

Among patients who had surgery for intractable temporal lobe epilepsy, mesial temporal sclerosis (MTS) was the most frequent pathology, and 30% of these patients had antecedents of prolonged

complex febrile seizures compared with 6% in those who did not have MTS. It is possible that MTS is the etiologic consequence of a prolonged seizure when the hippocampus is developmentally vulnerable. Mesial temporal sclerosis is frequently unilateral, however, although focal complex febrile seizures can actually originate in the temporal lobe in some children. An alternative explanation is that some preexisting damage or genetic predisposition may be present in patients with hippocampal sclerosis after prolonged febrile seizures, and the complex febrile seizure is an epiphenomenon.

A small percentage of infants with febrile seizures may develop Dravet syndrome, a phenotype influencing neurocognition as well as later resistant epilepsy, if they carry a particular channel subunit gene mutation.

CASE RESOLUTION

In the case history presented at the beginning of this chapter, the girl had a somewhat prolonged simple febrile seizure, a diagnosis supported by a family history positive for febrile seizures. Her family is educated about treatment options. They become comfortable with a decision to use intermittent therapy with diazepam for her subsequent febrile illnesses, realizing that a fever may not be recognized before the seizure occurs.

Respiratory Distress

David B. Burbulys, MD

CASE STUDY

A 6-month-old boy has been coughing and breathing fast for the past day. This morning he refused feeding and has been irritable. On examination, the infant is fussy. He has a respiratory rate of 60 breaths/min, a pulse of 140 beats/min, and a normal blood pressure and temperature. In addition, he has nasal flaring, intercostal and supraclavicular retractions, and occasional grunting.

Questions

1. What are the causes of respiratory distress in infants and children?
2. What are the signs and symptoms of respiratory distress in infants and children?
3. What are the signs and symptoms of impending respiratory failure in infants and children?
4. What are the critical interventions for infants and children in respiratory distress?

Respiratory distress and respiratory failure may cause significant morbidity and mortality in infants and children. The signs and symptoms of respiratory compromise may be subtle, particularly in small infants. Decompensation may occur rapidly if ventilation or oxygenation is inadequate but may be prevented by prompt recognition and treatment. **Respiratory distress** is defined as increased work of breathing, and it usually precedes respiratory failure. **Respiratory failure** occurs when ventilation or oxygenation is not sufficient to meet the metabolic demands of the tissues. Thus oxygenation of the blood is inadequate or carbon dioxide is not eliminated. This may be caused by diseases of the airway, inadequate gas exchange in the lungs, or poor respiratory effort (Box 57-1). Respiratory failure may lead to cardiopulmonary arrest if not corrected promptly.

Epidemiology

Primary care physicians frequently care for children in respiratory distress in both offices and emergency departments. Respiratory distress continues to be the most common reason for hospital

admission. Such admissions usually involve young infants with acute infections such as bronchiolitis or croup. Reactive airways disease (asthma) accounts for respiratory distress–related admission commonly in older children.

Clinical Presentation

Increases in respiratory rate and work of breathing are the most common signs of respiratory disease. Effortless tachypnea may be a sign of respiratory compensation for metabolic acidosis rather than an indication of pulmonary pathology. Similarly, hypoxia that fails to improve with supplemental oxygen may suggest a primary cardiac lesion. Tachycardia is often present, although bradycardia, if present, may be an ominous sign of impending cardiopulmonary failure. Signs of poor oxygenation include alterations in mental status, head bobbing, and change in skin color. Pallor, mottling, and cyanosis are often late signs indicating respiratory failure and shock. Children who are severely hypoxemic may first appear dusky or pale. If children are anemic, cyanosis may not be evident, although the oxygen saturation is low (Box 57-2).

Pathophysiology

The adequacy of respiration depends on effective gas exchange of carbon dioxide and oxygen and the ability to move an adequate volume of gas in and out of the airways. Infants and children generally breathe with minimal effort. In very young children, the **diaphragm** and abdominal musculature are primarily used for ventilation, and the tidal volume is approximately 6 to 8 mL/kg. If the tidal volume is decreased because of obstruction, children compensate by increasing the respiratory rate, thus attempting to maintain adequate **minute ventilation** (minute ventilation = rate × tidal volume). If the minute ventilation is still insufficient for adequate gas exchange, or the

Box 57-2. Respiratory Distress

- Increased respiratory rate
- Changes in tidal volume or minute ventilation
- Presence of retractions: intercostal, substernal, diaphragmatic, or supraclavicular
- Nasal flaring
- Decreased or absent breath sounds
- Changes in inspiratory-expiratory ratio
- Production of sounds with respiration (eg, gurgling, stridor, rhonchi, grunting)
- Diaphoresis
- Alterations in mental status
- Poor feeding
- Inability to speak in sentences
- Presence of pale or cyanotic skin
- Presence of central cyanosis

Box 57-3. Comparison of Respiratory Systems in Children and Adults

- The head in children is proportionally larger and has less muscular support.
- The tongue in children is larger in relation to the mouth, is poorly controlled, and can cause airway obstruction.
- The airway diameter is smaller in children and collapses easily. Reductions in size due to secretions or inflammation cause greater resistance to air flow (resistance is proportional to $1/\text{radius}^4$).
- The larynx is higher and more anterior in children and the epiglottis is floppy, which makes visualization of the vocal cords more difficult.
- The narrowest part of the airway in children is at the cricoid ring, unlike in adults, where the narrowest point is at the vocal cords.
- The trachea in children is short. In newborns it is 4-cm long, in 18-month-old infants 7-cm long, and in adults 12-cm long.
- The major muscle of respiration in children is the diaphragm. Any interference with diaphragmatic motion in young children impedes respiratory function. Intercostal muscles are immature in children and fatigue easily.
- Children have less pulmonary reserve and higher metabolic demands.
- Normal respiratory rates are higher in children and vary by age.

child can no longer sustain the increased work of breathing, then respiratory failure ensues. Respiratory failure may then lead to acidosis, myocardial dysfunction, and shock and may progress to complete cardiopulmonary arrest.

Infants and children are more prone than adults to respiratory distress because of the differences between their respiratory systems (Box 57-3).

Differential Diagnosis

The differential diagnosis of children with respiratory distress can include abnormalities with the pulmonary, cardiovascular, or metabolic systems or be related to a reduction in the central nervous system drive. It is also important to make an initial differentiation between upper and lower airway disease based on the presence or absence of stridor, rhonchi, rales, or wheezes on examination. Many common causes are shown in Box 57-1.

Evaluation**History**

A brief history should be taken (Questions Box) while physical examination proceeds and initial treatment is begun.

Questions**Respiratory Distress**

- For how long has this problem been occurring? Has a similar problem ever occurred before?
- Did the problem begin while the child was eating or playing?
- Has the child had any recent infections?
- Are any members of the household ill?
- Is the child taking any medications?

Physical Examination

Before a complete assessment can proceed, critical interventions that may change children's clinical status should be made. Children should be placed in a position of comfort and oxygen should be applied. Both **ventilation** and **oxygenation** should be assessed.

Respiratory and heart rates should be determined for a period of at least 30 seconds. In infants, abdominal excursions should be counted and, in older children, chest excursions should be counted. **Respiratory rates** in children are higher than in adults; infants may breathe 40 times per minute, 1-year-olds 25 times per minute, and 10-year-olds 18 times per minute (Table 57-1). These rates vary with age and changes of activity, emotion, and illness. Abnormal respiratory rates are defined as being faster than normal (**tachypnea**), slower than normal (**bradypnea**), or absent (**apnea**). Neonates may exhibit **periodic breathing**, with periods of regular respirations alternating with irregular breathing. This is a normal variant for age. True apnea (cessation of respiration) is accompanied by change in skin color or tone or altered level of consciousness.

The depth of respiration should be noted. Whether breaths are deep, gasping, or shallow should be determined. Rapid, shallow

Table 57-1. Vital Signs by Age

Age	Respiration (breaths/min)	Pulse (beats/min)	Systolic Blood Pressure (mm Hg)
Newborn	30–60	100–160	50–70
1–6 wk	30–60	100–160	70–95
6 mo	25–40	90–120	80–100
1 y	20–40	90–120	80–100
3 y	20–30	80–120	80–110
6 y	12–25	70–110	80–110
10 y	12–20	60–90	90–120

respirations may not provide enough **inspiratory time** for adequate gas exchange. The heart rate may also reflect respiratory compromise. Breath sounds should first be listened to in the axillae and then at the bases and apices. The absence of breath sounds may be an ominous sign. Children's breath sounds are usually well transmitted across the thorax because of the thin chest wall. It is common to hear upper airway noises when auscultating the lungs.

Abnormal sounds are caused by turbulent air passing through a narrowed airway. Resistance to flow through a hollow tube increases exponentially. Thus the smaller the airway, the greater the resistance to flow generated by even small changes in the radius (eg, as with edema, secretions, or foreign bodies). The nature of the sounds produced depends on the location of the narrowing in the airway. **Gurgling, snoring, and stridor** come from the upper airway; **rales, rhonchi, and wheezing** from the lower airway. If no abnormal sounds are evident and breath sounds are absent or decreased, the upper or lower airways may be totally obstructed. **Grunting** is caused by turbulent air coming in contact with a partially closed glottis. Children who grunt are generating their own partial obstruction of the upper airway and positive end-expiratory pressure to increase oxygenation.

The physician should also observe the effort children expend in breathing. Increased work of breathing occurs when intercostal, subcostal, or supraclavicular **retractions** are present, the **accessory muscles** of respiration are used, breathing is abnormally noisy, or **nasal flaring** is seen. The normal work of breathing consumes 2% to 3% of total oxygen consumption. The increased work of breathing in children with severe respiratory distress can potentially increase total oxygen consumption to 50%. Increased work of breathing can also be demonstrated by feeding difficulties and diaphoresis in young infants.

In addition, the physician should observe the inspiratory-expiratory ratio while assessing the work of breathing. The ratio is approximately 1:1 in most patients. Prolonged expirations are most often seen with reactive airways disease.

Oxygen saturation should be measured by pulse oximetry in all children with respiratory complaints. Levels less than 93% while awake indicate significant hypoxemia.

Laboratory Tests

Although the physical examination is the most important tool for assessing children in respiratory distress, laboratory tests such as complete and differential blood cell counts and blood cultures may help in the diagnosis of infection. It should be remembered that meningitis, sepsis, and metabolic derangement may present with effortless tachypnea not associated with increased work of breathing. Arterial or venous blood gases may be beneficial in this situation but in general should be reserved for patients in impending respiratory failure.

Peak expiratory flow or forced expiratory volume in 1-second determinations (FEV₁) can be helpful in assessing compliant older

children with reactive airways disease. Oxygen saturation measurements can also be helpful in these children because reduced levels below 100% often correlate with the severity of disease.

Imaging Studies

Chest radiographs can aid in assessing children in respiratory distress but should not be routinely performed in patients with known reactive airways disease unless children have a fever or are in status asthmaticus. A patient with significant respiratory distress should not be moved from a monitored setting to the radiology suite but rather portable radiographs should be obtained if needed.

Management

All infants or children in respiratory distress should be managed emergently. As stated earlier, in such situations, assessment and intervention often occur simultaneously. All children in respiratory distress should be reassessed frequently. The highest possible oxygen concentration should be delivered. Children who are able to maintain their own airway should never be forced to use an airway adjunct because this may cause increased anxiety and distress. Patients with clear airways can be maintained with simple interventions such as **oxygen** blown by the face or given by mask or nasal prongs. More advanced airway management such as bag-valve-mask ventilation or endotracheal intubation may be necessary for children who need assisted ventilation, airway protection, or hyperventilation.

Position

Children in respiratory distress who are alert and breathing spontaneously should be allowed to choose a **position of comfort**. Small infants who are incapable of positioning themselves are best placed upright with care taken not to flex or extend the neck. Children and their caregivers should be kept together to reduce anxiety.

The proper position for unconscious children is the "sniffing position," with the neck slightly flexed and the head extended to open the airway. This can be facilitated by placing a towel under the occiput of the head or the shoulders. If simple positioning does not relieve an obstruction, then the airway should be opened using the chin lift or jaw thrust. If spinal trauma is a possibility, only the jaw thrust should be used. If this fails, then **airway adjuncts**, such as nasopharyngeal or oropharyngeal airways, can be placed to help prevent the soft tissue of the oropharynx from collapsing against the posterior pharyngeal wall.

Monitoring

All infants and children in respiratory distress should be carefully monitored. Pulse oximetry will assist the clinician in determining the degree of oxygen saturation and, if available, a cardiac and respiratory monitor will provide constant readings of respirations and heart rate. Frequent assessments of the patient are critical to ensure a good outcome.

Oxygen Administration

Oxygen should be delivered by any method tolerated by children. **Nasal prongs** have 2 advantages: They are noninvasive and allow maintenance of a constant gas flow even when talking and eating. The concentration of oxygen delivered is limited, however, and irritation and drying of the mucous membranes may result.

Oxygen masks deliver a higher concentration of humidified oxygen. Disadvantages include obstruction of children's visual field, potential for carbon dioxide retention, and anxiety because the face is covered. Various types of masks are available.

The **simple mask** can deliver 30% to 60% oxygen concentration at flow rates of 6 to 10 L/min. Room air is drawn into the mask through the exhalation ports in the side of the mask.

A **non-rebreathing mask** has valves that allow only oxygen (85%–95%) to flow from the reservoir bag to the patient on inhalation and additional valves on the exhalation ports of the mask that prevent entrapment of room air (Figure 57-1).

Figure 57-1. A non-rebreathing mask can deliver a high concentration of oxygen to a patient in respiratory distress.

The **face tent** is a soft plastic bucket shaped to the chin that is well tolerated by children. The face tent allows up to 40% oxygen to be delivered, and it has the advantage of allowing access to the face and mouth (Figure 57-2).

A **venturi mask** is rarely used in children but has the advantage of precisely titrating the oxygen concentration to be delivered from 24% to 60%.

Children with potential respiratory failure require **assisted ventilation** with **bag-valve-mask** devices or **endotracheal intubation**. Masks of the proper size should be used. The upper edge of the mask should fit snugly over the bridge of the nose without touching the eyes. The lower edge should rest directly on or just above the mandible. An oropharyngeal airway should be inserted in unconscious children to prevent the tongue from obstructing the upper airway. A nasopharyngeal airway may be inserted if the patient has an

Figure 57-2. Use of a face tent.

Figure 57-3. A pocket mask with a one-way valve and side oxygen port that can be used for assisted ventilation in the office setting.

intact gag reflex to achieve the same goal. If a bag-valve-mask is not available, assisted ventilation can be given with a **pocket mask** with a one-way valve. Oxygen can be attached to the mask at the side port (Figure 57-3). Endotracheal intubation is indicated in those children who require control of the airway, who need airway protection, or who require hyperventilation.

Prognosis

Respiratory failure and resulting cardiopulmonary arrest are preventable in most infants and children if their condition is carefully assessed and appropriate critical interventions are made. Careful attention to ventilation and oxygenation of patients usually results in a good outcome.

CASE RESOLUTION

The fussy infant discussed in the case history has obvious signs of respiratory distress, including tachypnea, tachycardia, grunting, nasal flaring, and retractions. The differential diagnosis includes foreign body, infection, and reactive airways disease. It is important to place the infant in a position of comfort and provide supplemental oxygen before any diagnostic studies, such as chest radiograph, are performed. Pulse oximetry should be monitored. The clinical status of the infant should be reassessed periodically to prevent further deterioration.

Stridor and Croup

David B. Burbulys, MD

CASE STUDY

A 2-year-old boy has been breathing noisily for 1 day. For the past 3 days he has had a “cold,” with a runny nose, fever (temperature: up to 100.4°F [38°C]), and a slight cough. The cough has gradually become worse and now has a barking quality.

On examination, the child is sitting up and has a respiratory rate of 48 breaths/min with marked inspiratory stridor and an occasional barking cough. His other vital signs include a heart rate of 100 beats/min and temperature of

101.2°F (38.4°C). He has intercostal retractions, his breath sounds are slightly decreased bilaterally, and his skin is pale. The remainder of the examination is normal.

Questions

1. What is stridor?
2. What are the common causes of stridor?
3. What is the pathophysiology of viral croup?
4. How are children with stridor managed?

Noisy breathing is a common symptom that often accompanies respiratory infections in children. The presence of **stridor**, a high-pitched crowing sound, often concerns children’s caregivers. Some parents try home remedies to alleviate the symptoms, whereas many others immediately seek help in the office or emergency department setting. **Croup** is an inflammation of the larynx, trachea, and upper bronchioles (laryngotracheobronchitis) that causes noisy breathing and stridor. It is one of the most common causes of a seal-like barking cough and stridor in children.

Epidemiology

Croup most commonly affects children between 6 months and 3 years of age, generally in the fall or early winter. Children younger than 1 year make up 26% of cases. The condition is more common in boys than girls; two-thirds of all hospitalized children with croup are boys.

Stridor, which may be indicative of croup, may also be a sign of epiglottitis. The incidence of epiglottitis in children has dramatically decreased since 1988 following the development and widespread use of the vaccine against *Haemophilus influenzae* type b (Hib). Many young children may be incompletely immunized and there are other bacteria that may cause epiglottitis; therefore, epiglottitis should still be considered in toxic-appearing children with rapid onset of symptoms of upper airway obstruction. Prior to Hib immunization, the ratio of cases of epiglottitis to croup was 1:100. Today, epiglottitis in children is exceedingly rare.

Pathophysiology

Stridor

Stridor is generally caused by obstruction of the airway between the nose and the larger bronchi. Obstruction at the level of the nose or pharynx may produce snoring or gurgling sounds. Turbulence of airflow in the laryngeal area or upper trachea causes the high-pitched crowing sound characteristic of stridor. Edema and inflammation at the vocal cords and subglottic areas result in **inspiratory stridor**, whereas obstruction below the cricoid cartilage may lead to both inspiratory and **expiratory stridor**.

Some of the more common causes of stridor are listed in Box 58-1.

The sounds produced at various levels of obstruction can give the primary care provider clues as to the etiology of the problem. The most common cause of stridor that begins shortly after birth is tracheomalacia, a condition secondary to the immaturity of the cartilage of the trachea. Laryngomalacia, which is caused by floppy supraglottic structures, resolves after several months.

The upper airway of infants and children is more susceptible to obstruction as a result of anatomical differences between children and adults. The tongues of children are relatively large and the epiglottis is floppy and shaped somewhat like the Greek letter omega (Ω). The angle between the epiglottis and the glottis is more acute in children, which makes direct visualization of the airway more difficult. Cartilaginous structures are less rigid in infants. During inspiration, negative intraluminal pressure is generated below the level of obstruction, which leads to narrowing of the airway and turbulence of the airflow. This occurs more often in children because the tracheal rings are not well formed. In addition, the smaller size of the airway in children makes resistance to airflow greater when obstruction is present.

Box 58-1. Causes of Stridor

<i>Congenital Anomalies</i>	<i>Trauma</i>
Tracheomalacia	Direct trauma to the upper airway
Laryngomalacia	Post-intubation subglottic stenosis
Choanal atresia	<i>Neurogenic</i>
Laryngeal web	Laryngeal paralysis
Laryngocele	Poor pharyngeal muscle tone
Subglottic stenosis	<i>Caustic or Thermal Injury</i>
Vascular ring	Lye or caustic ingestion
Macroglossia (Beckwith syndrome)	Hot gas or liquid
Tracheal web or cyst	<i>Foreign Body</i>
<i>Inflammatory/Infectious Lesions</i>	Neoplasm
Viral croup	
Epiglottitis	
Abscess (retropharyngeal, peritonsillar, parapharyngeal)	
Tracheitis	
Bronchitis	
Severe tonsillitis	
Angioneurotic edema	
Infectious mononucleosis	
Diphtheria	

The smaller the airway, the greater the resistance to flow (resistance increases exponentially). Alterations in the diameter of the airway are most often caused by edema and inflammation from a variety of conditions, including congenital anomalies, infection, allergic and anaphylactic reactions, cysts, tumors, and trauma. Even small localized areas of airway narrowing in infants and children can lead to respiratory distress because the airway is so small, particularly at the cricoid ring, which is the narrowest portion of the airway in children.

Croup

Croup is most often caused by an infection with **parainfluenza virus** (type I or II). Several other causes include respiratory syncytial virus, influenza virus A or B, adenovirus, rhinovirus, coxsackievirus, measles, and herpes simplex virus. Metapneumovirus and a novel coronavirus, which more commonly cause bronchiolitis, have also been implicated. Particularly severe disease may be associated with influenza A, respiratory syncytial virus, or adenovirus infection. Infection occurs via respiratory droplets spread from other infected individuals.

The virus first attacks the nasopharynx and subsequently spreads to the larynx and upper trachea. The infection causes inflammation and edema of the airway that often involves the vocal cords producing the typical barking cough, hoarseness, and inspiratory stridor. Uncommonly, in severe cases, the lower airways also may be involved, leading to impaired alveolar ventilation and wheezing. In some children, secondary bacterial superinfection may rarely occur with bacterial tracheitis or extension of infection to the lower airway producing pneumonia. Airways of infants are small and particularly

susceptible to obstruction because of the narrow subglottic region and the laxity of the cartilaginous structures.

Spasmodic croup, an entirely different disease, is common, frequently occurs at night, and may be recurrent. It is characterized by the sudden onset of hoarseness, barking cough, and stridor. This condition may resolve when children are exposed to humid air. The etiology is unknown but is probably either a reaction to a viral infection or an allergic phenomenon. There may be a family history of recurrent stridor in children with spasmodic croup and it tends to occur in older aged children.

Differential Diagnosis

The differential diagnosis of stridor is presented in Table 58-1.

Evaluation**History**

A complete history should be obtained (Questions Box).

Questions**Stridor and Croup**

- Did the child have an antecedent respiratory infection?
- Does the child have a fever? If so, how high is the temperature?
- Was the onset of stridor abrupt?
- Is there stridor at rest/sleep or only with agitation?
- Does the child have any ill contacts?
- Does the child have any associated symptoms such as vomiting, diarrhea, or rash?
- Is the child feeding normally?
- Is the child drooling?

Physical Examination

It is important to assess the degree of respiratory distress and to place children in a position of comfort; monitor heart rate, ventilation, and oxygenation; and deliver oxygen (see Chapter 57). The stridorous sounds produced are usually inspiratory but may be inspiratory and expiratory if the disease progresses to the lower airway. The presence of stridor at rest or with sleep should be assessed as well as the severity of retractions with breathing. Breath sounds may be decreased bilaterally, and severe tachypnea, with respiratory rates from 40 breaths/min to 80 breaths/min, may occur. Peripheral or central cyanosis and alterations in mental status associated with severe disease should be noted. Assessment of the croup score may be helpful to direct initial therapy in mild, moderate, or severe cases (Table 58-2).

Laboratory Tests

Investigations, such as a complete blood cell count and cultures, are rarely helpful unless the physician is concerned about secondary bacterial infection. The white blood cell count may be normal or mildly

Table 58-1. Differential Diagnosis of Stridor

<i>Data</i>	<i>Viral Croup</i>	<i>Spasmodic Croup</i>	<i>Bacterial Tracheitis</i>	<i>Epiglottitis</i>	<i>Foreign Body</i>
Age	3–36 mo	3–36 mo	1–10 y	1–8 y	All Ages
Prodrome	Upper respiratory infection symptoms; onset over 2–5 d	None; sudden onset at night	Upper respiratory infection symptoms for days followed by rapid onset fever and respiratory distress	Usually none; rapid onset over several hours	None; sudden onset
Fever	Low grade	None	Low grade initially then higher	Usually above 102.2°F (39°C)	None
Cough	Barking	Barking	Dry initially then barking	None or dry	May or may not be present
Respiratory distress	Present	Present	Absent or mild initially then severe	Present and severe	Usually present
White blood cell count	Normal or slightly elevated	Normal	Normal initially then elevated	Elevated	Normal
Blood culture	No growth	No growth	Growth uncommon	<i>Haemophilus influenzae</i>	No growth
Radiograph	Subglottic narrowing; steeple sign	(±) Subglottic narrowing	Subglottic narrowing; steeple sign and ragged trachea	Swollen epiglottis	Air trapping; may show a foreign body

elevated, and the differential count may show a predominance of polymorphonuclear cells. If epiglottitis is being considered, no blood should be drawn until the airway has been visualized and secured.

Imaging Studies

Radiographs of the soft tissues of the upper airway are often helpful. In children with croup, lateral neck films may reveal ballooning of the hypopharynx, a normal epiglottis, and narrowing of the subglottic area (Figure 58-1). The frontal view shows the classic “steeple sign” of the subglottic area where the airway narrows like a church steeple or pencil tip. Radiographic studies should not delay the management of children with suspected epiglottitis nor should children with respiratory compromise be taken from a monitored area for radiographs. Thickening of the epiglottis (thumbprint-shaped) and obliteration of the vallecular space may be seen on lateral neck films in patients with epiglottitis if radiographs are obtained.

Other imaging studies, such as a barium swallow or computed tomography scan of the thorax, are helpful in diagnosing congenital anomalies (eg, vascular ring).

Management

Most children with croup and stridor can be managed as outpatients. Caregivers should be given careful instructions so that they understand the course of the illness, know what to expect, and realize when emergency care is needed. Children with a prolonged or recurrent history of stridor may require consultation with a head and neck specialist. If a specific cause of stridor, such as a foreign body, is identified, appropriate management should be instituted.

Children with croup should be treated with gentleness and should not be upset. They should remain with their caregivers and be allowed to assume a position of comfort. Agitation and crying increase respiratory distress and oxygen demand. Procedures should

Table 58-2. Croup Score^a

	0	1	2	3
Stridor	None	Only with agitation	Mild at rest	Severe at rest
Retraction	None	Mild	Moderate	Severe
Air entry	Normal	Mild decrease	Moderate decrease	Marked decrease
Color	Normal	Normal	Normal	Cyanotic
Level of consciousness	Normal	Restless when disturbed	Restless when undisturbed	Lethargic
Disease Category by Score				
Score	Degree	Management		
≤4	Mild	Consider mist therapy and dexamethasone 0.6 mg/kg orally. Outpatient observation.		
5–6	Mild to moderate	Dexamethasone 0.6 mg/kg orally and consider mist therapy. If child improves after observation, is >6 months, and has a reliable family then outpatient observation.		
7–8	Moderate	Dexamethasone 0.6 mg/kg orally or intramuscularly, consider racemic epinephrine and admission.		
≥9	Severe	Racemic epinephrine, dexamethasone 0.6 mg/kg orally or intramuscularly, oxygen, and admit to intensive care unit.		

^a Modified from Taussig LM, Castro O, Beaudry PH, Fox WW, Bureau M. Treatment of laryngotracheobronchitis (croup). Use of intermittent positive-pressure breathing and racemic epinephrine. *Am J Dis Child.* 1975;129:790, with permission from the American Medical Association.

Figure 58-1. Lateral neck radiograph of viral croup. Note the ballooning of the hypo-pharynx and the narrowing in the subglottic area. (Courtesy of Dr J. S. Seidel, Division of General and Emergency Pediatrics, Harbor-UCLA Medical Center.)

be kept to a minimum. The heart rate, respiratory status, and oxygen saturation should be continuously monitored while the patient is being treated and observed. Airway adjuncts that cause increased agitation should not be used.

Cool mist may be provided by blow-by or mask. **Humidified oxygen or air**, which is thought to decrease the viscosity of secretions and reduce the edema of the airway, has been the mainstay of therapy for croup for quite some time. This treatment is currently controversial. Several randomized, controlled trials have questioned this practice demonstrating no benefit of cool humidified mist therapy. Many find it difficult not to continue this treatment practice at this time though. Symptoms of spasmodic croup usually resolve within 6 hours of the onset without treatment but cool, humidified mist is often employed as the sole therapy in this disorder.

Treatment of croup with **corticosteroids** is less controversial. A number of studies have demonstrated that dexamethasone given as a single dose of 0.6 mg/kg is effective in shortening the course and severity of mild, moderate, and severe croup if given in the first 3 days. Several smaller randomized trials have also suggested that half the dose of dexamethasone may be equally effective. It should be given orally but may be given as an intramuscular injection for children who are unable to take oral medication. Use of the tablet preparation ground up in applesauce is recommended because the liquid

preparation does not taste good and is not well tolerated. Recent studies using nebulized budesonide also demonstrate the same efficacy in reducing respiratory distress and lowering of the croup score but at considerably more cost. Continuous or long-term therapy with steroids does not seem to alter the clinical course of the disease or the period of hospitalization and is not recommended. Treatment with antibiotics is not indicated unless infection with bacteria is evident.

Use of **racemic epinephrine** has also been somewhat controversial. Several older studies have shown that there was no difference in the long-term outcome between those children who were treated with epinephrine and those who received a placebo. Other studies have clearly demonstrated an acute effect of the drug when given via nebulizer. This effect lasts a few hours, and repeat respiratory distress after the drug effects have worn off has been reported in the literature. It is therefore prudent that racemic epinephrine only be used on patients who are going to be discharged if they can be observed for 3 to 4 hours after treatment. The anti-inflammatory effects of dexamethasone take several hours for onset, and racemic epinephrine may have more benefit in reducing symptoms during this period.

Hospitalization should be considered for children in severe respiratory distress or with significant stridor at rest who are unable to eat, and those whose parents are unable to cope with the tasks required to manage children at home. It is always indicated for children with a bacterial infection, such as epiglottitis or tracheitis.

About 10% of infants and children with croup may need **controlled ventilation with endotracheal intubation**. The indications for intubation include severe respiratory distress, altered mental status, hypoxia, and hypercapnia. A major complication of endotracheal intubation in children with croup is subglottic stenosis, which develops because the endotracheal tube may traumatize the inflamed airway, leading to permanent damage. Patients should be extubated as soon as possible.

Direct laryngoscopy may be necessary in some children where the etiology of the stridor is not clear. This procedure should be done by a practitioner who is experienced in managing the airway.

Prognosis

Stridor is a serious sign, which is indicative of upper airway obstruction and potential respiratory compromise. Although it has many causes, the prognosis is usually determined by the rapidity of diagnosis and the institution of appropriate therapeutic measures, particularly stabilizing the patient and ensuring patency of the airway. Certain conditions such as croup often resolve spontaneously within a few days, although some children require hospitalization and, rarely, assisted ventilation. Other conditions, such as foreign bodies or tumors, necessitate aggressive intervention to prevent death from airway obstruction.

CASE RESOLUTION

In the case history at the beginning of this chapter, the 2-year-old with the antecedent infection and stridor has the classic signs of croup and a croup score of 6. First, adequate ventilation and oxygenation should be ensured. As soon as the assessment and management of airway, breathing, and circulation are completed, other diagnostic studies and specific therapy, such as dexamethasone or racemic epinephrine, or both, can be considered.

Sudden Infant Death Syndrome and Apparent Life-Threatening Events

Lynne M. Smith, MD

CASE STUDY

A 4-month-old male infant is brought to the emergency department (ED) by paramedics after being found blue and not breathing by his mother. He had previously been well except for a mild upper respiratory infection. His mother fed him at 2:00 am, and when she checked on him at 6:00 am she found him blue and lifeless. Although the mother smoked cigarettes during pregnancy, the pregnancy and delivery were otherwise normal. The infant received the appropriate immunizations at 2 months of age.

Questions

1. What factors are associated with sudden infant death syndrome (SIDS)?
2. How are SIDS and apparent life-threatening events (ALTEs) related?
3. How are SIDS and sudden unexplained infant deaths (SUIDs) related?
4. What is the appropriate evaluation of infants who present with an ALTE?
5. What services are available to families who have lost infants to SIDS?
6. What should parents be advised to help prevent SUIDs?

Sudden infant death syndrome, previously referred to as **crib death**, is defined as the sudden, **unexpected death** of an apparently well infant younger than 1 year that is not adequately explained by a comprehensive medical history of the infant and family, a thorough postmortem examination, and a death scene investigation. The syndrome has been known since biblical times; parents were advised not to lie with their children for fear of suffocating them. In the United States, SIDS is the most common cause of death in children younger than 1 year beyond the neonatal period. Research suggests that infants who died of SIDS have **serotonin-mediated dysregulation** of the autonomic nervous system, which increases their vulnerability to exogenous stressors such as prone sleep position and environmental overheating.

Sudden infant death syndrome–like events associated with successful resuscitation were once described as **near-miss SIDS** or **aborted crib death**. The term that is now used is **apparent life-threatening event** and was adopted in 1987 at a National Institute of Health Consensus Development Conference on Infantile Apnea and Home Monitoring. Apparent life-threatening events are characterized by some combination of **apnea**, **color change**, **marked change in muscle tone**, and **choking** or **gagging**. Though some have

theorized ALTEs are precursors to SIDS, only approximately 5% to 10% of SIDS victims experienced a previous ALTE. In an attempt to establish the efficacy of home monitoring the **Collaborative Home Infant Monitoring Evaluation (CHIME)** study followed more than 1,000 healthy term infants as well as infants at varying risks for SIDS. The CHIME study found 43% of term infants experienced apnea/bradycardia episodes, indicating these cardiorespiratory events are common in all infants and unlikely to be precursors to SIDS. Further, SIDS usually occurs during infant sleep whereas an estimated 50% of ALTEs occur during wakefulness, which may explain why the Back to Sleep campaign has successfully decreased SIDS but not affected the incidence of ALTEs. Thus SIDS and ALTE should not be considered varying manifestations of a similar disease process.

With the expanded and more thorough home scene investigations, exogenous contributing factors have been increasingly noted in these deaths and are found in the vast majority of what is now referred to as **sudden unexplained infant death**.

Sudden unexplained death in childhood occurs in children older than 12 months. Sudden unexplained death in childhood is rare, with a reported incidence in the United States in 2002 of 1.3

deaths per 100,000 children, compared with 57 deaths per 100,000 live-birth infants under 12 months.

Epidemiology

Sudden unexplained infant death accounts for 2,000 to 3,000 deaths per year in the United States, with an overall incidence of 0.57 per 1,000. These figures were dramatically higher prior to the campaign of the American Academy of Pediatrics (AAP) to place babies in the supine position for sleep. Prior to the institution of the **Back to Sleep** campaign, the annual death rate from SIDS was approximately 5,000 to 8,000 with an incidence of approximately 2 per 1,000. Sudden infant death affects boys more commonly than girls and occurs more often in the winter months. This seasonality may be related to infection with respiratory syncytial virus (RSV). The highest incidence of SIDS occurs at 2 to 3 months of age, with 90% occurring before the age of 6 months.

The frequency of SIDS differs in different populations in both the United States and other countries. Though the incidence of SIDS is decreasing among all groups, SIDS rates in African American and American Indian/Alaska Native children is 2 to 3 times the national average. One factor contributing to the higher SIDS rate is the higher incidence of non-supine sleeping in African American infants. In 2001 the prevalence of prone positioning was 11% for white infants and 21% for African American infants.

Numerous epidemiological, maternal, and infant factors have been associated with SIDS, including **prematurity** and **intrauterine growth restriction** (Box 59-1). Mothers of children with SIDS are frequently young and unwed, smoke cigarettes, and have had fewer doctor visits during the prenatal and postpartum periods. Parental alcohol use is also a risk factor for SIDS. Sudden infant death syndrome rates in one study were 33% higher on New Year's Day, suggesting parents under the influence of alcohol are less able to safely monitor their infants. Despite initial reports and significant research efforts, no clear data have established a causal relationship of ALTEs, apnea, immunizations, or repeated episodes of cyanosis with SIDS.

Box 59-1. Risk Factors for Sudden Infant Death Syndrome

- Male gender
- Maternal youth
- Socioeconomic disadvantage
- Maternal smoking
- Prematurity
- Low birth weight
- Poor prenatal care
- Sleeping in prone or side position
- Soft bedding
- Overheating
- Bed sharing

Clinical Presentation

Victims of SIDS present in **cardiopulmonary arrest**, with a history of previous good health or antecedent upper respiratory infection. They often present in the early morning hours, having succumbed during sleep.

Infants who have experienced an ALTE at home may appear well without any need for medical intervention or resuscitation or may appear in the ED pale, cyanotic, hypotonic, lethargic, and have bradycardia. They often present during the day between the hours of 8:00 am and 8:00 pm, a different time of day than for SIDS victims. If resuscitation is successful en route, infants may look normal and be fully alert.

Pathophysiology and Risk Factors for SIDS

Sudden infant death syndrome is related to the interaction of a number of factors. Sudden infant death syndrome occurs in infants with an underlying vulnerability at a critical time during development when they are exposed to known risk factors such as sleeping in a non-supine position. The AAP recommends only the supine sleep position because side sleeping increases the risk of SIDS 2-fold relative to back sleeping.

Sleeping on a firm crib mattress covered by a fitted sheet is the recommended sleep surface for infants. Soft bedding such as waterbeds, couches, stuffed toys, pillows, quilts, and comforters are to be avoided. Though **bed sharing** has been promoted as enhancing breastfeeding, **accidental suffocation** and sudden infant deaths are associated with this practice. The AAP recommends parents sleep in a separate but proximate sleeping environment from their infant (room sharing but not bed sharing). The importance of a safe sleep environment is underscored by the work of Kemp and colleagues who investigated 119 SIDS cases over a 4-year period following the initiation of the Back to Sleep campaign. Only 8.4% of these SIDS victims were found in a non-prone position, alone in their bed, without any potential obstructions of the external airway by bedding. Overheating can increase the risk of SIDS, so dressing babies in light clothing during sleep and keeping the room temperature at a comfortable level for adults is recommended.

Because approximately 20% of SIDS cases in the United States occur while in the care of someone other than the parent, there is a critical need to educate secondary caregivers and child care centers regarding the need for babies to sleep on their backs. Another group of infants likely to sleep in a non-supine position are infants born weighing less than 1,500 g. These infants are twice as likely to be placed to sleep in the prone position at home than infants weighing 1,500 to 2,500 g. During the first weeks of hospitalization, premature newborns are often placed in a non-supine position because of respiratory complications and gastroesophageal reflux. The children become accustomed to this position, and the parents learn from the hospital staff's modeling to place them in these unsafe positions. The AAP Task Force on SIDS encourages neonatologists and nurses to begin placing premature newborns on their backs "significantly before the infant's anticipated discharge."

One unintended consequence of supine sleep positioning is the increased incidence of **positional plagiocephaly**. To minimize the risk for head deformities and to foster appropriate motor development, parents are encouraged to vary the head position at sleep times, avoid swing and "bouncy" seats that increase pressure on

the back of the head, and encourage adult-observed **tummy time** during waking hours starting from birth.

In addition to being exposed to an environment that increases the infant's risk for SIDS, most theories suggest that there is an underlying vulnerability in SIDS victims. The brain stems in infants who died of SIDS have significantly lower concentrations of serotonin and tryptophan hydroxylase, a key biosynthetic enzyme of serotonin; higher **serotonergic neuron** counts; decreased **serotonin 1A receptor** binding; and reduced **serotonin transporter** binding in the medulla. These findings suggest that abnormalities in serotonin synthesis, release, and clearance impair the infant's ability to appropriately regulate arousal and respiratory drive in response to potential life-threatening challenges during sleep.

Numerous other associations with SIDS have been reported including altered polymorphisms of pro-inflammatory cytokines, small mandibular size, disorders of fatty acid oxidation, and cardiac channelopathies including long QT syndrome. The AAP does not currently recommend universal electrocardiogram (ECG) screening at birth to identify potential SIDS victims.

The association between SIDS and **fatal child abuse** has also received attention, though infanticide is estimated to be the cause in less than 5% of suspected SIDS cases. The evaluation of the home environment of SIDS victims, referred to as *death scene investigations*, may reveal factors that contributed to the death of some of these infants. Unsafe sleeping environments (eg, sofas) and parental drug paraphernalia may identify such factors. A complete post-mortem examination may reveal prior or recent trauma. The autopsy should include an assessment for long bone fractures as well as intracranial hemorrhage, which establish inflicted trauma as the cause of the sudden death. In some municipalities, child fatality boards review each case of reputed SIDS to determine whether an etiology other than SIDS is present. Infants with parents who have Munchausen syndrome by proxy (MSBP) may present with SIDS or ALTE. Such infants are suffocated by the parents until they become apneic or die. Because distinguishing between SIDS and intentional suffocation is very difficult pathologically, the AAP Committee on Child Abuse and Neglect has cited factors that should heighten the clinician's suspicion for possible child abuse (Box 59-2). The use of in-hospital covert video surveillance has facilitated the recognition of apnea secondary to MSBP.

Box 59-2. Circumstances Where the Clinician Should Be Alert About the Possibilities of Child Abuse

- Previous recurrent cyanosis, apnea, or apparent life-threatening event (ALTE) while in the care of the same person
- Age at death older than 6 months
- Previous unexpected or unexplained deaths of one or more siblings
- Simultaneous or nearly simultaneous deaths of twins
- Previous death of infants under the care of the same unrelated person
- Discovery of blood on the infant's nose or mouth in association with ALTE

Differential Diagnosis

The physician is usually not charged with determining the cause of death of the deceased infant; that is the role of the coroner. The major challenge for physicians is to evaluate infants who have experienced an ALTE and determine if any underlying condition caused the episode (Box 59-3). In most cases, no etiology for an ALTE episode is established and the episode represents an isolated event.

Box 59-3. Differential Diagnosis of an Apparent Life-Threatening Event

- | | |
|-------------------------------------|---------------------------------|
| • Gastroesophageal reflux | • Inborn errors of metabolism |
| • Lower respiratory tract infection | • Child abuse |
| • Sepsis | • Intracranial hemorrhage |
| • Pertussis | • Airway anomalies |
| • Respiratory syncytial virus | • Aspiration |
| • Infantile botulism | • Breath-holding spell |
| • Seizures | • Cardiac arrhythmias/anomalies |
| • Medication misdose or overdose | |

Sepsis, respiratory infections, seizures, gastroesophageal reflux, inborn errors of metabolism, infantile botulism, cardiac anomalies, and child abuse should all be considered. The circumstances surrounding ALTEs suggest which of these conditions is suspect. A sepsis evaluation is particularly warranted in children who have symptoms such as fever, vomiting, or diarrhea or appear toxic at presentation. Infants with respiratory symptoms such as tachypnea and wheezing may have **RSV** infection, which is associated with apneic episodes, particularly during the first week of illness in infants younger than 3 months who had been premature and experienced apnea of prematurity. Young infants with pertussis do not exhibit the classic cough with whoop and may present with respiratory distress and apnea. Overuse or misuse of over-the-counter cough and cold medication has been associated with drowsiness and seizures, which can present as an ALTE. Infants with abnormal movements or ALTEs when awake may be experiencing seizures. The apnea may represent the seizure or a postictal event. Infantile botulism causes decreased muscle tone and weakness. Apnea may also accompany gastroesophageal reflux. In general, affected infants have a history of eating, regurgitating, and then developing apnea. As previously noted, child abuse, particularly with intracranial hemorrhage or MSBP, may result in apnea or SIDS.

Inborn errors of metabolism are reported in 4% to 8% of cases of ALTE. Inborn errors of metabolism should be considered in infants with other symptoms, such as vomiting or failure to thrive, or in the context of a positive family history. Symptoms may first appear when a previously well infant is metabolically stressed as by an acute infectious illness. Rarely cardiac arrhythmias, most notably long QT interval, are associated with apnea or sudden episodes of bradycardia.

Evaluation

History

The history may provide the clue to the etiology of SIDS or ALTE (Questions Box).

Questions

Sudden Infant Death Syndrome (SIDS) and Apparent Life-Threatening Event (ALTE)

- What were the events leading up to the episode?
- Was the child awake and eating, indicating that gastroesophageal reflux should be considered?
- Was the child awake and did the eyes roll back or the body stiffen or jerk, suggesting that a seizure may have occurred?
- How serious was the event? Did breathing resume spontaneously or did cardiopulmonary resuscitation have to be initiated?
- Have similar events occurred in the past?
- Is the infant basically well? Has the infant been ill recently?
- Has the child had respiratory symptoms such as wheezing or cough?
- Was the child given an over-the-counter cough and cold product?
- Do the siblings have a history of SIDS or ALTE that would suggest the presence of a familial disorder or child abuse?
- Were there any problems with the pregnancy or delivery?
- Is there a history of maternal smoking?
- Does the infant sleep in a supine, prone, or side-down position?

Physical Examination

A complete examination should be conducted. If infants are floppy and have poor color or have required either mouth-to-mouth resuscitation or vigorous stimulation, significant events are likely. Physicians should check for the presence of bruises, retinal hemorrhages, dysmorphic features, growth impairment, and abnormal neurologic or developmental findings, which may suggest an alternative etiology. The presence of tachypnea, retractions, wheezing, or cough is consistent with a respiratory infection such as RSV or pertussis.

Laboratory Tests

In general, the laboratory workup is guided by the findings of the history and physical examination (Box 59-4). A sepsis evaluation, including a complete blood cell count, blood culture, lumbar puncture, and urine culture, is appropriate to rule out sepsis in febrile or toxic-appearing infants. Serum electrolytes, serum ammonia, and glucose are important to check because they may indicate an inborn error of metabolism or other abnormalities (eg, hypoglycemia), which may be associated with apnea with or without the presence of a seizure. Hypotonic infants should be evaluated for infantile botulism by sending a stool specimen for testing. All infants with a history of apnea or ALTE should be admitted to the hospital for

Box 59-4. Laboratory Studies to Consider in Evaluating Infants With Apparent Life-Threatening Event

Often Indicated

- Complete blood cell count
- Blood culture
- Lumbar puncture
- Urine culture
- Chest radiograph
- Serum electrolytes
- Blood sugar
- Serum ammonia

Sometimes Indicated

- Electroencephalogram
- Computed tomography scan
- Barium swallow
- Electrocardiogram
- Skeletal survey

observation, workup, and monitoring. A pilot study has identified a subset of well-appearing, low-risk patients presenting with ALTE episodes that may be safe to discharge home after a thorough evaluation. However, these data need to be validated in a large study that includes children of all ethnicities. In addition, one must be certain that the family is comfortable with this course of action, and know what to do should there be a recurrence.

Imaging Studies

A chest radiograph should be performed to rule out pneumonia if respiratory symptoms are present or sepsis is suspected. If the history and physical examination suggest other etiologies, computed tomography and barium swallow may also be indicated, though the risks of radiation exposure need to be carefully considered.

Diagnostic Studies

An electroencephalogram should be obtained if a seizure disorder is suspected. In-hospital covert video surveillance is a complex procedure that may be undertaken if MSBP is suspected. Multichannel pneumograms detect apnea and bradycardia, but are not able to identify infants at risk for SIDS. They are no longer considered in the routine assessment of infants presenting with ALTE. An ECG may be useful in the rare infant with long QT syndrome.

Management

Infants who have not been fully resuscitated in the field should be resuscitated, stabilized, and admitted. Any identifiable conditions such as sepsis, seizures, and reflux should be appropriately managed. In general, infants who experienced an ALTE but do not have an identifiable precipitating condition are also admitted for monitoring and observation. Recent evidence suggests that infants older than 30 days who have not had multiple ALTEs and have no identifiable medical condition may be safely discharged from the ED. Prior to discharge from the hospital, the parents of infants who experienced an ALTE should receive cardiopulmonary resuscitation training and be advised to eliminate tobacco smoke exposure.

In the past home apnea monitoring was prescribed for newborns at risk for apnea. Based on a plethora of studies, the AAP does not

recommend home apnea monitors for the prevention of SIDS. Home apnea monitoring may be indicated for premature infants at risk for repeated episodes of apnea of prematurity on discharge from the hospital. Discontinuation should be considered at approximately 43 weeks' gestation.

Home monitoring may be indicated for individuals who are technology-dependent (home ventilators, tracheostomy) or those with ALTEs if the physician wants to monitor episodes of apnea or respiratory failure. The family of an infant who experienced an ALTE should clearly be informed that a home apnea monitor has not been shown to prevent SIDS and is not indicated for that purpose.

Pacifier use has been associated with a lower incidence of SIDS. The AAP recommends that caregivers consider offering a pacifier at nap time and bedtime throughout the first year of life. The pacifier should not be reinserted once the infant falls asleep or coated in any sweet solution. The pacifier should be cleaned often and replaced regularly. Breastfed infants should have pacifier introduction delayed until 1 month of age to ensure that breastfeeding is well established.

In addition to managing infants with ALTE, physicians must provide care to families whose infants have succumbed to SIDS. In most jurisdictions, cases of SIDS must be reported to the coroner's office. The AAP recommends a prompt death scene investigation; appropriate use of available medical specialists by medical examiners and coroners, including pediatricians; and a postmortem examination within 24 hours of death, including radiographic skeletal surveys and toxicological and metabolic screening. A complete review of the medical records of the victim is essential. It is important for physicians to tell families when they think the cause of death is probable SIDS even before definitive autopsy results are available. A timely information session with parents is recommended when the results of the investigation conclude SIDS or a medical causation for death.

Parents of children who have succumbed to SIDS should be guided through issues such as planning the funeral and ending lactation. For ongoing support they should be referred to groups and agencies to help them deal with the loss of their child. Information about these organizations can be obtained from First Candle (800/221-SIDS; www.firstcandle.org).

Prognosis

Prevention of SIDS has become a focus of public health measures. Improving maternal risk factors involves smoking cessation and access to prenatal care. Parents must be instructed to avoid soft bedding for their infants, not to bed share with their infants, not to place their infants on a sofa for sleep, to avoid overheating, and to place their infants in the supine position in a crib. The prognosis for children who have experienced an ALTE varies and depends on predisposing conditions. Parents can be assured that most ALTEs are

isolated events and the risk of a chronic condition, such as seizure disorders, is rare. Abnormal neurodevelopmental conditions are generally associated with a poor prognosis when associated with apnea.

CASE RESOLUTION

The infant presented in the case history succumbed to SIDS. In spite of resuscitative efforts by the paramedics, he could not be revived. The mother is advised of the diagnosis of suspected SIDS and referred to appropriate agencies and support groups. The coroner is notified about the case and the presence of any associated physical findings, such as bruises. The mother is advised that a coroner investigator will visit her to learn more about the circumstances surrounding the sudden death of her infant.

Syncope

David Atkinson, MD, and Elizabeth A. Edgerton, MD, MPH

CASE STUDY

A 15-year-old boy comes to your office a week before the beginning of the school year complaining of fainting during football practice the previous day. He has been trying out for the varsity football team and they are now in the midst of “hell week,” 2-a-day workout drills. He has never fainted before, but has gotten dizzy momentarily after standing up “too fast.” His mother contradicts him and says that he fainted about a year ago while having blood drawn. In addition, when he was about 18 months old, he fell off of his parents’ bed. He cried, gasped, stopped breathing, became pale, and passed out for about 30 seconds. He was diagnosed with a breath-holding spell. There is no family history of sudden death or seizures.

Prior to the recent event he had been sitting on the team bench when the coach blew his whistle, the boy stood up quickly and became dizzy. He came to on the ground and his coach told him he had passed out for about 10 to 15 seconds. He denies taking any medications or using any illicit drugs. The patient states that he ate his lunch, but did not have anything to drink between

the practice sessions. There is no family history of sudden death or seizures. The mother wants to know if it is safe for her son to continue participating in physical activities since she has read about sudden death in high school athletes.

His physical examination is unrevealing and his vital signs are all normal. Electrocardiogram shows normal sinus rhythm with normal voltages and intervals for his age.

Questions

1. What are the causes of syncope?
2. What type of workup is done primarily to evaluate for syncope?
3. When should patients who experience syncope be referred to a subspecialist?
4. Which pediatric subspecialists assist in the evaluation of a patient with syncope?
5. Which patients presenting with syncope are at the greatest risk for sudden death?

Syncope, or **fainting**, is a transient loss of consciousness and is a very common clinical problem in pediatrics, particularly in pubescent and adolescent patients. The most common causes of syncope in pediatrics are benign neurocardiogenic events; however, syncope may rarely be a harbinger of sudden death due to arrhythmia, obstruction of aortic outflow, or other serious cardiovascular events.

There are 3 general categories of syncope: **neurocardiogenic** (also called vasovagal syncope), **cardiac syncope**, and **noncardiac syncope** (Box 60-1). The workup for syncope can easily become expensive and time-consuming, and may provide little information beyond that gleaned by the initial history and physical examination. It is the role of the pediatrician to appropriately direct the evaluation for syncope so that a cost-effective evaluation may occur without missing the patient who may be at risk for a sudden death event.

Epidemiology

Syncope is defined as a temporary, transient loss of consciousness and muscle tone, usually associated with a rapid recovery. It is the result of a decrease in cerebral blood flow that can occur through many different mechanisms. Syncopal events are very common in the pediatric population; up to 50% of college undergraduates have

reported experiencing syncope or near syncope, and it accounts for about 1% of all pediatric emergency department visits. Females are more commonly affected than males, and the mean age at presentation is 10 to 12 years. Syncope is uncommon in children younger than 5 years. Many cases of syncope resolve quickly and medical attention is not sought, so the true incidence of syncope is almost certainly underestimated.

Clinical Presentation

The clinical presentation of syncope varies with the etiology. In **vasovagal syncope** there is often a prodrome of symptoms, including lightheadedness, visual disturbances, nausea, and diaphoresis. The patient has usually been standing for a long period or has suddenly gone from the supine or sitting position to standing. Other forms of **neurally mediated syncope** include **hair-grooming syncope**, which occurs mostly in girls while combing, brushing, or blow-drying their hair. Micturition syncope, while more common in the elderly, may occur in all ages of patients. Younger patients tend to be male; predisposing factors may include reduced food intake, fatigue, alcohol ingestion, and recent respiratory infection. The events often occur at night when voiding after awakening from sleep (ie, while standing

Box 60-1. Causes of Syncope

Neurocardiogenic (Vasovagal Syncope)

Cardiac

- Tachyarrhythmias
 - Supraventricular tachycardia
 - Ventricular tachycardia
- Bradyarrhythmias
 - Second or third degree heart block
 - Sinus node dysfunction
- Left or right ventricular outflow tract obstruction
 - Hypertrophic cardiomyopathy
 - Aortic stenosis
- Idiopathic pulmonary hypertension
- Coronary artery disease
 - Acquired coronary artery disease
 - Kawasaki disease
 - Congenital coronary anomaly
 - Intramural coronary artery
 - Anomalous origin of a coronary artery
- Primary cardiac dysfunction
 - Dilated cardiomyopathy
 - Non-compaction syndrome
- Secondary cardiac dysfunction
 - Viral or idiopathic myocarditis
 - Restrictive cardiomyopathy

Noncardiac

- Orthostatic hypotension
- Neurologic (seizures, atypical migraine, dysautonomia)
- Breath-holding spells
- Psychogenic (hysteria, hyperventilation)
- Metabolic abnormality (hypoglycemia, anemia)
- Drug or medication effect

immediately after being recumbent). Recurrences of micturition syncope are rare in young patients. **Breath-holding spells** in toddlers brought on by anger, pain, fear, or frustration may be associated with syncope; this is an infantile form of cardioinhibitory neurally mediated syncope. Infants who suffer syncopal breath-holding spells are more likely to grow up and have neurally mediated syncope (see Chapter 49).

Syncope of cardiac etiology will often lack the prodrome of vasovagal syncope. The main cardiac causes of syncope are arrhythmia and left ventricular outflow obstruction. Patients may complain of palpitations, chest pain, or chest tightness. Cardiac syncope commonly occurs during physical activity and may be accompanied by a complete loss of body tone.

Syncope related to **seizures** generally has a longer recovery time associated with the postictal phase; witnesses may describe the patient as being dazed or “having a blank look on their face” prior to fainting. These episodes may occur whether the patient is recumbent or upright.

Pathophysiology

Autonomic

Autonomic causes of syncope are the most common etiology, accounting for up to 80% of cases of syncope that comes to medical attention. They are also referred to as neurally mediated reflexive syncope, vasovagal syncope, neurocardiogenic syncope and, in toddlers, pallid breath-holding spells. They have in common disturbances in autonomic control of heart rate and blood pressure in response to postural changes, bodily functions, pain, fear, or other strong emotional events. Vasovagal syncopal events usually occur when the patient is upright, resulting in decreased venous return, decreased arterial blood pressure, and decreased left ventricular volume. There is a resultant reflex stimulation of vagal fibers leading to bradycardia, vasodilation, and worsening hypotension (Bezold-Jarisch reflex). There are 3 clinical types of neurally mediated syncope: vasodepressor, which starts and is primarily marked by profound hypotension; cardioinhibitory, marked by severe bradycardia or even brief asystole; and mixed response, which is a mixture of both vasodepressor and cardioinhibitory.

Cardiac

Cardiac causes of syncope are more likely to be associated with sudden death, so it is important to identify and treat these abnormalities. Cardiac mechanisms of syncope are mainly related to arrhythmias or to obstructive lesions. Obstructive lesions lead to decreased ventricular outflow, resulting in decreased cerebral perfusion; arrhythmia may lead to decreased ejection volume, also leading to cerebral hypoperfusion and syncope.

Left-sided obstructive lesions, including aortic stenosis and hypertrophic cardiomyopathy, are the most likely cause of obstructive syncope. Rarely, syncope can be caused by pulmonary stenosis or severe primary pulmonary hypertension, mitral stenosis, atrial myxoma, or cardiac tamponade. Cardiac syncope often occurs during exertion, owing to the inability of the heart to increase cardiac output to meet the demands placed on it by increased physical activity. Increased diastolic pressure caused by an obstructive lesion may also decrease myocardial perfusion leading to cardiac ischemia, dyskinesia, or ventricular arrhythmias, which lead to decreased ventricular output.

Anomalous origin of the coronary arteries, though not an obstructive lesion, may also cause syncope with exercise. The left coronary artery may arise from the pulmonary artery, delivering deoxygenated blood to the left coronary system, or the left coronary artery may arise from the right coronary cusp and course between the aorta and pulmonary arteries. When the patient is in a high cardiac output state, such as during exercise, the left coronary artery may be compressed between the great arteries, leading to ischemia or arrhythmias.

Primary arrhythmias causing syncope are a rare but important cause of syncope. Chest radiograph, echocardiogram, and other imaging modalities will generally be normal, with no evidence of

structural heart disease or pulmonary edema. Supraventricular tachycardia may cause syncope or near syncope. In most pediatric patients, the tachycardia is propagated through a concealed pathway, and the resting electrocardiogram (ECG) will be normal if the tachycardia is not occurring while the ECG is being obtained. Supraventricular tachycardia may also be associated with Wolff-Parkinson-White (WPW) syndrome. Wolff-Parkinson-White syndrome is characterized by a short P-R interval followed by an abnormally wide QRS complex with an initial delta wave.

Ventricular tachycardia is rare in children with no underlying structural heart disease, but may be brought on by infection (especially myocarditis or pericarditis), cardiomyopathies, drugs (cocaine, amphetamines), drug interactions (non-sedating antihistamines taken with erythromycin or ketoconazole), and long QT syndrome.

Patients with long QT syndrome have prolonged cardiac repolarization, which will usually manifest on the resting ECG as a prolonged corrected QT interval. The prolongation of the repolarization period of the heart puts patients with long QT syndrome at risk for torsades de pointes, a malignant form of ventricular tachycardia. The genetic forms of long QT syndrome result from mutations in genes that code for ion transport channels or related proteins. Romano-Ward syndrome is an autosomal-dominant form of long QT syndrome that is associated with congenital deafness. Autosomal-recessive long QT syndrome has historically been referred to as Jervell and Lange-Nielsen syndrome. Although the clinical diagnosis of long QT syndrome is based on a QTc that is prolonged for the patient's age, it is estimated that 20% of patients with a gene mutation associated with long QT syndrome will have a normal ECG; therefore, a critical part of the evaluation of the syncopal patient is obtaining a family history of long QT syndrome, sudden death or near sudden death, seizures, or a history of torsade de pointes. Long QT syndrome may also be brought on by electrolyte imbalance, increased intracranial pressure, or medications (Table 60-1).

Noncardiac

Noncardiac causes of syncope include neurologic etiologies (seizures, migraines), metabolic disturbances (hypoglycemia), hyperventilation (panic attacks or self-induced), and hysteria. Low iron stores have been associated with neurally mediated syncope in children and adolescents. Seizures may be difficult to distinguish from vasovagal events because both can have tonic-clonic movements. Unlike vasovagal or cardiac syncope, seizures result in unconsciousness secondary to neurologic dysfunction. Syncope associated with hypoglycemia is due to insufficient substrate being delivered to the brain. Cerebral vasoconstriction secondary to arterial hypocapnia produces syncope with hyperventilation that may be secondary to panic attacks or may be self-induced. Hysterical syncope lacks a true prodrome, and patients usually suffer no injury when they fall. This form of syncope is thought to be related to Munchausen syndrome.

Table 60-1. Drugs Known to Increase the Risk of Ventricular Arrhythmia in Patients With Long QT Syndrome^a

<i>Drug</i>	<i>Class/Clinical Use</i>
Amiodarone	Antiarrhythmic/abnormal heart rhythm
Arsenic trioxide	Anticancer/leukemia
Bepidil	Anti-anginal/heart pain
Chloroquine	Antimalarial/malaria infection
Chlorpromazine	Antipsychotic/antiemetic/schizophrenia/nausea
Cisapride	Gastrointestinal (GI) stimulant/heartburn
Clarithromycin	Antibiotic/bacterial infection
Disopyramide	Antiarrhythmic/abnormal heart rhythm
Dofetilide	Antiarrhythmic/abnormal heart rhythm
Droperidol	Sedative; anti-nausea/anesthesia adjunct, nausea
Erythromycin	Antibiotic; GI stimulant/bacterial infection; increase GI motility
Halofantrine	Antimalarial/malaria infection
Haloperidol	Antipsychotic/schizophrenia, agitation
Ibutilide	Antiarrhythmic/abnormal heart rhythm
Levomethadyl	Opiate agonist/pain control, narcotic dependence
Mesoridazine	Antipsychotic/schizophrenia
Methadone	Opiate agonist/pain control, narcotic dependence
Pentamidine	Anti-infective/pneumocystis pneumonia
Pimozide	Antipsychotic/Tourette tics
Procainamide	Antiarrhythmic/abnormal heart rhythm
Quinidine	Antiarrhythmic/abnormal heart rhythm
Sotalol	Antiarrhythmic/abnormal heart rhythm
Sparfloxacin	Antibiotic/bacterial infection
Thioridazine	Antipsychotic/schizophrenia

Differential Diagnosis

The differential diagnosis of syncope is presented in Box 60-1. Events that precede and follow the syncopal event are key in determining the etiology of syncope.

Evaluation

History

A thorough history should be obtained from the family and patient, focusing on the patient's symptoms, the situation surrounding the event, and the family history (Questions Box). A primary goal of the history is to identify any underlying cardiac problems because these patients are at the greatest risk for sudden death.

Questions

Syncopal

- What was the patient doing when the episode occurred?
- What was the position of the patient?
- Did the patient have any symptoms before the syncopal event?
- Did the patient have any chest pain or palpitations during the event?
- How long did it take for the patient to recover from the syncopal event?
- Were any residual symptoms present after the syncopal event?
- Has the patient recently been ill, dehydrated, or fatigued?
- Does the patient have a history of underlying cardiac disease?
- Is the patient taking any type of medication (prescribed, over the counter, or illicit)?
- Does the patient have a history of breath-holding or pallid spells?
- Is there a family history of sudden death, seizures, deafness, or cardiac abnormalities?

Physical Examination

The patient with syncope needs a thorough physical examination. Vital signs should assess the blood pressure to screen for hypotension and hypovolemia. The cardiac examination should include palpation of the chest for the point of maximal intensity, thrills and lifts, and auscultation to assess the intensity of the heart sounds and to detect the presence of murmurs or other adventitious sounds. Upper- and lower-extremity pulses should be palpated for their presence and quality. The remainder of the examination should focus on identifying any abnormal neurologic findings.

Laboratory Tests

The history and physical examination should guide which laboratory tests are necessary. In general, few tests are needed. Serum glucose shortly after the syncopal event may reveal hypoglycemia. Fasting glucose or glucose tolerance tests are usually normal, and such testing is not indicated. In pubertal females, a pregnancy test should be obtained as well as a hemoglobin level. Iron levels may be low in patients with neurally mediated syncope.

Imaging Studies

Every patient who is being evaluated for syncope requires an ECG. The ECG may reveal WPW or a prolonged QT interval, neither of which can be diagnosed by history and physical examination alone. These studies can also be useful in identifying underlying structural abnormalities such as right ventricular hypertrophy secondary to pulmonary hypertension, left ventricular hypertrophy secondary to hypertrophied cardiomyopathy, or Q waves associated with anomalous origin of the coronary arteries. Patients with findings suggestive of cardiac disease (positive history, physical findings, or an abnormal ECG) require referral to a pediatric cardiologist for further evaluation. The cardiac workup of syncope may include a Holter monitor or an event recorder. The Holter monitor is worn for 24 hours and continuously records the heart rhythm. Because this is a limited

window of observation, the Holter monitor will capture arrhythmia less than 20% of the time, even in patients with known arrhythmias. Event recorders are worn for longer periods, often up to several weeks. They can record and retain the cardiac rhythm prior to, during, and following an event. When the patient activates the monitor, the recording is saved for download to the cardiologist. If the monitor is not activated, the event recorder will not save the information but will record over it. Although the event recorder has a higher probability of capturing an arrhythmia if one is present than does a Holter monitor, the tracings are generally lower quality. Exercise stress testing is often used to evaluate the patient's response to exertion and to allow for replication of symptoms in a monitored setting. Electrophysiology studies may be ordered if an arrhythmia is uncovered during the evaluation.

The workup for patients without evidence of cardiac disease (negative family history of cardiac disease or of sudden death and no exertional symptoms such as chest pain) should focus on the non-cardiac or autonomic causes of syncope. Patients with prolonged recovery time or persistent neurologic symptoms following an event should be referred to a neurologist and may require an electroencephalogram to rule out seizure disorders.

A tilt test may be used to aid in the diagnosis of vasovagal syncope, although in most cases the history will be sufficient. The patient receiving a tilt test is placed on a table that is then tilted to simulate standing in an upright position, a condition that is commonly associated with vasovagal syncope. Unfortunately, there is great variability in the tilt test, with an incidence of up to 20% of false-positives. Factors that influence the test results include the time of day, whether the patient has fasted, hydration status, and whether the test was augmented with isoproterenol. There are very few false-negative tilt tests, but due to the high number of false-positives, the tilt test should be reserved only for refractory, recurrent, or unexplained syncope.

Management

Management of syncope depends on its cause. Recurrent vasovagal syncope may be treated simply by having the patient increase their fluid intake (including carrying a water bottle in school) and increasing their salt intake. Fludrocortisone, a mineralocorticoid, is the most common medical intervention for vasovagal syncope, although the efficacy is not well established. Other treatments include β -blockers (propranolol or atenolol), vagolytic drugs (disopyramide), or centrally acting drugs (imipramine, fluoxetine). These medications have varied benefits, and results between small controlled trials are not consistent.

Patients with neurologic syncope secondary to seizures should be treated with anticonvulsants. Patients with hyperventilation, hysteria, or hypoglycemia are most amenable to behavioral interventions. Patients with syncope secondary to a cardiac etiology should be referred to a cardiologist for further evaluation and correction of the underlying problem. These types of syncopal episodes may require more aggressive management, such as surgery or cardiac pacing, because they are more likely to result in sudden death.

Prognosis

The prognosis for autonomic and noncardiac syncope is good. Patients with vasovagal syncope will often suffer only a single event, and those with recurrent events can be treated with increased fluid intake or with medication. One subgroup to be aware of is children with pallid breath-holding spells; while most will have resolution of these spells by 5 years of age, up to 17% may continue to have syncope in adulthood. Patients who have syncope with an underlying cardiac etiology are at the greatest risk for sudden death, and it is only through identification and treatment of these structural or rhythm abnormalities that sudden death may be prevented.

CASE RESOLUTION

The adolescent boy in the opening scenario describes symptoms consistent with vasovagal syncope. His family history, physical examination, and ECG do not suggest any underlying cardiac disease. The patient and his family should be informed that certain factors, such as dehydration, fatigue, and hunger, can precipitate syncope. Behavioral changes, such as eating breakfast and drinking plenty of water, should be implemented to prevent or limit recurrence of syncope. The patient should be encouraged to carry a water bottle in school, and a note written to the school to allow him to do so, if necessary. Management with medications is not indicated at this time.

Shock

Kelly D. Young, MD, MS

CASE STUDY

A 7-month-old infant boy is brought in by his parents with a history of vomiting and diarrhea for 2 days. He also has had a low-grade fever and, according to his parents, has become progressively more listless. Vital signs show a heart rate of 200 beats/min, respiratory rate of 30 breaths/min, and blood pressure of 72/35 mm Hg. The infant is lethargic and mottled. Capillary refill time is 3 seconds. His anterior fontanelle is sunken, and his mucous membranes are dry. The abdomen is flat and non-tender and displays hyperactive bowel sounds.

Questions

1. What is shock, and what clinical signs can help in the recognition and assessment of shock?
2. What are the stages of shock?
3. What different types of shock are there, and what are the possible causes for each type?
4. What are the management priorities in treating shock?

Shock is defined as a state of circulatory dysfunction resulting in insufficient delivery of oxygen and other metabolic substrates to the tissues. Shock is not a disease but rather an abnormal physiological state that may result from many disease processes. Early recognition and prompt therapy of shock are critical to avoid permanent end-organ damage or death.

Epidemiology

The most common type of shock in children is hypovolemic shock, and the most common causes are dehydration from gastrointestinal infections that cause vomiting and diarrhea, and hemorrhage from traumatic injury. However, in a case series of 147 pediatric shock patients (excluding trauma patients) from Children's Hospital of Nevada, septic shock was the most common etiology, accounting for 57% of patients. Of the remaining patients, 24% had hypovolemic shock, 14% distributive, and 5% cardiogenic. Shock may be seen in any age group, but it is more difficult to recognize the early stages in young children because early clinical signs of shock in children are subjective and may be attributed to other causes. By the time young children have developed more typical signs, such as thready pulses and hypotension, they are in the late stages of shock.

Clinical Presentation

Early signs of shock include tachycardia; cool, clammy, pale, or mottled skin; and delayed capillary refill time. There may be a history of decreased urine output. In this early stage, perfusion to vital organs such as the brain and heart is maintained by compensatory physiological processes. As the shock state progresses, it becomes uncompensated, resulting in impairment of vital organ perfusion. Signs of uncompensated shock include hypotension; altered mental status

(irritability, lethargy, decreased interactiveness); weak, thready, or absent pulses (although pulses may be bounding in “warm” septic shock); and severely mottled or cyanotic skin (Dx Box). In the Nevada epidemiologic study, young children commonly presented with poor extremity perfusion and poor pulses, while adolescents presented with hypotension. Irreversible shock occurs when multiple organs fail and death occurs.

Dx Shock

Compensated

- Tachycardia
- Normal blood pressure
- Normal or bounding pulses
- Normal or cool, clammy skin
- Pale or mottled skin color
- Alert, anxious mental state
- Mildly delayed capillary refill time
- Decreased urine output

Uncompensated

- Tachycardia or bradycardia
- Hypotension
- Weak, thready, or absent pulses
- Cool, clammy skin
- Severely mottled or cyanotic skin color
- Altered mental state, lethargic
- Delayed capillary refill time
- Decreased or absent urine output

Pathophysiology

Shock occurs when oxygen delivery to tissues is impaired. Adequate oxygen delivery depends on sufficient blood oxygen content and adequate circulatory blood flow (Figure 61-1). The oxygen content in blood depends primarily on the concentration of hemoglobin and the amount of oxygen bound to hemoglobin. In children, oxygen consumption by end organs depends most on oxygen delivery, while in adults it depends on oxygen extraction by the tissues.

Figure 61-1. Pathophysiology of shock. Factors affecting oxygen delivery to tissue.

Blood flow, or cardiac output, is determined by heart rate and stroke volume. Stroke volume depends on preload, contractility, and afterload. Preload refers to the amount of blood entering the heart from the systemic vasculature. Increasing preload, for example, via administration of intravenous (IV) fluid boluses, will increase cardiac output until a point of optimal heart muscle fiber length is reached. The Starling curve demonstrates that increased stretching of a muscle fiber results in improved performance of that muscle fiber (ie, improved stroke volume and cardiac output); but, after the point of optimal stretching is reached, there is decreased performance (Figure 61-2).

Contractility, or inotropy, is the heart's intrinsic ability to contract and pump blood to the body. Afterload refers to the systemic vascular resistance impeding ejection of blood from the ventricles. Optimal cardiac output depends on sufficient preload, unimpaired cardiac contractility, and the ability of the heart to overcome any afterload. During states of decreased cardiac output leading to decreased tissue perfusion, adults compensate primarily by increasing cardiac contractility, whereas children compensate primarily by increasing their heart rate. Irreversible shock in adults is most likely to be due to vasomotor collapse, while in children cardiac failure plays a larger role.

Differential Diagnosis

There are several types of shock depending on the underlying pathophysiology (Table 61-1).

Hypovolemic shock is the most common type seen in children and usually results from dehydration or traumatic hemorrhage. Hypovolemia results in inadequate preload, which leads to impaired cardiac output and impaired perfusion. Other causes of hypovolemic shock include diabetic ketoacidosis (dehydration due to osmotic diuresis) and peritonitis and burns leading to third-spacing of fluids (shifting from intravascular to extravascular sites) with resultant

Figure 61-2. Starling curve of cardiac output. A. As muscle fiber length increases, performance increases. B. Muscle fiber reaches its optimal length, after which performance declines.

intravascular hypovolemia. Non-traumatic hemorrhage may occur from entities such as epistaxis, gastrointestinal bleeding, and vessel fistula formation.

Distributive shock is a relative hypovolemia; vasodilation results in inadequate circulating blood volume relative to the vasodilation (ie, the “tank” has been made larger by vasodilation, and now there is insufficient fluid to fill the tank). Causes include anaphylaxis and sepsis, which result in the release of vasoactive mediators that cause

Table 61-1. Types of Shock

Type of Shock	Physiological Mechanism	Common Causes
Hypovolemic	Decreased preload	Dehydration Traumatic hemorrhage Non-traumatic hemorrhage Diabetic ketoacidosis Peritonitis Burns
Distributive	Relative hypovolemia due to vasodilation	Sepsis Anaphylaxis Neurogenic Toxin-mediated
Cardiogenic	Decreased contractility	Congestive heart failure from congenital lesions Myocarditis Tachydysrhythmias
Obstructive	Impaired cardiac output to systemic circulation	Pulmonary embolus Pericardial tamponade Tension pneumothorax Ductal-dependent cardiac lesions
Dissociative	Abnormal hemoglobin— inadequate oxygen bound	Carbon monoxide poisoning Methemoglobinemia

vasodilation. Spinal cord injury (**neurogenic shock**) may result in loss of sympathetic nerve-mediated vascular tone and subsequent vasodilation. Finally, certain intoxications such as iron, barbiturates, and tricyclic antidepressants can cause vasodilation and distributive shock.

Cardiogenic shock is an uncommon but important cause of shock in children. Congestive heart failure from a congenital heart lesion, myocarditis, or cardiomyopathy results in impaired cardiac contractility and decreased cardiac output. Tachydysrhythmias, such as supraventricular tachycardia, do not allow sufficient time for the ventricles to fill with blood, resulting in decreased stroke volume.

Rare causes of shock in pediatric patients include obstructive and dissociative types. In **obstructive shock**, there is obstruction to cardiac output to the systemic circulation due to pulmonary embolus, cardiac tamponade, or tension pneumothorax. Closure of the ductus arteriosus in a neonate with a ductal-dependent congenital heart lesion is another cause of insufficient cardiac output and obstructive shock. In **dissociative shock** abnormal hemoglobin such as methemoglobin or carboxyhemoglobin from carbon monoxide poisoning results in decreased oxygen bound to hemoglobin and decreased oxygen delivered to tissues.

Septic shock combines elements of distributive, hypovolemic, and cardiogenic shock. Vasoactive mediators lead to decreased systemic vascular resistance and a relative hypovolemia. Third-spacing of fluid leads to a true intravascular hypovolemia as well. In addition, mediators of sepsis cause impaired cardiac function.

Because shock is a physiological state resulting from a variety of etiologies, and because it is recognized through clinical findings, it is important to interpret individual findings in the context of the patient as a whole. Heart rate may be elevated for many reasons, including fear, anxiety, fever, and other reasons. Capillary refill may appear delayed in the extremities of a child who is cold. Blood pressure may appear artificially low when too large of a cuff is used to measure it. The clinician must consider whether the child's history is consistent with risk for shock, and whether the physical examination taken as a whole supports the diagnosis.

Evaluation

Early recognition and prompt treatment of shock is the goal. A rapid, focused history and physical examination should be performed to identify patients in shock, and then early therapy should be instituted before returning for a more complete evaluation. Recognition of shock depends on history and physical examination alone; therapy should never be withheld while awaiting results of diagnostic tests.

History

A history of vomiting with or without diarrhea, decreased oral intake, and decreased urine output, especially in infants, should alert the clinician to possible hypovolemic shock. Children presenting with major trauma should be evaluated for hemorrhagic shock. A history of fever, lethargy, or irritability, and sometimes a rash, may point toward septic shock. Patients with asplenia, sickle cell disease, or

indwelling catheters and those who are immunocompromised (eg, young infants or children on chemotherapy) are at increased risk for sepsis. Children in cardiogenic shock may have a history of a murmur, poor feeding, sweating with feeds, cyanosis, tachypnea, and dyspnea and, in the older child, palpitations.

Physical Examination

A brief examination to identify shock focuses on mental status, vital signs, pulses, and skin signs. Impaired level of consciousness, such as lethargy or lack of recognition of parents, occurs later in shock. Earlier, children are anxious or fussy but alert. Tachycardia occurs early in shock but must be interpreted in the context of other signs of shock because tachycardia may also result from fever, pain, or simply the child's fear of the examination process. Bradycardia is a late, ominous sign in shock and often results from hypoxemia. Hypotension is also a late sign in shock. It is important to remember that normal values for heart rate and blood pressure vary by age. The lower limit of acceptable systolic blood pressure in a neonate from birth to 1 month is 60 mm Hg; in an infant from 1 month to 1 year is 70 mm Hg. For a child 1 year or older, the lower limit can be estimated using the formula $70 + (2 \times \text{age in years})$ mm Hg; the lower limit is 90 mm Hg for children 10 years or older. Systolic blood pressures lower than these guidelines represent hypotension and late uncompensated shock. Heart rate and blood pressure values requiring immediate attention are shown in Table 61-2.

Table 61-2. Critically Abnormal Heart Rate and Blood Pressure

Age	Bradycardia	Tachycardia	Hypotension
Neonate 0–28 d	<100 bpm	>180 bpm	<60 mm Hg
Infant 1–12 m	<90 bpm	>160 bpm	<70 mm Hg
Child 1–10 y	<60 bpm	>140 bpm	<70 + (2 x age) mm Hg
Child >10 y	<60 bpm	>120 bpm	<90 mm Hg

Abbreviation: bpm, beats per minute.

Presence and quality of pulses should be checked. Weak, thready, or absent peripheral pulses are indicative of shock. However, in warm septic shock, pulses may be bounding. Skin color, moisture, and temperature give valuable clues to diagnosis. Children in shock may have pale, cyanotic, or mottled skin. Early in shock, however, skin color may be normal. Some infants may also have mottled skin normally. As with tachycardia, isolated signs must be correlated with the bigger clinical picture to diagnose shock. Decreased perfusion in shock leads to cool and clammy skin. This is often best appreciated in the hands and feet initially.

Capillary refill is tested by compressing the capillary bed of a fingertip, palm, or dorsal foot with gentle pressure until it blanches. On release, color should return in 2 seconds or less; a capillary refill time of 3 seconds or more is abnormal and indicative of shock. Children in warm septic shock may display “flash” (ie, shortened) capillary refill

time. Capillary refill should be tested with the extremity elevated above the heart so that arterial, not venous, perfusion is tested. Also, cool ambient temperatures can falsely delay capillary refill times.

In hypovolemic shock due to dehydration, look for signs of dehydration such as dry mucous membranes, lack of tears, sunken eyes, sunken anterior fontanelle in infants, and tenting of the skin. The degree of dehydration can often be estimated clinically (see Chapter 66). Patients with hemorrhage, traumatic or non-traumatic, must be examined thoroughly to locate the source of hemorrhage.

Children with congestive heart failure and cardiogenic shock may demonstrate dyspnea on exertion, tachypnea, orthopnea, rales, hepatomegaly, gallop rhythm, and a heart murmur. Jugular venous distention and peripheral edema are appreciated less often in children compared with adults. Other signs may include a cardiac murmur, hepatomegaly, cardiomegaly on chest radiograph, and a differential in pulses or blood pressure between upper and lower extremities.

Ductal-dependent cardiogenic shock should be suspected in the infant in the first few weeks of life presenting with severe cyanosis unresponsive to oxygen therapy and shock. Cardiac tamponade is suspected when there are muffled or decreased heart tones, pulsus paradoxus (decrease in systolic blood pressure >10 mm Hg during inspiration), and distended neck veins. Tension pneumothorax is suspected in patients with deviated trachea (away from the affected side), decreased breath sounds and hyperresonance to percussion on the affected side, and distended neck veins. Pulmonary embolism is rare in pediatric patients, and signs are subtle. It is mainly suspected when there are predisposing factors.

Approximately 20% of children present with the classic adult form of warm septic shock—including increased cardiac output, hypotension, decreased systemic vascular resistance, warm non-mottled skin, bounding pulses, and flash capillary refill. Children are more likely (60%) to present with cold septic shock—including decreased cardiac output; increased systemic vascular resistance; normal blood pressure to hypotension; cool, clammy, or mottled skin; thready pulses; and delayed capillary refill. The remaining 20% of children with septic shock present with both decreased cardiac output and decreased systemic vascular resistance. Petechiae or purpura point toward meningococemia as the etiology of septic shock. A sunburn-like rash may be seen in toxic shock syndrome due to streptococcus or staphylococcus.

Laboratory Tests

The suspected cause of the shock will determine which laboratory tests are performed. In hypovolemic shock secondary to dehydration, a chemistry panel should be obtained for electrolyte abnormalities and acidosis. Serial hematocrit determinations and a type and crossmatch are important studies in traumatic and non-traumatic hemorrhage, either known or suspected. In septic shock, a complete blood cell count and blood cultures should be obtained, as well as cultures of other potential sources of infection (urine, cerebrospinal fluid, wound, indwelling venous access line, etc). Coagulation studies including panels to evaluate for disseminated intravascular

coagulopathy, and electrolyte studies including calcium and magnesium levels, are frequently abnormal in sepsis. Hypoglycemia is a common finding in any type of shock, and a rapid bedside glucose determination should be performed. Arterial blood gases can demonstrate adequacy of oxygenation and degree of acidosis, and are necessary to diagnose elevated carboxyhemoglobin and methemoglobin levels. Initial lactate levels, particularly for septic shock and trauma patients, may be correlated with overall prognosis, and can be followed serially to chart progress. Troponins may be useful in determining severity of disease and following patients with cardiogenic shock. D-dimer is useful in patients with suspected pulmonary embolism.

Other Studies

Chest radiography, electrocardiogram, and echocardiogram may be obtained in cardiogenic or ductal-dependent obstructive shock to further elucidate the specific etiology. Workup of stabilized trauma patients may include bedside ultrasound, radiographs, or computed tomography scans. Imaging studies contribute to the diagnoses of cardiac tamponade, tension pneumothorax, and pulmonary embolism. Invasive monitoring with arterial lines for systemic arterial blood pressure and central venous lines for central venous pressure or pulmonary artery wedge pressure may be helpful in the ongoing management of shock, particularly fluid-resistant shock.

Management

The first management priority in the treatment of any critically ill child is attention to airway patency and ventilation. If there is significant respiratory compromise, bag-mask ventilation followed by endotracheal intubation is performed. Usually, however, patients in compensated shock do not require immediate attention to airway management. Instead, the immediate priorities are administration of **oxygen** and initiation of **cardiorespiratory monitoring**. Elective, rather than emergent, endotracheal intubation should be considered to reduce metabolic demands caused by increased work of breathing. When intubating patients in shock, induction agents without hemodynamic effects are preferred instead of opiates or benzodiazepines, for example, ketamine and etomidate (although etomidate is not recommended in septic shock due to its effect of cortisol suppression).

Almost concurrently with the above, the next priority is achieving **intravascular access** and, in most cases, administering fluids. Peripheral IV access should be attempted. If this is unsuccessful after 3 attempts or 90 seconds, an intraosseous line may be placed, or IV access may be obtained by placement of a central venous catheter or by cutdown technique. Intraosseous line has been demonstrated to provide much more rapid vascular access compared to central line placement. Umbilical venous lines can sometimes be placed in neonates within the first 1 to 2 weeks of life. More than one intravascular line is usually needed for managing patients in shock.

Decreased preload and hypovolemia (actual or relative) are present in the most common causes of shock. Only cardiogenic shock may not benefit from increasing preload via a fluid bolus. Generally,

an **initial fluid bolus of 20 mL/kg isotonic crystalloid fluid**, such as normal saline or lactated Ringer's, should be rapidly infused (this may require manually pushing the fluid using a large syringe). The patient should be assessed for improvement in mentation, vital signs, peripheral pulses, and skin signs after each fluid bolus. **Repeat fluid boluses** of 20 mL/kg to a total of 80 mL/kg or more may be necessary to restore intravascular volume. Colloid fluid (eg, albumin) theoretically has the advantage of staying intravascular longer, but this has not been proved to result in a measurable benefit. Crystalloid fluid is recommended for initial boluses because it is less expensive and more readily available. If a patient with traumatic hemorrhage is still hemodynamically unstable after 2 crystalloid fluid boluses, packed red blood cells at 10 mL/kg may be required. Patients should be reassessed after *each* bolus prior to ordering another bolus. Development of hepatomegaly or rales may indicate fluid overload, and the need to begin other therapies such as vasoactive infusions. This is particularly true for cardiogenic and septic shock.

The mnemonic SHOCKED may be used to recall overall management (Table 61-3). Further management in addition to fluids depends on the specific etiology. Patients in septic shock should receive empiric broad-spectrum antibiotic coverage within the first hour after presentation. A surgeon must assist in identifying the source of hemorrhage and controlling the bleeding in patients with traumatic hemorrhage, and may be required for non-traumatic hemorrhage as well depending on the specific etiology. Blood transfusions may be required. Spinal cord injury is treated with supportive care in consultation with a neurosurgeon. Anaphylactic shock is treated with IV epinephrine, IV diphenhydramine, antihistamine H₂ receptor blockers, glucocorticoids, and nebulized albuterol. Pericardial tamponade is relieved by pericardiocentesis, tension pneumothorax by needle thoracostomy and/or tube thoracostomy, and pulmonary embolus with supportive care and thrombolytics. Carbon monoxide poisoning is treated with 100% oxygen and, if severe, hyperbaric oxygen therapy. Patients with methemoglobinemia appear cyanotic even while receiving 100% oxygen and may be treated with methylene blue. Supraventricular tachycardia should be treated with adenosine if the patient is hemodynamically stable and with synchronized cardioversion if the patient is unstable. Ductal-dependent obstructive shock should be treated with prostaglandin E1 (PGE1) infusion.

Patients with cardiogenic shock require **inotropic agents** to increase cardiac contractility and improve tissue perfusion. Patients in the later stages of other forms of shock (hypovolemic, distributive, septic) may also suffer cardiac dysfunction. In such patients, only after adequate fluid resuscitation has been performed and there are still signs of shock or hypotension should inotropic agents be started. Central venous pressure monitoring may be needed to determine whether fluid resuscitation is adequate. Patients with septic shock may require **vasoactive agents** to reduce or increase systemic vascular resistance.

Dopamine or epinephrine is often the first-line inotropic agent. At low doses (2–5 µg/kg/min), dopamine improves renal blood flow and enhances urine output. At mid-range doses

Table 61-3. SHOCKED Mnemonic for Management

S	Sound the alarm: Obtain help from consultants, intensivists, ancillary personnel. Move the patient to a monitored room, and place on cardiorespiratory monitor, automated blood pressure measurement, and pulse oximetry.
H	Help hypovolemia: Get intravascular access and start 20 cc/kg crystalloid fluid bolus. Reassess after each bolus, and continue giving boluses unless hepatomegaly or rales develop. Patients may require 80 cc/kg of fluids or more.
O	Optimize oxygenation: Give supplemental oxygen regardless of pulse oximetry values. Consider elective intubation and artificial ventilation to reduce metabolic demands as indicated. Transfusion may be required if hemoglobin is low (<8–10 g/dL).
C	Constrict and contract: Use inotropic and vasoconstricting agents as needed for fluid-refractory shock.
K	Keep in mind underlying causes: Give or apply therapies specific to the underlying cause.
E	Electrolytes and glucose normalized: Measure and normalize electrolytes (especially calcium) and glucose.
D	Decrease metabolic demand: Treat hyperthermia and pain to reduce metabolic demand on the patient. Consider elective intubation. Keep patient NPO.

(5–10 µg/kg/min), dopamine exerts primarily a b-adrenergic effect, improving contractility and increasing heart rate. At higher doses (10–20 µg/kg/min), dopamine's a-adrenergic effects cause peripheral vasoconstriction to improve hypotension. **Epinephrine** has predominantly β-adrenergic effects at lower doses (0.05–0.1 µg/kg/min) and α-adrenergic effects at higher doses (up to 1.0 µg/kg/min). Because epinephrine is a strong inotrope, it is recommended for dopamine-resistant cold septic shock. **Norepinephrine** (0.01–1.0 µg/kg/min) has predominantly α-adrenergic vasoconstricting effects, and is therefore preferred for warm septic shock with low systemic vascular resistance and for distributive shock states (anaphylaxis, neurogenic shock, certain toxin-induced shock states). **Dobutamine** (1–20 µg/kg/min) may be the most useful drug for cardiogenic shock because it is selective for β-adrenergic effects, increasing cardiac contractility. However, if hypotension is present, dobutamine-mediated peripheral vasodilation may be detrimental. Dobutamine is typically used in a range of 10 to 20 µg/kg/min. Combinations of inotropic agents may be beneficial to maximize improvements in cardiac contractility and cardiac output without compromising renal perfusion or worsening hypotension. Both dopamine and dobutamine may be less effective in children younger than 6 to 12 months. For this reason, some centers recommend epinephrine as the first-line inotropic agent.

Patients in cardiogenic shock or cold septic shock may also benefit from afterload reduction using systemic vasodilators such as **nitroprusside** (0.5–5 µg/kg/min). If these are used, blood pressure should be continuously monitored, typically in the setting of the intensive

care unit. Cold septic shock refractory to epinephrine may also be treated with type III phosphodiesterase inhibitors (**amrinone** 1–20 µg/kg/min, **milrinone** 0.25–1.0 µg/kg/min), which exert inotropic and vasodilator actions. Typically, a pediatric intensive care specialist should be involved in the care of the patient, and central venous pressure monitoring should be begun before vasodilator agents are started.

Neonates with ductal-dependent lesions present with a sudden onset of shock and cyanosis in the second half of the first week of life. Common lesions include hypoplastic left heart syndrome, aortic coarctation, and tricuspid atresia. **Prostaglandin E₁** (0.1 µg/kg/min, titrated to effect), which acts to keep the ductus arteriosus open, should be immediately infused if a ductal-dependent lesion is suspected as the cause of shock. Apnea may result from PGE₁ therapy, and attention to airway management is key.

It used to be common to mix vasoactive infusions using the **rule of 6 and 0.6**. For dopamine, dobutamine, and nitroprusside, mix 6 µg/kg of drug with enough dextrose 5% in water (D5W) to produce a final volume of 100 mL. Infusion at 1 mL/hour provides a dose of 1 µg/kg/min. For epinephrine, norepinephrine, and PGE₁, mix 0.6 µg/kg of drug with enough D5W to produce a final volume of 100 mL. Infusion of 1 mL/hour provides a dose of 0.1 µg/kg/min. However, calculations such as these are error prone, and computerized order forms with automatic error alerts, or “smart” pumps that automatically calculate doses based on the patient’s inputted weight, are better choices.

Treatment of patients in shock must include attention to conditions that increase metabolic demand. Acidosis should be assessed and, if severe, treatment with bicarbonate may be considered, although such therapy is controversial. Temperature should be kept neutral with use of antipyretics and cooling measures as needed. Electrolyte abnormalities, particularly hypocalcemia, and hypoglycemia must be assessed and corrected. If a hypothyroid state is suspected, thyroid hormone replacement therapy is important. Blood products may be required for patients with septic shock and disseminated intravascular coagulation. Packed red blood cells, 10 cc/kg at a time, should be given to maintain hemoglobin of at least 10 g/dL. Fresh frozen plasma may be given to correct abnormalities in prothrombin and partial thromboplastin times, but should not be pushed due to its propensity to cause further hypotension. Cryoprecipitate should be reserved for documented hypofibrinogenic states.

An expert panel from the American College of Critical Care Medicine created **clinical practice parameters for the treatment of pediatric septic shock**. Recommended therapy is divided between therapies for the first hour (the “golden hour”) and therapies beyond the first hour (often with critical care specialists involved). In the first 15 minutes after recognition of septic shock, practitioners should attend to the airway and establish intravascular access, begin fluid boluses in 20 cc/kg increments, and diagnose and correct any hypoglycemia and hypocalcemia. The goal of therapy is normalization of heart rate, blood pressure, and capillary refill; cardiac index more

than 3.3 and less than 6.0 L/min/m²; and superior vena cava (SVC) oxygen saturation (O₂ sat) 70% or higher. Patients who are responsive to fluid may be observed in the pediatric intensive care unit. Dopamine therapy should be started for those who are still hypotensive after fluid resuscitation. Once dopamine therapy is titrated up to 20 µg/kg/min, epinephrine should be added for dopamine-resistant cold septic shock, while norepinephrine should be added for dopamine-resistant warm septic shock. The updated guidelines emphasize that inotropic therapy should not be withheld because there is no central line, and can be given peripherally if there are no other options. Two studies of patients transferred into a tertiary pediatric medical center showed significantly reduced mortality and morbidity for patients cared for by community practitioners who followed the above guidelines for the first hour of care.

Corticosteroids are controversial in the treatment of sepsis. Guidelines suggest administering “stress doses” of hydrocortisone 2 mg/kg or 50 mg/m² body surface area beyond the first hour of therapy for catecholamine-resistant septic shock when adrenal insufficiency is suspected. Adrenal insufficiency may be suspected in patients with a history of a central nervous system abnormality or pituitary abnormality, a known adrenal gland disorder, recent surgery, history of chronic steroid therapy (eg, for asthma, inflammatory bowel disease, or a rheumatologic condition), and in purpura fulminans. “Shock doses” of hydrocortisone (50 mg/kg) may be given in catecholamine-resistant fulminant septic shock and dopamine-resistant purpura fulminans. It is suggested that a baseline cortisol level be drawn prior to giving corticosteroids.

Following the first hour of therapy, a vasodilator (nitroprusside) or type III phosphodiesterase inhibitor (amrinone or milrinone) along with further volume loading may be helpful in catecholamine-resistant cold septic shock with normal blood pressure and SVC O₂ sat less than 70%. In cases of “cold” septic shock with low blood pressure and SVC O₂ sat less than 70%, continued titration of epinephrine and volume is recommended. For “warm” septic shock, continued titration of norepinephrine and volume is recommended, with the possible addition of vasopressin (0.0003–0.0008 U/kg/min). Vasopressin has not been well studied in children, but shows promise in adults. Finally, for persistent catecholamine-resistant septic shock, consideration may be given to extracorporeal membrane oxygenation. Recombinant activated protein C (drotrecogin alfa) is recommended for some septic adult patients, but not for pediatric patients.

Prevention

Improving outcomes focuses primarily on early recognition and early appropriate therapy of shock. Carcillo et al showed significantly reduced morbidity and mortality in shock patients transferred to a tertiary pediatric medical center if community hospital physicians recognized shock and used pediatric advanced life support (PALS)–recommended interventions early. Appropriate PALS–recommended therapy was defined as more than 20 mL/kg of fluids (except in those with cardiac conditions) and use of inotropes in fluid-refractory shock. Unfortunately, while 37% of the patients transferred during

the study period were in shock, as defined by prolonged capillary refill time or hypotension, only 7% were identified as in shock during the referral process. **Early recognition of compensated shock** is a key preventive measure to reduce mortality. In the study, of those in shock only 36% received appropriate PALS-recommended therapy prior to transfer. Community practitioners must concentrate on obtaining vascular access (with an intraosseous needle if necessary), giving fluid boluses early, and starting inotropes (through a peripheral intravenous line if necessary) for fluid-refractory shock within the first hour. **Early therapy**, often before the patient reaches a tertiary care center, is also a key preventive measure. Rapid response teams are increasingly being used in hospitals to institute appropriate medical therapy for inpatients with concerning symptoms or vital signs. At a minimum, community pediatricians should have the ability to obtain intravascular or intraosseous access and administer rapid fluid boluses in their offices.

Prognosis

Children in shock are critically ill and at risk for progression to multi-organ failure and death. Prognosis depends on how early shock is recognized and treated, and on the underlying etiology. Pediatric septic shock carries a 9% mortality rate, which is significantly improved from 60% in the 1980s and 97% in the 1960s, and is also lower than the adult septic shock mortality rate. Mortality rates are even lower (6% in one study) with prompt recognition and adequate treatment.

CASE RESOLUTION

The boy in the case history is in barely compensated (he is not hypotensive) hypovolemic shock due to diarrhea, vomiting, and dehydration. He should receive oxygen and cardiorespiratory monitoring, and intravenous access should be rapidly established. Isotonic fluid boluses of 20 mL/kg should be given with reassessment between each bolus. As much as 80 mL/kg may be needed before improvements in mentation, vital signs, pulses, and skin signs are seen.

Approach to the Traumatized Child

David B. Burbulys, MD

CASE STUDY

A 6-year-old boy is brought to the emergency department after being struck by an automobile while crossing the street. He was found unconscious at the scene. Initial evaluation shows that he has an altered level of consciousness; shallow respirations; ecchymosis across the upper abdomen; and a deformed, swollen left thigh. The pediatric emergency physician is called in to discuss an initial assessment and management plan for the injured child with the trauma surgeon.

Questions

1. What are the most common mechanisms of injury responsible for trauma in children?
2. What are some of the physiological differences between adults and children that make children more susceptible to certain types of injuries?
3. Which areas of the body are most likely to be injured in a typical automobile versus pedestrian collision?
4. What are the components of a primary survey in pediatric trauma patients?
5. What radiographic and laboratory studies should be performed in children with multiple injuries?

Trauma is often referred to as the neglected disease of modern society. Childhood trauma, in particular, is poorly understood and studied. Death from trauma is higher in pediatric patients than in adult patients. Mechanisms of injury may be similar in adults and children, but children have particular anatomical differences and physiological responses to injury. Health care professionals should realize that children have unique anatomical and physiological features compared with adults (Box 62-1). Evaluation and management of traumatized children requires specialized knowledge, training, and equipment. Recognition of such facts, coupled with expertise in the performance of emergency procedures, should improve the outcome of children who sustain major injuries.

Epidemiology

More than 64% of the deaths of children aged 1 to 14 years are caused by traumatic injuries. This number peaks at 8 years of age. Approximately 1.5 million pediatric injuries result in a quarter million to half million hospitalizations, and 15,000 to 25,000 deaths (1.5%) each year. Adolescents are most likely to die in motor vehicle crashes and school-aged children are most likely to die after being struck by automobiles. This figure, unfortunately, may be an underestimation, as most childhood injury fatalities occur in the field prior to arrival at a health care facility. The magnitude of the problem becomes even more evident when morbidity is considered.

Box 62-1. Characteristics of Children That Lead to Increased Susceptibility to Injury

Anatomical Characteristics

- Smaller body size allows for the greater distribution of force with trauma, so multiple system injury is common.
- A prominent occiput, exaggerated head-to-body ratio, weak neck muscles, and higher center of gravity predispose younger children to head injury.
- Cranial bones are thinner and the brain is less myelinated, resulting in more serious head injury.
- Skeletal and ligamentous structures have increased flexibility, which results in greater transmission of force to internal organs.
- Less protective muscle and subcutaneous tissue over internal organs expose them to injury.
- Growth plates are not yet fused, which leads to Salter-type fractures and possible bone growth abnormalities with healing.

Physiological Characteristics

- High body surface area-to-weight ratio predisposes children to hypothermia, which may complicate shock and worsen acidosis and coagulopathy if it is not corrected.
- Hypoxia and respiratory failure are increasingly likely in children.
- Hemorrhagic shock is initially well tolerated by increasing heart rate and peripheral vascular resistance without significant changes in systolic blood pressure.

Between 50,000 and 100,000 children per year become permanently disabled as a result of their injuries. Such disabilities have an enormous impact on society; they result in financial and emotional losses for families and many years of lost productivity for individuals.

Blunt trauma, which is more common than penetrating injury in children, represents about 87% of all childhood injuries. Head injuries, followed by thoracoabdominal injuries, are the leading causes of death in this group. In adolescents, however, penetrating injury (suicide and homicide) accounts for a higher percentage of the total, especially among minority populations in urban areas. Causes of non-penetrating trauma are motor vehicle crashes (>40%), falls (25%–30%), drowning (10%–15%), and burns (5%–10%). Included in the remainder are bicycle-related and automobile versus pedestrian injuries. These numbers vary somewhat by locale. Male children are injured twice as often as female children. Different mechanisms of injury predominate in different age groups; the figures given above refer to overall causes of trauma. Perhaps as much as 25% to 35% of trauma deaths are related to child abuse in some centers.

Clinical Presentation

Children who sustain severe trauma present with multiple organ system injury manifested by shock, respiratory failure, or altered mental status (singly or in combination). Those with mild to moderate injury may present in this way or simply with localized signs and symptoms in the injured area.

Pathophysiology

Patterns of injury are important to identify to develop strategies for injury prevention as well as anticipate injuries during patient management. One common pattern is the triad of injuries that result from an automobile versus pedestrian collision (Waddell triad) (Figure 62-1).

Multisystem injury is the rule rather than the exception in children. Internal injury must always be suspected, even if no evidence suggestive of external trauma is apparent when the mechanism of injury warrants. Because children are anatomically and physiologically different from adults, they are more susceptible to different types of injuries (Box 62-1). The most striking physiological differences between adults and children concern responses to acute blood loss. Children have a tremendous capacity to maintain systolic blood pressure despite 25% to 30% acute blood loss.

Hypovolemic shock secondary to acute blood loss is the most common cause of shock in pediatric trauma patients. In general, hemorrhagic shock is a clinical state where the cardiac output is unable to meet the metabolic demands of the tissues for oxygen and nutrients; it is not defined by any absolute blood pressure value.

Acute blood loss stimulates peripheral and central receptors and results in an increased production of catecholamines and adrenocorticoids. The body responds by increasing peripheral vascular resistance, stroke volume, and heart rate. Children are able to dramatically increase heart rate and peripheral vascular resistance and

Figure 62-1. Illustration of Waddell triad. Femur, abdominal, and contralateral head injuries (Waddell triad) should be expected to result from automobile versus pedestrian collisions in the United States. A child crossing the street is struck on the left side of the body by an automobile traveling on the right side of the road. The left femur is likely to be injured by the bumper, and the abdomen or chest strikes the grille as the child is lifted into the air and lands on the opposite side of the head, sustaining blunt head trauma. The Waddell triad illustrates the necessity of having a high degree of suspicion for a complex of injuries based on a well-known mechanism.

they often may exhibit normal blood pressure in the presence of hypovolemic shock. By the time their blood pressure falls, they commonly have lost 20% to 25% of their circulating blood volume. In adults, blood pressure tends to decline after a less significant blood loss and therefore may be recognized sooner (Figure 62-2). Subtle changes in heart rate, blood pressure, pulse pressure, and capillary refill may indicate impending cardiovascular collapse in traumatically injured children and should not be overlooked.

Another obstacle to the recognition of shock in children is the lack of knowledge on the part of many health professionals of age-appropriate vital signs, particularly blood pressure. Table 62-1 gives the normal blood pressure ranges for children of different ages.

Three stages of shock correspond to the progression of volume loss. In the first stage, **compensated shock**, mechanisms for preserving blood pressure are still effective. Decreased capillary refill, diminished pulses, cool extremities, and tachypnea may be apparent, but blood pressure is normal and accompanied by tachycardia. Unrecognized, untreated compensated shock rapidly progresses to **uncompensated shock**. Examination reveals decreased level of consciousness, pallor, reduced urine output, and lower blood pressure with weak, thready pulses and marked tachycardia. With inadequate therapy, uncompensated shock becomes **irreversible shock**, resulting in irreparable organ damage and often unpreventable death. (See Chapter 61 for a more extensive discussion.)

Figure 62-2. Graph showing cardiovascular response to hypovolemia in children. Blood pressure does not begin to decline until the volume deficit is more than 25% because of the compensatory increase in vascular resistance. Cardiac output drops earlier and is manifested clinically as delayed capillary refill; cool, clammy skin; and tachycardia.

Shock has several causes, and it is important to emphasize that, in trauma patients, it should always be initially attributed to hemorrhage. Shock due to obstructive cardiac output causes, such as tension pneumothorax or cardiac tamponade, are much less common. Shock due to spinal cord injury is exceedingly rare. Shock should never be attributed solely to head trauma. The pathways resulting in decreased blood pressure in patients with head trauma are present only at the terminal stages. Therefore, the possibility of blood loss from internal organs should be pursued promptly.

Evaluation and Management

Because of the high potential for serious morbidity and mortality in trauma patients, evaluation and management are performed simultaneously. This care is best handled using an organized, multidisciplinary team approach, with preestablished criteria for activation of the trauma team. History of the event provides important information when implementing these criteria. For example, the entire team responds for all pedestrians struck by an automobile. The types of subspecialists that make up a trauma team are decided by individual institutions.*

Several approaches to the assessment of trauma patients have been developed by professional organizations. The Advanced Trauma Life Support (ATLS) course of the American College of Surgeons and the Basic Trauma Life Support (BTLS) course of the American College of Emergency Physicians (now renamed International Trauma Life Support) are 2 such approaches. Both the ATLS and the BTLS methods stress the importance of a primary evaluation, or primary survey, to identify and treat immediate life-threatening injuries and a more detailed regional examination, or secondary

* Most institutions have trauma teams composed of pediatric emergency and critical care specialists, anesthesiologists, trauma surgeons, surgical subspecialists, emergency nurses, respiratory therapists, social workers, and radiograph technicians.

Table 62-1. Normal Vital Signs for Children of Different Ages

Age	Respiration (breaths/min)	Pulse (beats/min)	Blood Pressure (Systolic)
Newborn	30–60	100–160	50–70
1–6 wk	30–60	100–160	70–95
6 mo	25–40	90–120	80–100
1 y	20–40	90–120	80–100
3 y	20–30	80–120	80–110
6 y	12–25	70–110	80–110
10 y	12–20	60–90	90–120

survey, after stabilization to identify and treat all other injuries. In addition, they both adhere to the principles of serial examination and reassessment after each intervention. The primary survey and initial resuscitation efforts must occur simultaneously and within the first several minutes of the evaluation. The secondary survey is meant to enhance the primary survey. Vital signs should be repeated every 5 minutes during the primary survey and every 15 minutes during the secondary survey until the trauma team feels the patient has been adequately stabilized. The reader should understand the rationale for the trauma examination and its parts. (See Selected References for articles that explain the rationale for trauma examination and provide detailed descriptions of evaluation and management techniques.)

Physical Examination

The **primary survey** begins with an assessment of **level of consciousness**, patency of the **airway** (Box 62-2), and quality of **breathing** (Box 62-3). When evaluating injured patients, physicians should always assume that the cervical spine has been injured and should use in-line immobilization to secure it. Basic airway maneuvers for positioning should be performed. The safest method is the jaw thrust to avoid moving the cervical spine (Figure 62-3). The oral cavity should be examined for foreign bodies, blood, or secretions. The most common form of airway obstruction in children is a posteriorly displaced tongue, which is relieved by good airway positioning. Advanced airway maneuvers (bag-valve-mask ventilation

Box 62-2. Airway Assessment and Treatment

Assessment

- Airway patency and ability to protect it
- Level of consciousness
- Stridor

Treatment

- Spinal immobilization
- Jaw thrust and suctioning
- 100% oxygen by non-rebreathing mask
- Intubate for Glasgow Coma Scale score <9, no gag reflex

Box 62-3. Breathing Assessment and Treatment**Assessment**

- Respiratory rate and depth
- Chest wall compliance, symmetry, and movement
- Tracheal deviation

Treatment

- 100% oxygen by non-rebreathing mask
- Intubate for respiratory failure, severe flail chest
- Compress obvious bleeding sites
- Seal open pneumothorax with occlusive dressing
- Needle decompress tension pneumothorax
- Place chest tube for pneumothorax or hemothorax

Box 62-4. Circulation Assessment and Treatment**Assessment**

- Identify obvious bleeding sites
- Peripheral pulses and capillary refill
- Heart rate
- Level of consciousness

Treatment

- Compress obvious bleeding sites
- 100% oxygen by non-rebreathing mask
- 2 large-bore intravenous lines
- Fluid resuscitation; 20 mL/kg normal saline
- Packed red blood cells; 10 mL/kg after 60 mL/kg normal saline and still in shock

Figure 62-3. Correct method for positioning the head with chin lift or jaw thrust.

or endotracheal tube intubation) are performed during the primary survey if children have apnea, significant respiratory distress, severe head trauma, or an airway that cannot be maintained with basic techniques. All trauma patients are initially given supplemental oxygen by non-rebreathing mask at a concentration of 100% and the adequacy of ventilation is assessed by a general evaluation of the respiratory rate, depth, chest movement and symmetry, and tracheal deviation.

After a patent airway and adequate ventilation have been established, **circulatory status** is assessed. All pediatric trauma patients require placement of the largest bore intravenous catheter obtainable for that patient; these should be placed, if possible, in each antecubital fossa. In life-threatening situations, peripheral vascular access is attempted either 3 times or for 90 seconds, whichever comes first. If peripheral attempts fail, then intraosseous infusion or central venous access should be used. A bolus of 20 mL/kg of an isotonic fluid (normal saline or Ringer's lactate) should be given. This may be repeated,

if necessary, to treat hypovolemic shock. After 60 mL/kg, administration of 10 mL/kg of blood should be considered, and the likelihood of surgical exploration is high. Acutely exsanguinating wounds are treated using direct pressure bandages (Box 62-4).

A brief neurologic assessment to assess patient **disability** is also performed during the primary survey. One rapid assessment technique is the **AVPU** system (**A**, alert; **V**, responds to verbal stimuli; **P**, responds to painful stimuli; and **U**, unresponsive). Subsequently, a Glasgow Coma Scale score or Children's Coma Scale score should be calculated (Box 62-5).

Once life-threatening conditions are stabilized, more information can be collected. The **secondary survey** involves a complete and thorough head-to-toe examination of the child, fully exposed, to identify additional injuries, while taking great care to maintain normothermia. It also includes a **SAMPLE** history (symptoms, allergies, medications, past history/ hospitalizations/surgeries, last meal, events preceding trauma). A detailed history of events preceding trauma should ensure that injuries are consistent with the causal mechanism. Health care professionals should be prepared to consider abuse when specific diagnoses do not correlate with either the history given by the caregiver or the developmental ability of the child. Measurement of vital signs should occur as previously described and other devices, such as Foley catheters, nasogastric tubes, and pulse oximetry, should be used at this time. Every time an intervention is performed, repeat assessments that incorporate the elements of the primary survey are made.

Laboratory Tests

Most institutions have a standardized trauma panel (complete blood cell count with differential, electrolytes, blood urea nitrogen, creatinine, glucose, amylase, lipase, prothrombin time, partial thromboplastin time, urine analysis, and blood typing and crossmatching). In addition, drug and alcohol screens may provide important information, particularly in the child with altered mental status. Female children of potential childbearing age should have a point of care pregnancy test performed as well.

- 9–13 Moderate
- <9 Severe

^a Younger than 1 year.

Imaging Studies

When major trauma is suspected, radiographs of at least the chest, pelvis/abdomen, and cervical spine should be obtained. This prevents missing injuries in children who may be unconscious or who need lifesaving procedures during resuscitation, which obscure an area of injury from examination. Additional radiographs, for example, of the extremities, may be indicated when other areas of injury are detected on secondary survey. Children are often initially distracted from one injury because of the presence of a more painful one.

More sophisticated imaging techniques, such as computed tomography scans and ultrasound, are a usual part of the evaluation of the seriously injured pediatric trauma patient. The choice of test depends on the experience of the trauma team and the individual characteristics of the patient.

Prognosis

The highest survival rates for seriously injured children have been found among those who are brought to the operating room for treatment within 1 hour of the injury. Definitive care for trauma takes place in the operating room, and initial stabilization takes place in the emergency department. Absolute indications for surgery include hemodynamic instability despite aggressive resuscitation, transfusion of more than 50% of the total blood volume, pneumoperitoneum, intraperitoneal bladder rupture, severe renovascular injury,

gunshot wounds to the abdomen, evisceration, and peritonitis. Other injuries, often in contradistinction to similarly injured adult patients, are frequently treated more conservatively in the intensive care unit after complete consultation with all involved providers.

An organized, preestablished, multidisciplinary approach to care is essential. Studies have shown that the single most important element for any hospital treating injured children is the commitment on the part of the institution and its surgeons. Regional pediatric trauma centers have increased resources for dealing with severely injured patients that include long-term care and rehabilitation. Other non-designated hospitals may do an excellent job in the initial stabilization phase of care. Indications for transfer to a specialty center include inability to provide definitive surgical intervention, inability to provide an appropriate intensive care environment, the presence of multisystem injuries or injuries requiring extensive orthopedic or plastic surgery procedures, or major burns. Health care professionals who treat children should not only become adept at the recognition and initial stabilization of injuries, but should also serve as advocates for injury prevention and coordinated prehospital care services in the community.

CASE RESOLUTION

The 6-year-old boy in the case history sustained multiple trauma from an automobile versus pedestrian collision. He presents with altered level of consciousness; respiratory failure (shallow respirations); potential internal organ injury, which may lead to shock; and probable fracture of the left femur, which may also contribute to the development of shock. These injuries are identified by performance of a primary and secondary survey. Proper management includes stabilization of the cervical spine, airway management, aggressive early shock treatment with fluid replacement, and a vigilant search for additional injuries. Continued reassessment is also an integral part of emergency department stabilization. Due to the presence of multisystem injuries, after initial stabilization, the patient should be transferred to a regional pediatric trauma center for extended care.

Abdominal Trauma

David B. Burbulys, MD

CASE STUDY

An 8-year-old boy who rode a bicycle quickly and unintentionally crashed into a tree is transported to the pediatric emergency department by emergency medical services. On arrival at the trauma center, the paramedics report that the bike handlebars struck the child's stomach, "knocking the wind out of him." The boy complains of dizziness and vomits several times. Initial vital signs show a heart rate of 135 beats/min and a respiratory rate of 24 breaths/min. The abdomen is flat but tender to palpation in the mid-epigastric region and left upper quadrant.

Questions

1. What are the most frequent types of intra-abdominal trauma in children?
2. What are the diagnostic studies used to evaluate abdominal trauma?
3. What are the basic components of the treatment of shock that occurs following abdominal trauma?
4. What is a simple rule for establishing the lower limit of normal blood pressure in children?

Abdominal trauma is the leading preventable cause of fatal injury in trauma patients. Death results when the extent and nature of abdominal injuries are neither appreciated nor appropriately managed, fluid replacement is inadequate, and airway maintenance and surgical intervention are not implemented soon enough. Abdominal trauma is the third leading cause of traumatic death, following head and thoracic injury. Clinicians should be knowledgeable about mechanisms of injury that result in abdominal trauma, the early manifestations of shock, and the methods for aggressive treatment of hemorrhagic shock.

Epidemiology

Twenty-five percent of children who sustain multisystem trauma have significant abdominal injury and 9% die from abdominal-associated trauma. When both head and abdominal injury occur simultaneously, the risk of death is higher than when either occurs alone. Blunt-force mechanisms are responsible for almost 85% of abdominal injuries; the remainder result from penetrating injuries. Examples of blunt-force mechanisms, presented in order of frequency, include motor vehicle crashes (also the most lethal), pedestrian versus automobile collisions, falls, bicycle injuries, sports injuries, and direct blows from both abuse and assault. Injuries to the spleen and liver predominate followed by injuries to the kidney, bowel, and pancreas. In multiple injuries, the incidence of trauma involving pelvic bones and organs (bladder, ureter, iliac vessels) is also high. A straddle injury (eg, fall that occurs when climbing over a fence) can also result in abdominal and pelvic trauma.

Clinical Presentation

Pain, tenderness, ecchymoses, and peritoneal signs tend to be more reliable signs of pathology, whereas distension or the absence of

bowel sounds are less consistent as a marker for injury. (See Dx Box for signs and symptoms suggestive of abdominal trauma.) It is particularly important to note that no sign, however, is completely reliable and that acute hemorrhage into the abdomen doesn't lead to irritation initially. Unexplained hypotension or shock mandates further investigation to assess for intra-abdominal hemorrhage.

Dx Abdominal Trauma

- Pain
- Tenderness
- Distention
- Peritoneal signs (absent or diminished bowel sounds, rebound tenderness)
- Ecchymoses
- Tire tracks
- Seat belt marks
- Urine, stool, or nasogastric aspirate positive for blood
- Unexplained hypotension or other signs of hypovolemic shock

Pathophysiology

Blunt trauma largely involves injury to solid, not hollow, intra-abdominal organs (ie, spleen and liver rather than small bowel) for a variety of reasons. First, the rib cage is flexible in children. Therefore, rib fractures are less likely to occur, reducing the potential for penetration of abdominal organs by broken ribs. Second, children have less well-developed abdominal musculature and less adipose tissue than adults and relatively larger organs. Blunt force is therefore transmitted to the solid organs more easily and more diffusely. Third, because the diaphragm is oriented more horizontally

in children than in adults, the liver and spleen lie more anteriorly and caudally within the abdomen.

It is important to emphasize that abdominal injury may lead to excessive blood loss. The pathophysiology of hemorrhagic shock is discussed in detail in chapter 61 and 62. The liver and spleen are highly vascularized organs that bleed profusely when lacerated. Even the accumulation of subcapsular hematomas without rupture may cause a profound drop in hematocrit. Because intra-abdominal organs are not directly visible when a patient is examined, signs and symptoms of injury are not always obvious. Therefore, hemorrhagic shock should always be suspected with abdominal trauma. Likewise, large volumes of blood can accumulate in the pelvis and retroperitoneum, and because of their proximity to the abdomen, they should always be considered as a reservoir for hemorrhage in abdominal as well as pelvic trauma.

Differential Diagnosis

Physicians should be familiar with the most common patterns of abdominal injury, and they should consider the possibility of specific injuries. Any solid abdominal organ can be injured by any mechanism, either blunt or penetrating. The spleen is the most common intra-abdominal organ injured by a blunt force. **Hepatic injuries** are the most common fatal abdominal injuries, although they are less frequent than **splenic injuries**. The right lobe of the liver is injured more frequently than the left lobe.

Injuries to **hollow viscera** such as the stomach and intestines, which represent only about 5% to 15% of injuries from blunt forces, are difficult to diagnose and often present late. Three mechanisms lead to injuries of hollow structures: (1) “crush” between the anterior wall of the abdomen and the vertebral column; (2) deceleration, which causes shearing of the bowel from its mesenteric attachments; and (3) “burst,” which occurs when an air-filled or fluid-filled loop of bowel is closed at both ends at the time of impact. Peritonitis may develop in 6 to 48 hours secondary to fecal spillage or devascularization as a consequence of any of these mechanisms. Occasionally, a diagnosis of hollow viscera injury is made incidentally or may be delayed more than 48 hours, highlighting the need for serial examinations. **Duodenal** and **pancreatic** injuries are examples of potentially delayed diagnoses that can have grave consequences. Leakage of bile and enzymes may activate autodigestion of the pancreas and result in sepsis.

Evaluation

Determining which organ or organs may be injured from abdominal trauma is difficult. Children are often uncooperative or unable to assist with the physical examination. Physicians tend to focus on injuries to the extremities, pelvis, face, or chest that are painful and distracting to children and more clinically obvious to the examiner. Initial clinical impressions may be incorrect, causing delay in diagnosis or unnecessary surgical exploration.

History

The history should focus on the mechanism of injury and the physiological response of the child, especially in the pre-hospital setting (eg, initial hypotension, tachycardia, cyanosis) (Questions Box). A poor history concerning the circumstances of the injury may contribute to a delayed diagnosis.

Questions

Abdominal Trauma

- How was the child injured?
- How long ago did the injury occur?
- What parts of the body were injured?
- Has the child received any treatment prior to coming to the hospital, and what was the response?

Physical Examination

An abnormal physical examination may not always be indicative of pathology. Clinicians should avoid relying on physical examination alone as a predictor of abdominal injury. Studies have demonstrated that patients with and without proven injuries often showed no significant differences with respect to physical findings. In particular, children with abusive abdominal trauma often have no cutaneous evidence of bruising, especially immediately after the injury is inflicted (see Chapter 127). Definitive evaluation of the abdomen is therefore mandated with significant mechanism of injury and often includes rapid computed tomography (CT) scan, ultrasound, diagnostic peritoneal lavage, laparoscopy, or laparotomy.

Vital signs should be monitored. In children, the range for normal heart rate, respiratory rate, and blood pressure is age-dependent. A simple rule for calculating the lower limit of normal systolic blood pressure is $70 + (2 \times \text{age in years})$. Physicians should always remember that a drop in blood pressure is a very late sign in the development of shock in children (see chapters 61 and 62).

Serial abdominal examinations increase the likelihood of detecting a previously missed condition. Inspection of the abdomen to look for ecchymoses, distention, tire tracks, penetrations, or paradoxical motion should occur first. Auscultation for bowel sounds follows this inspection, and palpation should come last. Palpation should be done in all 4 quadrants to elicit tenderness, rebound, and guarding. If a hepatic or splenic injury is initially suspected, palpation should be minimized to avoid further hemorrhaging.

Laboratory Tests

Laboratory evaluation should be guided by the history and physical examination. A urinalysis to look for hematuria and check for associated genitourinary injuries is helpful. Elevated serum transaminases, amylase, lipase, and alkaline phosphatase may be indicative of injury, but normal values do not exclude pathology. A comprehensive trauma panel, which usually includes a complete blood cell count and differential, serum electrolytes, blood urea nitrogen, creatinine,

glucose, prothrombin time, partial thromboplastin time, urinalysis, and blood type and crossmatch, should be carried out for all patients with serious or multiple injuries (see Chapter 62).

Imaging Studies

Multiple imaging modalities are available to assess the pediatric trauma patient with suspected abdominal injuries. The time to perform an imaging study is after the patient is responding appropriately to resuscitation (ie, fluid therapy). Unstable patients require surgical exploration for definitive treatment of abdominal or pelvic injury.

Computed tomography scanning remains the standard of care for imaging the injured abdomen of a pediatric trauma patient. Computed tomography scans have greater than 97% accuracy in identifying abdominal or retroperitoneal injury, are noninvasive, and most notably provide detailed specific information regarding injuries. The images are also routinely extended to include the pelvis, as necessary. Disadvantages of CT scanning may include the lack of proximity to the trauma suite, which may not be ideal for unstable patients; the length of time it takes to perform the procedure; and the need for an intravenous (IV) contrast, which has inherent risks such as allergic reactions and renal toxicity.

The use of ultrasonography has become very popular, with encouraging results for the identification of abdominal injury, though its use in pediatric trauma patients remains unclear. Ultrasound can rapidly and noninvasively document the presence of intraperitoneal and pelvic fluid (blood). While it is as effective as CT scanning for documenting the **presence of injury** it does not provide as much specific information about the **nature** of the injury. Ultrasound has a few additional advantages: It is relatively inexpensive; does not require contrast or radiation exposure; can be performed in 5 to 10 minutes in the trauma room, thus minimizing the risk to an unstable patient; and can be used many times for serial assessments.

Over the last several decades, diagnostic peritoneal lavage has been a dependable method of detecting intra-abdominal hemorrhage. However, its use may be limited in the pediatric population because many children with blunt trauma to the abdomen are now managed nonoperatively as stated above.

Management

Management of abdominal trauma in children occurs simultaneously with evaluation. The stabilization of children with abdominal trauma, especially in the context of multiple trauma, requires a multidisciplinary team approach that includes surgeons, pediatricians, and emergency physicians. A discussion on the approach to trauma management can be found in Chapter 62.

Hypovolemic shock, if present, is the primary complication of abdominal trauma on which to focus because the leading unrecognized cause of death in affected children is profound blood loss. **Airway problems** and **breathing difficulties** should be addressed initially, followed by **vascular access** and **fluid replacement**. No more than 3 attempts at peripheral vascular access should be made (≤ 90 seconds) before moving on to more invasive procedures.

The intraosseous route should be used for the next vascular access attempt. The flat, medial portion of the proximal tibia is most commonly used for the procedure, which is performed with an intraosseous, bone marrow, or spinal needle (Figure 63-1). Fluids and medications, delivered into the marrow cavity, then flow into the venous circulation. Intraosseous cannulation is rapid, simple, and may be lifesaving. It is limited by low flow rates (approximately 30 mL/min), which can be augmented either by using pressure on the IV bag or by pushing fluid by hand through a syringe. Complications associated with intraosseous line placement are rare. All physicians who care for pediatric trauma patients should be familiar with this technique.

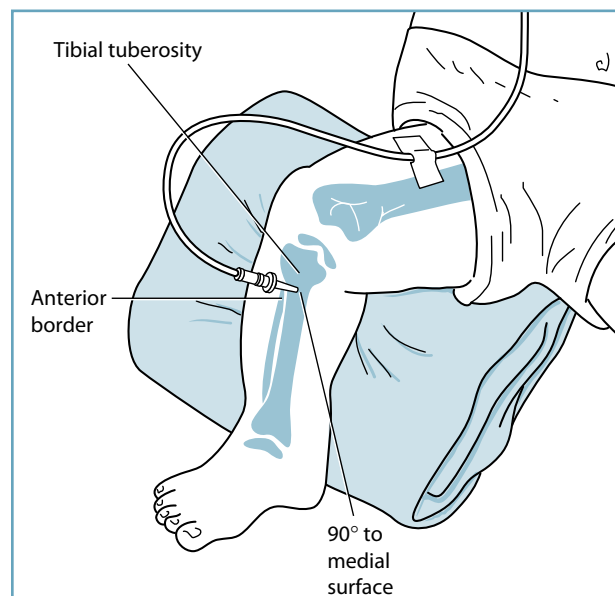

Figure 63-1. Intraosseous cannulation technique. (Adapted with permission from American Heart Association. 2005 American Heart Association [AHA] guidelines for cardiopulmonary resuscitation [CPR] and emergency cardiovascular care [ECC] of pediatric and -neonatal patients: pediatric advanced life support. *Pediatrics*. 2006;117:e1005–e1028.)

A variety of central venous access sites, such as femoral, subclavian, and internal jugular, may be used in older children. Upper and lower saphenous vein cutdowns are also possible access sites. The Seldinger technique, with insertion of a large-bore catheter over a guidewire, is often used. A description of these procedures is beyond the scope of this book but may be found in many other publications, including the 2010 American Heart Association (AHA) Guidelines for Cardiopulmonary Resuscitation (CPR) and Emergency Cardiovascular Care (ECC) of Pediatric and Neonatal Patients: Pediatric Advanced Life Support published by the American Heart Association (see Selected References). Intravenous access above the diaphragm is preferred in patients with blunt or penetrating abdominal trauma who have potential disruption of the vena cava or other large veins.

Fluid replacement begins with a 20- to 40-mL/kg bolus of crystalloid solution, either warmed normal saline or Ringer's lactate. If no improvement in circulation occurs, additional 10- to 20-mL/kg

boluses may be given, and type-specific blood should be considered. In most scenarios, type-specific blood is given after 60 mL/kg of crystalloid has failed to improve circulatory parameters. Frequent hematocrits or hemoglobins should be determined to monitor ongoing blood loss. Vital signs should be repeated frequently. Serial examinations, which detect the signs and symptoms of shock (Box 63-1), are the most important gauge of hemodynamic recovery and stability. All children require close hospital observation, preferably in a pediatric trauma center and pediatric intensive care unit.

Box 63-1. Signs and Symptoms of Hemorrhagic Shock in Children

- Tachycardia
- Delayed capillary refill (>2 s)
- Cool and mottled skin, pallor
- Respiratory distress
- Anxiety, irritability, decreased responsiveness
- Thirst

Orthostatic fall in blood pressure and supine hypotension (late sign) must be aggressively managed. If hemodynamic stabilization is not achieved after appropriate vascular access and fluid resuscitation, the trauma surgeon will most likely perform an exploratory laparotomy. If children have been stabilized with initial airway and circulatory support, diagnostic procedures such as CT scans can be performed as part of the emergency department evaluation. Once identified, specific organ injury can be managed.

Other specific management concerns for pediatric patients with abdominal injury are early decompression of the stomach with a nasogastric or orogastric tube to prevent respiratory compromise and urinary catheter insertion to decompress the bladder. Before inserting a urinary catheter, the trauma team should evaluate for possible urethral trauma and check for the presence of blood in the urine, which may indicate other genitourinary trauma.

Nonoperative management of minor to moderate liver or spleen injuries is common in children. More severe injuries, including bowel rupture, require surgical intervention.

Prognosis

Morbidity and mortality related to abdominal trauma depend on the specific organ injury and the style of management. More than 40% of patients with major liver injuries die in the prehospital setting. However, a large number of minor liver injuries can be managed

nonoperatively. Currently an increasing number of injuries to the spleen and liver are managed with observation in the pediatric intensive care unit. Surgical exploration and repair are performed only if patients become hemodynamically unstable. Reduction in anesthetic-related mortality, post-splenectomy sepsis, and a decrease in other postoperative complications have resulted from this shift in practice style. Without surgical intervention, however, a severe injury such as complete splenic rupture has a 90% to 100% mortality rate.

CASE RESOLUTION

The boy in the case scenario sustained isolated abdominal trauma. Initial presenting signs and symptoms are consistent with internal organ injury, specifically splenic hematoma, pancreatic injury, internal hemorrhage, and compensated shock (eg, tachycardia, tachypnea). The child should undergo initial resuscitation with attention to the airway, breathing, and circulation, especially fluid repletion. Serial hemodynamic measurement and hematocrits, if stable, permit diagnosis of specific injuries by CT scanning. Surgical consultation with expectant observation is the likely management choice. If the child deteriorates, surgical intervention would ensue. Trauma to the small intestine, particularly a duodenal hematoma, must also be suspected because of the mechanism of injury.

Head Trauma

Paul Bryan, MD

CASE STUDY

A 2-year-old girl is playing on a window ledge unsupervised. She pushes the screen out and falls onto the concrete sidewalk below, striking her head. A neighbor reports that she is unconscious for 10 minutes. When paramedics arrive, the girl is awake but lethargic. She is transported to the emergency department (ED). Her vital signs are normal. A scalp hematoma is present, and a depressed area of cranial bone is palpated.

Questions

1. What are the priorities in the initial stabilization and management of pediatric head trauma?
2. What is the difference between primary and secondary brain injury?
3. What are the common structural injuries sustained by children with head trauma?
4. What are the various modalities available for treatment of increased intracranial pressure?
5. What are the scoring systems used in the evaluation of mental status in children with head trauma?

Although most childhood head injuries are minor and can be treated on an outpatient basis, it is important for clinicians to become adept at recognizing and managing concussions and more severe forms of head injury. Health care providers can also help lower mortality from head trauma by actively promoting injury prevention to patients and communities.

Epidemiology

Head trauma is one of the most common pediatric injuries and is the leading cause of morbidity and mortality among pediatric trauma patients. Pediatric head trauma accounts for more than 500,000 ED visits; 95,000 hospital admissions; 7,000 deaths; and 29,000 permanent disabilities per year in the United States. The hospital care costs exceed a billion dollars annually. In multiple-injured pediatric patients, 70% of the deaths that occur within 48 hours of hospitalization are the result of trauma to the head. The rates of intracranial injuries in children with only minor head trauma, however, are low with the largest numbers occurring in young children and infants with an incidence of 3% to 6%. Only 0.4% to 1% of children require surgical intervention after minor closed injury.

Falls account for most cases of pediatric head trauma. Other major causes include motor vehicle crashes, vehicle versus pedestrian collisions, bicycle crashes, sports-related injuries, and recreational activities. Non-accidental trauma (ie, child abuse) must be recognized as another important cause of head injury in children, particularly among those younger than 2 years.

Clinical Presentation

Children who have sustained head trauma may present with a history of an antecedent event (eg, fall or collision with another child) or signs and symptoms related to the injury. These include external bruises or lacerations; alterations in the level of consciousness; and neurologic findings, including seizures. Vital signs may be altered; in particular, deep or irregular respirations, hypertension, or bradycardia may be apparent (Dx Box). These changes are indicative of elevated intracranial pressure (ICP).

Pathophysiology

Children have significant anatomical differences from adults that predispose them to head trauma and certain types of intracranial injuries. They have a higher center of gravity, an increased head-to-body ratio, and weaker neck muscles compared with adults. In addition, children have thinner cranial bones and less myelinated brain

Dx

Head Trauma^a

tissue, predisposing them to intraparenchymal injuries. Whereas adults are more likely to have focal intracranial hematomas, children are more likely to develop diffuse cerebral edema. Cerebral edema can disrupt cerebral blood flow resulting in ischemic injury.

Normally, blood flow to the brain is maintained at a constant rate by a process known as *autoregulation*. With severe brain injury, autoregulation is disrupted and blood flow to the brain is determined by cerebral perfusion pressure (CPP), which is a measure of the mean arterial pressure (MAP) minus ICP [$CPP = MAP - ICP$]. Cerebral blood flow is therefore compromised when the MAP is too low (ie, hypotension) or the ICP is too high (ie, cerebral edema). Several of the management strategies in severely brain-injured children focus on maintaining MAP and reducing ICP, but control of CPP after head injury can be quite difficult. Children have a greater capacity for recovery than adults, especially infants and very young children, whose open sutures and fontanelles permit expansion of the skull in response to edema and blood.

In head trauma, both primary and secondary brain injury can occur (Figure 64-1). Primary injury is the structural damage that occurs to the cranium and its contents at the time of the injury. Secondary injury is damage to the brain tissue after the initial event. Such damage may result from hypoxia, hypoperfusion, hypercarbia, hyperthermia, and altered glucose or sodium metabolism. The main management strategies for head trauma victims focus on the prevention of secondary brain injury. Primary brain injury can only be prevented through education and safety.

Minor head trauma in the pediatric patient. *Pediatr Emerg Care*. 1991;7:40–47, with permission from Wolters Kluwer Health.)

Types of Head Injuries

Even minor head trauma in children can result in fractures to the skull or intracranial injuries. Most skull fractures are simple and linear. Other fracture types are comminuted, diastatic, basilar, and depressed. Comminuted fractures occur when there are multiple skull fragments. Diastatic fractures occur when there is a wide separation at the fracture site. Basilar fractures occur at the base of the skull and often have characteristic findings on physical examination (ie, bilateral periorbital ecchymosis, hemotympanum, postauricular ecchymosis [Battle sign]). Depressed fracture occurs when fragments of the skull are displaced inward, potentially damaging intracranial structures.

Head trauma may result in a **concussion** or mild traumatic brain injury. A concussion is defined as a trauma-induced impairment of neurologic function. This may occur with or without a loss of consciousness (LOC). Neurologic examination is usually normal, but patients may experience somatic symptoms (eg, headache), physical signs (eg, LOC, amnesia), behavioral changes, cognitive impairment, or sleep disturbances. Some of these minor and subtle neurologic sequelae can last for months following the injury (post-concussive syndrome). Most resolve over a relatively short period, typically 7 to 10 days.

A **cerebral contusion** is essentially a bruise of the brain tissue and typically occurs with a more severe injury, such as a high-speed motor vehicle crash. A coup-contrecoup type injury may be produced when the brain strikes the skull on direct impact, bruising one portion of the brain, and then injury occurs to the opposite portion of the brain when rapid deceleration occurs. Clinical manifestations depend on the location of the contusion but often include altered mental status, excessive sleepiness, confusion, and agitation. Small intraparenchymal hemorrhages and swelling of the surrounding tissues are often seen on computed tomography (CT) scan.

Epidural hematomas are collections of blood that accumulate between the skull bone and the tough outer covering of the brain (dura). They are often the result of tears in the middle meningeal artery caused by skull fractures. Classically, patients have initial LOC followed by a lucid interval and then rapid deterioration secondary to brain compression. On CT scan an epidural hematoma appears as a large collection of blood with convex borders next to the skull (Figure 64-2A). Surgical evacuation is required in most cases.

Subdural hematomas accumulate between the dura and the underlying brain tissue. They are associated with both skull fractures and contusions. On CT scan they appear to have crescent-shaped borders (Figure 64-2B). Large subdural hematomas usually require surgical evacuation. In infants and young children, these are often the result of non-accidental trauma.

Diffuse axonal injury occurs when there is extensive damage to the axonal white matter of the brain that results from shearing forces that typically occur with rapid acceleration or deceleration of the brain (Figure 64-2C).

Figure 64-2. A. Epidural hematoma, marked by the asterisk. Note convex borders and midline shift. B. Subdural hematoma. Note crescent shape. C. Diffuse axonal injury. Note ground-glass appearance and tightly compressed ventricles. (Reproduced with permission from Harris JH Jr, Harris WH, Norelline RA. *The Radiology of Emergency Medicine*. 3rd ed. Baltimore, MD: Williams & Wilkins; 1993:15, 16, 17.)

Evaluation

History

Historical data are obtained during the secondary survey or reassessment phase of evaluation. Prehospital health care providers or witnesses to the injury should be asked about details of the event and the child's status following the event (Questions Box).

Questions

Head Trauma

- What was the mechanism of injury (motor vehicle crash, ejection from motor vehicle, fall, assault)?
- What was the height of the fall?
- What was the type of impact surface?
- What was the shape of the object(s) striking the head?
- What was the child's immediate status after injury?
- What changes in status occurred before arrival at the hospital?
- Did the child lose consciousness? If so, for how long?
- Did the child vomit?
- Did the child have a seizure? If so, when did it occur in relation to the injury and does the child have an underlying seizure disorder?

Physical Examination

Careful attention to the vital signs of children with head injuries is important. The presence of hypertension, bradycardia, and an irregular breathing pattern (**Cushing triad**) all suggest a significant intracranial injury with associated increased ICP.

Secondary survey actions include palpation and inspection of the scalp for soft-tissue swelling, step-offs, lacerations, and fullness of the fontanelle. Facial bones should be tested for stability and deformities. Other clues to possible head trauma include the presence of a septal hematoma, draining blood or fluid from the nose or ears, dental injury, and malocclusion of the mandible. The tympanic membranes should be visualized for the presence of hemotympanum or

cerebrospinal fluid (CSF) otorrhea, which along with postauricular ecchymosis (**Battle sign**), periorbital ecchymosis, or cranial nerve palsies suggest a basilar skull fracture. Funduscopic examination should be performed if possible to look for the presence of papilledema associated with increased ICP or **retinal hemorrhages** that indicate non-accidental trauma.

A comprehensive neurologic examination is the most important part of the secondary survey. This examination should include a mental status assessment, cranial nerve evaluation, presence and quality of deep tendon reflexes, muscle tone, muscle strength, sensation, and cerebellar function. When describing mental status, imprecise terms such as *altered*, *lethargic*, and *obtunded* should be avoided. Several widely used scoring systems are available for mental status assessment of children who have suffered head trauma that are useful predictors of intracranial injury. A number of scales exist for assessment of the level of consciousness. The most universally accepted and widely used of these scales is the **Glasgow Coma Score (GCS)**. It is used routinely in children older than 5 years, but can be modified for younger children. Each scoring system has 3 measured responses (eye opening, verbal, and motor) to a variety of stimuli. Scores should be tabulated when children first present to establish a baseline. They can then be used for reassessment on a regular basis until patients have stabilized or returned to normal mental status. Use of these scores helps promote consistent and accurate communication among health care providers. Tables 64-1 and 64-2 show how to calculate the GCS and modified GCS scores.

Table 64-1. Glasgow Coma Scale

Elements	Points
I. Eye opening	
a. Spontaneous	4
b. To command	3
c. With pain	2
d. No response	1
II. Verbal response^a	
a. Oriented, converses normally	5
b. Disoriented, confused	4
c. Utters inappropriate words	3
d. Incomprehensible sounds	2
e. No response	1
III. Motor response	
a. Obeys commands	6
b. Localizes pain	5
c. Flexes with pain	4
d. Flexes abnormally with pain	3
e. Extensor response	2
f. None	1
Maximum score	15

^a Assessment of verbal response is modified in children.

Table 64-2. Modified Glasgow Coma Scale for Younger Children

<i>Elements</i>	<i>Points</i>
I. Eye opening	
a. Spontaneous	4
b. To command	3
c. With pain	2
d. No response	1
II. Verbal response^a	
a. Coos and babbles	5
b. Irritable cry	4
c. Cries to pain	3
d. Moans to pain	2
e. None	1
III. Motor response	
a. Normal spontaneous movement	6
b. Withdraws to touch	5
c. Withdraws to pain	4
d. Abnormal flexion	3
e. Abnormal extension	2
f. None	1
Maximum score	15

^a Assessment of verbal response is modified in children.

The secondary survey should be completed to identify any additional life- or limb-threatening injuries.

Laboratory Testing

All pediatric patients with significant head trauma should have a complete blood cell count and serum electrolytes performed. Bedside glucose should be performed in any child with a head injury with an altered level of consciousness. Toxicological evaluation may be indicated in adolescents who appear to be intoxicated or have an altered level of consciousness. Those infants and children with an intracranial hemorrhage should have screening coagulation studies performed (ie, prothrombin time, activated partial thromboplastin time), as well as a type and screen or crossmatch, should surgery be required.

Imaging Studies

In cases of acute pediatric blunt or penetrating trauma, a non-contrast CT of the head is currently the diagnostic study of choice. It is very sensitive for the detection of acute hemorrhages and skull fractures. It can also provide additional information as to the severity of injury indicating increased ICP, cerebral edema, or pending herniation. Some of the findings on CT that indicate severe brain injury are the shift of midline structures, effacement of the sulci, ventricular enlargement or compression, and loss of the normal gray-white matter differentiation.

Box 64-1. Indications for Computed Tomography Scans in Children With Head Trauma

- Alteration in level of consciousness, with waxing and waning or deteriorating mental status
- Glasgow Coma Score lower than 14
- Focal neurologic deficit(s) on examination
- Examination findings suggestive of a skull fracture
- Posttraumatic seizures
- Persistent vomiting or headache
- Scalp hematoma in a child younger than 2 years
- Prolonged loss of consciousness
- Possibility of penetration of the skull

A list of suggested criteria for obtaining a CT scan for patients with head injuries can be found in Box 64-1. All children classified with moderate to severe head trauma (GCS <14) should have a head CT performed. There is considerable debate about which children who have suffered minor closed head trauma with a normal examination and a GCS of 14 to 15 warrant imaging. There is no pediatric study thus far that has been able to identify a set of clinical criteria to identify all children with radiographic lesions. Vomiting, LOC, and seizures, which can all be seen in intracranial injuries, are relatively poor predictors of radiographic intracranial abnormality in children. The best predictors in children are altered mental status, focal neurologic deficit, and the presence of a skull fracture. Given the small numbers that require actual surgical intervention, some argue that the goal should not necessarily be to identify all of these clinically insignificant lesions but to be selective and thereby minimize unnecessary radiation exposure (see Chapter 15). Others argue that given the lack of reliable clinical criteria, and the possibility of significant intracranial injury in the face of a normal examination, a more liberal use of CT should be employed. The decision to perform a CT scan in these children with minor head trauma currently is based on a variety of factors including historical data, physical findings, age of the child, physician experience, and the psychosocial situation of patients and their families.

With the speed and widespread availability of CT scanners, skull radiographs have relatively little role in the acute evaluation of pediatric head trauma patients. Current CT scans can be performed very quickly, often with the need for no or little sedation. Although sensitive for the detection of skull fractures, plain films do not provide any information about associated intracranial injuries. In addition, several studies have demonstrated that intracranial injuries occur in the absence of a skull fracture, particularly among young pediatric patients. The role of plain films is limited to part of the skeletal survey in suspected cases of non-accidental trauma.

Magnetic resonance imaging (MRI) has little role in the management of the acutely injured head trauma victim. Computed tomography scan is often more sensitive at detecting acute intracranial hemorrhages and is sufficient to guide most immediate patient care issues. Magnetic resonance imaging may be superior to CT for identifying diffuse axonal injury and subtle brain injuries. In general, MRI

takes longer to complete, often requires sedation, and the scanners are frequently located away from the ED where the child cannot be monitored appropriately.

One important consideration of any trauma victim is the possibility of a cervical spine injury. Although cervical spine injuries are less common in children, the clinician must maintain a high index of suspicion when presented with a child who has suffered significant head trauma. All children with an altered level of consciousness; significant painful/distracting injuries; an inability to communicate; focal neurologic deficits; or localized pain, swelling, or ecchymosis of the cervical spine require careful evaluation and imaging of the cervical spine.

Management

Assessment and management occur simultaneously when an acutely injured child presents. A primary survey is initially performed with attention to airway, breathing, circulation (ABCs), and cervical spine immobilization. Prompt neurosurgical consultation should be obtained for all children with significant head trauma to assess the need for operative management and ICP monitoring. The primary management goal of significant acute head trauma is the prevention of secondary brain injury by (1) maximizing oxygenation and ventilation, (2) supporting circulation to maximize cerebral perfusion, (3) decreasing elevated ICP, and (4) decreasing cerebral metabolic demands.

Individuals with significant intracranial injuries will often require intubation for airway protection. Those individuals with a GCS of 8 or lower should undergo **rapid sequence intubation** to control the airway. These individuals should be premedicated with etomidate and lidocaine prior to the use of paralytics. Etomidate is a sedative that is cardiovascularly neutral with minimal effect on blood pressure. Most other sedatives can result in hypotension thereby lowering MAP and reducing CPP. Lidocaine is recommended to potentially blunt the transient increase in ICP often associated with orotracheal intubation. In the past, moderate hyperventilation was advocated to reduce ICP. Hyperventilation lowers arterial carbon dioxide partial pressure (P_{CO_2}), leading to cerebral vasoconstriction and decreased cerebral blood flow, lowering ICP. This has been shown to have the unwanted effect of disrupting cerebral metabolism and possibly exacerbating ischemic injury. Currently normoventilation is recommended with the goal of maintaining P_{CO_2} no lower than 34 mm Hg. Moderate hyperventilation may have a role in the transient management of serious or acute life-threatening elevations in ICP (ie, acute herniation).

Circulation and MAP should be aggressively supported with fluids to prevent hypoperfusion to the brain. Hypovolemia or hypotension should never be assumed to result from head trauma alone. Children should be examined carefully for evidence of additional injury. Central venous pressure monitoring is often necessary to accurately assess volume status. Pressors may be necessary to maintain MAP in euvolemic patients. Morbidity has been shown to significantly increase with subsequent episodes of hypotension that occur.

Elevations in ICP may impede cerebral blood flow and exacerbate ischemic injury. Administration of hypertonic solutions (3% saline), osmotic agents (mannitol), diuretics, and elevation of the head of the bed to 30 degrees to promote venous drainage are all examples of methods used to reduce ICP. Use of mannitol and other diuretics is contraindicated in patients with borderline blood pressures because they can cause hypotension, which can in turn lower MAP, worsening cerebral perfusion. Paralytic agents, sedatives, and analgesics may be needed to prevent agitation, which also leads to increased ICP and increases cerebral metabolic demands. Painful procedures (eg, suctioning) should receive adequate pre-medication with sedatives and analgesics. Intraventricular pressure catheters are often necessary to allow for close monitoring of ICP. In addition, they can be used to drain CSF to help lower elevated ICP.

Hyperthermia and seizure activity should be managed aggressively because these all increase cerebral metabolic demands. Hyperthermia should be managed with antipyretics and active cooling measures. There is conflicting evidence regarding controlled hypothermia in children with severe brain injuries. Future studies will hopefully determine if this is of some benefit as has been shown in certain animal models. Anticonvulsant prophylaxis should also be considered in severely brain-injured children, especially within the first 7 days. It is important to remember that the ability to detect clinical seizure activity is lost if the child is paralyzed.

Serum electrolytes should be followed closely, and any alterations should be minimized. Patients with head injuries should be monitored closely for the development of diabetes insipidus or syndrome of inappropriate secretion of antidiuretic hormone.

Children with large epidural and subdural hematomas will frequently require surgical evacuation. Individuals with depressed skull fractures often require operative management to lift the depressed fragment away from the underlying brain. Children who have suffered significant penetrating head trauma warrant antibiotic and antiepileptic prophylaxis, and may need angiography to assess for vascular injury. They should all have their tetanus status updated if necessary.

Children with minor head injuries (GCS = 14–15) with no LOC or a brief witnessed period of LOC, no focal deficits on neurologic examination, no skull fractures, and without persistent vomiting who demonstrate improvement and normal mental status (GCS = 15) after 4 to 6 hours of observation can be discharged with written instructions if they have adequate transportation back to the hospital, a telephone, and a reliable parent or guardian. Children should be admitted if these criteria cannot be met. Younger children (<2 years of age) are more difficult to assess accurately and consistently and are at higher risk for intracranial injuries. Admission should be strongly considered if their mental status is not completely normal or at baseline. Physicians should be wary of discharging children whose conditions have not improved to baseline following minor injuries or who have persistent emesis, even if their CT scans are normal.

More moderate head injuries (initial GCS = 9–12) necessitate a longer period of evaluation, probably in a monitored setting along with neurosurgical consultation. Severe head injuries (GCS <8) require aggressive stabilization in the ED with the measures described previously and admission to a pediatric intensive care unit.

Children who have suffered a concussion warrant close observation and reevaluation before resuming sporting activities. In the past, grading scales for concussions were devised using severity and duration of symptoms to determine the appropriateness of return to activity. These classification systems have been abandoned, and the decision regarding the resumption of athletic participation should be tailored to the individual. In general, athletes should have complete physical and cognitive rest until they are symptom-free. In addition, they should have a normal neurologic examination, and normal imaging (if performed). Athletes should return to play in a gradual stepwise fashion rather than an abrupt return to full activity and game play. Pediatric and adolescent athletes who have suffered a concussion should never be allowed to return to play the same day of their injury.

Prognosis

Age is the most important prognostic factor in outcome. Younger children tend to do better than older children. It is still difficult to predict the outcome of any individual patient. Scalp lacerations, most skull fractures, and concussions are low-risk injuries. Intracranial hemorrhage, specific skull fractures, head injury secondary to non-accidental trauma, and trauma accompanied by diffuse cerebral edema are high-risk injuries. If untreated, severe head injury may lead to death from herniation.

Other complications from severe head trauma are posttraumatic seizures, requiring lifelong treatment with anticonvulsants; hydrocephalus, necessitating placement of a ventriculoperitoneal shunt catheter; and persistent vegetative or severely impaired mental states. Penetrating head injuries can result in infections (eg, meningitis, abscess) and vascular injuries (eg, aneurysm, arteriovenous malformations). Sequelae such as post-concussive syndrome may result from less severe head trauma. Some of the characteristics of this syndrome include dizziness, headache, irritability, memory deficits, impaired behavior, and impaired cognitive development. These may persist for months after the head injury and can sometimes be permanent. These children may warrant formal neurobehavioral testing.

Prevention

Despite advancing medical knowledge and excellent critical care available to children with head trauma, little can be done to reduce the severity of primary brain injury once it has occurred. Therefore, pediatric health care providers should make every attempt to educate patients and families about prevention strategies. Some of the most successful prevention strategies involve the required use of restraint devices such as seat belts, and of proper safety gear such as bicycle helmets. Anticipatory guidance and home safety recommendations

provided to parents are also worthwhile. Finally, communities can contribute to injury prevention by providing playground resurfacing, reducing the height of playground equipment, and changing traffic laws. It is only through a combination of these prevention strategies that morbidity and mortality of pediatric head trauma will be truly reduced.

CASE RESOLUTION

The case scenario involves a young child with a significant mechanism of injury; brief LOC; and a depressed, altered mental status. Initial physical findings prompt suspicion of a depressed skull fracture and overlying soft tissue injury. Appropriate diagnostic tools after evaluation of airway, breathing, and circulation are a cranial CT scan followed by admission for observation, monitoring, and serial neurologic examination. Operative repair of the skull fracture may be necessary.

Increased Intracranial Pressure

Kenneth R. Huff, MD

CASE STUDY

A 7-year-old boy has a 2-week history of recurrent vomiting. No fever, abdominal pain, or diarrhea has accompanied the vomiting; the vomiting has no particular relationship to meals; and the boy's appetite has decreased only slightly. The vomiting has gradually increased in frequency and is occurring every night. Yesterday there were 4 episodes. The boy's parents have noticed that their son is generally less active; he spends more time playing on the floor of his room and does not want to ride his bicycle or play with neighborhood friends. Some unsteadiness in the boy's gait has developed in the last few days. His parents attribute this to weakness from the vomiting.

The child's vital signs are normal except for a blood pressure of 130/80 mm Hg. Although the boy is somewhat pale and uncomfortable, he does not appear to be in acute distress. His abdominal examination is unremarkable. His speech is grammatically correct but sparse and hesitant, and he seems inattentive. On lateral and upgaze the boy has coarse nystagmus, and upgaze is somewhat limited.

Some diplopia on left gaze is apparent, with slight failure of left eye abduction. The left eye does not blink as much as the right eye. Fundal examination discloses elevated disks with indistinct margins. No upper extremity weakness is evident. The right foot is slightly weaker than the left, ankle tone is bilaterally increased, and 3 to 4 beats of clonus on the right and bilateral positive Babinski reflexes are present. Some tremor occurs in both arms with finger-to-nose testing. The boy walks with shuffling, small steps; his gait has a slight lurching character; and he veers to the right.

Questions

1. What clinical situations are associated with increased intracranial pressure (ICP)?
2. What is the pathophysiological process leading to ICP?
3. What studies are used to evaluate children with ICP?
4. What measures are used to treat children with ICP?

The signs and symptoms of increased ICP are often a signal of a serious intracranial process that may require surgical or intensive care intervention depending on the underlying cause. Although only a relatively small number of effective medical and surgical treatments for increased ICP are available, greater understanding is accumulating about when to initiate them. It is important to recognize signs and symptoms early and determine the underlying cause; treatment of the cause often resolves the secondarily increased ICP problem, particularly if deployed early in its course. In some cases, however, increased ICP is a potentially life-threatening critical care issue of itself where ongoing management, along with that of the underlying cause, is key for the child's survival.

Epidemiology

Head trauma is a leading cause of increased ICP. Infants may be victims of non-accidental trauma; older children may be stricken pedestrians or bicycle riders, occupants of crashed motor vehicles, or victims of falls or sports injuries; and children of any age may be

victims of penetrating trauma such as gunshots. Such trauma is a major source of morbidity in children and requires careful monitoring and management of ICP.

Brain tumors are the most common solid neoplasms in children and frequently lead to increased ICP either by direct mass effect or blockage of cerebrospinal fluid (CSF) flow. Ischemic brain damage resulting from a difficult delivery at birth, a submersion incident, or a major cerebral vessel thrombosis is also a cause of increased ICP. Cytotoxic causes of brain swelling, such as lead intoxication and liver failure in Reye syndrome, are less common etiologies.

Idiopathic intracranial hypertension (also called benign intracranial hypertension or pseudotumor cerebri) may also lead to increased ICP. This condition is associated most frequently with obese adolescent females, but has also been seen with thrombosis of a venous sinus caused by a clotting diathesis or following complicated otitis media or mastoiditis, following the use of high doses of vitamin A or tetracycline, or following withdrawal of steroid therapy.

Clinical Presentation

Children with increased ICP may present with a history of recurrent vomiting, lethargy, and new headaches of increasing frequency or severity (crescendo headaches) or that awaken them from sleep. A prior history of trauma, ischemia, meningitis, or having a CSF shunt, or a concomitant history of intoxication, such as with lead or metabolic aberration (ie, Reye syndrome or diabetic ketoacidosis), may also raise suspicions of increased ICP in the child with compatible examination findings. Neonates with intraventricular hemorrhage or meningomyelocele are prone to hydrocephalus. Children with cyanotic congenital heart disease are prone to abscesses, and children with sickle cell disease can present with strokes or hemorrhages causing increased ICP. In endemic areas of the world, cerebral malaria and intraventricular cysticercosis are frequent causes of increased ICP. Physical findings may include elevated optic disk, failure of upward gaze, hypertonicity of the extremities, and depressed alertness or inattention. Localized findings on neurologic examination may point to a lesion indicative of a space-occupying intracranial mass, which could contribute to increased ICP (Dx Box).

Dx

Increased Intracranial Pressure

- Loss of appetite, nausea, vomiting, headache, or lethargy
- Inattention, decreased arousability
- Papilledema, upward gaze paresis
- Increased tone, positive Babinski reflex
- Focal signs and history compatible with an intracranial mass
- Mass lesion, cerebral edema, or enlarged ventricles in an imaging study
- Elevated cerebrospinal fluid pressure measured manometrically by needle or catheter in the intrathecal or intracranial space

Pathophysiology

The problem of increased ICP can be understood in terms of the Monro-Kellie doctrine, which applies to the rigid cranial compartment and pressure-volume relationships of the contents. This doctrine is conceptually useful even though not always quantitatively predictive because of the variable compliance of the child's skull and dural membranes. Intracranial volume has 3 main components: brain parenchyma, CSF, and blood. Except in the first 2 years of life before most of the cranial sutures are fused, the skull and dura form a relatively rigid compartment; any increase in 1 of the 3 intracranial volume components must occur at the expense of 1 or both of the other 2. Decreased volume leads to increased pressure in a somewhat indirect inverse relationship, however, because of compliance of the skull, sutures, and dura. As compliance decreases, pressure rises more rapidly. Irreversible damage to brain tissue occurs primarily as a result of pressure of the other components overtaking the arterial blood pressure and not allowing adequate tissue perfusion. In younger children, non-fused sutures allow more compliance if volume increases are relatively slow, but this factor is not as

true for acute volume increases. In addition, pressure gradients exist across compartments, sites of CSF flow obstruction, or even around lesions within brain parenchyma, which may lead to focal findings that are more difficult to explain by global ICP or perfusion changes.

Changes in any of the 3 components making up the intracranial volume may result in increased ICP in several ways. First, the brain parenchyma component may be directly increased by mass lesions such as neoplasms, abscesses, or hemorrhages. Edema may increase the brain parenchyma volume. Fluid may accumulate because of vascular leakage due to cytokines, termed vasogenic edema. Brain edema may also result from cytotoxic damage, cell death, and necrosis. Cytotoxic processes include swelling of intact cells, cell rupture producing increased interstitial oncotic pressure from released proteins and ions, and cellular inflammatory and repair processes. Cytotoxic brain edema may be caused by various cellular insults including hypoxemia; ischemia; toxins, including neuronal excitotoxins; and depletion of energy substrates. These cellular insults may in turn be a consequence of a diversity of local or diffuse brain problems including major vessel thrombosis, trauma (eg, local contusion or diffuse axonal injury), anoxia from cardiac arrest, hypertension, encephalitic infection, or metabolic poisoning. Edema with head trauma may be a combination of vasogenic and cytotoxic edema, but also may be related to neurogenic inflammatory release of substance P and calcitonin gene-related peptide.

Second, the pressure of the CSF volume component (ventricles or subarachnoid spaces) may increase in hydrocephalus. Hydrocephalus can result in 2 ways: (1) from a discrepancy in the rate of formation of CSF relative to absorption and (2) from an obstruction between the point of formation in the lateral ventricles and the sites of absorption at the arachnoid granulations in the post-neonatal brain or brain parenchyma itself in the neonatal brain. An obstruction can occur with a congenital malformation; parenchymal or CSF mass such as a cyst or neoplasm; CSF inflammatory cells from meningitis, ventriculitis, or hemorrhage; displaced brain parenchyma; subarachnoid protein or debris; or even overgrowth of dural tissue. The small passageways connecting the ventricular system, the foramen of Monro and the aqueduct of Sylvius; the exits of the ventricular system, the foramen of Magendie and foramen of Luschka; and the cisterns surrounding the brain stem are particularly vulnerable points of obstruction. A third type of brain edema, interstitial edema, is characterized by transependymal transudation of CSF into the adjacent white matter and is generally seen in patients with hydrocephalus.

Third, ICP may rise because the intravascular volume component may increase. One process that leads to this increase is venous outflow obstruction such as occurs with a dural sinus thrombosis. Other processes that raise jugular venous pressure may also increase ICP. In addition, the intracranial arterial vascular volume is affected by carbon dioxide partial pressure. It not only increases with hypercarbia but also decreases with hypocarbia, which allows for central neurogenic or iatrogenic lowering of ICP by hyperventilation.

Because the process is frequently dynamic, it has proven useful to quantitate ICP for management purposes, although values in children are not as well correlated with pathophysiology as in

adults. Intracranial pressure is often recorded as cm H₂O while blood pressure is noted as mm Hg, and both types of units are noted here. Normal ICP levels are somewhat lower in the neonatal and infantile period at 2.5 to 6.5 cm H₂O (2–5 mm Hg), but in older children, pressures above 20 cm H₂O (15 mm Hg) are abnormal and may become symptomatic above 26 cm H₂O (20 mm Hg). Although it is possible to have normal mental function up to 52 cm H₂O (40 mm Hg), the ICP becomes clinically significant when the perfusion pressure is compromised, which begins when the ICP is 91 cm H₂O (70 mm Hg) below the mean arterial pressure, and it becomes more dangerous as the ICP approaches 52 to 65 cm H₂O (40–50 mm Hg) below the mean arterial pressure. Decreased perfusion produces swollen, damaged tissue, which further exacerbates the pressure-volume problem in a snowballing fashion.

As ICP increases, brain perfusion pressure may be maintained transiently by a spontaneous increase in mean arterial pressure, a response referred to as Cushing phenomenon. Although the relationship may not be universally reliable, when it is present with other suggestive clinical circumstances, the rise in systemic pressure can be a useful clinical sign of increased ICP. Normally changes in arterial cerebrovascular resistance meet changes in perfusion pressure to maintain constant cerebral blood flow, a process called *autoregulation*. However, this process is frequently compromised after head trauma or asphyxia.

Acute or subacute changes in pressure in an intracranial compartment may produce a pressure gradient that may precipitate a brain herniation syndrome (Figure 65-1). An ominous heralding sign of transtentorial herniation of the uncus of the temporal lobe is loss of the pupillary light reflex caused by entrapment of the third cranial nerve. This herniation often leads to irreversible brain stem damage as well as infarcts and additional secondary edema. Focally increased

posterior fossa pressure may result in a pressure cone downward through the foramen magnum—compressing medullary centers leading to apnea and death. A marginally compensated system could be decompensated by an ill-advised lumbar puncture when the spinal compartment pressure is acutely lowered, increasing the pressure gradient across the foramen magnum.

Differential Diagnosis

Seizures, metabolic derangements, and complicated migraine sometimes have a clinical presentation similar to increased ICP. In children who are only partially responsive, distinguishing an ictal or postictal state from a condition that may be producing increased ICP is sometimes difficult. Findings that suggest a seizure include rhythmic, clonic movements or sudden myoclonic jerks; rapid or variable changes of tone or posturing that are different from decerebrate posturing; abrupt, fluctuating changes of autonomic function (eg, heart rate, blood pressure, pupillary size); saliva production without swallowing; and history of prior seizures. Sometimes, however, only direct electroencephalogram (EEG) monitoring and ICP monitoring are able to distinguish ongoing electrographic “subclinical” seizure activity from increased ICP as the cause of the change in level of responsiveness.

In some cases, diffuse brain dysfunction from a toxic or metabolic etiology mimics increased ICP. Such toxic/metabolic causes include medication toxicity, electrolyte or blood chemistry imbalances, and systemic infections. With toxic/metabolic disorders, inattention is often accompanied by a confusional state with disorientation, incoherence, and sometimes agitation. In contrast, with increased ICP, inattention is frequently accompanied by slowness of thought, perseveration, decreased mental activity, and impaired gait, although these differences are not universal.

Figure 65-1. Depiction of the anatomy of several potential herniation syndromes caused by intracranial compartment pressure gradients related to a mass (hematoma, neoplasm, or acutely necrotic brain tissue) in a cerebral hemisphere. 1. Transfalcine herniation. 2. Uncal herniation. 3. Contralateral tentorial-midbrain damage. 4. Central herniation and foramen magnum pressure cone. These syndromes often lead to further brain ischemia and additional increases in intracranial pressure. The drawing on the left depicts a normal brain.

The symptoms and signs of complicated migraine sometimes also mimic those of increased ICP. A characteristic prodromal symptom period or the “pounding” nature of the pain may help separate migraine from increased ICP. At the initial headache presentation or when only a short headache history is present, the complicated migraine diagnosis may be one of exclusion, however. If children display focal neurologic signs along with some of the general symptoms of increased ICP, imaging studies to rule out a space-occupying lesion and confirm the safety of a lumbar puncture, and a measurement of normal pressure by lumbar puncture manometry, may need to be performed to support the diagnosis of migraine.

Evaluation

History

A thorough neurologic history should be taken (Questions Box). Headache, nausea and vomiting, drowsiness, personality change, and changes in visual acuity are important historical factors. The headache history may be “crescendo” in frequency or intensity and of only a few days’ or weeks’ duration. The headache may be worsened by cough, micturition, defecation, or other valsalva-like actions.

Questions

Increased Intracranial Pressure

- How long has the child been vomiting?
- When does the vomiting occur?
- Is the vomiting related to meals?
- Do the headaches awaken the child?
- Has there been a progressive decline in activity level or loss of developmental skills?
- Does the child display weakness or change in gait?
- Does the child have a recent history of trauma or potential ischemic event?

Physical Examination

Vital signs and head circumference should be noted. A careful neurologic examination is warranted whenever increased ICP is suspected. Particular attention should be paid to the components of the mental status and level of responsiveness and alertness of patients. The presence of papilledema and the cranial nerve functions should be assessed. Retinal hemorrhages may raise the suspicion of non-accidental trauma. Cranial nerve VI is particularly susceptible to increased ICP. Impaired upward gaze and lid retraction may be present. Specific muscle tone and strength as well as the gait characteristics should be evaluated in cooperative children who are able to resist and stand up. Posturing responses and the breathing pattern should be noted in comatose children to help ascertain brain stem localization of the lesion. In such children, findings should be reassessed at frequent intervals to follow a potentially rapid process such

as impending tentorial or brain stem herniation, which would necessitate immediate intervention measures.

Useful quick-assessment instruments for initial, rapid evaluation and subsequent monitoring are the Glasgow Coma Scale (GCS) and Children’s (ages ≤ 4 years) Coma Scale (see Table 64-1 and Table 64-2 in Chapter 64). However, these scales are a useful stratifying “shorthand” description but are not sufficient for every clinical decision related to patients with increased ICP.

In infants, a unique collection of signs—enlarged head circumference; bulging, raised fontanelle; frontal bone bossing with prominent venous distention; “sunset sign” (inability to elevate the eyes and lid retraction from midbrain tectal pressure); hypertonicity; and hyperreflexia—may be secondary to increased ICP from hydrocephalus. Papilledema is not present, perhaps related to greater compliance of the infant skull.

Chronic hydrocephalus may result in optic atrophy, depressed hypothalamic functions, spastic lower limbs, incontinence, and learning problems.

Laboratory Tests

If mental status changes are suggestive of a toxic or metabolic aberration, appropriate laboratory screens should be performed. These may include electrolytes, toxicological screen, liver function tests, and kidney function tests. A CSF examination should be done if signs of meningeal irritation or infection are present without lateralized signs of altered tone or strength. Imaging study evidence of an intercompartmental pressure gradient that could lead to herniation after lumbar puncture would also lead one away from that procedure, but CSF analysis and pressure measurements can also be made from ventricular taps after ventriculostomy. If there are clinical signs of increased ICP and no focal clinical or imaging signs of a mass, then a lumbar puncture can be both diagnostic and therapeutic for idiopathic intracranial hypertension.

Imaging Studies

A computed tomography (CT) or magnetic resonance imaging scan should be performed whenever children’s signs or symptoms indicate the possibility of increased ICP. Severe head trauma patients frequently have a dynamic pathophysiology and may benefit from serial CT scanning in the early hours along with their ICP monitoring. Intravenous (IV) contrast should be given if disruption in the blood–brain barrier (eg, infection, inflammation, neoplasia) is suspected and children are not hypersensitive and have adequate kidney function. A magnetic resonance venogram can be obtained if there is a possibility of a venous sinus thrombosis. Computed tomography angiography or traditional intraluminal angiography with the capability of intervention may be the best studies in the case of intracranial hemorrhage of unknown source.

Management

If idiopathic intracranial hypertension is diagnosed, pressure should be monitored periodically with lumbar punctures. Increased

ICP may respond to diuretics such as acetazolamide at high dose (20 mg/kg/d) or furosemide, as well as the removal of CSF during the lumbar puncture. The primary danger in this condition is an expanding blind spot and eventual blindness due to pressure at the optic nerve head. Visual fields should also be monitored, and if medical therapy is not successful, then optic nerve sheath fenestration or lumbar peritoneal shunt placement can be done surgically.

When diagnostic imaging studies reveal an etiology for the increased ICP, if it is a rapidly enlarging surgically accessible lesion such as an epidural hematoma, then management is emergently directed there, and immediate **neurosurgical craniotomy for drainage and hemostasis** may be necessary. Other focal space-occupying lesions seen on scans may not require immediate craniotomy, depending on size, position, and accompanying edema of the lesion as well as the compliance of the surrounding structures and the distortion of normal brain tissue and potential for loss of perfusion; neoplastic lesions may require diagnostic biopsy or excisional biopsy within a few days if surgically accessible. **Mineralocorticoids (dexamethasone 0.25–0.5 mg/kg every 6 hours)** are useful in situations in which the pressure is produced by a component of vasogenic edema, such as that surrounding neoplasms. A histamine H₂ blocker should also be used to help prevent gastric stress ulcer. Hypotonic IV fluids should be avoided, and the patient should be monitored for the syndrome of inappropriate secretion of antidiuretic hormone with serum and urine osmolalities. Hypoglycemia and hyperglycemia should also be avoided. If acute danger of herniation due to a pressure gradient produced by CSF flow blockage is present, then a temporary ventriculostomy may be indicated to relieve the CSF pressure. If an infectious process is present, including focal lesions, abscess, cerebritis, or encephalitis, **antibiotics** and/or **antiviral** agents are indicated after appropriate cultures, serology, and molecular diagnostic tests have been done. Following directed specific treatment of the underlying lesion, increased ICP may eventually resolve spontaneously. If hydrocephalus due to CSF flow obstruction is still present after initial therapy, **ventriculoperitoneal shunting of CSF** may be necessary. Endoscopic third ventriculotomy avoids long-term shunt hardware complications of obstruction and infection, but is less successful in younger children than older ones.

Encephalopathic children whose ICP is markedly elevated or likely to rise rapidly require treatment in an intensive care unit. If there is no mass or other space-occupying lesion or necrotic, traumatized tissue able to be surgically removed, then interventional measures are directed toward preventing eventual loss of perfusion of normal brain tissue. In patients with head injury, a GCS score of 8 or less can be used as a guideline for ICP monitoring. Intracranial pressure can be monitored on an ongoing basis with commonly used neurosurgically placed devices including the fiberoptic microtransducer and intraventricular catheter or ventriculostomy. The former device can measure pressure in brain parenchyma as well as in fluid-filled spaces. An advantage of the latter device is that it also allows for therapeutic CSF drainage to relieve pressure. It carries a slight

risk of infection (increasing to a plateau at day 4 of 1%–2% per day) or hemorrhage and may be difficult to place if ventricles are small or shifted. Intracranial pressure monitoring with neurosurgically placed devices and therapy based on the measurements, however, have not been helpful in many cases of ischemic damage, infection, or poisoning because of the totality of brain involvement without normal remaining tissue to which perfusion could be maintained.

Children with a decreased or fluctuating level of responsiveness may require EEG monitoring of cerebral electrical activity. The EEG helps diagnose the abnormal responsiveness as seizure threshold may fluctuate and seizures may occur even in the presence of increased ICP. Anticonvulsant therapy is indicated if evidence of clinical or electrographic seizures is present. In addition, the EEG may be used to monitor barbiturate- or benzodiazepine-induced coma, which may be used for severely increased ICP.

Airway patency and ventilation are important in children with increased ICP because hypoxia and hypercarbia can contribute to vasodilation and increased pressure. Rapid sequence intubation should be performed to minimize elevations of ICP. Ketamine and succinylcholine can increase ICP also. Transmission of elevated intrathoracic pressure to intracranial vessels can be avoided by sedation and decreasing the inspiratory phase of the ventilator. If acute lowering of pressure is necessary, hyperventilation to reduce the intracranial arterial blood volume is most effective, but care must be taken to avoid decreasing brain cell perfusion to the point of producing ischemic damage and exacerbating the problem. It is recommended that carbon dioxide partial pressure be kept at 30 to 35 mm Hg. Elevating the head to about 30 degrees and avoiding flexion or excessive turning of the neck to prevent jugular kinking are also effective in reducing ICP. Because the goal is to ensure perfusion while lowering ICP, maintaining and even elevating systemic mean arterial pressure by appropriate use of fluid therapy and pressor agents are key. Central venous pressure monitoring may also be helpful.

Diuretic agents such as mannitol (osmotherapy) (0.25–1 g/kg bolus) may also be useful in reducing brain volume by removing water, changing the rheologic characteristics of blood, and producing reflex vasoconstriction, but caution is advised. Mannitol, as a chronic infusion, can eventually cross the blood–brain barrier and draw more fluid into the brain. It is most effective where the blood–brain barrier is intact. Hypertonic saline (3%) as a continuous infusion may be an effective alternative. Serum osmolarity greater than 320 mOsm/kg can lead to renal failure. By giving diuretic agents at intervals as a bolus and titrating up to the ICP-lowering dose, such effects can generally be avoided. Sometimes these agents are used to counter ICP plateau waves or increased pressure with endotracheal suctioning or other procedures.

In children with severe refractory increased ICP, especially if secondary to an acute focal process, barbiturates such as pentobarbital or the benzodiazepine midazolam can be given as a continuous IV infusion with appropriate monitoring of brain electrical activity, serum levels, and systemic and brain perfusion pressures

Box 65-1. Management Interventions in Increased ICP

- Maintain serum osmols at 300–320 mOsm.
 - Keep head elevated to 30 degrees.
 - Maintain normal or elevated systemic blood pressure.
 - Control hyperventilation to PaCO₂ at 30–35 mm Hg.
 - Provide supplemental O₂ and PEEP as needed to keep PaO₂ >90 mm Hg and FiO₂ <50%.
 - If ICP progressively rises, pressure waves >20 mm Hg last longer than 5 minutes, or any pressure in first 24 hours is >30 mm Hg, then give mannitol, 250–1,000 mg/kg IV.
 - If mannitol needs repeating in <4 hours or osmolality is >320 mOsm
 - Give pentobarbital, 5 mg/kg IV, then 2 mg/kg/h IV monitoring to blood level of 25–35 mg/mL, burst-suppression pattern with 10 s between bursts on EEG, and cardiac index >2.7 L/min/m².
- or*
- Give midazolam by titrating the dose starting at 0.1 mg/kg/hr IV to the same EEG criteria and limited by the same cardiac index criteria.

If the cerebral lesion is primarily unihemispheric and pressure is rapidly increasing, hemicraniectomy should be considered

Abbreviations: EEG, electroencephalogram; FiO₂, fraction of inspired oxygen; ICP, intracranial pressure; IV, intravenous; PaCO₂, carbon dioxide partial pressure; PaO₂, oxygen partial pressure; PEEP, positive end-expiratory pressure.

(Box 65-1). These agents may serve to reduce brain metabolism without impairing vascular autoregulation significantly. Their risk is in reducing cardiac output and with associated infections, particularly pneumonia. Xenon CT measures multiple areas of local blood flow and may be a useful bedside technique to help specify targeted therapies. Decompressive craniotomy or craniectomy in early severe trauma in small series of patients has been associated with up to 50% good outcomes. Hypothermia to 93.2°F (34°C) for head injury and cardiac arrest, and numerous “neuroprotective” agents, have been and continue to be studied as means to slow metabolism and excitotoxic glutamatergic damage and reduce the rate of cytotoxic edema increase and spread in the penumbra surrounding the irreversibly damaged brain tissue.

Prognosis

Children may recover fully from increased ICP if brain perfusion pressure is adequately maintained and the underlying brain lesion generating the increased pressure can be resolved. Ultimately the prognosis depends on the nature of the lesion; its propensity to generate ICP that may be refractory to treatment, leading to irreversible brain tissue damage or death; and its permanence or potential for recurrence.

CASE RESOLUTION

The boy in the case history has focal signs and symptoms referable to the posterior fossa brain stem and cerebellum as well as symptoms of increased ICP. An emergent CT scan shows subacute hydrocephalus due to obstruction of CSF flow produced by a large mass in the cerebellum and brain stem on the left side. He begins taking dexamethasone with some relief of the increased ICP symptoms. Two days later a ventriculostomy is placed along with surgical removal of the mass, which is found to be a medulloblastoma. Because the ICP eventually subsides over the next few days and the CT scans show decreasing ventriculomegaly, a ventriculoperitoneal shunt is not required and the ventricular drain is removed. The boy's recovery is otherwise uneventful, and he begins staging evaluation for further malignant brain tumor therapy.

Management of Dehydration in Children: Fluid and Electrolyte Therapy

Sudhir K. Anand, MD

CASE STUDY

A 2-year-old boy presents to your office after 2 days of vomiting and diarrhea. His siblings were both ill a few days ago with similar symptoms. Two weeks ago his weight was 12 kg at a well-child visit. Today his weight is 10.8 kg. He has a pulse of 130 beats/min, respiratory rate of 28 breaths/min, and blood pressure of 85/55. He is alert and responsive but appears tired. He has dry mucous membranes, no tears with crying, and slightly sunken-appearing eyeballs. His capillary refill is 2 seconds. He urinated a small amount about 6 hours ago. Despite his mother's best efforts in your office, the patient has vomited all of the oral rehydration therapy (ORT) given to him. You draw serum electrolytes, blood urea nitrogen (BUN), and creatinine and initiate intravenous (IV) rehydration and give 2 boluses of 240 mL normal saline (NS; 0.9% NaCl solution) each.

Questions

1. How does one assess the magnitude of dehydration in children?
2. What are the different types of dehydration?
3. How does one determine the type and amount of fluid that a dehydrated child requires?
4. How does one assess renal status in a dehydrated child?
5. What is the role of electrolyte and acid-base laboratory studies in the evaluation of the dehydrated child?

Dehydration due to gastrointestinal and other disorders, especially diarrhea, is one of the most common medical problems encountered in children younger than 5 years. During the past 50 years or more, the usual therapy for children who are hospitalized with dehydration has been to administer IV fluids starting with 1 or 2 boluses of NS (0.9% NaCl solution). This is followed by the administration of a sodium solution of variable concentration (usually 0.45% NaCl) mixed with 5% dextrose over next 24 to 48 hours until the child is able to take oral fluids. The exact amount of fluid and electrolytes is calculated using complicated formulas to provide maintenance fluids and correction of remaining deficit (deficit therapy). Holliday, who in the 1950s first recommended the calculation of maintenance therapy, more recently has suggested that dehydration management should focus on rapid restoration of extracellular fluids (ECF deficit) followed by ORT and traditional calculations of fluid deficits should be abandoned. Alternatively, Moritz along with several pediatric nephrologists and intensivists have recommended that we forgo

Na⁺ calculations in hospitalized children and rely solely on isotonic NS (0.9% NaCl solution) for their management. While this chapter incorporates the above suggestions where appropriate, it continues the traditional approach to maintenance and deficit therapy because an understanding of the pathophysiology of dehydration helps in the management not only of dehydrated children but also of children with other types of fluid and electrolyte disorders.

Epidemiology

Over the past 25 years and associated with the advent of ORT, hospital admissions and mortality due to diarrhea and dehydration have decreased all over the world; nevertheless, diarrhea continues to be one of the leading medical problems in children younger than 5 years. In the United States an estimated 150,000 to 180,000 hospitalizations due to diarrhea occur each year in such children. In addition, diarrhea is responsible for 2 million to 3 million outpatient visits.

Table 66-1. Caloric Method of Determining Maintenance Fluid Requirements in Healthy Children (Holliday-Segar Method)

Weight	Maintenance Fluid Requirement for 24 Hours
3 ^a –10 kg	100 mL/kg/d ^b = 4 mL/kg/h
11–20 kg	50 mL/kg/d for each kg above 10 kg + 1,000 mL (fluid requirement for first 10 kg) = 40+2 mL/kg/h for each kg between 11–20 kg
>20 kg	20 mL/kg/d for each kg above 20 kg + 1,500 mL (fluid requirement for first 20 kg) = 60+1 mL/kg/h for each kg >20 kg

^a Children weighing less than 3 kg may have altered fluid requirements owing to prematurity or other conditions.

^b During the first 2 to 3 days of life, normal term infants require less fluid (approximately 80 mL/kg) because they mobilize excess extracellular fluid.

Maintenance Fluid and Electrolyte Requirements

The body has a **maintenance fluid requirement** to replace daily normal losses that occur through the kidney, intestines, skin, and respiratory tract. Of the various methods used to determine fluid needs, the most common is the **caloric method**, also called Holliday-Segar method, which is based on the linear relationship between metabolic rate and fluid needs. For every calorie expended in metabolism, a child requires about 1 mL of water. Metabolic rate in children is a function of body surface area. Infants, with higher relative surface areas per unit of body weight, have higher metabolic rates and, therefore, higher fluid requirements per unit weight. As children grow, their relative surface area decreases as does their metabolic rate and fluid requirement per unit weight. Using this relationship, maintenance fluid needs can be calculated for the healthy child using the method outlined in Table 66-1. These calculations of fluid needs are often used to determine the amount of IV fluids provided to a hospitalized child or to calculate the approximate amount of fluid a healthy child requires orally to maintain hydration. However, **these calculations may not be appropriate for critically ill children, some of whom require fluid restriction and others of whom may have increased fluid needs.** Moreover, the caloric method makes no allowance for extra fluid needed for weight gain, growth, activity, or pathophysiological states that increase fluid needs (such as fever). The fluid requirement derived from this method is valid to determine the daily fluid need for an essentially healthy child. Thriving infants normally drink more fluid than this method suggests. On average, growing infants may take 150 to 200 mL/kg/day of milk (breast milk or infant formula) as desired to support the average weight gain of 30 g/day usually observed in the first few months of life.

Replacement of normal daily losses of electrolytes is considered when a child is not able to take an adequate nutritional intake orally (as in the example in Box 66-1, where the child receives nothing orally in preparation for surgery). Electrolyte quantities are usually expressed as milliequivalent (mEq) or millimole (mmol) amount per 100 mL of fluid required. Traditionally, the recommended **sodium**

Box 66-1. Example of Fluid Calculations^a

Part A

Case: A 22-kg boy is given nothing orally in preparation for an elective abdominal surgery. How much intravenous (IV) fluid per hour should he receive as he awaits the surgery?

- For first 10 kg: 100 mL/kg/d \times 10 kg = 1,000 mL
- For next 10 kg (to get to 20 kg): 50 mL/kg/d \times 10 kg = 500 mL
- For next 2 kg (to get to 22 kg): 20 mL/kg/d \times 2 kg = 40 mL

1,000 mL + 500 mL + 40 mL = 1,540 mL/24 h

IV rate per hour = 64.2 mL/h (with a healthy child, round off to 65 mL/h for ease of administration)

Part B

Question: How much sodium (Na⁺) and potassium (K⁺) should this patient receive in his IV fluids?

Answer: 3 mEq Na⁺/100 mL (1 dL) of fluid = 3 mEq \times 15.4 dL = 46.2 mEq Na⁺/d in 1,540 mL of water or 30 mEq NaCl/L

2.0 mEq K⁺/100 mL (1 dL) of fluid = 2.0 \times 15.4 = 30.8 mEq K⁺/d in 1,540 mL of water or 20 mEq KCl/L

One possible way to write an IV order for this patient

D5 0.2% NaCl (or 0.25 NS) with 20 mEq KCl/L to run at 65 mL/h.

Abbreviation: D5 = 5% dextrose water.

^a NS contains 154 mEq NaCl/L and 0.2% NaCl contains 34 mEq NaCl. This solution is a widely available, premade IV solution that provides the approximate daily Na⁺ requirement of the patient. Even though the above calculations for sodium concentration are physiologic, at many institutions 0.5 NS in 5% dextrose is used preoperatively to prevent potential post-operative hyponatremia.

(Na⁺) requirement for a healthy child is 3 mEq/100 mL fluid required (approximately 0.2% NaCl or 1/4 NS), and the **potassium** (K⁺) requirement is 2 to 2.5 mEq/100 mL of fluid (see Box 66-1, part B for sample calculation and IV order). As discussed in more detail below, K⁺ should only be given to a patient after ensuring adequate renal function. These estimations of Na⁺ and K⁺ requirements are meant to replace normal daily losses and would not be adequate in the face of increased electrolyte losses that can occur in a number of pathologic conditions (such as diarrhea). Moreover, there has recently been increasing focus on the risk of hyponatremia and related complications developing in hospitalized ill children (see below for details).

Relatively healthy, well-nourished children receiving IV fluids for a brief period (ie, 1–2 days) while hospitalized do not routinely require supplementation with other electrolytes, such as calcium and magnesium. However, it is important to realize that standard IV fluids containing 5% dextrose, sodium chloride (NaCl), and potassium chloride (KCl) provide only minimal caloric needs and do not adequately support weight gain or provide other necessary nutrients. Children who require prolonged IV therapy because of inadequate gastrointestinal (GI) tract function should receive total parenteral nutrition to better meet their caloric and nutritional needs.

Alterations in Fluid Needs in Illness

A number of conditions alter fluid requirements. Conditions that increase a patient's metabolic rate (eg, fever) will also increase their fluid requirement. A child's metabolic rate is increased 12% for every

1°C temperature elevation above normal. Most otherwise healthy children with free access to fluids will increase their own intake to account for increased needs when febrile. Other less common hypermetabolic states, such as thyrotoxicosis or salicylate poisoning, may have an even more dramatic effect, perhaps increasing metabolic rate by 25% to 50% over maintenance. In these cases and for children who are dependent on others to provide their fluids, clinicians must be aware of the magnitude of increased need and provide supplemental fluids to avoid dehydration.

Other conditions may decrease a child's fluid requirement. In hypometabolic states such as hypothyroidism, metabolic rate and fluid needs are decreased by 10% to 25%. Fluid requirements are decreased by 10% to 25% in high environmental humidity unless the ambient temperature is also high and results in visible sweating. In these situations, a healthy child with normal renal function given extra fluid beyond what is needed can, within limits, effectively excrete any excessive intake. Children with renal failure, however, pose a special challenge for the clinician in the management of fluid and electrolytes. When a child is unable to adequately excrete excessive fluid intake, this fluid can accumulate and lead to complications such as congestive heart failure and pulmonary edema. Without functioning kidneys, only **insensible fluid losses** need to be replaced. Insensible losses occur primarily through the skin and respiratory tract; they account for approximately 40% of maintenance fluid needs. However, fluid needs for patients with renal failure are usually estimated at 30% of the maintenance requirement, with additional fluids provided if needed. This is to avoid giving excessive fluids that may require dialysis for removal.

Fluid requirements may also be decreased under circumstances where **arginine vasopressin** (AVP, also called antidiuretic hormone or ADH) is increased. In addition to hypovolemia or hypertonicity (hyperosmolality), AVP release is also stimulated by pain, nausea, surgery (postoperatively), central nervous system (CNS) infections such as meningitis and encephalitis, severe pneumonia or respiratory use, and certain medications (including thiazide diuretics, chemotherapeutic agents, and selective serotonin reuptake inhibitors). Arginine vasopressin release in the absence of hypovolemia or hypertonicity results in hyponatremia, and is referred to as **SIADH** (syndrome of inappropriate antidiuretic hormone secretion). In patients with SIADH, both fluid restriction as well as administration of fluids with a higher Na⁺ concentration may be indicated.

The most appropriate Na⁺ concentration of IV fluids for hospitalized children admitted to a pediatric intensive care unit or in postoperative patients is an area of current controversy. Over the past 25 years most such children have been maintained on a solution containing 5% dextrose water in half NS (D5 0.5 NS) or lower Na⁺ concentrations (D5 0.25 NS). Studies suggest that children, due to the kidney retaining free water in response to excessive AVP, are at risk for hyponatremia, hyponatremic encephalopathy, brain stem herniation, permanent brain damage, or death. Recently, some pediatric nephrologists (see Moritz et al) and intensivists recommended forgoing Na⁺ calculations in hospitalized very sick children and instead relying solely on isotonic fluids. Others (see Holliday et al

and Friedman) have cautioned that we must make certain that the new recommendations to use isotonic fluids do not result in excessive congestive heart failure or hypernatremia before we abandon previous practices. Regardless of the approach that is taken, close attention to the type and quantity of fluids provided, quantity of body fluid output, weight change, and serial electrolyte assessments are important in the management of all sick children, and fluid and electrolytes must be individualized to prevent serious complications.

Pathophysiology

Dehydration is one of the most common pathophysiological alterations in fluid balance encountered in pediatrics. Although strictly speaking dehydration means deficit of water only, most children with dehydration have lost both water and electrolytes. Dehydration can result from (1) diminished intake, (2) excessive losses through the GI tract (eg, diarrhea or vomiting), (3) excessive losses from the kidney or skin (eg, polyuria due to osmotic diuresis in uncontrolled diabetes), or (4) a combination of these factors.

Children are at increased risk for episodes of dehydration for a number of reasons. Young children have 3 to 4 times the body surface area per unit body weight compared with adults and so have relatively higher fluid needs. It is therefore much easier for children to become dehydrated in the face of the decreased intake or increased losses that often accompany common childhood illnesses. For example, acute gastroenteritis, which is common in young children, often leads to anorexia, recurrent vomiting, and frequent or large-volume stools, with proportionately more severe fluid loss than in older children and adults. In addition, infants and young children are dependent beings who are unable to increase their own fluid intake in response to thirst and must rely on others to provide their fluid needs. If these fluid needs are not met or are underestimated, children can easily become dehydrated.

Dehydration is classified as **isotonic**, **hypotonic**, or **hypertonic**. When considering acute dehydration, these terms are often used interchangeably with **isonatremic**, **hyponatremic**, and **hypernatremic** dehydration, respectively, because it is the Na⁺ content of the ECF that largely determines serum osmolality in otherwise healthy dehydrated children. In acute **isotonic** or isonatremic dehydration (serum Na⁺ 135–150 mEq/L), the most common type of dehydration, there is net loss of isotonic fluid containing both Na⁺ and K⁺ (Figure 66-1, top). Sodium, the primary ECF cation, is lost not only to the environment but some also shifts to the intracellular fluid (ICF) to balance the loss of K⁺, because K⁺ losses from cells are generally not accompanied by intracellular anionic losses in acute dehydration. The Na⁺ that has shifted into the ICF will return to the ECF compartment with rehydration. There is no net loss of fluid from the ICF in this process; the total water deficit in dehydration comes primarily from the ECF, although some have suggested, in the absence of valid data that two-thirds of the losses come from ECF and one-third from ICF.

There are a variety of mechanisms by which **hyponatremia** (serum Na⁺ <135 mEq/L) occurs in association with dehydration.

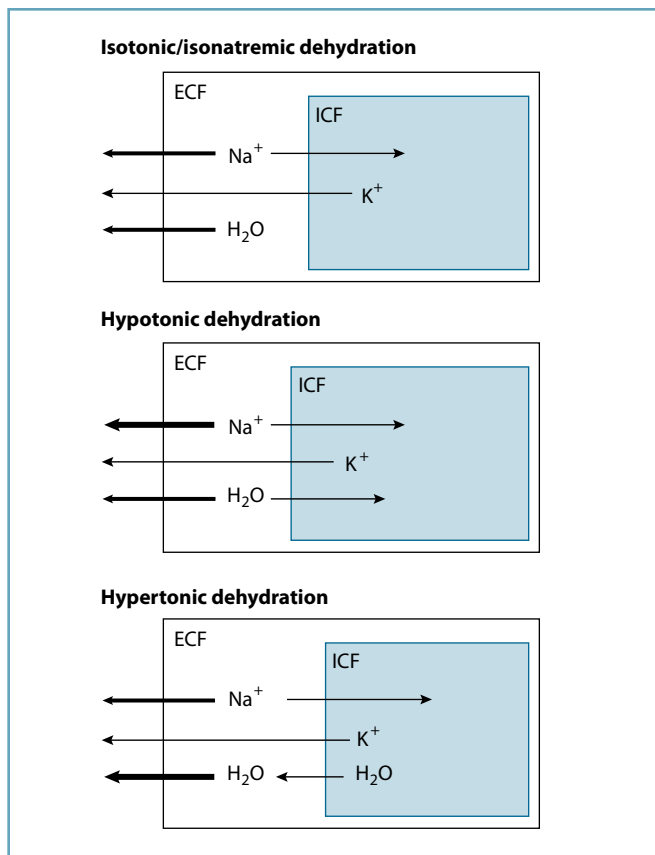

Figure 66-1. Pathophysiology of various types of dehydration. ECF, extracellular fluid; H₂O, water; ICF, intracellular fluid; K⁺, potassium; Na⁺, sodium.

In **hyponatremic dehydration**, the ECF volume is compromised to a greater degree than in isotonic dehydration because of osmotic shifts of ECF into the cell, resulting in more severe signs of dehydration (Figure 66-1, middle). Hyponatremic dehydration typically occurs in children with gastroenteritis when there are excessive Na⁺ losses in stool along with a parent giving oral replacement with water or very low Na⁺ beverages such as apple juice or tea. In hyponatremic dehydration, the kidney often excretes a concentrated urine (ie, retains free water) despite hyponatremia because AVP is stimulated by the decreased effective circulating volume. Intravascular volume depletion seems to be a potent stimulus for AVP release, overriding the AVP suppressive effect of hypotonicity/hyponatremia. The result is that serum Na⁺ levels are lowered due to dilution. Hyponatremic dehydration may sometimes also occur due to excessive loss of Na⁺ (relative to body water) in stool (eg, cholera) or in the urine (eg, adrenogenital syndrome, cerebral salt wasting, pseudohypoaldosteronism, and other salt-wasting renal disorders).

Hypertonic or **hypernatremic dehydration** (serum Na⁺ >150 mEq/L) occurs when net loss of water exceeds that of solute loss (Figure 66-1, bottom). It is usually seen in clinical conditions where there is rapid loss of hypotonic fluid in stool, vomit, or urine accompanied by failure of adequate water intake due to anorexia or vomiting. Fever or hyperventilation, if present, may intensify the disproportionate loss of water. Occasionally, hypernatremic dehydration

may be due to excessive solute intake. The urinary excretion of the excess solute obligates loss of large volumes of water, resulting in dehydration. The history may reveal that the child was accidentally fed a high Na⁺ solution due to incorrect mixing of oral rehydration packets or concentrated formula. In hypernatremic dehydration, there is shift of fluid from the ICF to the ECF to attain osmotic balance. As such, the ECF volume is somewhat spared at the expense of the ICF, and signs of dehydration may be delayed. However, fluid loss from the ICF results in intracellular dehydration, the most serious effect of which can occur in the brain. If hypernatremia occurs rapidly, there is not only a decrease in brain size but also a fall in cerebral spinal fluid (CSF) pressure owing to diffusion of water from CSF to the blood. As the brain shrinks, the bridging veins within the skull may stretch and even tear, resulting in subdural hemorrhage or other complications. If the hypernatremic state develops more slowly, the brain cell size may initially shrink minimally but will gradually return to normal size even in the face of continued hypernatremia. The preservation of the brain cell volume despite hypernatremia is thought to be due to the generation of idiogenic osmoles (myoinositol, trimethylamines, taurine, and other amino acids) that prevent water loss and attract water back into the cell and thus maintain cell volume. Rehydration of the patient with hypernatremia must occur slowly and cautiously to avoid brain cell swelling (Figure 66-2). The skin, on clinical examination, in hypernatremic dehydration may sometimes feel “doughy” due to intracellular dehydration. This finding, however, is inconsistent even in the hands of experienced pediatricians and should not substitute for serum Na⁺ measurements to diagnose hypernatremia.

Evaluation

History

In addition to signs and symptoms of the current illness, the history should focus on the cause of dehydration. Parents should be questioned on the type and amount of oral intake; the duration, quality, and frequency of vomiting and/or diarrhea; whether blood is present in the stool; the presence or absence of fever; frequency of urination; and whether a recent pre-illness weight is known for the child (Questions Box). When parents report change in mental status, it is of particular concern because this may occur because of significant electrolyte (eg, Na⁺) disturbance, marked dehydration, or other serious infection or illness. The most accurate way to assess the degree of dehydration is to compare current weight with a recent pre-illness weight, although a prior weight is often unavailable. In acute dehydration, the loss of weight is primarily due to fluid loss. The difference between pre-illness and current weight can be used to determine the degree of the fluid deficit.

Physical Examination

An important goal of the physical examination of the dehydrated child is to assess the degree of dehydration. In the process, vital signs including blood pressure and a current weight should be obtained.

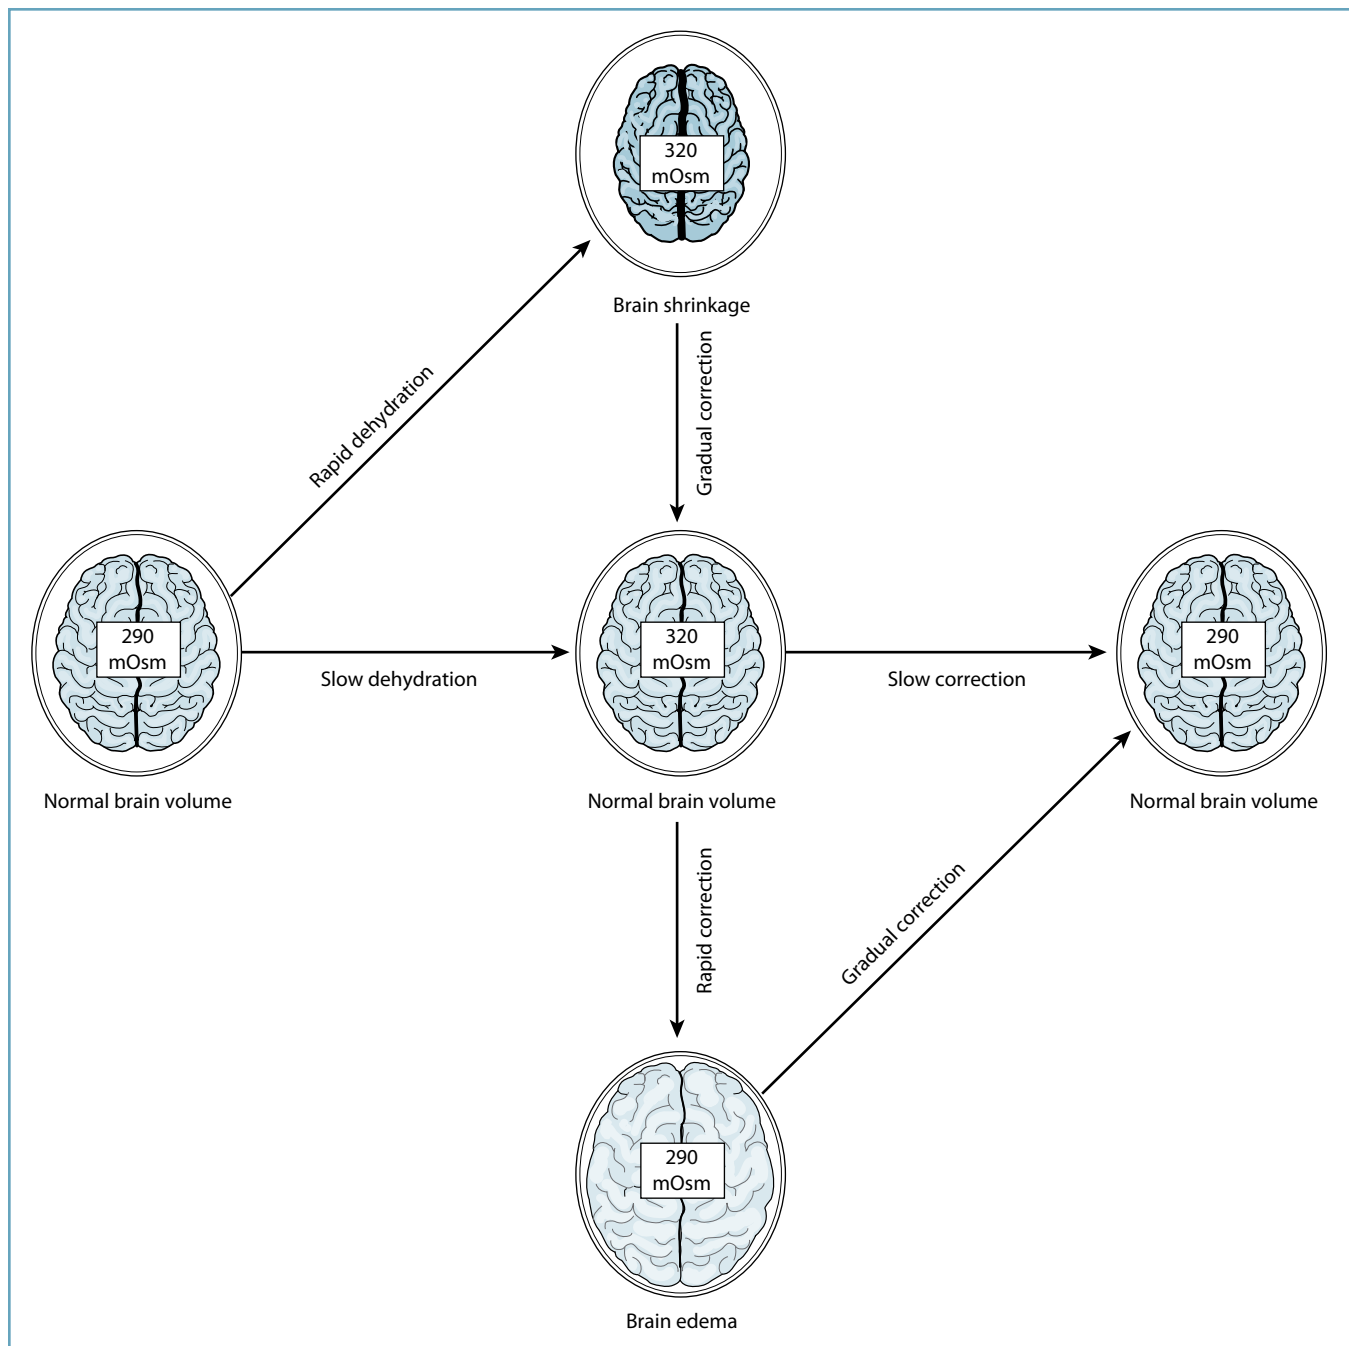

Figure 66-2. Hypernatremic dehydration. Effects on brain volume of rapid versus slow development of hypernatremia and results of rapid versus slow correction of hypernatremia.

Dehydration

- Has the child had vomiting or diarrhea?
- Has the child had fever?
- What has the child been eating or drinking?
- Has the child been urinating? How many wet diapers did the child have?
- How much did the child weigh at the last visit to the physician?
- Is your child's behavior or level of alertness changed from normal?

Questions

Specific attention should be focused on the general appearance of the child and in particular whether he or she is ill-appearing, listless, or less reactive. In addition to the usual components of the physical examination, assessing for the following is important: whether the oral mucosal membranes appear tacky or dry, whether tears are present or absent, if tenting of the skin is present (abnormal when tenting remains after the skin is pinched between 2 fingers), and perfusion status of the extremities. In the process, it is important that the clinician recognize whether shock is present because this is a life-threatening condition that requires emergent treatment (see Chapter 61).

Table 66-2. Clinical Assessment of Magnitude of Dehydration

<i>Clinical Signs</i>	<i>Mild Dehydration</i>	<i>Moderate Dehydration</i>	<i>Severe Dehydration</i>
Loss of body weight Infant/young child Older child/adult	5% 3%	10% 6%	15% 9%
Skin turgor	Normal to slightly reduced	Decreased	Markedly decreased (tenting)
Skin color and temperature	Pale or normal	Ashen, cool	Mottled, cool
Dry mucous membranes	±	+	++
Absent tears	±	+	++
Sunken eyeballs	±	+	++
Increased pulse	±	+	++ (may be thready)
Blood pressure	Normal	Normal Postural decrease ±	Reduced (in late shock)
Urine output	Normal or reduced ^a	Oliguria ^a	Oliguria/anuria
Capillary refill time	Slightly prolonged	Prolonged	Prolonged

^a Usually corrects with restoration of intravascular volume.

Because comparison to an accurate recent pre-illness weight usually is not possible, clinicians must rely on vital signs and clinical signs and symptoms to assess the degree of dehydration (Table 66-2). In infants and young children (<5 years), the estimated fluid loss for mild dehydration is 5% deficit of body water; moderate dehydration, 10%; and severe dehydration, 15%. The corresponding numbers for estimated fluid loss in older children are 3%, 6%, and 9%, respectively. A variety of clinical signs have been proposed to evaluate the degree of dehydration—some more valid and reliable than others. A 2004 systematic review found that assessment of capillary refill was the most useful single sign in detecting 5% or greater dehydration (capillary refill is assessed by placing brief pressure on the distal palmar aspect of a fingertip and assessing the amount of time for the blanched area to refill—normal is considered ≤ 2 seconds). Two other single signs found to be important in predicting 5% or greater dehydration were abnormal skin turgor (ie, tenting) and respiratory disturbance, in particular hyperpnea (deep, rapid breathing without other signs of respiratory distress) suggestive of acidosis. In general, the more signs that are present the greater the severity of dehydration; however, a combination of delayed capillary refill time, absent tears, dry mucosal membranes, and general ill appearance may be equally as good as capillary refill, tenting, and hyperpnea combined in identifying children who have more than mild dehydration.

Laboratory Studies

Laboratory studies typically are not indicated in children who present with mild dehydration. Dehydrated children who are treated with IV fluids after having failed oral rehydration (at home or in the emergency department) should have initial assessment of their serum electrolytes, BUN, and creatinine. Initial and serial measurements of these laboratory studies should also be performed during rehydration in children with (1) shock, (2) severe dehydration, (3) decreased urine output that does not improve after initial restoration of intravascular volume, or (4) a history and clinical findings inconsistent with

straightforward isotonic dehydration or found to have dysnatremia (ie, serum Na^+ outside of the normal range [135–150], whether too low or too high). Dehydration in association with dysnatremia can have serious complications, and treatment requires special considerations. Hemolytic uremic syndrome, although uncommon, should be considered in any child with gastroenteritis, particularly with a history of grossly bloody stool, who also has decreased urine output.

Very ill children may require an arterial blood gas measurement to more accurately assess their acid-base status; in others, serum electrolytes are sufficient. The usual acid-base derangement in the moderately dehydrated child is a non-anion gap acidosis (with hyperchloremia) due to bicarbonate losses in the stool. Severely dehydrated children may have an anion gap acidosis due to lactic acid and/or ketone accumulation in the peripheral tissues secondary to the decreased perfusion that accompanies hypovolemia. An interesting exception is seen in infants with pyloric stenosis, who typically manifest a hypokalemic, hypochloremic metabolic alkalosis.

Imaging Studies

Imaging studies such as chest radiograph, abdominal ultrasound, and computed tomography scans are indicated based on the suspected etiology of the dehydration.

Management

The management of the dehydrated child involves consideration of 3 components (1) normal **maintenance** fluid and electrolyte requirement, (2) fluid and electrolyte **deficit** incurred during the present illness, and (3) **ongoing fluid and electrolyte losses**. Most commonly, ongoing losses result from continued vomiting and diarrhea. Losses from diarrhea can be estimated at 10 mL/kg per stool and from vomitus at 5 mL/kg per vomiting episode. Other forms of ongoing losses that occasionally must be considered and replaced include those associated with burns, gastric secretion suctioned via nasogastric

tube, hyperventilation, or prolonged fever. The estimation of children's fluid and electrolyte needs and losses are almost always an approximation and require close follow-up, reassessment, and readjustment throughout treatment. At the very least, monitoring during treatment for dehydration requires regular assessment of vital signs, body weight, intake, and output.

Fluid given to dehydrated children may be provided either **enterally** or **parenterally**. Whenever possible, **ORT** using oral rehydration solution (ORS) is preferred for children with mild dehydration and most children with moderate dehydration. Parenteral fluid therapy should be used in children with more severe dehydration, when oral therapy has failed despite an adequate trial (eg, due to intractable vomiting or lethargy), in children in shock or impending shock, or when an anatomical defect such as pyloric stenosis or ileus is suspected.

Parenteral Fluid Therapy

The parenteral management of moderate or severe dehydration can be divided into 2 phases: an initial phase (first 1–2 hours) and the main phase of rehydration. The aim of the initial phase is to restore intravascular volume, thus improving perfusion and renal function and reversing tissue hypoxia, metabolic acidosis, and increased AVP. Regardless of the type of dehydration (isonatremic, hypernatremic, or hyponatremic), NS (0.9% sodium chloride) at 20 mL/kg/hour generally provides the most rapid and effective means to expand the intravascular volume at acute presentation. If shock is present or imminent, the treatment is more aggressive (see Chapter 61). The child should in rapid succession receive 2 to 4 boluses of 20 mL/kg of NS given over 20 to 30 minutes each. After each bolus, the child should be reassessed, and if signs and symptoms of intravascular depletion persist, the next IV bolus of 20 mL/kg of NS should be given over 20 to 30 minutes and the child admitted to the hospital for further careful evaluation, including assessment for other causes of shock such as sepsis. **The rapid restoration of ECF volume with up to 4 boluses of NS is a change in recommendation for the management of dehydrated children when compared with the past** (see Holliday et al and Friedman). However, caution must be used not to give excessive fluids to a child with a compromised heart and thereby induce congestive heart failure. This approach will also decrease AVP/ADH levels and the chances of hyponatremia in subsequent therapy even if 0.45% sodium chloride (1/2 NS) solutions are used instead of NS to correct the remaining deficit and maintenance therapy. All ORT is based on the use of hypotonic fluids generally containing Na⁺ concentration of 45 to 75 mEq/L.

During the second phase of rehydration, the remaining fluid and electrolyte deficits are replaced based on the magnitude of these losses. These replacements are in addition to the daily maintenance requirements as well as any ongoing losses, as discussed previously, but must take into consideration the NS boluses administered during the initial phase, which may have already restored a substantial portion of the total fluid deficit. Various protocols exist to restore fluid and electrolyte deficits; approaches to treatment of dehydration

at different institutions will vary. Many of the differences in rehydration strategies lie in the composition of treatment fluid and the rate at which it is administered. Some clinicians prefer to administer half of the total fluid needs over the first 8 hours and the remainder over the next 16 hours; others replace the fluid at the same rate over the entire rehydration period. The latter method is presented in the case resolution at the end of the chapter. Usually the fluid deficit is replaced within 24 hours. There are noteworthy exceptions. Treating dehydration associated with **dysnatremia** (ie, abnormally low or high serum Na⁺) should entail slower return (12 mEq serum Na⁺ change per 24 hours or 0.5 mEq change per hour) to a normal range and may require 48 to 72 hours for correction.

Sodium replacement in the dehydrated child depends on the type of dehydration. In isotonic dehydration some clinicians elect to replace the entire fluid deficit with NS, others use a saline solution containing 110 mEq Na⁺/L, and still others use 0.5 NS (77 mEq Na⁺/L). We recommend NS (154 mEq Na⁺/L) to replace the fluid deficit (see Case Resolution for example). This amount of sodium is somewhat more than the actual loss of sodium to the environment, which is closer to 110 mEq Na⁺/L because during isotonic dehydration some Na⁺, lost from the ECF, is shifted intracellularly to balance K⁺ losses and thus will return to the ECF during rehydration. To calculate the ongoing losses, although the content of excreted body fluids can be analyzed for electrolyte content for more exact replacement, the diarrheal stools are commonly replaced with 0.5 NS at 10 mL/kg per stool. (This should be adequate in Na⁺ content for most cases given diarrhea in rotavirus contains approximately 30 to 40 mEq Na⁺/L and enterotoxigenic *Escherichia coli*: 50 to 60 mEq/L; however, Na⁺ stool losses in cholera are 90–120 mEq/L.)

Management of Dehydration With Dysnatremia

In hypernatremic dehydration, the patient is considered to have a relative free water deficit but usually has lost not only body water, but also some Na⁺. The amount of free water a patient requires to restore their serum Na⁺ to normal (eg, 145 mEq/L is desired serum Na⁺) is calculated as follows:

$$[\text{patient's weight in kilograms}] \times [\text{actual serum Na}^+ - 145] \\ \times 4 \text{ mL/kg}$$

For serum Na⁺ greater than 170 mEq/L, 3 mL/kg of free water is estimated to lower the Na⁺ to the desired level (and thus the 4 mL/kg in the above equation is changed to 3 mL/kg). The quantity of free water provided by this equation is only part of the patient's total needs. The remainder of their fluid needs include isotonic losses that occurred during the dehydration process, ongoing losses, and maintenance fluids as well. Hypernatremic dehydration is corrected slowly to avoid cerebral edema, which can lead to brain stem herniation and death. In hypernatremia, the various equations used for calculations for phase 2 of therapy, the results for the sodium concentration of the final solution are often less than 30 mEq/L. Many clinicians, however, will initially provide 0.45% NaCl in 5% dextrose (a higher content Na⁺ fluid than calculated by various equations) to

ensure a slow rate of serum Na^+ decline and at a later stage decrease the sodium concentration to 0.2 % NaCl. Serial monitoring of electrolytes is important to ensure that the serum Na^+ is decreasing at the expected slow rate and not so quickly as to lead to life-threatening brain complications.

Management of **hyponatremic dehydration** also poses challenges. In addition to isotonic losses, additional Na^+ loss may have occurred. The amount of additional Na^+ (in mEq) to correct the serum Na^+ into a normal range (desired Na^+ level, eg, 135 mEq/L) has traditionally been calculated by the following equation (where 0.6 represents the body space which is affected by Na^+ changes):

$$[\text{patient's weight in kilograms}] \times [135 - \text{actual Na}^+ \text{ level}] \times 0.6$$

This amount of Na^+ represents an additional need beyond a patient's isotonic losses, ongoing losses, and maintenance requirements. The use of hypertonic saline (3% containing 513 mEq Na^+ /L) is generally reserved for children with symptomatic hyponatremia (eg, a child who is seizing). Hypertonic saline is administered as 3.0 mL/kg of 3% saline given by IV over 15 to 30 minutes or until seizures stop. This volume of 3% saline will raise the serum Na^+ approximately 2.5 mEq/L and is usually sufficient to correct the serum Na^+ to a level where serious signs and symptoms improve. This dose may be repeated once if there is no improvement in the CNS-related symptoms. The remaining hyponatremia is corrected more slowly so as not to exceed 12 mEq/L per 24 hours because too rapid correction of serum Na^+ , particularly when hyponatremia has been long-standing, can potentially cause pontine demyelination.

Hyponatremia in hospitalized children, as stated earlier (see Maintenance), can result from other factors besides or in addition to Na^+ loss. Arginine vasopressin release in response to hypovolemia, hypertonicity, or other stimuli followed by free water retention can lead to dilutional hyponatremia (water intoxication). Hyponatremia in infants given excessively diluted baby formula (WIC [Special Supplemental Nutrition Program for Women, Infants, and Children] syndrome) results from inadequate Na^+ intake and free water retention. There have been a number of recent reports of encephalopathy, brain stem herniation, and death occurring in hospitalized children with hyponatremia whose low Na^+ level was not appreciated or who received inappropriately low Na^+ content IV fluids or excessive volumes of IV fluids (see Moritz et al). The adverse effects of hyponatremia on the CNS seem to be accentuated in the setting of hypoxemia, thus further pointing to the importance of close monitoring of children with electrolyte disturbances. Moreover, with rehydration and provision of Na^+ , the kidneys excrete relatively more dilute urine that can sometimes lead to rapid and unpredictable increases in serum Na^+ levels. As is the case with treatment of hypernatremia, close attention to type and quantity of fluids provided, quantity of body fluid output, weight change, and serial electrolyte assessment is important to prevent serious complications during therapy for low Na^+ . When faced with such issues, consultation with a pediatric nephrologist or pediatric intensivist experienced in managing alterations in fluid and electrolyte balance is very important.

Potassium Replacement

Potassium deficits are more difficult to determine, and there is no specific method to calculate the exact amount of K^+ that a dehydrated child requires. Additionally, as the acidosis that commonly accompanies moderate and severe dehydration corrects, K^+ shifts intracellularly. What initially seems to be a normal serum K^+ may fall into the hypokalemic zone, potentially resulting in adverse effects on neuromuscular and cardiac function. Frequent reassessment of serum K^+ and adjustment of K^+ content of the IV fluids may be necessary. In general, once adequate urine output has been established, K^+ may be added to the IV fluids to provide 3 to 4 mEq/kg/24 hours. This need can usually be met by adding KCl 20 mEq/L to the IV fluids. Children who have decreased urine output or other indicators of renal impairment should not receive K^+ until normal urine output has been restored. Hyperkalemia, a serious and life-threatening condition, may occur if a child is unable to excrete excess K^+ via the kidney because of renal impairment.

Oral Rehydration

Oral rehydration therapy refers to specially prepared, balanced preparations of carbohydrates and electrolytes meant for oral consumption. Clinical trials have repeatedly shown that ORT is as efficacious as IV therapy in the treatment of the child with mild or moderate dehydration. Additional advantages of ORT over IV therapy are that it is less expensive and noninvasive, and requires little technology. Oral rehydration therapy has been credited with the dramatic reduction in death associated with diarrhea in the developing world. In 2002 the World Health Organization and UNICEF announced a new ORS with reduced osmolarity (proportionally lower Na^+ and glucose concentration) based on a number of clinical studies demonstrating less vomiting, lower stool output, and reduced need for IV fluids relative to the prior formulation.

In the United States, Pedialyte (Ross Laboratories, Abbott) and generic equivalents are the most widely commercially available products. Flavored solutions and ice-pop versions of these solutions are available and often preferred by older children over the unflavored variety. Enfalyte (Mead Johnson) contains rice syrup solids as its carbohydrate source and is only available in unflavored, 6 oz ready-to-use bottles. It is not necessary to change to ORT in a breastfed child who is tolerating breast milk; these children can continue to receive breast milk for rehydration, though they may require shorter, more frequent feedings.

The composition of various ORS is presented in Table 66-3. The cost of commercially available ORS may be prohibitive for some families. Given the simplicity of the ORS packet in the developing world and commercially available ORS in the developed world, these remain the first choice. However, homemade ORT, using the recipes in Box 66-2, can be effective as long as families have, and know how to use, measuring spoons and cups and have a clean source of water. Some solutions, such as fruit juices or chicken broth, do not contain the proper balance of Na^+ and carbohydrate to effectively rehydrate a dehydrated patient and should not be used (Table 66-4).

Table 66-3. Composition of Various Oral Rehydration Solution

<i>Solution</i>	<i>Carbo- hydrate (gm/L)</i>	<i>Sodium (mEq/L)</i>	<i>Potassium (mEq/L)</i>	<i>Base (mmol/L)</i>	<i>Osmolarity (mOsm/L)</i>
Pedialyte	25	45	20	30	250
Enfalyte	30 ^a	50	25	34	170
World Health Organization-UNICEF Oral Rehydration Solution	13.5	70	20	30	245

^a As rice syrup solids.

Table 66-4. Composition of Some Clear Liquids Not Appropriate for Rehydration

<i>Liquid</i>	<i>Carbo- hydrate (g/L)</i>	<i>Sodium (mEq/L)</i>	<i>Potassium (mEq/L)</i>	<i>Base (mmol/L)</i>	<i>Osmolality</i>
Cola	110	2	0	13	750
Apple juice	120	3	32	0	730
Chicken broth	0	250	8	0	500
Sport beverage	40	20	3	3	330

The amount of ORT fluid needed for rehydration can be calculated much the same way as is done when determining the parenteral fluid requirement for a dehydrated child. However, most children with mild dehydration can be rehydrated relatively quickly and then are likely to request, in response to thirst, the amount of fluid they need. Therefore, a simplified method of determining ORT fluid requirements has been developed (Table 66-5). This quantity of fluid is given over a period of 3 to 4 hours. Children with ongoing losses should have these replaced. For the most part, it is not necessary to calculate the quantity of electrolytes that should be provided because these solutions are designed to adequately replace electrolytes in otherwise healthy children who are dehydrated.

Box 66-2. Recipes for 2 Homemade Oral Rehydration Solutions^a**Starch-Based Solution**

- 1 quart clean water (4 cups, or 32 ounces)
- ½ teaspoon salt
- 1 cup dry baby rice cereal (about 2 ounces in weight)

Sugar-Based Solution

- 1 quart clean water (4 cups, or 32 ounces)
- ½ teaspoon salt
- 6 teaspoons sugar
- One teaspoon of flavored gelatin powder may be added to either recipe to improve palatability.

^a The proportion of ingredients in these recipes is important. These recipes should only be given to families who have and know how to use measuring spoons and cups. (Courtesy of Kathi Kemper, MD.)

Parents should receive guidance about the volume (converted into common household measures, eg, 5 mL = 1 teaspoon and 15 mL = 1 tablespoon of water or ORS) and the frequency and duration of ORT to be given at home. Small volumes of 5 to 15 mL administered with a syringe or teaspoon every 2 to 5 minutes are much more likely to be retained by children who vomit larger volumes. Although this technique is labor intensive, it can be done by the parent and can deliver 150 to 300 mL/hour. As dehydration is corrected, vomiting often decreases and the child is then able to tolerate larger volumes. With ORT the frequency and amount of stooling often increases during the initial period of treatment. Parents should be made aware that the primary purpose of ORT is to rehydrate and not to stop diarrhea, which will gradually decrease spontaneously. “Gut rest” is not appropriate in most cases, and early refeeding with a return to the usual formula or milk and solids, if appropriate, should be prioritized.

Prognosis

Children with mild or moderate dehydration as a consequence of a self-limited childhood illness are likely to recover completely when given timely and appropriate rehydration therapy. It is more difficult to predict the prognosis of children with severe dehydration or significant aberrations in electrolyte balance. If managed appropriately, most of these children also completely recover; however, some, despite closely monitored care, may have permanent sequelae or poor outcomes.

Table 66-5. Treatment With Oral Rehydration Therapy (ORT)

<i>Degree</i>	<i>Dehydration ORT (Given Over 3–4 h)</i>	<i>Replacement of Losses</i>	<i>Dietary Therapy</i>
Mild (5%) (older children = 3%)	50 mL/kg of oral rehydration solution (ORS)	10 mL/kg for each diarrheal stool 5 mL/kg for each vomitus	Return to formula or milk as soon as vomiting resolves. Children who eat solid food can continue their regular diet.
Moderate (10%) (older children = 6%)	100 mL/kg of ORS	10 mL/kg for each diarrheal stool 5 mL/kg for each vomitus	Return to formula or milk as soon as vomiting resolves. Children who eat solid food can continue their regular diet.

CASE RESOLUTION

The opening vignette describes a child who is moderately dehydrated. Based on clinical assessment and weight change since his last clinic visit, he is approximately 10% dehydrated. He does not show evidence of shock. His laboratory studies show an Na^+ of 138 mEq/L, K^+ of 3.7 mEq/L, chloride of 108 mEq/L, bicarbonate of 14 mEq/L, BUN of 13 mg/dL, and creatinine 0.4 of mg/dL. His renal status is likely to be adequate because he is urinating, and BUN and creatinine are normal for patient age. The child's serum Na^+ is 138 mEq/L, which is in the isotonic range. The serum K^+ is 3.7 mEq/L, which is within normal range; however, this may not accurately reflect this patient's total body K^+ status. This level may decrease substantially as he is rehydrated and acidosis is corrected, indicating total body K^+ depletion. His serum bicarbonate is 14 mEq/L, and his anion gap is 16 [$138 - (108 + 14)$], which is mildly increased and probably related to ketosis or mild lactic acidosis.

A calculation of this child's fluid and electrolyte needs follows:
His pre-illness weight was 12 kg.

Maintenance

Fluid needs: 1,000 mL for first 10 kg + 100 mL for next 2 kg = 1,100 mL.

Sodium needs: 33 mEq Na^+ (3 mEq/100 mL of maintenance fluid requirement)

Deficit

Fluid: 10% of child's weight has been lost during this episode of dehydration = 1,200 mL deficit

Sodium: 185 mEq Na^+ (154 mEq/1,000 mL of isotonic losses):
 $154/1,000 \times 1,200 = 185$ mEq.

Ongoing Losses

Fluid: Estimate this child's ongoing losses at 10 mL/kg for each stool. He had one loose stool while in the office, so add 120 mL of additional fluid.

Sodium: The Na^+ content of diarrhea is variable; however, it is usually replaced with 0.5 NS or about 77 mEq/1,000 mL. We estimate about 9 mEq of Na^+ in his one loose stool.

Total fluid needs: 1,100 mL (maintenance) + 1,200 mL (deficit) + 120 mL (ongoing losses) = 2,420 mL/24 hours.

Electrolyte Needs

Sodium: 33 mEq (maintenance) + 185 mEq (deficit) + 9 mEq (ongoing losses) = 227 mEq Na^+ /24 hours.

Potassium: Estimate his maintenance and replacement needs to be 20 mEq K^+ /1,000 mL fluid provided.

Treatment

In the initial phase of therapy, provide 40 mL/kg/hour NS for about 2 hours. During this period, his heart rate normalizes and he urinates. The initial parenteral phase provides 480 mL fluid and 74 mEq Na^+ . This amount of fluid and Na^+ is subtracted from the patient's total fluid needs. The remaining amount to be provided is 1,940 mL fluid and 153 mEq Na^+ , or about 79 mEq Na^+ /1,000 mL fluid. It is not necessary to prepare a special IV solution; 0.5 NS (77 mEq NaCl/L) with 5% dextrose ordered as **D5 0.5 NS with 20 mEq KCl/L to run at 80 mL/hour** is appropriate. As his GI symptoms improve, IV therapy is discontinued and ORT instituted. The patient tolerates the ORT well and is discharged home.

Acute Kidney Injury

Gangadarshni Chandramohan, MD, MS, and Sudhir K. Anand, MD

CASE STUDY

A 10-month-old girl has a 2-day history of fever, vomiting, and watery diarrhea. The child has previously been healthy. Her diet has consisted of Similac with iron, baby food, and some table food. Since the onset of her illness, she has not been drinking or eating well, and she has thrown up most of what she has eaten. Her mother has tried to give her Pedialyte and apple juice on several occasions but has had limited success. The child has had 8 to 10 watery stools without blood or mucus each day. Her temperature has varied between 98.6°F and 101.8°F (37.0°C and 38.8°C); the mother has given her daughter acetaminophen, which she has vomited. The girl's 4-year-old brother and her parents are doing well and have no vomiting or diarrhea.

The physical examination reveals a severely dehydrated (15%), listless infant. Her weight is 9.4 kg, her height is 74 cm, her temperature is 101.1°F (38.4°C), her heart rate is 168 beats/min, her respiratory rate is 30 breaths/min, and her blood pressure is 72/40 with an

appropriately sized cuff. Capillary refill is 2 to 3 seconds. The skin appears dry, but no rash is present. Head and neck, chest, heart, and abdominal examinations are normal. Pending the results of her blood studies, an intravenous (IV) fluid bolus of 180 mL normal saline (20 mL/kg) over 20 to 30 minutes is administered. This is followed by 2 more boluses of 180 mL normal saline each. The girl is catheterized to obtain urine and determine the urine flow rate over the next several hours. A urinalysis is performed.

Questions

1. What are the 3 categories of acute kidney injury (AKI)?
2. What is the etiology of AKI?
3. How would one make an assessment of a patient with AKI?
4. What is the appropriate management for children with AKI?
5. What are the indications for renal replacement therapy?

Acute kidney injury is encountered in both outpatient and hospital inpatient settings and is associated with high morbidity and mortality depending on the primary cause of the insult. There are more than 30 different definitions of AKI in the literature. For the past 50 to 60 years, a sudden decrease in kidney function, signified by the accumulation of nitrogenous waste products (eg, blood urea nitrogen [BUN], creatinine) and often accompanied by a decrease in urine output, has been called acute renal failure. With better understanding of the pathophysiology of acute deterioration in renal function, many nephrologists and intensivists have suggested that the term **acute kidney injury (AKI)** be used instead of acute renal failure (ARF). Acute kidney injury is a more descriptive term that encompasses the full spectrum of renal dysfunction, from early and mild renal injury with only a small elevation in serum creatinine, to severe kidney injury requiring renal replacement therapy (dialysis).

In order to better delineate the progression of AKI as a continuum, in 2004 the Acute Dialysis Quality Initiative work group set forth the “RIFLE” criteria, which is based on serum creatinine level and urine output. The acronym “RIFLE” defines 3 stages of progressively increasing severity of renal injury (*risk*, *injury*, and *failure*) followed by 2 outcome variables (*loss* and *end stage renal disease*). This criterion was recently modified for the pediatric population

(pRIFLE), and the clinical use of it has been shown to improve the outcome in children (Figure 67-1). This classification is in part based on declining urine output; however, in some children, urine output

Risk	Urine output <0.5 mL/kg/h for 8h and/or eGFR is 75%
Injury	Urine output <0.5 mL/kg/h for 16h and/or eGFR is 50%
Failure	Urine output <0.3 mL/kg/h for 24h or anuric for 12h, and/or eGFR is 25%
Loss	Persistent failure for >4 weeks
ESRD	Persistent failure for >3 months

Figure 67-1. Modified pediatric RIFLE (pRIFLE) criteria. eGFR, estimated glomerular filtration rate; ESRD, end stage renal disease. (Adapted from Bellomo et al.)

may remain normal or even become increased, generally known as nonoliguric renal failure. The pRIFLE criteria, however, are not applicable in newborn infants during the first few days of life because newborns may be physiologically oliguric during the first 24 hours of life and their serum creatinine initially reflects maternal creatinine values.

The pRIFLE classification is intended to emphasize the reversible nature of the renal insult, which is often present in critically ill children admitted in pediatric intensive care units (PICUs). It is anticipated that this precise and universal definition of AKI will probably enable clinicians to rapidly recognize the at-risk individuals and intervene promptly to improve the immediate and long-term outcomes.

Epidemiology

Acute kidney injury occurs in children with a wide variety of medical or surgical conditions and especially in children who are critically ill. The exact incidence of AKI in children is not known, but a late 1990s study from the United Kingdom estimated an incidence of 0.8 per 100,000 children. Acute kidney injury is often observed in patients in PICUs who are septic, have major trauma with severe bleeding, and in the postoperative period following major heart surgery with reported incidence as low as 4.5% and as high as 82% depending on the criteria used for inclusion (see Hsu and Symons in Selected References). Primary renal disease leading to AKI seems to be decreasing in incidence when compared with AKI caused by other systemic illnesses and/or their treatments. The incidence of AKI is about 5% to 10% in neonatal intensive care units and the most common cause in most cases is perinatal hypoxia and hypotension.

Clinical Presentation

Most children with AKI initially present with the clinical findings of the primary condition that ultimately leads to the renal problem. In critically ill children, a small increase in the serum creatinine may be the first indication of AKI. Other findings, such as decreased urine output, edema, and heart failure (following administration of excessive fluids), are specifically related to declining renal function (Dx Box). Additionally, hyperkalemia with cardiac arrhythmia, hyperventilation due to acidosis, and nausea and vomiting due to uremia may occur as renal failure progresses.

Dx

Acute Renal Failure/Kidney Injury

- Decreased urine output
- Hypertension
- Hematuria
- Edema
- Elevated serum creatinine
- Blood urea nitrogen/creatinine ratio <20
- Elevated fractional excretion of sodium

Box 67-1. Etiology of Acute Renal Failure/Kidney Injury in Children

Prerenal Causes

- Decreased plasma volume
- Dehydration
- Hemorrhage
- Third spacing of plasma volume in burns, sepsis, bowel obstruction
- Other causes of renal hypoperfusion
- Shock
- Hypoxia
- Congestive heart failure
- Hepatorenal syndrome
- Bilateral renal artery stenosis
- Cardiac surgery

Postrenal Causes

- Bilateral ureteropelvic or ureterovesical junction obstruction
- Posterior urethral valves
- Trauma to urethra
- Urethral stricture
- Neurogenic bladder
- Ureteropelvic or ureterovesical obstruction of a solitary kidney
- Obstruction due to kidney stone at the bladder neck

Intrinsic Renal Causes

- Vascular: renal artery or vein thrombosis, disseminated intravascular coagulation
- Glomerular: hemolytic uremic syndrome, severe (rapidly progressive) glomerulonephritis from any etiology
- Interstitial: interstitial nephritis due to allergic reaction to drugs (eg, nonsteroidal anti-inflammatory drugs, oxacillin, methicillin), sepsis
- Tubular (acute tubular necrosis [ATN]): sepsis, post-cardiac surgery, ischemia due to prolonged hypoperfusion; all causes listed in prerenal category, if sufficiently prolonged may lead to ATN
- Nephrotoxins: aminoglycoside antibiotics, indomethacin, radiocontrast agents, ethylene glycol, methanol, heavy metals
- Pigments: myoglobinuria, hemoglobinuria
- Uric acid: hyperuricemia, tumor lysis syndrome
- Congenital renal anomalies (especially in newborns and young infants)
- Bilateral cystic dysplastic kidneys, reflux nephropathy, polycystic kidneys, oligomeganephronia

Etiology and Pathophysiology

The causes of AKI are usually grouped into 3 categories: prerenal, intrinsic renal, and postrenal disorders (Box 67-1 and Figure 67-2). Although prerenal failure and acute tubular necrosis (intrinsic renal failure) may actually be on opposite ends of a continuum, rather than separate entities, this classification system still aids in the conceptualization of the underlying problem and formulation of the initial treatment plan. Correspondingly, it is important to note that postrenal failure could also inflict renal damage if intervention is not timely and ultimately can result in intrinsic renal failure.

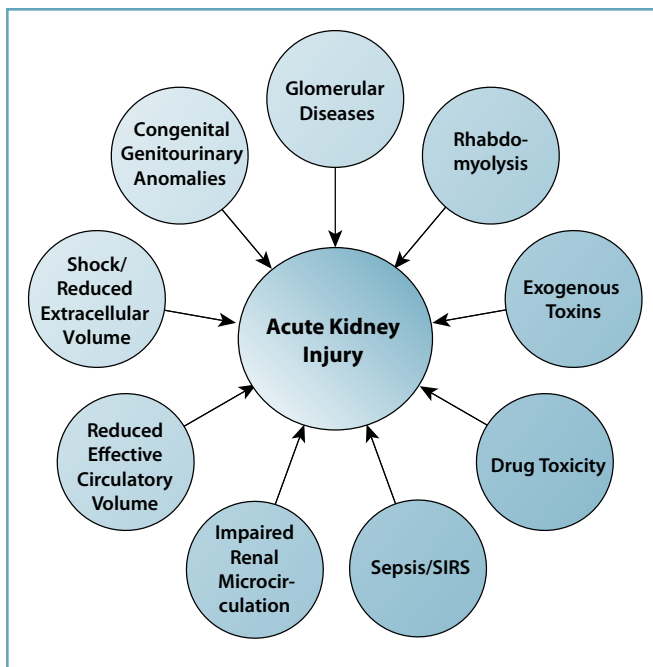

Figure 67-2. Common causes of acute kidney injury in children. SIRS, systemic inflammatory response syndrome.

Prerenal Disorders

Prerenal disorders are the most common cause of AKI in pediatrics and lead to a decrease in total or “effective” circulating blood volume. An absolute decrease in circulating volume can be caused by blood loss from acute hemorrhage secondary to trauma or fluid loss and dehydration secondary to gastroenteritis. Heart failure or redistribution of body fluids (third spacing) can lead to a decrease in effective circulating volume. In each of these situations, the resulting decrease in the glomerular filtration rate (GFR) can be readily reversed by improving renal perfusion in its early stages. If hypoperfusion is prolonged, however, ischemic damage to the kidney occurs and intrinsic renal failure develops (see below).

Postrenal Disorders

Urinary obstruction due to posterior urethral valves or other congenital lesions involving the urinary tract occasionally lead to AKI, especially during infancy. In older children, kidney stones or postoperative complications after pelvic surgeries or trauma could be the cause for postrenal failure.

Intrinsic Disorders

Intrinsic renal failure occurs because of injury to the vascular, glomerular, interstitial, or tubular components of the kidney (see Box 67-1). Intrinsic AKI can result from ischemia, sepsis, or toxins. Acute kidney injury resulting from renal tubular lesions is also called acute tubular necrosis (ATN), although in many patients with ATN, necrosis of tubular cells visible by light microscopy is minimal. Certain histologic changes that characterize ATN include loss of brush border microvilli in tubular cells, detachment of epithelial

cells from basement membrane, and cast formation from cellular debris and protein.

Children with prolonged shock due to sepsis, post-cardiac surgery, trauma (hemorrhage), or dehydration often develop ATN if the effective circulating volume is not expanded. This is the most frequent type of intrinsic AKI observed in children. Hemolytic uremic syndrome (HUS) had been the most common cause of AKI in young children in 1970s–1980s, but its incidence has markedly declined in recent years. Nonsteroidal anti-inflammatory drugs are increasingly being recognized as a cause of AKI in children, especially when used in volume-depleted patients. In newborns and young infants, AKI may result from, or be superimposed on, a preexisting congenital renal disorder.

The pathogenesis of ATN in humans is controversial, and no single mechanism completely explains the sequence of events that lead to ATN. Ischemic and toxic ATN results from a complex interplay of hemodynamic, vascular, and tubulointerstitial changes. These include decreased blood flow to glomerular and tubular capillaries, resulting in reduced GFR; injury to cortical and medullary tubules with their cellular debris, leading to tubular obstruction; and “back leak” of solute and water from the lumen to the interstitium with further decrease in GFR. Increased production of endothelin and reduced production of nitrous oxide in the microvascular smooth muscle cells lead to increased vasoconstriction and reduced perfusion, perpetuating the renal injury. Renal tubular cells respond to the injury in many different ways, including no or minimal damage, sublethal injury, apoptosis, or necrosis. In the tubules, at the cellular level, when there is decreased oxygen delivery, there is decreased production of ATP that leads to damage to cell membranes and cell cytoskeletons. The cell damage alters the cell polarity, promotes entry of increased amounts of calcium into the cells, and increases intracellular free radical formation that eventually result in altered cellular function, cellular swelling, and cell apoptosis/necrosis. It is hoped that with better understanding of the pathophysiology of AKI, innovative, improved ways to prevent, diagnose, and treat the disease will be developed.

Differential Diagnosis

The diagnosis of AKI is established by the demonstration of a sudden increase in serum creatinine and/or BUN. Decreased urine output is also helpful. Identification of the clinical disorder that led to AKI is sometimes obvious, but at other times extensive evaluation to discover the etiology of the primary disorder may be necessary. It should also be determined whether children have chronic kidney disease or superimposition of AKI on a preexisting renal condition (Figure 67-2).

Evaluation

This is one of the few settings in which laboratory and radiologic tests are often more helpful diagnostically than history and physical examination.

History

The possibility of developing AKI should be anticipated in all critically ill children. A history of decreasing urine output, hematuria, dysuria, nausea, and vomiting should be sought in all patients. Prenatal and birth history may help to identify causes such as oligomeganephronia in children who were small for gestational age at birth or other complications that would have led to the current condition. The presence of previous genitourinary disorders, delayed growth, and anemia may point to preexisting kidney conditions (Questions Box). Also, family history of renal disorders can help in the differential diagnoses.

Questions

Acute Renal Failure/Kidney Injury

- How frequently is the child passing urine?
- Is the amount of daily urine decreased, increased, or unchanged?
- Does the child have hematuria or dysuria?
- Does the child have nausea or vomiting?
- Has the child had any previous urinary problems?
- (Older children) Does the child have a history of enuresis or nocturia?
- Is the child's physical development normal or delayed?
- Does the child have a history consistent with a primary condition that may have led to the acute renal failure/acute kidney injury?

Physical Examination

An evaluation of physical growth, hypotension or hypertension, arrhythmia, dehydration, or edema should be made. Examination of the flank area for renal enlargement or tenderness and of the bladder for distention is necessary to help determine the etiology of AKI.

Laboratory Tests

The following laboratory tests are recommended in all children with AKI: complete blood cell count, with red blood cell (RBC) morphology and platelet count; serum sodium, potassium, and bicarbonate; BUN; creatinine, uric acid, calcium, and phosphorus; glucose; total protein and albumin serum concentration; urinalysis and urine culture (if indicated); and spot urinary sodium and creatinine concentration and osmolality. If children are not voiding frequently, catheterization of the bladder is advisable temporarily (4–6 hours) to obtain urine for analysis. Residual volume should also be assessed, and the urinary flow rate (especially the response to initial fluid therapy) and presence of an outflow obstruction should be determined. All children with AKI and evidence of hyperkalemia should have an electrocardiogram (ECG).

The diagnosis of AKI can easily be established by laboratory tests and determination of urinary output over a specific time. Oliguria is defined as urine output less than 400 mL/m²/day or less than 1 mL/kg/hour in infants younger than 1 year, less than 0.75 mL/kg/hour in children 2 to 6 years of age, and less than

Table 67-1. Diagnostic Indices in Acute Kidney Injury^a

Test	Prerenal	Intrinsic Renal
Urinalysis	Normal, occasional granular casts	Renal epithelial cells; pigment casts
Urine osmolality (mOsm/kg H ₂ O)	>600	<400
Urine specific gravity	>1.020	<1.015
Urine sodium (mEq/L)	<15	>40
U-P creatinine	>40	<20
Fractional excretion of sodium (FE _{Na}) ^b	<1%	>2%

Abbreviation: U-P creatinine, urine-plasma creatinine ratio (mg/mg).

^a Values in patients with nonoliguric AKI often overlap and fall between prerenal and renal values. In addition, values in newborn infants differ from those in children beyond 1 year of age.

^b FE_{Na} = (UNa /UCr) × (PCr / PNa) × 100; UNa = urine sodium (mEq/L)

FE_{Na}, fractional excretion of sodium; UCr, urine creatinine (mg/dL); PCr, plasma creatinine (mg/dL); PNa, plasma sodium (mEq/L)

0.5 mL/kg/hour in children older than 6 years. Urinalysis, urine-specific gravity or osmolality, urine-plasma creatinine ratio, urinary sodium concentration, and fractional excretion of sodium help differentiate prerenal from intrinsic AKI (Table 67-1). While a BUN-creatinine ratio of greater than 20:1 suggests prerenal azotemia in adults, this is not necessarily true in infants and young children because they often normally have a BUN-creatinine ratio equal to or greater than 20.

Tubular epithelial cells and brown-pigmented casts are often seen in patients with ATN. Evidence of hematuria or proteinuria signifies glomerular disease, especially glomerulonephritis or HUS. Presence of blood on dipstick but absence of RBCs on sediment examination suggests hemoglobinuria or myoglobinuria as the basis of ATN.

Although urinary indices are helpful in differentiating prerenal from intrinsic AKI, a simple clinical method to distinguish between the 2 can be used. A therapeutic trial of volume expansion with 20 mL/kg of normal saline is administered intravenously over one-half to 1 hour (after the possibilities of congestive heart failure and urinary obstruction are excluded). If oliguria persists at the end of 1 hour, furosemide (2 mg/kg) can be given. If urinary output does not increase following furosemide administration, intrinsic AKI should be suspected and fluid administration should be reduced. Once intrinsic AKI has developed, repeated administration of high-dose furosemide has few benefits and can cause toxicity, especially hearing loss.

Many biomarkers have been investigated for the early diagnosis of AKI in adults and children (see Al-Ismaïli et al in Selected References). The hope is that one day biomarkers found in either the serum or urine will allow us to better detect early kidney injury, differentiate among the multiple etiologies, and predict its severity. There are many promising urinary biomarkers, including IL18, KIM-1, NGAL, β₂-microglobulin, and osteopontin, which have been

recently identified by proteomic analysis and all correlate with AKI to a variable degree. Both NGAL and β_2 -microglobulin have been shown to correlate significantly with AKI in children seen in the emergency department with various forms of predisposing conditions. The concept of multiple biomarkers together to determine the changes in the kidneys during the early phase of AKI has been recently entertained, and various investigators are currently studying the value of this tool in clinical practice. Furthermore, more than one genetic polymorphism has identified in adults that are known to be linked to individuals who are susceptible to develop AKI. Perhaps, in the future, this information can help physicians to recognize the at-risk individuals and intervene early to prevent renal injury.

Imaging Studies

Renal ultrasonography is the most useful test for differentiating postrenal from other forms of AKI. Renal ultrasound can detect the presence or absence of kidneys, enlarged kidneys, dilated pelvocalyceal system, a distended bladder, and other congenital anomalies. Other investigative tests, such as voiding cystourethrography, renal scans, angiography, computed tomography, magnetic resonance imaging, or renal biopsy, may occasionally be necessary but are generally not indicated in children with AKI during the initial phase of the workup. Once a glomerular cause is suspected based on laboratory findings or radiologic evaluation, a biopsy will be an appropriate next step. A chest radiograph may also be helpful in detecting cardiac enlargement or pulmonary edema due to fluid overload.

Management

Prerenal azotemia is corrected by reestablishing adequate circulating volume, but unfortunately no current treatment leads to rapid recovery of renal function in humans with established intrinsic AKI. Although low-dose dopamine and furosemide are often used in the initial management of AKI, many studies have shown that these medications do not enhance recovery of renal function. Fenoldopam, a dopamine receptor agonist, has been used in critically ill, hemodynamically unstable patients with AKI to improve renal perfusion with some benefit in selected patients. Certain drugs, such as ATP-magnesium chloride, thyroxine, atrial natriuretic hormone, and insulin-like growth factors (IGF-1) have been used in experimental animals and some human trials without much success. The goal of therapeutic management of intrinsic AKI is maintenance of normal body homeostasis while awaiting spontaneous improvement because proximal tubules can undergo repair and regeneration after damage.

After dehydration is corrected, **daily fluid intake** is limited to replacement of insensible water loss (about 30%–40% of daily recommended fluid intake for age), urinary losses, and fluid losses from non-renal sources (eg, nasogastric drainage). Overhydration should be avoided in patients with AKI because it can cause edema, congestive heart failure, hypertension, hyponatremia, encephalopathy, and seizures.

Patients with complete anuria require no sodium intake. **Sodium** losses should be replaced daily in patients with urinary output, however. Preferably, the amount of sodium required should be determined by measuring daily urinary sodium losses.

Once AKI is suspected, **potassium** intake from all sources should be restricted. Severe hyperkalemia can often be avoided early in the course of the disease with strict adherence to potassium restriction. The level of serum potassium as well as ECG changes should be closely monitored. Patients with mild hyperkalemia may be treated with ion exchange resins; sodium polystyrene sulfonate (Kayexalate) may be given orally every 4 to 6 hours or by retention enema every 1 to 2 hours. Sodium polystyrene sulfonate should be mixed in water and mixtures containing polysorbate avoided because the latter may lead to bowel perforation. Moderate hyperkalemia can be treated with insulin and glucose infusions or β -agonists, which will drive the potassium intracellularly. Calcium gluconate should be given to stabilize the myocardium in patients who have ECG changes of hyperkalemia, such as tall T waves or widened QRS complexes. Dialysis is the most effective treatment for hyperkalemia and may be warranted if serum potassium has been rising slowly over several days or there is evidence of cardiac instability despite conservative treatment. Dialysis is also indicated for other reasons (see below).

Hypocalcemia and hyperphosphatemia are common in AKI, and small alterations in levels of **calcium** and **phosphorus** require no treatment. For serum phosphate greater than 8 mg/dL, phosphate binders such as calcium carbonate or calcium acetate may be used. If serum calcium is less than 8 mg/dL, IV or oral calcium should be given to prevent tetany.

Mild metabolic acidosis is common in AKI and requires no treatment. If blood pH is less than 7.2 or serum bicarbonate is less than 12 mEq/L, sodium **bicarbonate** may be administered.

Adequate nutrition is important in AKI because it prevents excessive tissue breakdown. If renal failure is expected to be short in duration (3–4 days), most calories may be provided as carbohydrates. If AKI is expected to last longer, adequate calories in the form of carbohydrates along with daily protein intake of 1 g/kg should be provided.

Anemia should be identified and corrected if hemoglobin is less than 10g/dL in order to improve the oxygen and nutrient delivery to the tubules to facilitate the regeneration of cells and to establish their function. This can be achieved by maintaining an optimal hemoglobin level either by transfusing packed red cells and by subcutaneous or IV administration of epogen if renal failure is prolonged.

Many children with AKI can be managed by the conservative measures described previously. If renal failure lasts more than a few days or if complications develop, however, **dialysis** should be planned. The usual indications for dialysis include uncontrollable hyperkalemia or acidosis, volume overload with pulmonary edema and/or congestive heart failure unresponsive to diuretic treatment, progressive uremia with BUN greater than 100 mg/dL, or creatinine clearance less than 15 mL/min/1.73 m². In preemies and newborn babies, peritoneal dialysis is usually preferred over hemodialysis to avoid major

hemodynamic instability that is often seen with hemodialysis. In critically ill children with overwhelming sepsis or multisystem organ dysfunction, however, early continuous venovenous hemodiafiltration is indicated for more gradual fluid removal, avoiding significant fluctuations in the fluid balance and to optimize nutritional support.

Acute renal failure/AKI can often be prevented by anticipating its possible occurrence in children with high-risk conditions such as dehydration, trauma, sepsis, and shock, or after cardiac surgery. Prompt recognition of prerenal failure and its aggressive management with volume expansion may prevent the development of intrinsic AKI. Nephrotoxic agents such as gentamicin should be avoided in high-risk patients if possible. When these drugs are used, they should be monitored meticulously, with frequent measurement of blood levels.

Prognosis

The duration of oliguria in AKI may be short (1–2 days) or long (a few weeks). Recovery is usually first indicated by an increase in urinary output. Blood urea nitrogen and creatinine may rise during the first few days of diuresis before beginning to return to normal. During diuresis, large quantities of sodium and potassium may be lost in the urine. Serum electrolytes should be closely monitored, and adequate replacements should be made to prevent hyponatremia or hypokalemia.

In children with AKI, outcome largely depends on the primary condition, the severity of damage to other organs, and physician expertise in managing AKI. Nonoliguric AKI is consistently associated with a shorter clinical course and better prognosis than oliguric AKI. Most children with ATN recover completely. However, children with more severe kidney involvement (cortical necrosis) may have residual renal impairment or chronic renal failure, and critically ill children have a 60% mortality rate.

CASE RESOLUTION

In the case scenario, a series of diagnostic studies are performed. The laboratory results are: hemoglobin, 13.8 g/dL; hematocrit, 41%; white blood cell (WBC) count, 12,400/ μ L; neutrophils, 58%; band forms, 6%; lymphocytes, 32%; monocytes, 3%; and eosinophils, 1%. The platelet count is 277,500/ μ L. Serum sodium is 136 mEq/L; potassium, 5.1 mEq/L; chloride, 110 mEq/L; bicarbonate, 10 mEq/L; BUN, 84 mg/dL; creatinine, 2.8 mg/dL; and glucose, 68 mg/dL. The specific gravity is 1.015; the specimen shows protein trace, blood, WBC, and nitrite negative; and the sediment has many epithelial cells, 1 to 2 RBCs, and many granular and pigmented casts. Spot urinary sodium is 65 mEq/L, creatinine is 39 mg/dL, and the fractional excretion of sodium is 3.4%.

These results are most consistent with the diagnosis of intrinsic renal failure/AKI because the fractional excretion of sodium is increased. Recovery may take a few days to a few weeks. The patient is admitted to the pediatric step-down unit where fluids are adjusted according to her urine output and electrolytes are monitored frequently.

Ingestions: Diagnosis and Management

Kelly D. Young, MD, MS

CASE STUDY

A 2-year-old girl is found by her mother with an open bottle of pills and pill fragments in her hands and mouth. She is rushed into the emergency department. She is sleepy but arousable. The vital signs are temperature of 98.8°F (37.1°C), heart rate of 120 beats/min, respiratory rate of 12 breaths/min, and blood pressure of 85/42 mm Hg. Pupils are 2 mm and reactive. Skin color, temperature, and moisture are normal. She has no other medical problems.

Questions

1. What history questions should be asked to help identify the substance ingested?
2. What physical examination findings can give clues to the substance ingested and the seriousness of the ingestion?
3. What other diagnostic tests might be helpful in managing ingestion patients?
4. What are the management priorities?

Ingestions are a common problem faced by pediatric practitioners. Two scenarios frequently encountered are accidental ingestions by preschool-aged children and intentional suicide attempts by adolescents. This chapter discusses the general approach to the child who has ingested a potentially poisonous substance; ingestions of specific substances are beyond the scope of this chapter, as is toxicity occurring by dermal, ophthalmologic, or inhalational routes. However, the general approach to history, physical examination, laboratory tests and diagnostic studies, and management, especially decontamination, is useful for all ingestions.

Epidemiology

Most calls made to poison control centers involve pediatric patients. Poison control center data (2008) show that pediatric patients younger than 20 years accounted for 65% of exposures, and young children aged 0 to 5 years accounted for 52%. For children aged 0 to 12 years, 3% of exposures are intentional, while for adolescent 13- to 19-year-olds 24% are intentional, and for adults 71% are intentional. The most common substances ingested overall are analgesics (including acetaminophen, nonsteroidal anti-inflammatory drugs, and narcotics) and cosmetics/personal care products. The most common fatal ingestion in children is narcotic analgesics (often not their own prescription). Another common fatal poisoning for young children is carbon monoxide poisoning. Fatalities are uncommon overall and are more likely to be seen in intentional ingestions by older children. Poison control center data (2008) revealed 42 pediatric fatalities (0–12 years old) and 74 adolescent fatalities (13–19 years old). Children accounted for 2.6% of total toxicological fatalities for

the year, while adolescents accounted for 5.6% and adults for the remainder. Young children tend to ingest either nontoxic substances or small quantities of toxic substances. While 24% of overall children whose caregivers called into poison control centers are managed in a health care facility (as opposed to observed at home), only 10% of children 0 to 5 years old are.

Clinical Presentation

The clinical presentation varies considerably depending on the substance ingested. Some patients may not present with a clear history of a toxic ingestion. The clinician must maintain a high index of suspicion for poisoning as the cause of symptoms such as altered behavior, depressed level of consciousness, cardiac dysrhythmias, vomiting, seizures, and autonomic changes.

Pathophysiology

The pathophysiological picture depends on the substance. Some toxins act on a particular organ system (eg, acetaminophen on the liver, ethanol on the central nervous system), while others act diffusely at the cellular level (eg, cyanide). Generally, drugs are absorbed, distributed within the body, metabolized, then excreted. Drug levels obtained prior to completion of absorption and distribution may not reflect the peak level. Interventions focus on preventing absorption, sometimes on preventing metabolism into a more toxic by-product, and on enhancing excretion. Toxic effects may be delayed or prolonged when an extended-release form of a drug has been ingested, with drugs likely to form concretions (iron, aspirin, theophylline), or

when toxicity results from an active metabolite (toxic alcohols, acetaminophen, acetonitrile, dapsone). Pharmacogenetics are increasingly recognized as possibly playing an important role in individual responses to medications and toxins. Genetic variations in enzymatic activity in drug metabolism may result in toxicity through excessively rapid metabolism of a drug to its active metabolite, or through slow metabolism of a drug to its inactive metabolite. For example, a cytochrome P450 CYP2D6 genotype has been linked to rapid metabolism of codeine to active morphine, resulting in toxicity, and even fatality.

Differential Diagnosis

The differential diagnosis of toxic ingestions is broad. If there is a history of ingestion, the differential is narrowed to substances available to the child. If no history of ingestion is given, practitioners should include ingestion in the differential when evaluating symptoms and signs such as altered mental status, altered behavior, metabolic derangements, cardiac dysrhythmias, hypotension and shock states, seizures, respiratory distress or apnea, cyanosis, vomiting, and diarrhea (Symptoms Box). In fact, almost any symptom complex may result from a toxic ingestion.

Suspicious for Poisoning

- Bradycardia or tachycardia
- Hypothermia or hyperthermia
- Respiratory depression or hyperpnea
- Hypotension or hypertension
- Mydriasis or miosis
- Altered mental status or abnormal behavior
- Seizure
- Cardiac dysrhythmias
- Metabolic derangements
- Nausea, vomiting, diarrhea

Symptoms

Evaluation

A detailed history of what and how much the patient ingested is key to the evaluation. Physical examination should focus on identifying symptoms and serious complications. Patients should be monitored and reassessed frequently. Laboratory and other diagnostic studies can be tailored to the specific ingestion.

History

The most important questions address the ingestion (Questions Box): What did the patient ingest? What is the maximum possible amount that was ingested? When did the ingestion occur? What symptoms are occurring? History regarding previous medical conditions is also important to identify increased susceptibility to a particular toxin (eg, seizure disorder with ingestion of a substance that

Questions

Poisonings

- What did the child take? (If unknown, what is available to the child?)
- How much did the child take? (If unknown, what is the maximum amount possible?)
- When did the child take it? (If unknown, how long was the child unattended or unobserved?)
- What symptoms have occurred, and when did the symptoms start relative to the time of ingestion?
- What other medical conditions does the child have? What medications does the child take regularly?

causes seizures); assess for factors that may have precipitated the ingestion, such as depression; and assess for medications that may interact with or exacerbate the toxic effects of the ingested substance (eg, acetaminophen ingestion in a patient taking a cytochrome P-450 inhibiting medication).

Parents should be encouraged to bring in the container and any remains of the substance ingested. The practitioner should try to obtain the exact formulation because generic and brand name drugs may differ. One must also be aware of possible combination products. Sleuthing methods such as calling or sending a family member to the home to identify the product, calling the pharmacy on a prescription label, or identifying a pill by comparing its picture and imprint to those in a pharmaceuticals reference may be necessary. Internet search engines may be used to search the imprint on a pill, or to identify foreign medications.

Caretakers should be questioned regarding all available drugs or other toxic substances in the household. Sometimes caretakers must be encouraged to mention all substances in the household, even those they don't think the child could possibly have obtained. The practitioner must also ask about medications used by recent visitors (eg, grandparents) and the possibility of an exposure at a recently visited household or location. It is important not to overlook herbal preparations, vitamins, alternative medications, household products (including cleaning and personal care products), gardening products, chemicals used in hobbies or work, and alcohol or drugs of abuse belonging to an adult. Caretakers may initially overlook these as they concentrate only on recalling "medications." It may be helpful to interview siblings or friends of an adolescent suspected of recreational drug use. One must maintain a high index of suspicion for unreported co-ingestants, especially in adolescent suicide attempts.

Although often difficult, it is important to attempt to determine the quantity of drug that was available to the patient and how much is currently missing. One may need to count pills or measure liquid to determine this. For estimating liquids, the approximate volume of a swallow is 0.3 mL/kg. The practitioner should always assume the "worst case" (ie, the patient took all of the drug that is missing). History concerning the amount ingested may be inaccurate, especially when taken from adolescents with intentional ingestion.

Table 68-1. Toxidromes

Toxidrome	Toxins	Symptoms	Treatment
Narcotic or opiate	Oxycodone, hydrocodone, methadone, fentanyl, heroin, codeine, morphine	Nausea/vomiting, respiratory depression, miosis, altered mental status, or coma	Naloxone, respiratory support
Cholinergic (parasympathomimetic)	Organophosphate and carbamate pesticides	DUMBELLS mnemonic: <i>d</i> iarrhea, <i>u</i> rination, <i>m</i> iosis, <i>b</i> ronchorrhea and bronchospasm, <i>e</i> mesis, <i>l</i> acrimation, <i>l</i> ethargy, <i>s</i> alivation	Atropine, 2-PAM (pralidoxime)
Anticholinergic	Antihistamines, jimson weed, antipsychotics, some antidepressants, Parkinson's medications	Flushing ("red as a beet"), dry skin and mucous membranes ("dry as a bone"), hyperthermia ("hot as a hare"), delirium ("mad as a hatter"); mydriasis ("blind as a bat"), also tachycardia, urinary retention, ileus/decreased bowel sounds	Supportive care
Sympathomimetic	Cocaine, amphetamines, ephedrine	Mydriasis, anxiety, tachycardia, hypertension, hyperthermia, diaphoresis	Quiet environment, benzodiazepines
Sympatholytic	Clonidine, β -blocker (eg, propranolol)	Bradycardia, hypotension, miosis, may have lethargy	Supportive care, fluids and pressors if needed for hypotension, atropine for symptomatic bradycardia
Tricyclic antidepressant	Imipramine, amitriptyline, many others	Seizures, tachycardia, prolonged QRS complex, altered level of consciousness, cardiac dysrhythmias	Sodium bicarbonate
Salicylate	Aspirin, methyl salicylate, oil of wintergreen	Hyperventilation, nausea/vomiting, tinnitus, hyperthermia, metabolic acidosis	Alkalinization with NaHCO ₃ (confirm salicylate level)
Serotonin syndrome	Selective serotonin reuptake inhibitors, many other drugs	Altered mental status, neuromuscular rigidity, tremors, or hyperreflexia, autonomic instability: hyperthermia, mydriasis, tachycardia, hyper- or hypotension	Supportive care

The practitioner should try to determine approximately what time the ingestion occurred. Symptoms are usually expected within a defined time range. Recommended observation periods before discharge usually take into account expected symptoms based on the length of time since the ingestion. Timing may also be important in determining what substance was most likely ingested. For example, ingestion of mushrooms that cause a self-limited illness usually causes gastrointestinal (GI) upset within 4 to 6 hours, whereas *Amanita* mushrooms that may ultimately result in hepatic failure typically present with GI upset in 6 to 12 hours.

The practitioner should ask about current symptoms and when they started relative to the time of the ingestion. In a patient without a definite history of ingestion, certain combinations of symptoms may point toward a specific substance or class of substances. Whether the patient is symptomatic and what symptoms are present may guide the workup for an unknown ingestion, determine whether the patient needs to be hospitalized, or dictate therapy.

Physical Examination

If the substance ingested is known, the physical examination should be directed toward identifying expected symptoms of toxicity. A general physical examination should always be performed, however, because co-ingestion of another undisclosed substance must be considered. Particular attention should be paid to all 4 vital signs (temperature, respiratory rate, heart rate, and blood pressure); pupillary size and reaction; breathing (eg, Kussmaul respiration seen in

acidosis); mental status; distinctive breath odors; presence or absence of bowel sounds; and skin color, temperature, and moisture. The patient's weight should be measured because toxicity is often estimated based on milligrams of drug ingested per kilogram of body weight. Because symptoms may develop or worsen if peak levels of the toxic substance have not been reached at the time of initial evaluation, continual reassessment and cardiorespiratory monitoring are imperative. A recognizable set of symptoms suggestive of a certain class of medications or toxins is called a toxidrome. If a symptomatic patient is noted to have a typical toxidrome, therapy may be initiated based on the toxidrome without confirmation of the exact substance ingested. Some common toxidromes and their treatments are listed in Table 68-1.

Laboratory Tests (Box 68-1)

Qualitative drug screens (reporting only presence or absence of the drug) of urine or blood are often used when poisoning is part of a broader differential for symptoms such as altered mental status or acute behavioral changes. Such drug screens are rarely helpful acutely in the poisoned patient because results are often not rapidly reported, testing can only be done for a limited number of substances, and false-positives and false-negatives may occur. Given the frequency of narcotic ingestions, it is important to note that synthetic opioids (eg, fentanyl, methadone, oxycodone, and hydrocodone) are not detected by typical hospital immunoassay "tox screens."

Box 68-1. Laboratory Tests and Diagnostic Studies to Consider

- Specific drug levels as indicated
- Qualitative urine or blood “tox screen”
- Acetaminophen level, consider ethanol level and salicylate level
- Serum chemistries, calculated anion gap
- Serum osmolality, calculated osmolar gap
- Liver function panel, renal function tests
- Rapid bedside glucose test
- Urine pregnancy test
- Pulse oximetry
- Electrocardiogram
- Arterial blood gas with carbon monoxide and methemoglobin levels
- Urinalysis
- Creatinine phosphokinase level
- Chest radiograph
- Abdominal film for radiopaque tablets

However, quantitative drug levels for specific drugs can be helpful to estimate severity of expected symptoms or to rule out ingestion of that drug. Examples include acetaminophen, salicylate, ethanol, methanol, ethylene glycol, iron, theophylline, lithium, anticonvulsants, and levels of carboxyhemoglobin or methemoglobin by blood gas analysis. Such levels should only be measured when suggested by history or physical examination, with the exception of acetaminophen and ethanol. Many experts in toxicology feel that because acetaminophen overdose produces few acute symptoms, may lead to fulminant hepatic failure, and is readily treatable with an antidote, all patients with a history of ingestion should have an acetaminophen level determined. In adolescents and adults, ethanol is a common co-ingestant, and ethanol levels are often routinely measured. Routine salicylate levels are likely to be low yield in the absence of suspicion by history or physical examination, although some practitioners also obtain them.

Serum chemistries and osmolality may offer clues in ingestion of an unknown substance. The **anion gap** is calculated as $[Na] - ([Cl] + [HCO_3])$ and is normally 8 to 12 mEq/L. An elevated anion gap indicates presence of metabolic acidosis and is seen in ingestions and conditions identified by the **MUDPILES** mnemonic: *m*ethanol, *u*remia, *d*iabetic ketoacidosis, *p*araldehyde and phenformin, *i*ron and isoniazid, *l*actic acidosis, *e*thylene glycol and ethanol, *s*alicylates and solvents (eg, toluene). The **osmolar gap** is the difference between the measured serum osmolality and the calculated osmolality (given by the formula $2[Na] + [glucose]/18 + [BUN]/2.8$). The normal osmolar gap is less than 10 mOsm. An elevated osmolar gap is seen with ingestion of alcohols such as ethanol, methanol, ethylene glycol, and isopropanol.

Depending on one's suspicion for acidosis, hypoxemia, or abnormal hemoglobins (carboxyhemoglobin and methemoglobin), arterial blood gas analysis may be indicated. Because hypoglycemia may be seen with some ingestions and is easily treated, a rapid bedside glucose test should be done on all patients. Urinalysis and creatinine

phosphokinase level tests may be performed to look for signs of rhabdomyolysis if the patient is deemed at risk. All females of child-bearing age should have a urine pregnancy test. Assessment of liver and renal function is often important because many substances are metabolized by these routes.

Diagnostic Studies

Pulse oximetry and cardiorespiratory monitoring should be instituted for all serious ingestions. An electrocardiogram may be indicated if cardiac toxicity is expected. Other studies are tailored to the specific ingestion, such as endoscopy after ingestion of caustic acids or alkalis.

Imaging Studies

Specific imaging studies may be indicated for certain ingestions, such as chest radiography in hydrocarbon ingestion, to look for signs of aspiration. An abdominal film may be helpful in identifying ingestion of radiopaque substances and monitoring the effectiveness of GI decontamination procedures for removing such substances. The mnemonic **CHIPS** can be used for radiopaque medications: *ch*loral hydrate, *h*eavy metals, *i*ron, *p*henothiazines, and *s*low-release (enteric-coated) medications. In practice, abdominal radiography is primarily used in iron ingestion and suspected body-packing with illicit drugs.

Management

Management strategies are specific for the substance ingested. The regional poison control center should be consulted for advice regarding management and length of time to observe asymptomatic patients. A single number, 1-800-222-1222, automatically routes the caller to one of the appropriate 62 regional poison control centers in the nation. In general, the approach to management includes attention to the basic ABCs (airway, breathing, circulation) of resuscitation, decontamination methods, specific antidotes when available and indicated, and meticulous supportive care, often in an intensive care unit.

Decontamination

Decontamination techniques are strategies used to prevent or minimize absorption of the toxic substance and to enhance its elimination. They are a critical part of the management of acutely poisoned patients and should be used whenever a significant ingestion is suspected (Table 68-2).

Syrup of ipecac was commonly recommended in the past for home use to induce vomiting in the event of an accidental ingestion. **Gastric lavage**, in which a large nasogastric tube is placed and the stomach is washed with normal saline, is the hospital counterpart to syrup of ipecac. Both techniques theoretically remove toxic substance from the stomach, thus preventing absorption. However, at best (immediate performance after ingestion), less than a third of gastric contents are removed by these methods. In addition, these techniques may interfere with the use of activated charcoal, usually a more effective therapy. Gastric lavage is technically difficult to

Table 68-2. Summary of Gastric Decontamination Techniques

Technique	Dose	Contraindications
Syrup of ipecac	6 months–1 year: 10 mL (use with caution) 1–12 years: 15 mL >12 years: 30 mL Follow with 8 oz water	Not recommended for routine use Altered level of consciousness (ALOC) Caustics: acids and alkalis Hydrocarbons Expected ALOC (eg, tricyclic antidepressants)
Gastric lavage	15 mL/kg aliquots normal saline to maximum of 400 mL until lavage fluid is clear (may be several liters)	ALOC with unprotected airway Caustics: acids and alkalis Hydrocarbons Expected ALOC >1 hour since ingestion
Activated charcoal	1–2 g/kg or <6 years: 25–50 g >6 years: 50–100 g	ALOC with unprotected airway Absent bowel sounds or bowel obstruction Substance not bound by charcoal
Cathartics	Magnesium citrate 4 mL/kg 70% sorbitol 1 g/kg	Not recommended for routine use Repeated doses can cause dehydration or electrolyte imbalances.
Whole-bowel irrigation	Toddler and preschool age: polyethylene glycol solution 500 mL/h 6–12 y: 1,000 mL/h Adolescent and adult: 1.5–2 L/h Continue until rectal effluent is clear	Bowel obstruction, ileus, perforation, or hemorrhage ALOC with unprotected airway
20% intralipid	1.5 mL/kg initial bolus intravenous, then 0.25 mL/kg/min for 30–60 minutes	For lipophilic drug overdose with severe cardiotoxicity

perform in young children owing to the need to pass a large-bore tube. Gastric lavage also has a high rate of complications, such as aspiration and esophageal trauma. Neither syrup of ipecac nor gastric lavage is recommended for routine use. The American Academy of Pediatrics released a policy statement in 2003 stating that syrup of ipecac should no longer be kept in homes. Syrup of ipecac was administered in less than 0.01% of pediatric ingestions in 2008. The American Academy of Clinical Toxicology (AACT) reserves gastric lavage only for life-threatening ingestions presenting at less than 60 minutes since ingestion, with the caveat that there is no confirmed clinical benefit.

Activated charcoal is the mainstay in decontamination therapy of ingestion. Charcoal binds toxins, and because it is not absorbed in the GI tract, the charcoal-toxin complex passes through and is eliminated. Its efficacy decreases with increasing time since the ingestion, and ideally it should be started within an hour of the ingestion. The optimal dose of charcoal is 10 times the amount of substance ingested. Because the exact amount of toxin ingested is often unknown, activated charcoal is usually dosed at 1 to 2 g/kg. The amount of charcoal given is limited only by what the child is able to tolerate. Only a few substances are not absorbed by activated charcoal. The mnemonic **PHAILS** can be used to remember them: *pesticides*; *hydrocarbons* and heavy metals; *acids*, alkalis, and alcohols; *iron*; *lithium*; and solvents. The main complication of charcoal administration is aspiration pneumonitis, primarily seen in patients with altered level of consciousness and an unprotected airway. If charcoal is not voluntarily taken by the child, it may be administered via nasogastric

tube. Endotracheal intubation to protect the airway first may be necessary in the patient with altered mental status. It is imperative that nasogastric tube placement in the GI tract (as opposed to the respiratory tract) be confirmed prior to charcoal administration.

Cathartics (most commonly sorbitol) have been used to decrease transit time and improve elimination of the toxin through the GI tract and to counteract activated charcoal-induced constipation. The cathartic is often mixed with the activated charcoal and may serve to improve the palatability of the charcoal. A significant benefit from cathartic use has never been demonstrated, however, and there is a risk of dehydration and electrolyte disturbances, particularly in young children. The AACT recommends *against* use of cathartics. Under no circumstances should repeated doses of cathartics be given.

Multiple-dose charcoal may remove drugs from the bloodstream by promoting diffusion back into the GI tract and subsequent binding to charcoal. It has been called the “GI dialysis.” Activated charcoal at the same dose previously used is repeated approximately every 4 hours. Cathartics should *not* be mixed with the charcoal for repeat doses. Multiple-dose charcoal is useful for a small number of drugs, such as phenobarbital, theophylline, carbamazepine, dapsone, and quinine. It should only be used if a potentially life-threatening amount has been ingested. It should not be used for drugs that can cause an ileus (eg, tricyclic antidepressants).

Whole-bowel irrigation involves infusion of a solution usually used for cleansing of the bowel prior to GI surgery (eg, polyethylene glycol). It is especially useful for slow-release medications, for tablets that dissolve slowly and may cause concretions (eg, iron), and

in ingestions where charcoal is not likely to be effective (eg, heavy metals). A nasogastric tube is used to infuse the solution at a rate of 500 mL/hour in young children, and 1 to 2 L/hour in older children and adolescents. Clear rectal effluent is the endpoint; a bedpan may be necessary. Whole-bowel irrigation should not be used when there is bowel obstruction, ileus, perforation, or hemorrhage or altered mental status with an unprotected airway.

Hemodialysis may be used for serious ingestions of ethylene glycol, methanol, phenobarbital, lithium, salicylate, or theophylline. **Charcoal hemoperfusion**, in which blood goes through a charcoal cartridge instead of a dialysis machine, is used rarely for severe theophylline poisoning. **Urinary alkalization** (by administration of sodium bicarbonate) can increase elimination of weak acids by keeping the drug in its ionic state, thus preventing reabsorption in the renal tubule. It is primarily used for significant salicylate, phenobarbital, and isoniazid poisonings.

Intralipid is becoming recognized as a potential treatment for lipophilic drug overdoses, and has been used successfully for treating severe cardiotoxicity from bupivacaine, haloperidol, and verapamil overdoses. It is unclear by what method intralipid works. Although ideal dosing and indications have not been established, one suggested treatment protocol to consider would be: 1.5 mL/kg of 20% intralipid initial bolus, followed by 0.25 mL/kg/min for 30 to 60 minutes. Boluses may be repeated for severe cardiotoxicity and dysrhythmias.

Supportive Care

Attention to the basic ABCs (airway, breathing, circulation) of resuscitation is always the first step in management. **Hypoglycemia** must be assessed and managed as soon as possible. Dextrose 0.5 to 1 g/kg intravenously is given; glucagon may be used if dextrose cannot be given. **Seizures** are generally treatable with benzodiazepines. Glucose and electrolyte levels should be normalized. With isoniazid ingestions, pyridoxine may be helpful. **Shock** requires aggressive fluid resuscitation. Fluid-resistant shock may require vasopressors, most commonly dopamine, epinephrine, or norepinephrine. Resistant shock in a β -blocker ingestion may respond to glucagon, and in a calcium channel blocker ingestion to insulin plus glucose. **Dysrhythmias** should generally be treated by following Pediatric Advanced Life Support (PALS) protocols, although specific ingestions may respond to specific therapies. Sodium bicarbonate is the first-line treatment for dysrhythmias associated with ingestions of antihistamines, class I antiarrhythmics (lidocaine, quinidine, procainamide), cocaine, and tricyclic antidepressants. β -blocker ingestions may respond to atropine and glucagon, while ingestions of calcium channel blockers are managed with calcium. Procainamide, found on PALS algorithms, should be avoided for dysrhythmias due to overdoses of antihistamines, quinidine and other class I antiarrhythmics, digoxin, quinine, and tricyclic antidepressants. Amiodarone, also found on PALS algorithms, should also be avoided in the treatment of antihistamine ingestions. Electrolyte imbalances should be assessed and corrected. **Suicidality** should be assessed, often in conjunction with a mental health professional.

Table 68-3. Antidotes

<i>Toxin</i>	<i>Antidote</i>
Acetaminophen	N-acetylcysteine
Anticoagulants (coumadin-like)	Vitamin K
Anticholinergic	Physostigmine
Benzodiazepine	Flumazenil
β -blocker	Glucagon
Calcium channel blocker	Calcium, insulin + glucose
Carbamate pesticide	Atropine
Carbon monoxide	Oxygen
Cyanide	Cyanide antidote kit
Digoxin	Digibind
Ethylene glycol	Fomepizole, ethanol
Iron	Deferoxamine
Isoniazid	Pyridoxine
Lead	Dimercaprol (BAL), ethylene diamine tetraacetic acid, dimercaptosuccinic acid (DMSA)
Mercury	BAL, DMSA
Methanol	Fomepizole, ethanol
Methemoglobinemia	Methylene blue
Narcotics	Naloxone
Organophosphate pesticide	Atropine, 2-PAM (pralidoxime)
Rattlesnake bite	Crofab (crotalidae polyvalent immune fab [ovine])
Sulfonylurea oral hypoglycemic	Dextrose, octreotide
Tricyclic antidepressant	Sodium bicarbonate

Antidotes

Antidotes or medications that counteract the pathophysiological mechanisms of the toxin are available for only a few ingestions (Table 68-3). Important antidotes are N-acetylcysteine for acetaminophen, naloxone for narcotics, oxygen for carbon monoxide poisoning, bicarbonate for tricyclic antidepressant cardiotoxicity, Digibind for digoxin, and deferoxamine for iron. Antidotes are not without adverse effects themselves and should only be given in cases of symptomatic or potentially symptomatic (acetaminophen) ingestions of significant amounts. The poison control center staff can be very helpful in guiding practitioners in the use of antidotes.

Anticipatory Guidance and Prevention

Most ingestions are nontoxic and require only observation for a few hours. They do, however, provide an excellent opportunity to discuss poisoning prevention with parents and caretakers. Possible toxins, including prescription and over-the-counter medications, cleaning and household products, cosmetics and nail care products, toxic

plants, gardening and hobby chemicals, and kitchen items such as alcohol should be kept out of reach of children. Visitors to the household should also be cautioned to keep medications out of reach of children. Substances should never be stored in unmarked containers, particularly in containers that typically hold beverages such as old soda bottles or cups. Medications should not be referred to as “candy” to entice youngsters to take them. Family members and visitors should be asked to store medications out of the child’s reach, and to dispose of leftover medications and used transdermal patches safely. Used transdermal patches may still contain up to 75% of the medication dose. Also, chewing on patches, as toddlers may do, releases the medication much faster. Parents should have the universal telephone number for the poison control center and telephone numbers for local emergency departments readily available. Carbon monoxide detectors should be placed near children’s bedrooms. Activated charcoal for home use is controversial and not currently recommended, although it is available without prescription from many pharmacies. Parents should not give activated charcoal without speaking to poison control center staff or medical personnel first.

Prognosis

Prognosis depends on the toxicity of the substance ingested. For a few substances, a small amount can be fatal (Box 68-2), whereas for others, even large ingestions are generally benign. Prognosis is generally excellent; fatalities in children are rare. Prognosis is worse for intentional ingestions, often because patients delay or fail to reveal that they attempted overdose.

Box 68-2. Substances Potentially Fatal in 1 to 2 Pills or Teaspoons

- Camphor (found in Vicks VapoRub, Campho-Phenique, Tiger Balm)
- Imidazoline decongestants (found in over-the-counter nasal and eye drops)
- Acetonitrile nail glue remover
- Clonidine (available in transdermal patches also)
- Opiates (available in transdermal patches also)
- Methyl salicylate (oil of wintergreen, Ben-gay)
- Calcium channel blockers
- Toxic alcohols (methanol, ethylene glycol, ethanol, isopropanol)
- Tricyclic antidepressants
- Lomotil (opiate diphenoxylate + atropine)
- Sulfonylurea oral hypoglycemics
- Chloroquine and hydrochloroquine antimalarial agents
- Hydrofluoric acid
- Selenious acid (gun bluing solution)
- Buffered saline solution
- Benzocaine-induced methemoglobinemia

CASE RESOLUTION

Because the respiratory rate of this 2-year-old is slow and there are symptoms of miosis and altered level of consciousness, narcotic ingestion is suspected and naloxone is administered. The child becomes more alert and respiratory rate increases to 24 breaths/min. The father is instructed to retrieve the bottle, and it turns out to be a prescription narcotic analgesic left in the house by a recent visitor. The child is given activated charcoal, observed overnight in the hospital, and discharged on the following day without sequelae.

Approach to the Dysmorphic Child

Julie E. Noble, MD

CASE STUDY

A 13-year-old male presents to the office for the first time for an evaluation after moving to the area. Parents note that he has unexplained mental retardation and has had problems with hyperactivity in school. The pregnancy was uncomplicated and the mother, who was a 32-year-old gravida 1 para 1 at the time of the child's birth, denies alcohol or drug use or exposure to any teratogens during pregnancy. Delivery was by cesarean section secondary to cephalopelvic disproportion, but Apgar scores were 8 at 1 minute and 9 at 5 minutes. The infant was noted to have macrocephaly and to be large for gestational age. He did well in the newborn period and had no feeding problems. Subsequently, he had no significant medical illnesses, including no seizures, but at 1 year of age was noted to be developmentally delayed. This delay continued, and he has been in special education classes throughout his school career. Family history is negative for any family members with retardation.

On physical examination, the boy is greater than 90th percentile for height and weight. He is mildly prognathic with large ears. He has hyperextensible fingers. A complete examination reveals that his testicles appear large (6 cm) and his sexual maturity rating (Tanner stage) is 3. The rest of the examination is normal.

Questions

1. What history is important to elicit in evaluating a child with dysmorphic features?
2. What are the possible causes of errors in morphogenesis?
3. What clues on physical examination can aid in establishing a specific diagnosis?
4. What laboratory tests can confirm a diagnosis?
5. When is it appropriate to obtain a genetics consultation or refer a patient for genetic counseling?
6. What are the benefits of establishing a specific diagnosis?

Evaluation for structural anomalies is an essential part of all pediatric examinations. Visible errors in morphogenesis give the physician valuable information in evaluating a patient with abnormal symptoms, such as seizures. Additionally, major malformations frequently require treatment, and the presence of one anomaly suggests that others may also exist.

The study of these congenital defects was termed dysmorphism by David Smith in 1966. The anomalies fall into 2 categories: minor and major. Minor malformations are those of “no medical or cosmetic consequence to the patient.” An example would be a supernumerary nipple that appears as a hyperpigmented papule along the nipple line. Identification of minor malformations is important because they may indicate the presence of a more generalized pattern of malformation. Major malformations are those that have “an adverse effect on either the function or social acceptability of the individual.” A cleft lip and palate are major malformations that have functional as well as cosmetic relevance to the patient's health.

Epidemiology

Structural anomalies are common in the general population. Most are minor. In the first comprehensive analysis of minor structural anomalies, Marden in 1964 identified 7% to 14% of newborn infants with at least one minor anomaly on surface examination. Other studies identify up to 40% of newborns with one anomaly. Three or more minor malformations have predictive value in identifying a major malformation. In newborns, 0.8% have 2 minor malformations, and 11% of these patients will have a major malformation. Three or more minor malformations occur in 0.5% of newborns, and 90% of these will have a major malformation. Data from the National Collaborative Perinatal Program revealed that 44.78% of these anomalies were craniofacial and 45.3% were skin. Males are affected with minor malformations more often than females. Autopsies of dead fetuses reveal an increased incidence of both minor and major malformations. Frequencies of both minor and major malformations vary along racial lines, depending on the specific malformations. For example, postaxial polydactyly is seen in 16 of 10,000 births in the

white population and 140 of 10,000 births in the African American population. Hemangiomas are seen in 350 of 10,000 births in whites and only 100 of 10,000 births in African Americans.

Three percent of all pregnancies produce a child with a significant genetic disease or a birth defect. These malformations account for a great proportion of morbidity and mortality in the pediatric population. Of all pediatric hospital admissions, one-third to one-half involve a child with a disease with a genetic component.

Clinical Presentation

With the advent of more prenatal tests and diagnostic modalities (see Chapter 20), the detection of anomalies may first occur in the prenatal period. Routine prenatal screening tests that are abnormal raise the possibility that the infant will have an anomaly. For instance, an elevated maternal α -fetoprotein indicates the possibility of a spinal cord defect. Amniocentesis or chorionic villus biopsy may reveal abnormal chromosomes with associated structural defects. Prenatal ultrasound demonstrates structural defects in utero and a specific fetal ultrasound can further delineate those abnormalities.

Most structural anomalies develop during the first trimester of gestation and, if not detected prenatally, are noted at birth in the delivery room or the newborn nursery. Many major congenital defects are obvious on a thorough physical examination. Some major defects, such as a tracheoesophageal fistula, will not be manifest on surface examination but will be readily apparent as the infant adapts to extra-uterine life and experiences symptoms when feeding begins. Minor anomalies may be overlooked on an infant's initial examination. However, if that infant manifests developmental delay at 6 months of age, the physician may be more inclined to evaluate for minor anomalies that may aid in identifying the cause of the developmental delay.

Sometimes dysmorphic features are not present at birth but become apparent later in life as the child grows and develops. These types of features are associated with dysplasias, defects in cellular metabolism that become manifest after birth. An example is a skeletal dysplasia that becomes more apparent as the bones grow.

Pathophysiology

The pathophysiology of structural defects can be separated into 4 different types of errors in morphogenesis: malformations, deformations, disruptions, and dysplasias (Box 69-1).

Previously, the term **malformation** was used descriptively to denote an anomaly; but it is also used to denote a specific pathogenic mechanism. Malformations are permanent defects in a structure caused by an intrinsic abnormality in the development of that structure. An example of a malformation is an endocardial cushion defect in a patient with Down syndrome. Malformations frequently are caused by chromosomal abnormalities and single-gene disorders that program for abnormal structure.

Deformations occur in an infant when external forces exert a mechanical pressure on the developing fetus. There is no intrinsic defect of the fetus. These deformations from intrauterine forces can

Box 69-1. Pathophysiology of Structural Defects

Malformation

Mechanical—amniotic bands
Teratogens—alcohol, drugs, irradiation

Dysplasia

Metabolic disorder

be caused by uterine constraint, an abnormally shaped uterus, or multiparous pregnancy. A flexible clubfoot is a deformation caused by uterine constraint. Deformations can also be caused by extrauterine forces such as plagiocephaly caused by an infant sleeping on his back. **Disruptions** occur when an agent outside a fetus causes cell death and a permanent defect in fetal development. These disruptive events result in tissue destruction. Disruptions can occur during development when there is tissue ischemia secondary to vascular compromise, when a viral infection disrupts development at a critical gestational age, or when a mechanical disruption interferes with normal development. An amniotic band is an example of a mechanical disruptive agent that can cause an amputation of a limb by constricting the extremity during development. Teratogens can also function as disruptive agents by interfering during a critical period in embryogenesis, causing dysgenesis of fetal organs. Alcohol, specific drugs, and irradiation can all be teratogens. Fewer than 30 drugs have been proved to be teratogenic.

Dysplasias, often caused by a single-gene defect, are structural abnormalities that develop from abnormal cellular metabolism and organization. They can occur intrauterine, and be apparent at birth such as a skeletal dysplasia, or extrauterine. Mucopolysaccharidosis is a dysplasia that develops postnatally secondary to the absence of the lysosomal hydrolase of α -L-iduronidase. As a result, mucopolysaccharides accumulate in parenchymal and mesenchymal tissues. As affected children grow, they develop coarse facies, enlarged tongue, misshapen bones, and hepatosplenomegaly among other features.

Differential Diagnosis

In generating an appropriate differential diagnosis for a dysmorphic child, it is essential to identify all minor and major malformations. The differential will vary depending on the specific findings. A thorough history and physical examination will help greatly to establish the list of conditions to consider. If there are multiple anomalies, identifying the most specific and rarest anomaly can direct the practitioner to a narrower list of possible diagnoses. For example, nail hypoplasia, which is seen in fetal hydantoin syndrome, is much rarer than congenital cardiac disease, which is seen in multiple

syndromes. A practitioner should be familiar with the prominent features of the more common syndromes but also should have readily available reference texts, such as *Smith's Recognizable Patterns of Human Malformation*, to aid in establishing differential lists as well as finalizing diagnoses. In addition, the Internet has developed into a valuable tool through Web sites such as PubMed or Google, or those specifically developed for the delineation of syndromes and genetic disorders.

In evaluating an infant with congenital anomalies, the practitioner should attempt to separate the findings into 1 of 5 categories: an isolated defect, a developmental field defect, a birth defect association, a sequence pattern, or a dysmorphic syndrome (Box 69-2). The first step is to determine whether the anomaly is **isolated**. If so, does it represent a failure in development in one location, such as a cleft lip? Most isolated anomalies are believed to have a multifactorial inheritance, representing the interaction between multiple genes and unknown external influences. They usually have a recurrence risk of 2% to 5%.

Box 69-2. Categories of Anomalies

Isolated defect	Sequence pattern
Developmental field defect	Dysmorphic syndrome
Birth defect association	

A **developmental field defect** is a pattern of anomalies that develops in structures that are together during embryologic development. These defects involve one limited region and are secondary to a disruptive event such as vascular compromise. They therefore have a low recurrence risk. An example would be hemifacial microsomia (oculo-auriculo-vertebral defect), where the defects are secondary to disruption in vascular flow to the first and second branchial arches. This disruption results in hypoplasia of the malar, maxillary, and mandibular region on one side with associated microtia and vertebral defects.

Birth defect associations are diagnosed when the combination of anomalies occurs together frequently but the pattern does not fit a known field defect or syndrome. The etiology of association defects is unknown at this time, and the recurrence risk is low. One of the more common associations is the VACTERL association (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, radial defects, renal defects, and limb defects). Emerging information in gene research may identify an etiology in the near future.

A **sequence pattern** of anomalies occurs when one malformation leads to multiple dysmorphic features. Potter oligohydramnios sequence results from renal agenesis. The renal malformation causes oligohydramnios with resultant fetal contractures, pulmonary hypoplasia, and a flattened face.

A **syndrome** is a pattern of anomalies that are pathologically related. Chromosomal abnormalities such as Down syndrome (trisomy 21), single-gene disorders, and teratogens fall into this category. Alcohol is the most common teratogen to which fetuses

are exposed. Alcohol exposure in utero causes growth failure, developmental delay, microcephaly, a short nose, and small distal phalanges. Children with developmental delay and anomalies have a higher likelihood of having a syndrome and should undergo a chromosome analysis.

Evaluation

History

A complete history is essential (Questions Box). The history begins prenatally with information from the mother on duration of pregnancy, possible teratogen exposure, fetal activity, diagnostic test results, and any complications of pregnancy. The delivery history should include type of delivery, infant presentation, and size at birth, including growth percentiles. Neonatal adaptation and feeding patterns are important parameters to assess. The subsequent medical history should be obtained.

A thorough family history is equally important, and a pedigree should be outlined. Specifically, the family should be questioned for parental age, possible consanguinity, and history of fetal loss or early infant deaths. Family history of birth defects or retardation should be documented.

Questions

The Dysmorphic Child

- How long was the pregnancy?
- Did the mother take any medications, smoke cigarettes, or use alcohol or any illicit drug?
- What was the fetal activity?
- Were there any complications of pregnancy?
- What was the type of delivery and presentation of the baby?
- What was the infant's size at birth?
- How did the infant feed?
- What is the subsequent medical and developmental history?
- Are the parents related?
- What are the parents' ages?
- Is there a history of fetal or infant deaths?
- Is there a history of birth defects in the family?
- Are any family members retarded?

Physical Examination

The physical examination should be extremely thorough with all morphological findings noted. As previously mentioned, the craniofacial area and skin are common sites for anomalies, but all organ systems should be extensively evaluated. Even minor anomalies, such as a supernumerary nipple or clinodactyly, may have significance. Objective measurements should be obtained when possible. Normal grids are available for evaluating inner canthus distance, palpebral fissure length, ear length, etc. Hair whorl patterns and

dermatoglyphics should be evaluated. Physical data, including height, weight, and head circumference, should be plotted and the growth percentiles noted. A complete ophthalmologic evaluation may be indicated to detect abnormalities such as cataracts or cherry-red spots.

Laboratory Tests

In assessments of dysmorphic-appearing children, the physical examination is the most important part. Findings on physical examination direct which further studies will be of benefit. Additional studies may give added or confirmatory information regarding a suspected diagnosis. Prenatal screening tests may be used to detect a fetal abnormality, and specific prenatal tests are available to assess a fetus at risk for a given disease. Cytogenetic evaluation is essential in evaluating a child with a suspected syndrome and also in evaluating a child with malformations and developmental delay. Standard chromosomal analysis is the first-line laboratory test but may not detect many small chromosomal or gene defects. More sophisticated testing may be indicated. Small chromosomal aberrations can be detected by FISH (fluorescent in situ hybridization) analysis, in which labeled probes are applied to chromosomal preparations. These probes are specific for given disorders and should be used to confirm a suspected clinical syndrome. Prader-Willi and DiGeorge syndromes may be diagnosed by FISH analysis. FISH probes can now be applied to subtelomeric regions of the chromosome, which are very gene rich. Whole chromosome painting is another technique in which FISH probes are used to paint the entire chromosome, thus identifying the origin of additional chromosomal material or cryptic translocations. Molecular testing is available for many single-gene disorders. Comparative genomic hybridization is a cytogenetic method for analysis of copy number changes in DNA. It is a supplement to karyotyping and is the prime genome-wide screening method. This test has revealed genetic etiologies in many previously unidentified patients with abnormalities.

Many dysplasias and some syndromes can be detected by metabolic testing. Serum amino acids and urine organic acids should be ordered if a diagnosis is suspected. Many states are now including an analysis for metabolic disorders in their expanded newborn screening protocols. There is a federal effort to standardize the newborn screening guidelines statewide.

Imaging Studies

Imaging studies are extremely useful in deriving information on internal malformations. Radiographs, including a skeletal survey, may detect skeletal anomalies. Echocardiogram, ultrasound, computed tomography scan, and magnetic resonance imaging (MRI) studies can all be used when appropriate. With the findings of anomalies and global developmental delay in a patient, the American Academy of Neurology recommends routine neuroimaging with an MRI.

Management

When children present with dysmorphic features, they should be evaluated to determine a specific diagnosis. Obtaining a diagnosis is of vital importance to the care of the patient and parental counseling. Knowing the diagnosis can direct subsequent testing for associated abnormalities. Treatment options may also be available for the condition, and a prognosis can be established. Defining the developmental prognosis for children is essential to establish appropriate school planning. If developmental delay is not associated with the diagnosis, such as with cleft lip and palate, the parents should be reassured. Parents also need to know the recurrence risk for themselves and for their children. Occasionally, further testing of the parents may be necessary to determine the accurate recurrence risk. If one of the parents is a translocation carrier, the risk of subsequent children having the abnormality is increased.

Consultation with a geneticist can help the practitioner in establishing the correct diagnosis and provide the practitioner with the latest information regarding evaluation and possible treatment. New information in the field of genetic disease appears daily, and it is difficult for a primary care practitioner to stay abreast. A genetic consultation should also be obtained in most patients with major malformations to confirm the diagnosis and to help counsel parents.

Health supervision strategies have been established for specific disorders. For instance, published guidelines recommend hearing, ophthalmologic, and thyroid screening, among other tests, for patients with Down syndrome. A geneticist can give guidance regarding revised recommendations.

If support groups are available for specific conditions, parents should be referred to these groups. Such groups can be invaluable in helping parents understand as well as adjust to the disorder. They can also advise parents about community and educational resources available for their child's care and help parents advocate for their child's unique needs.

A referral to a genetics counselor can provide parents with education about prenatal testing, recurrence risk, and alternatives for dealing with this recurrence risk. Counseling is extremely useful to help parents understand the inheritance pattern.

Prognosis

As with management, defining an accurate prognosis for each patient depends on recognition of the specific condition. Some conditions, such as trisomy 13, are lethal while other conditions allow for a normal life span.

Malformations are permanent defects that generally have a recurrence risk. They may be correctable with surgery or treatment but frequently leave a residual disability.

Deformations usually resolve with treatment and have no recurrence risk unless the deformation is secondary to a uterine abnormality such as a bicornuate uterus.

A disruption may be treated with surgery or therapy to improve function but, as in malformations, a residual disability frequently remains. When the disruption is due to tissue ischemia or a mechanical agent, there is no recurrence risk. If it is due to a teratogen, the disruption will recur with the same teratogenic exposure.

Dysplasias tend to persist or worsen with time unless a specific treatment is available. Only a limited number of diseases have specific treatments available. Generally, there is a recurrence risk.

CASE RESOLUTION

The child in the case scenario has features that suggest a dysmorphic syndrome. The most specific finding on examination is macro-orchidism. This finding is associated with fragile X syndrome. The patient is referred to a genetic specialist for diagnosis and counseling. Specific DNA-based molecular analysis is performed and is positive for a fragile site on the X chromosome at Xq27.3.

Parents are counseled that this condition has an X-linked inheritance pattern. The child will have a normal life span but may need early intervention services and later a special education program, and may not be capable of independent living as an adult. The primary care physician will be notified of the diagnosis and coordinate further services. Parents are encouraged to attend a parents' support group and consult with experts to learn how their child's full potential may be realized.

Craniofacial Anomalies

Carol D. Berkowitz, MD

CASE STUDY

A 3,500-g boy is born by normal spontaneous vaginal delivery to a 28-year-old gravida III para III mother after an uncomplicated full-term gestation. The Apgar scores are 9 and 10. On physical examination, the infant is well but has an incomplete, left-sided unilateral cleft of the lip and palate.

No other family members have such a deformity, but the mother and father are distantly related. The mother had prenatal care. During the pregnancy she had no illnesses; took vitamins but no other medications; and did not smoke, drink alcohol, or use illicit drugs.

The mother is planning to feed the infant with formula and wonders if she should do anything special. She is also wondering if her son's lip deformity can be repaired before she takes him home from the hospital. Except for the cleft, the physical examination is normal.

Questions

1. What craniofacial anomalies are common in children?
2. What are feeding considerations in infants with cleft lip or palate?
3. What is the appropriate timing of surgery for the more common craniofacial anomalies?
4. What are the major medical problems that children with craniofacial anomalies, particularly clefts of the lip or palate, experience?
5. What is positional plagiocephaly? How is its prevalence related to the Back to Sleep campaign?

Infants may be born with readily apparent craniofacial anomalies such as cleft lip, cleft palate, or microtia, or anomalies may emerge as an infant grows older. The latter includes conditions that may be genetically based but do not manifest until later, such as facial asymmetry (hemifacial microsomia) and premature closure of one or more sutures. Alternatively, these anomalies may be environmentally influenced, such as positional or deformational plagiocephaly. Deformational plagiocephaly is defined as a condition in which the infant's head and sometimes face are misshapen as a result of prenatal and, in recent years, postnatal external molding, which occur on the infant's malleable cranium.

Epidemiology

The overall incidence of cleft lip with or without cleft palate is 1 in 1,000, and that of isolated cleft palate is 1 in 2,500. Cleft lip with or without cleft palate is the fourth most common birth defect. There is racial, ethnic, and geographic variation in the incidence of clefts. For example, the incidence of clefts in parts of the Philippines is 1 in 200. Similarly, cleft lip with or without cleft palate is most common among Native Americans (1 in 230 to 1,000) and least common among African Americans (1 in 1,300 to 5,000). The gender distribution varies with the type of cleft. Isolated clefts of the palate occur twice as frequently in girls, but clefts of the lip with or without clefts of the palate appear twice as often in boys.

The type of cleft, the gender of the child, and whether parents or other siblings are similarly affected influence the risk for recurrence of clefts in subsequent offspring. In general, the risk for recurrence of clefts is 4% to 7% for cleft lip with or without cleft palate and 3% for isolated cleft palate.

Clefts may occur either as isolated findings or as part of syndromes or sequences. In Van der Woude syndrome, clefts of the lip or palate are associated with lip pits. This condition is inherited in an autosomal-dominant manner. There are now more than 200 disorders associated with clefts, although only 10% to 15% of children with clefts fit a syndrome. Pierre Robin sequence includes micrognathia and glossoptosis (retropositioned tongue) and a distinct u-shaped cleft. One theory relates the sequence to failure of the fetal neck to extend normally, leading to compression of the mandible on the chest thereby restricting its growth, causing the tongue to be malpositioned, thus preventing closure of the palate.

True craniosynostosis occurs in about 1 in 2,000 to 3,000 births, and this incidence is the same in all ethnic groups. There is gender variation among the different types of craniosynostosis. Mild deformational plagiocephaly is reported to be present in up to 13% of newborns, 16% of 6-week-olds, and nearly 20% of 4-month-olds. The term plagiocephaly comes from the Greek *plagio*, meaning oblique, twisted, or slanted, and *kephale* for head. First born and male gender increase the risk of deformational plagiocephaly at birth.

Most cases of deformational plagiocephaly resolve over time without specific medical intervention. When infants slept in the prone position, plagiocephaly occurred in 1 in 300. The prevalence of plagiocephaly increased to 1 in 60 following the recommendation for supine sleep position.

Microtia is less common and occurs in 1 in 6,000 to 8,000 births. Other ear malformations, such as auricular dystopia (ear located on the cheek) or total atresia of the external area, are less common and can be associated with other syndromes.

Clinical Presentation

Most craniofacial anomalies are readily apparent (see Dx Box). Some anomalies, such as cleft lips or microtia, are noted immediately in the delivery room. Other anomalies, such as craniosynostosis, develop over time. Because the onset of craniosynostosis may be gradual, parents may fail to recognize the condition, which usually appears as asymmetry of the face or skull. Deformational plagiocephaly also evolves over time and is more often noted by the clinician rather than the parents.

Children with craniofacial anomalies may also have medical problems that occur secondary to the deformity. Infants with cleft palate may present with failure to thrive because of difficulty feeding. Older infants and children may experience recurrent otitis media, speech impairments, or psychosocial stress. Nasal regurgitation of liquids may occur in children with obvious palatal clefts or more subtle deformities, such as submucous clefts of the soft palate.

Dx

Craniofacial Anomalies

- Cleft of the lip or palate
- Small, atretic, or malformed ear
- Asymmetry of the face
- Misshapen skull
- Recurrent otitis media
- Speech impairment

Pathophysiology

Clefts of the lip and palate (Figure 70-1) are believed to develop as a result of an interruption in the merging of the middle and lateral portions of the face during the sixth to seventh week of gestation. The palate normally closes with an anterior to posterior progression. Any interference with this progression (eg, tumor or encephalocele in the roof of the mouth) leads to a cleft. A vascular disruption may also result in ischemia in the involved areas. Although the etiology of clefts is not fully determined, it is felt to be multifactorial. Studies establish a link between clefting and transforming growth factor- α (TGF- α). The locus for TGF- α is on the short arm of 2p13. As with other clinical conditions, genetic predisposition interacts with environmental factors to increase the risk of the emergence of a disorder. Infants with the A2 form of the TGF- α gene are 8 times more

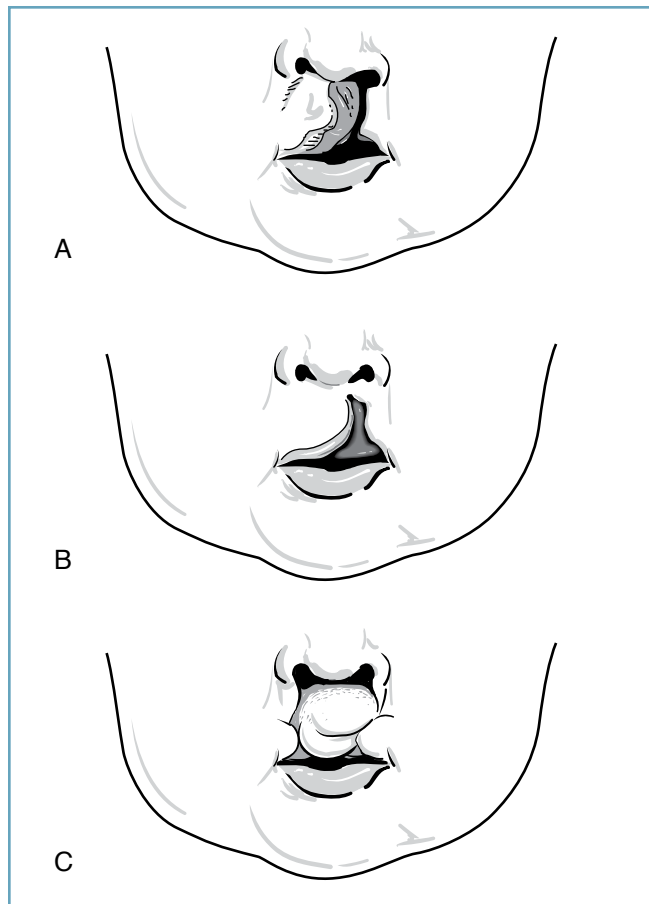

Figure 70-1. Cleft lips. A. Unilateral, complete cleft lip. B. Unilateral, incomplete cleft lip. C. Bilateral, complete cleft lip.

likely to have facial clefts if their mothers smoke. Other environmental teratogens associated with clefts include hydantoin, alcohol, warfarin, trimethadione, thalidomide, aminopterin, and topiramate.

The presence of a cleft palate affects normal oropharyngeal functioning, including sucking and speech. Children may exhibit hypernasal speech, due to the escape of air through the nose, and have articulation problems. Recurrent otitis media seems to be related to dysfunction of the eustachian tube.

Microtia, a small atretic pinna of the ear, results from failure of development of the pinna and portions of the external auditory canal. It is most likely caused by a vascular accident during the 12th week of gestation. Similar anomalies have been created in laboratory animals by ligation of the stapedius artery. Microtia is considered in the spectrum of branchial arch defects.

Craniosynostosis refers to the premature closure of the sutures, which should remain open until 2 to 3 years of age. The newborn skull consists of membranous bones that meet at the suture lines. The newborn skull is therefore moldable, can change during the birthing process, and can expand in response to growth of the brain. Premature closure of the sutures is a pathological process. What initiates this pathological ossification is unclear. There is some evidence to suggest that skull compression, such as occurs in utero with breech presentation or twins, contributes to the process. When there are other associated anomalies, such as syndactyly, embryologic disturbances in

fibrocartilaginous development are suspected. Abnormalities in one region of chromosome 10 are implicated in syndromic synostosis. Genes associated with fibroblast growth factor receptor have been implicated in some genetic syndromes with craniosynostosis. Any or all of the sutures can be affected, and the closure may result in asymmetry of the skull or microcephaly. Single suture synostosis is classified as simple; multiple synostosis is classified as compound. When closure is related to pathology at the suture, the condition is primary. When there is underlying brain pathology, the disorder is secondary. Premature closure of all sutures is often associated with diseases of the central nervous system, with failure of the brain to grow.

Microcephaly may result from premature closure of some or all of the sutures as a primary event or from impairment of the brain and its growth related to some other problem, such as hypoxic encephalopathy or congenital infection. Other disorders involving head size include macrocephaly, where the head circumference is greater than

the 97th percentile. There are numerous causes of macrocephaly, including hydrocephalus characterized by enlargement of the ventricular system, and megalencephaly. Megalencephaly may be due to enlargement of the brain from anatomical or metabolic conditions, including the mucopolysaccharidoses. Children who have large heads and are neurologically normal have benign or idiopathic megalencephaly. Measuring parental head size is frequently a clue to the correct diagnosis.

Fusion of individual sutures prevents growth of the skull perpendicular to the suture, and skull expansion proceeds in an axis parallel to that of the suture (Figure 70-2). If the sagittal suture fuses prematurely, the head is long and narrow, a condition referred to as **scaphocephaly** (boat head). This is the most common type of craniosynostosis, occurring in about 54% to 58%. If the coronal sutures fuse too soon, the head is flattened; this condition is called **brachycephaly** and occurs in 18% to 29% of cases of craniosynostosis. The incidence

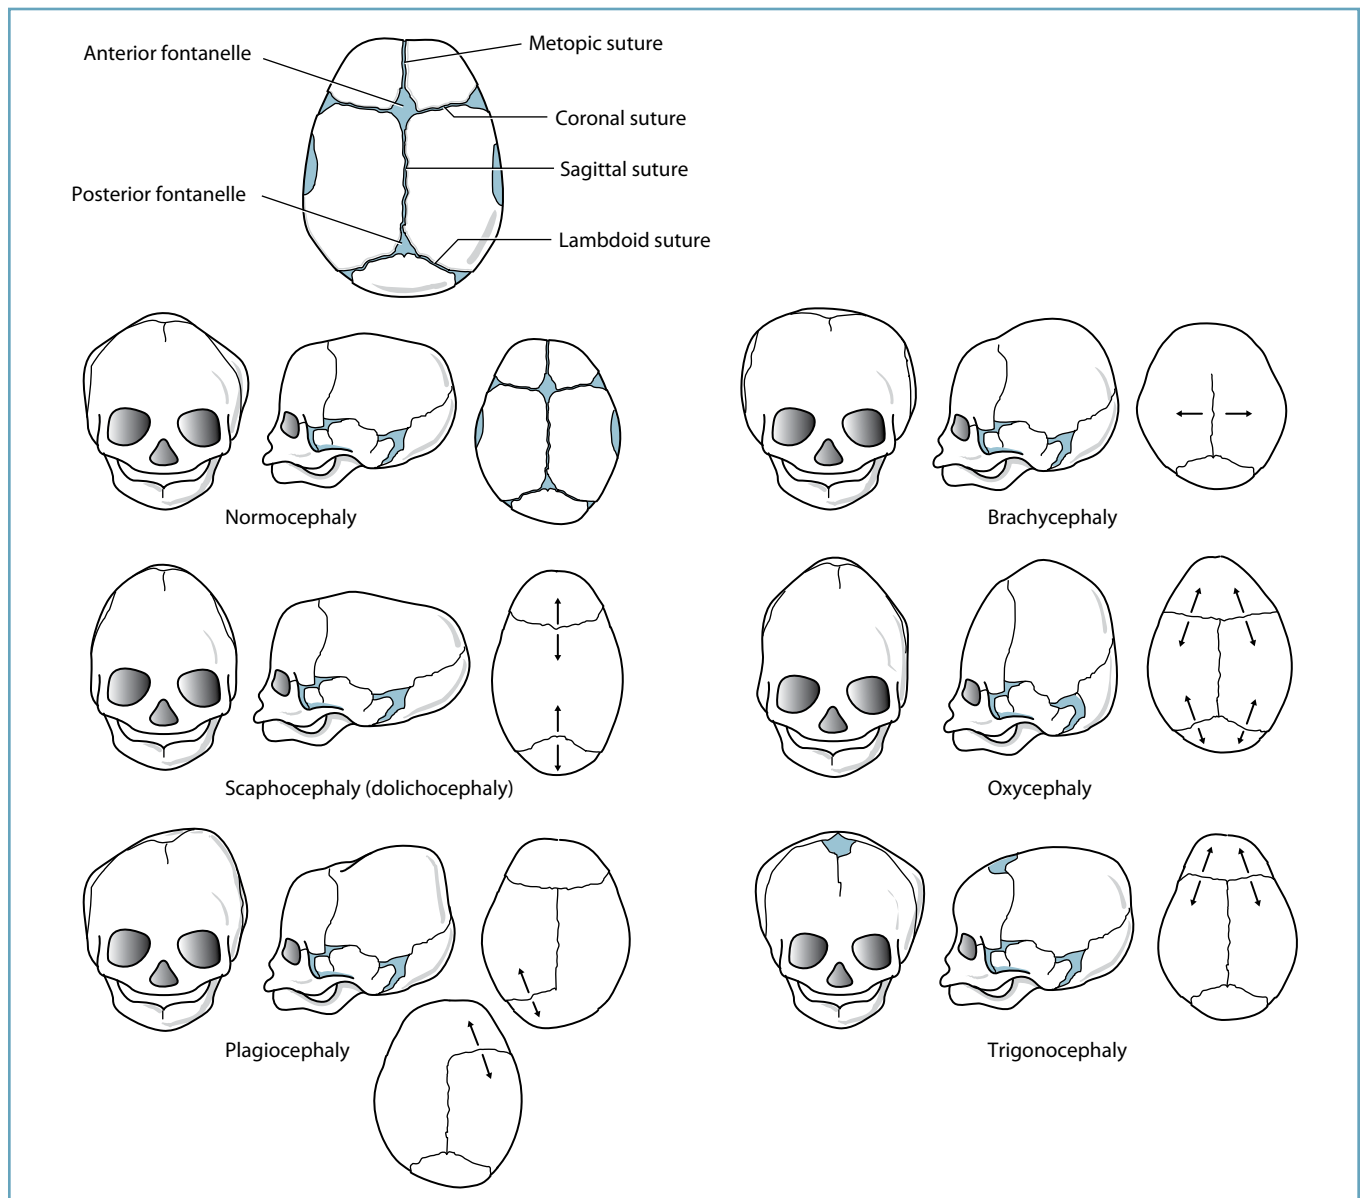

Figure 70-2. Changes in the shape of the skull when sutures fuse prematurely. Growth occurs parallel to the fused suture.

is 1 in 10,000 live births. Unilateral fusion of a coronal suture produces facial asymmetry and a characteristic appearance of the orbit on the affected side called a “harlequin” deformity noted on facial radiograph. Premature closure of the metopic suture results in the triangular-shaped head characteristic of **trigonocephaly**, reported in 4% to 10%. Familial cases have been reported, as well as abnormalities of chromosomes 3, 9, and 11.

Premature closure of the lambdoidal sutures leads to **plagiocephaly** (oblique head) (Figure 70-3). Plagiocephaly may also result from malpositioning in utero or after birth, a condition referred to as non-synostotic, deformational, or positional plagiocephaly. The skull has been likened to a parallelogram in appearance when there is also involvement of the facial structures. Torticollis, often related to injury to the sternocleidomastoid muscle at birth (see Chapter 106) and abnormal positioning after birth, may contribute to plagiocephaly. Plagiocephaly–torticollis sequence occurs in 1 in 300 live births. Malar and contralateral occipital flattening related to preferential positioning by infants are characteristically seen in affected infants. Some affected babies also have hip dislocation or positional clubfoot from in utero constraint (see Chapter 100). Positional plagiocephaly may be seen without torticollis and has been attributed to supine sleeping.

Differential Diagnosis

In general, the differential diagnosis of clefts of the lip and palate presents few problems. However, submucous clefts may be more difficult to diagnose. Children with such clefts may present with recurrent otitis media or hypernasal speech. Physical examination may reveal a bifid uvula and occasionally a notch at the junction of the hard and soft palates.

Determining whether any physical finding represents an isolated anomaly or is part of a genetic syndrome may be challenging. Any associated anomalies (eg, syndactyly or atrial septal defect) suggest the possibility of a genetic problem (Boxes 70-1 and 70-2).

Microtia does not present a diagnostic dilemma. The anomaly usually appears sporadically as an isolated condition although, like a cleft, it may be part of some other syndrome. Microtia is associated with midfacial hypoplasia and antimongoloid slant to the eyes in Treacher Collins syndrome. Microtia may also occur in Goldenhar syndrome, which is characterized by several associated findings, including hemifacial microsomia (one side of the face smaller than the other), epibulbar dermoids, hemivertebrae, microphthalmia, and renal and cardiac anomalies.

Box 70-1. Genetic Syndromes Associated With Clefts

Ankyloblepharon filiforme adnatum	Optiz
Apert	Oral-facial-digital
Ectrodactyly-ectodermal dysplasia-clefting	Popliteal pterygium
Goldenhar	Stickler
Meckel	Treacher Collins
	Van der Woude

Box 70-2. Anomalies Associated With Cleft Lips and Palates

Nasal glioma or meningoencephalocele	Sacral agenesis
Persistent buccopharyngeal membrane	Aniridia
Congenital neuroblastoma	Cleft larynx
Congenital heart disease	Polydactyly
Thoracopagus twins	Anencephaly
Congenital oral teratoma	Foot deformities
Forearm bone aplasia	Oral duplication
Lateral proboscis	Spina bifida
	Aplasia of trochlea
	Laryngeal web

Box 70-3. Genetic Disorders With Craniosynostosis

Apert syndrome	Jackson-Weiss syndrome
Crouzon disease	Pfeiffer syndrome

Craniosynostosis may also be an isolated finding or associated with a condition such as Apert syndrome, in which clefts of the palate are also seen (Box 70-3). A careful neurodevelopmental assessment helps determine whether microcephaly is related to an underlying neurodevelopmental disorder. Plagiocephaly may present a diagnostic dilemma: Is the condition related to unilateral craniosynostosis, torticollis, or supine sleeping? A careful assessment of the neck for masses or mobility helps determine the role of the neck musculature in the cranial flattening and defines the management approach (eg, neck exercises).

Evaluation

Care must be taken to assess children and determine if the anomalies are isolated findings or components of a syndrome. This information is important both in terms of patient care and genetic counseling for parents regarding the likelihood of having future offspring with similar anomalies.

History

A medical, family, and psychosocial history should be obtained (Questions Box). Whether the condition appeared at birth or some time later is particularly significant in lesions affecting the skull, such as craniosynostosis. Maternal use of certain medications, such as diazepam, phenytoin, and isotretinoin (Accutane), and alcohol is associated with an increased incidence of clefts of the lip and palate. Maternal smoking also increases the risk of clefting, especially in a genetically vulnerable population. Maternal smoking and high altitude are associated with an increased occurrence of craniosynostosis.

Physical Examination

Height, weight, and head circumference should be measured and plotted at each visit. Head circumference is especially important in children with craniosynostosis or facial asymmetry. The skull

Questions

Craniofacial Anomalies

- Did the child suffer any injuries at birth?
- Was the child born in an abnormal position?
- What is the child's usual sleeping position?
- Have the findings been present since birth, or did they appear later?
- Has the anomaly led to any changes in the child's health, such as recurrent ear infections or speech difficulties?
- Does the child have any family history of craniofacial anomalies?
- Does the mother have a history of illness during pregnancy?
- Was the mother exposed to any medications, particularly teratogenic agents, during pregnancy?
- Did the mother use alcohol during pregnancy?
- Did the mother smoke during pregnancy?
- Is the child experiencing difficulties in school (eg, teasing)?
- How is the child performing in school?
- Is development progressing normally? What are the child's milestones?
- Is the child's speech understandable?
- Does the child have any trouble with eating or drinking? Are fluids expelled through the child's nose with swallowing?

should be palpated to detect perisutural ridging. Inner canthal distance may reveal hypotelorism, a finding seen in trigonocephaly. The neck should be palpated for masses and the range of neck motion assessed. The growth of children with craniofacial anomalies must be carefully monitored. Problems with adequate weight gain are frequently experienced by infants with clefts.

The physical examination should focus on defining the extent of the anomaly and determining if associated abnormalities are present. Such abnormalities may involve the face or other parts of the body, including the skeleton. The pharynx should be carefully examined for mobility of the palate. While some children with nasal regurgitation have a structural deformity, such as a submucosal cleft, others, including infants with DiGeorge syndrome (22q11 deletion syndrome), have functional impairment with decreased palatal mobility. In children with microtia, the position of the ear should be noted. When the ear is displaced to the cheek, the condition is called *auricular dystopia*. Cardiac murmurs may be noted in children with clefts, and these murmurs should be carefully evaluated.

Children with clefts should be carefully assessed for the presence of otitis media at each visit. Periodic hearing assessments should be carried out in children with clefts or microtia. Speech and development should also be evaluated.

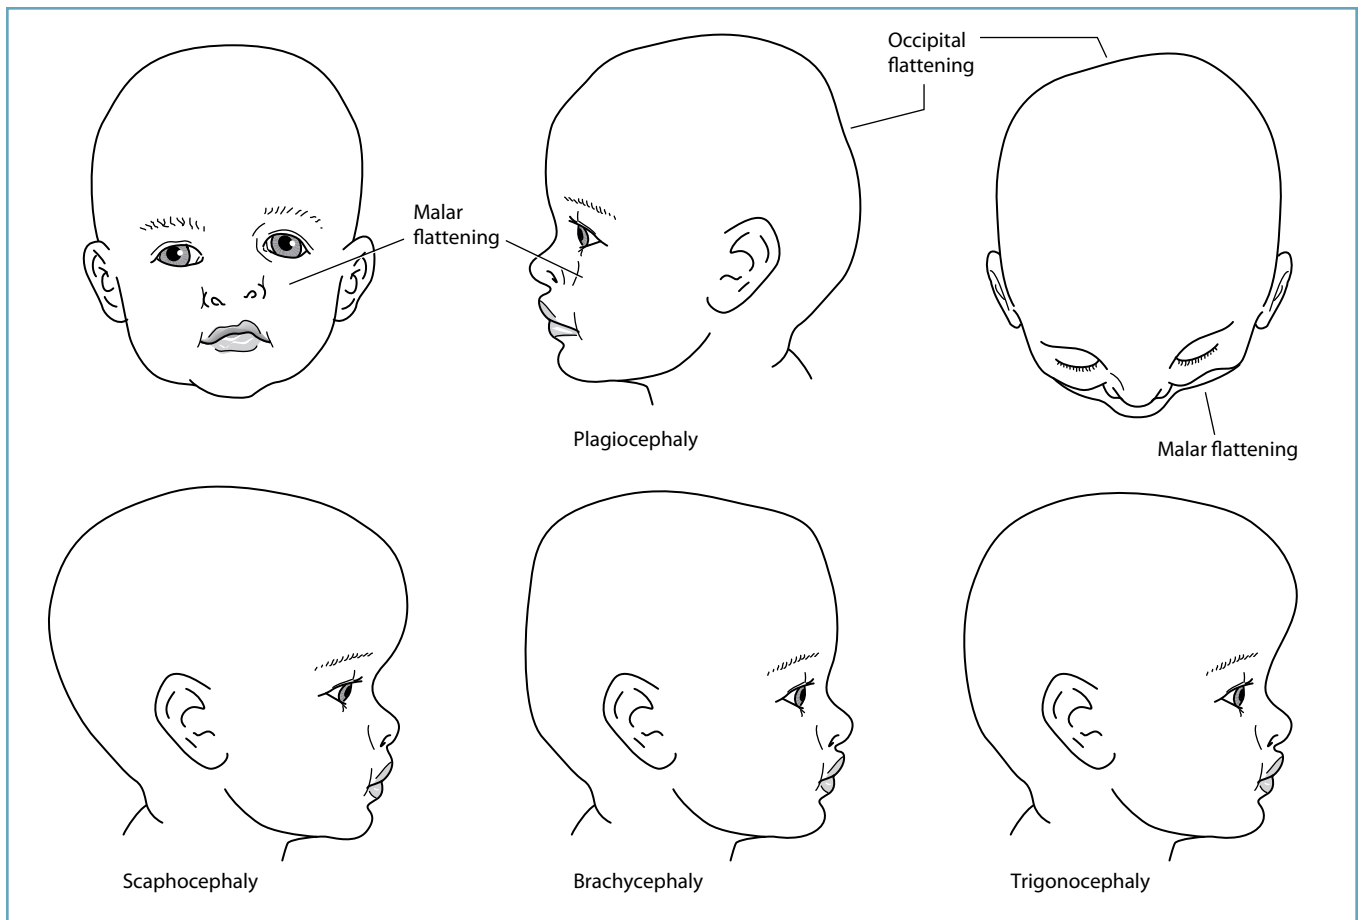

Figure 70-3. Top row. Classic appearance of an infant with facial asymmetry secondary to plagiocephaly. Bottom row. Classic appearance of infants with craniosynostosis.

Laboratory Tests

Routine laboratory tests are not indicated in most children with craniofacial anomalies. Chromosomal studies are indicated if a genetic disorder is suspected. Refined studies including FISH (fluorescent in situ hybridization) may be needed to detect certain chromosomal abnormalities (see Chapter 69).

Imaging Studies

Radiographs and imaging studies may be indicated in children with facial asymmetry, microcephaly and macrocephaly, and craniosynostosis. A 3-dimensional computed tomography scan of the skull is particularly helpful in defining which if any sutures are fused. Such studies are helpful in differentiating craniosynostosis and deformational disorders. Renal ultrasound may be indicated in children with microtia or other ear anomalies because of the association between ear and renal anomalies.

Management

The management of children with craniofacial anomalies usually requires the expertise of a multidisciplinary team, including a pediatrician; plastic surgeon; ear, nose, and throat specialist; speech pathologist; social worker; psychologist; orthodontist; and prosthodontist. Primary care physicians who are not part of the team can receive information regarding appropriate patient care and follow-up. It is important for primary care physicians to be familiar with the appropriate nomenclature to be able to communicate with consultants. In brief, clefts of the lip are unilateral or bilateral and complete or incomplete. A complete cleft extends into the nares (see Figure 70-1). Clefts of the palate may involve the entire palate or be confined to the secondary or soft palate.

Routine **well-child care**, including monitoring of growth and administration of immunizations, is most important in the management of children with craniofacial anomalies. Some infants with clefts are slow feeders. Mothers should be told that although breastfeeding can be carried out, it may present unique challenges; however, the compliancy of the breast tissue creates a natural seal for the lip and palate. If difficulties are encountered, consultation with a lactation specialist may be especially helpful. Some formula-fed infants require the use of special adaptive nipples or feeders. A specific cleft palate feeder, which consists of a plastic bottle that allows for compression of the unit during feeding, is available. A soft, premature-type nipple can also be obtained. Long nipples, such as lamb's nipples, which are used to feed infant lambs, are not routinely recommended because they cause infants to gag. Infants who gain weight slowly may need to be given concentrated formulas (see Chapter 129).

Hearing and speech should be monitored. Chronic prophylactic **antibiotics** or the insertion of **pressure equalization tubes** may be needed to manage recurrent otitis media (see Chapter 72). Speech problems require the expertise of a speech pathologist and placement of children in **speech therapy** in either the community or school.

Surgical correction is indicated for many anomalies. Clefts are usually repaired as staged procedures during the first 2 years of life.

Repair of the cleft lip, the first procedure, is traditionally scheduled when infants weigh 10 pounds, are 10 weeks of age, and their hemoglobin is 10 (rule of tens). Appropriate weight gain is therefore critical to ensure timely surgery. If skilled anesthesiologists and nurses are available, cleft lip repair can be carried out within the first 2 weeks of life. Early repair is recommended at some centers. Repair of the cleft palate, the second procedure, is usually undertaken when infants are between 12 and 18 months of age. Better speech develops with earlier palatal repair. Surgical correction of clefts does not alter children's propensity to otitis media. This condition improves as children get older, however. Refinement of the cosmetic results, including rhinoplasty, occurs throughout childhood. Orthodontia is frequently a key component to achieve a cosmetically acceptable result and appropriate occlusion of the dentition for speech and chewing. About 10% to 20% of children will develop velopharyngeal insufficiency following repair of a cleft palate. In these cases, the posterior soft palate fails to make a tight seal with the pharynx. Children may experience nasal regurgitation of food or hypernasal speech. Surgical correction of velopharyngeal insufficiency involves lengthening the shortened palate. Additional surgery may also be required by children who have significant jaw deformities. These may include the placement of bone grafts or maxillary advancement.

Children with isolated unilateral microtia often hear, and surgery is recommended for cosmetic purposes. Surgical correction of microtia is usually initiated when children are 5 years of age, before they start school. At this time the ear has achieved 90% of its growth, and children are spared the potential embarrassment of their deformity in the school setting. Surgical reconstruction can involve the implantation of the child's costal cartilage or a prosthetic device shaped like the pinnae. In either case, several surgical procedures are usually needed. If there are other facial anomalies, more extensive reconstructive surgery is indicated.

Craniosynostosis can be corrected surgically, although the procedure is major and has significant risks. Endoscopic craniosynostosis repair is less invasive and requires shorter operative time and a reduced length of hospital stay. It is the preferred approach in some centers. The age of the infant and the site of the synostosis influence the complexity of the surgical procedure. A controversy about whether neurodevelopmental problems are related to craniosynostosis or whether they represent a preexisting condition has arisen. In developmentally normal children with evidence of closure of all the sutures, surgical repair is believed to be warranted. In other cases, the procedure is thought to be reconstructive because it normalizes the appearance of children with a deformation.

In children with plagiocephaly, where the deformation is believed to be related to torticollis, **passive stretching of the neck** 5 to 6 times a day (with each diaper change) is used to manage the condition. In addition, it is recommended that bright objects such as mobiles be placed over children's cribs to encourage head turning. Changing the crib position, or the position of the infant in the crib, may also encourage movement of the head. Studies have shown that 90% of infants with congenital torticollis improve with manual stretching.

Children who do not improve with stretching, have a deformity related to supine sleeping, or have a deformity that is still present at 6 months of age may be fitted with a specially designed helmet or band referred to as a *dynamic orthotic cranioplasty device* that reshapes the skull. The device is not used prior to 6 months of age and is generally worn for a minimum of 4 months. In an effort to reverse the trend of increasing positional plagiocephaly related to supine sleeping, the American Academy of Pediatrics has recommended that parents rotate their infant's position when they are awake and allow for "tummy time." Tummy time is time when infants are placed prone, sometimes with a rolled receiving blanket under their upper chest. This promotes the development of the neck musculature and head control. Positional plagiocephaly secondary to supine sleeping usually resolves with either repositioning or the use of a helmet and does not require surgical intervention.

Psychological counseling should be available to affected children and their families to help them adjust to the anomalies and the reactions of society. Parents may be referred to community agencies such as the Cleft Palate Foundation (www.cleftline.org) to help them cope with the potential stress related to giving birth to children with this anomaly and to advise them about the medical and surgical interventions that are available. FACES, the National Craniofacial Association (www.faces-cranio.org), is a referral source for parents.

Prognosis

Some anomalies, such as deformational plagiocephaly, resolve spontaneously or with exercise and positioning. Most other anomalies can be surgically corrected, leaving little residual evidence of the deformity. School success and psychological well-being may be more resistant to remediation and are highly dependent on the supportiveness of the family and their emotional resources. Children who grow up in settings where the deformity is thought to be embarrassing have long-term problems with low self-esteem.

CASE RESOLUTION

The infant in the case history has a cleft of the lip and palate. The mother is advised that the infant can be given formula, and she is given a supply of special feeders. She is given the contact information for a parents' support group and meets other parents of children with similar anomalies. During her visit to the local craniofacial team, she views pictures of children who have undergone a repair and feels relieved.

The mother is advised about the timing of surgery and told that the surgery will be scheduled when the infant is approximately 10 weeks old. A follow-up appointment in about 2 weeks is arranged. Weight gain is monitored, and the adjustment between the mother and the infant is assessed.

Common Oral Lesions

Charlotte W. Lewis, MD, MPH

CASE STUDY

A 7-year-old girl is brought to the office for evaluation of a swelling on the inside of her lower lip of 4 to 6 weeks' duration. Her mother reports that it increases and decreases in size. The girl says that the swelling is not painful, and she cannot remember hurting her lower lip. On examination, a raised, bluish, non-tender, 1 x 1 cm swelling is apparent along the mucosa of the lower lip.

Questions

1. What is the differential diagnosis of lip masses?
2. What laboratory or radiographic tests are useful in the evaluation of oral lesions?
3. What management strategies are used to treat cyst-like oral lesions?
4. When should children with oral lesions be referred to subspecialists?

Primary care physicians are often required to evaluate lesions in the oral cavity. Knowledge of common congenital, developmental, infectious, traumatic, and neoplastic conditions that affect the mouth and its structures can help physicians to recognize and manage these lesions appropriately. Although many oral lesions are benign or represent normal variants, others may require specific medical or surgical treatment. Some oral lesions offer clues to underlying syndromic diagnoses, indicate more serious systemic disease, or occur as side effects of certain medications.

Epidemiology

Oral pathology is common and covers a broad range of lesions. Benign oral lesions such as gingival cysts occur in about 75% of newborns. Approximately 20% of the population has at least a small **torus palatinus**, a benign bony overgrowth of the palate that usually begins in childhood. **Ankyloglossia**, commonly referred to as tongue-tie, affects approximately 5% of newborns. **Fissured tongue** affects approximately 2% of the population. Fissured tongue may be associated with **benign migratory glossitis** (geographic tongue), which occurs in approximately 1% to 2% of children. **Tobacco-associated keratosis** occurs at the site of habitual placement of snuff or chewing tobacco and is estimated to affect more than 300,000 US children. **Leukoplakia**, a premalignant condition associated with smokeless tobacco, occurs in approximately half of users. Although the resulting oral cancer is often diagnosed in the sixth or seventh decade of life, the habit of oral tobacco use typically starts in childhood—typically between 9 to 16 years of age. The popularity of oral forms of snuff and chewing tobacco has rapidly increased in North America, especially among white adolescent males; approximately 10% of male high school students use smokeless tobacco, with quite a bit of variation by state.

Aphthous ulcers (commonly known as canker sores) are one of the most common oral lesions seen in developed countries, with typical onset early in childhood. Approximately 20% to 25% of the US population experiences recurrent aphthous ulcers (RAU). Oral lesions resulting from infections are also common. Approximately 35% of newborns and young infants will develop **oral candidiasis**, commonly known as thrush. Oral **herpes** lesions are also common and are due to herpes simplex virus (HSV) group, usually type 1 (HSV-1). By young adulthood, more than half of US individuals will be seropositive for HSV-1. Approximately 20% to 40% of the population has experienced oral herpes at least one time.

Chronic (“ordinary”) gingivitis usually has its onset in older children and will ultimately affect as many as 90% of adults.

Clinical Presentation

Oral lesions may come to the clinician's attention in any number of ways. Some may be obvious at birth, most notably a **congenital epulis**, which while benign in histology typically presents as a mass protruding from an infant's oral cavity and potentially interfering with breathing or eating. Oral lesions may be an incidental finding on physical examination. For example, in examining a newborn, the pediatrician may notice small (approximately 2–3 mm) yellow-white papules along the palatal midline and can then reassure the family that these are Epstein pearls, common lesions of no clinical significance. Most oral vascular malformations (1 of the 3 vessel types usually predominate: arterial, venous, or lymphatic) are present at birth, become more noticeable over time, and rarely regress. Microcystic lymphatic malformations often affect the tongue and surrounding soft tissue, can be friable, may interfere with eating and speaking, and can lead to overgrowth of adjacent bones. When these lesions become infected they rapidly enlarge and can result in potential airway compromise.

Either the clinician or parent may be the first to notice thrush. The incidence of oral candidiasis peaks around the fourth week of life; thrush is uncommon in infants older than 6 to 9 months. Thrush can occur, however, at any age in predisposed patients (ie, immunosuppressed or deficient) and can affect the esophagus as well as the oropharynx. *Candida albicans* in combination with contact irritation has been implicated in **angular cheilitis**, which appear as crusty or scaling erythematous fissures at the corners of the mouth. Other benign oral lesions, such as benign migratory glossitis, are brought to the clinician's attention because parents are concerned that they represent pathology; however, reassurance is appropriate.

Concerns for ankyloglossia may arise when newborns have difficulty breastfeeding or as a cause of speech problems in older children although these connections are controversial. Nevertheless, it can be difficult for children to use their tongue to clean food debris from around their teeth when the lingual frenulum is short. The maxillary labial frenulum can appear quite prominent in young children. It is common for parents to inquire whether this is contributing to what appears to be abnormal spacing between the upper central incisors (midline **diastema**). However, the prominent frenulum may be more a result of a diastema rather than a cause of it.

Clinicians may be the first to note swollen, friable, erythematous gingiva along with plaque buildup on and between the teeth representing the initial presentation of chronic gingivitis. Chronic gingivitis is the first stage of periodontal disease. Onset is typically in peripubertal children. Although young children experience gingivostomatitis from other causes, they do not usually harbor *Actinobacillus actinomycetemcomitans* or *Porphyromonas gingivalis*, and thus do not commonly experience chronic gingivitis or periodontal disease. Thickening of the mucosa, usually in the labial vestibule, offers clues to smokeless tobacco use. The severity of tobacco-related oral lesions demonstrates a dose-response relationship with the amount, frequency, and duration of smokeless tobacco exposure. Tobacco-associated keratosis is a predictable lesion that manifests as an area of thickening at the site of habitual placement of snuff or chewing tobacco. Chronic exposure to smokeless tobacco can lead to the development of opaque-white to yellow-brown lesions with a wrinkled appearance, known as leukoplakia and considered to be a premalignant condition.

Other oral lesions may present in conjunction with systemic symptoms. **Primary herpetic gingivostomatitis** typically occurs in infants and young children with the initial HSV-1 infection and is characterized by multiple oral vesicular or ulcerative lesions, fever, malaise, cervical lymphadenopathy, and decreased oral intake. Reactivation of prior HSV-1 infection often affects the vermilion border of the lip, which is known as herpes labialis. Oral lesions may also indicate underlying serious systemic illness such as Crohn disease, systemic lupus erythematosus, or acute myelogenous leukemia. Some genetic syndromes are first detected because of oral lesions. For example, lip pits or mounds in conjunction with cleft lip/cleft palate are virtually pathognomonic of van der Woude syndrome, an autosomal-dominant cause of orofacial clefting. Hyperpigmented lesions (brown or dark blue, similar to freckles) on the lips or buccal mucosa

may provide a clue toward the diagnosis of Peutz-Jeghers syndrome, an autosomal-dominant condition of multiple intestinal hamartomas. Patients with Peutz-Jeghers syndrome may experience recurrent abdominal pain, intestinal obstruction, or bleeding, and have a 15-fold increased risk of intestinal cancer.

Pathophysiology

Neonatal and Other Developmental Lesions

Gingival cysts in the neonate include Epstein pearls, Bohn nodules, and dental lamina cysts and are due to entrapment of tissues during embryologic development. Congenital epulis of the newborn is a rare, gingival tumor of unclear etiology that occurs more commonly in the maxilla than the mandible, with a marked female predilection (8:1), and may occur as a single or multiple tumors. The etiology of fissured tongue and geographic tongue are unknown. Fissured tongue tends to cluster in families, suggesting a genetic etiology, and can also be seen in Down syndrome. Benign migratory glossitis results from the loss of the tiny finger-like projections, called papillae, on the tongue's surface, giving the tongue a map-like appearance. The inciting factors responsible for oral vascular malformations are not well understood.

Traumatic

Some of the most common oral lesions noted on physical examination result from minor accidental self-bites to the lip or buccal mucosa. Most of these resolve quickly, but recurrent trauma may lead to **pyogenic granuloma** or **fibroma** formation. A **mucocele** results from traumatic rupture of a minor salivary gland with subsequent cyst formation.

Infectious

Although an infectious etiology to aphthous ulcers has been proposed, their true etiology remains unclear. Oral herpes lesions are usually due to infection with HSV-1. **Herpangina** results from coxsackievirus A infection. *C albicans* causes oral candidiasis. Thrush occurs when normal host immunity is immature (as in neonates) or suppressed (eg, during steroid treatment) or when normal flora is disrupted (eg, while on antibiotics). Infants may be colonized with *C albicans* during birth. Other sources of transmission to neonates include colonized skin (particularly around the breasts for breastfed infants) and/or improperly cleaned bottle nipples.

Chronic gingivitis occurs after build-up of bacterial plaque on the teeth, adjacent gingiva, and pockets between teeth and gums. Bacteria within plaque (most common species involved are gram-negative anaerobic bacteria (*A actinomycetemcomitans* and *P gingivalis*) release toxins that cause an inflammatory response.

Other

Drug-induced gingival hyperplasia can occur in patients taking corticosteroids, phenytoin (most common cause in children), cyclosporine-A, and nifedipine. It results from fibrous tissue overgrowth

but is exacerbated by poor oral hygiene and presence of plaque in much the same way as ordinary gingivitis is.

Differential Diagnosis

Age at onset, location and characteristics of the lesion, and accompanying signs and symptoms often help to narrow the differential diagnosis. The appearance of 1- to 3-mm cysts in the mouth of a neonate brings to mind (1) **Epstein pearls**, which are the most common and are usually present along the palatal midline; (2) **dental lamina cysts**, which are usually located bilaterally along the crest of the dental ridge about where the first molars usually will erupt; or (3) **Bohn nodules**, which are found on the buccal and lingual aspects of the ridge, away from the midline. A protuberant mass from the anterior maxillary ridge of a newborn should suggest a congenital epulis; however, examination by a pathologist after resection is important to confirm the diagnosis. A mucocele is a painless, clear or bluish, fluid-filled cyst that results from damage to the salivary duct leading to extravasation of mucus from the gland into the surrounding soft tissue.

White plaques involving the buccal, lingual, and palatal mucosa bring to mind oral candidiasis. Thrush can sometimes be confused with milk remaining in the child's mouth after feeding. Scraping the lesion to determine if the white substance is readily removed (as milk is) helps to differentiate this from oral candidiasis, where the white plaques do not easily scrape off, and after scraping, the base of the thrush lesion may be erythematous or bleed. Thrush involving the tongue may also be confused with the erythematous denuded areas of the tongue seen in benign migratory glossitis. In fissured tongue, grooves that vary in depth are noted along the dorsal and lateral aspects of the tongue.

Common oral ulcers include aphthous ulcers, herpes gingivostomatitis, or herpangina. Oral herpes may be characterized by multiple vesicular lesions, which after rupture appear as ulcers, involving the lips, skin around the mouth, tongue, and mucosal membranes, typically in the anterior portion of the mouth. The initial infection may occur between 1 to 3 years of age. Aphthous ulcers also involve the anterior mouth, typically along the wet vermilion, but they usually first appear at a somewhat older age (ie, in the preschool years or later) and with fewer lesions than oral herpes. Herpangina may present similarly to herpes but it more typically involves the posterior pharynx and the palate. Similar lesions on the hands and/or foot, as in hand-foot-and-mouth disease, may lend support to coxsackievirus A as the etiology.

Trauma to the salivary duct may result in a mucocele. In contrast, a pyogenic granuloma is an erythematous, non-painful, smooth or lobulated mass that often bleeds easily when touched, while a fibroma is a moderately firm, smooth-surfaced, pink, sessile or pedunculated nodule, usually noted on the buccal mucosa in the occlusal plane.

Erythematous and friable gums often indicate the presence of chronic gingivitis. Typically plaque is seen on and between the teeth. In contrast to plaque-associated chronic gingivitis, which is usually

painless, **acute necrotizing ulcerative gingivitis** is characterized by painful, edematous, bleeding gums with ulcers, necrosis, and pseudomembrane formation in affected areas. When this spreads to the oropharynx, it is referred to as **Vincent angina** (trench mouth), which can progress rapidly and interfere with speech and swallowing, and obstruct the airway.

Evaluation

History

The history is very important in evaluating oral lesions and determining the need for further treatment or referral. Key factors to include in the history are age at onset, duration, inciting factors, other medical problems, medications, use of tobacco, family history, ill contacts, and associated or systemic symptoms such as fever (Questions Box).

Questions

Common Oral Lesions

- How long has the child had the lesion?
- Is the lesion painful?
- Did the child recently injure the affected area?
- Has the child had any fever?
- Is the child eating as usual?
- Does the child have any other lesions?
- Is the child currently taking any medications? Has the child recently taken any medications?

Physical Examination

Physical examination of the oral structures should start with the lip (both the dry and wet vermilion) and surrounding skin (the "white lip"). The examination should then turn to the mucosa, gingiva, teeth, and palate; superior, lateral, and posterior aspect of the tongue; sublingual structures; frena; and posterior pharynx. The clinician should note the number, size, location, and characteristics of the lesions because this information can be helpful in narrowing the differential diagnosis. Whether fever is present should be determined. The rest of the body should be examined with specific attention to the presence of other lesions, rashes, or arthritis.

Laboratory Tests

In otherwise healthy children who present with oral ulcerative lesions, supportive care is typically implemented without pursuing a definitive etiology. When there is need for specific diagnosis, HSV can be diagnosed via polymerase chain reaction techniques, immunofluorescence, or culture. Tzanck smears are no longer commonly performed to diagnose HSV because they require special skills and are not specific to HSV, and more specific tests are available. Likewise, oral candidiasis in an otherwise healthy infant

is usually treated without diagnostic tests. However, a potassium hydroxide 10% microscopic slide preparation of scrapings from the lesion should demonstrate the characteristic spherical budding yeasts and pseudohyphae.

An excisional biopsy or resection may be needed to determine histology and diagnosis of an oral lesion.

Laboratory tests, including a complete blood cell count, C-reactive protein, or erythrocyte sedimentation rate, may be helpful in the initial evaluation of the ill-appearing child with oral lesions or when serious infection, systemic illness, or inflammatory conditions are suspected.

Imaging Studies

Imaging studies are not indicated in the evaluation of most oral lesions unless the lesions are related to problems of dentition such as dental abscesses, in which case the radiographs are obtained by the dentist rather than the pediatrician. Computed tomography is usually the best way to initially characterize oral vascular malformations.

Management

Many of the common oral lesions are developmental or normal variants and/or are self-limited, and their management entails observation to ensure the lesions follow their expected course. For example, gingival cysts in newborns typically regress spontaneously. Oral lesions such as torus palatinus or benign migratory glossitis do not require treatment. Although HSV-1 gingivostomatitis is self-limiting, primary infection can cause considerable pain and lead to decreased intake by mouth. Early (within 72 hours) antiviral therapy in the form of acyclovir 5 to 10 mg/kg/dose 5 times per day for 7 to 10 days has been shown to shorten duration of fever, lesions, and odynophagia. Other oral lesions respond well to supportive care. For example, a child with herpangina may benefit from regular ibuprofen or acetaminophen, topical application of a 1:1 mixture of attapulgite (Kaopectate) and diphenhydramine elixir (Benadryl) to form a protective coating over the lesion, avoidance of acidic beverages such as orange juice that may burn on contact with the ulcers, and close attention to fluid intake and signs/symptoms of dehydration. Viscous lidocaine has been associated with systemic absorption and subsequent dysrhythmia or seizure, thus substantial caution is warranted before prescribing. Over-the-counter topical anesthetic agents contain a high content of alcohol and should not be used in children. Amlexanox 5% oral paste or high-dose steroid gel reduces pain, duration, and size of aphthous ulcers and is used in adults with RAU; however, safety of these treatments in children has not been established.

Complicated vascular and lymphatic malformations of the oral cavity require specialty consultation with a team experienced in the care of these lesions. Unlike infantile hemangiomas, vascular malformations do not involute. Treatment of choice for lymphatic malformations is usually surgical resection; however, microcystic lymphatic malformations are difficult to remove and may recur even

after resection. Sclerosing therapy and laser treatment are sometimes options. Supportive care includes treatment with antibiotics when the lesion becomes infected and ongoing, aggressive preventive oral hygiene.

Other oral lesions require specific therapy. Thrush is typically treated with nystatin suspension (100,000 units/mL) as 1 mL swabbed to lesions 4 times per day until lesions are resolved. It is important to consider the possibility of an underlying immunodeficiency when thrush occurs outside of infancy or without a reasonable explanation. Angular cheilitis can be treated with nystatin cream or ointment and a low-potency hydrocortisone cream. Some oral lesions are best treated by resection. These would include congenital epulis, mucocele, pyogenic granuloma, and fibroma.

Treatment of gingivitis includes regular rinsing with alcohol-containing phenolic mouth rinse (eg, Listerine) or chlorhexidine gluconate oral preparation, improving oral hygiene (flossing, tooth-brushing), and referral for professional dental care. The goals of therapy for gingivitis are to reduce clinical signs of inflammation and gingival bleeding and arrest or reduce the risk of progression of the periodontal disease and maintain dentition. Drug-induced gingival hyperplasia requires similar therapy to ordinary gingivitis. In addition, if the causative medication cannot be discontinued or changed, patients can be referred for surgical removal of excess gingival tissue and fitting of a positive-pressure mouth guard to inhibit further tissue growth. Acute necrotizing ulcerative gingivitis should be treated with penicillin V (or erythromycin for patients allergic to penicillin). Clindamycin can be used in refractory cases.

It is controversial whether treatment of ankyloglossia with frenectomy decreases breastfeeding difficulties, although some small studies suggest there may be a benefit. Consultation with a lactation consultant is often helpful as a first step when questions arise about whether ankyloglossia is contributing to breastfeeding difficulty. Management of oral lesions may require consultation and collaboration with dental, oral surgery, head and neck surgery, or other subspecialty colleagues. If the etiology of a lesion is unclear or if an oral lesion does not follow its expected course, referral is essential to ensure appropriate diagnosis and treatment.

Prognosis

Most oral lesions in children respond to appropriate intervention without residual problems. However, oral lesions can signal the onset of or occur in association with serious systemic conditions. In addition, chronic gingivitis represents the first and only reversible stage of periodontal disease, which is the leading cause of tooth loss in adulthood. Because chronic gingivitis has its onset during childhood, physicians can play an important role in prevention of periodontal disease by promoting oral hygiene early in life. Once periodontal disease extends beyond the gums, it is no longer reversible and gradually destroys the bone and tissue that support the teeth, resulting in halitosis and tooth loss.

CASE RESOLUTION

The child described in the case history at the beginning of this chapter seems to have a mucocele. She should be referred to either an oral or head and neck surgeon for surgical excision of the lesion.

Otitis Media

Nasser Redjal, MD

CASE STUDY

An 18-month-old male infant is brought to your office with a 2-day history of fever and decreased food intake. He has had symptoms of an upper respiratory infection for the past 4 days but no vomiting or diarrhea. Otherwise he is healthy.

The infant appears tired but not toxic. On physical examination the vital signs are normal except for a temperature of 101°F (38.3°C). The left tympanic membrane (TM) is erythematous and bulging, with yellow pus behind the membrane. The light reflex is splayed, and mobility is decreased. The right TM is gray and mobile, with a sharp light reflex. The neck is supple with shotty anterior cervical adenopathy, and the lungs are clear.

He has a 10- to 15-word vocabulary, and no one smokes in the household.

Questions

1. What are the differences between acute, persistent, and recurrent otitis media (OM)?
2. What factors predispose to the development of ear infections?
3. What are the most common presenting signs and symptoms of an ear infection in infants, older children, and adolescents?
4. How do the treatment considerations differ between acute, persistent, and recurrent ear infections?
5. What are some of the complications of OM?

Otitis media is the second most common reason after well-child care for a visit to the pediatrician and is the most common reason for which antibiotics are prescribed for children. It is estimated that approximately 30 million office visits per year are for the evaluation and treatment of OM and that billions of dollars are spent annually for OM care. Moreover, more than a quarter of all prescriptions written each year for oral antibiotics are for the treatment of middle-ear infections. In addition, many surgical procedures such as **myringotomy** with **tympanostomy tube** placement or adenoidectomy are performed on children for treatment of recurrent disease. Therefore, the primary care physician must have a good understanding of these very common pediatric conditions.

Otitis media can be classified into the following 5 categories: **acute OM (AOM)**, **OM with effusion (OME)**, **recurrent AOM**, **chronic OME**, and **chronic suppurative OM (CSOM)**. It is important to distinguish between each of these entities because their presentation and management differ.

Acute OM (acute suppurative or purulent OM) is the sudden onset of inflammation of the middle ear, which is often accompanied by fever and ear pain (otalgia) (Box 72-1). Otitis media with effusion is the presence of middle-ear fluid after antimicrobial treatment. Resolution of acute inflammatory signs has occurred, with persistence of a more serous, non-purulent effusion. Although the fluid may persist for 2 to 3 months, it resolves within 3 to 4 weeks in 60% of cases. Recurrent OM is defined as frequent episodes of AOM with complete clearing between each episode. A more specific definition is 3 new episodes of AOM requiring antibiotic treatment within a

6-month period, or 4 documented infections in 1 year. This condition affects approximately 20% of children who are “otitis prone”; such children are usually infants who have their first infection at younger than 1 year. Chronic OME (serous OM, secretory OM,

Box 72-1. Components of Acute Otitis Media (AOM)^a

Definition of AOM

A diagnosis of AOM requires

1. A history of acute onset of signs and symptoms
2. The presence of middle-ear effusion (MEE)
3. Signs and symptoms of middle-ear inflammation

Elements of the definition of AOM are all of the following:

1. Recent, usually abrupt, onset of signs and symptoms of middle-ear inflammation and MEE
2. The presence of MEE that is indicated by any of the following:
 - a. Bulging of the tympanic membrane
 - b. Limited or absent mobility of the tympanic membrane
 - c. Air-fluid level behind the tympanic membrane
 - d. Otorrhea
3. Signs or symptoms of middle-ear inflammation as indicated by either
 - a. Distinct erythema of the tympanic membrane

or

 - b. Distinct otalgia (discomfort clearly referable to the ear[s]) that results in interference with or precludes normal activity)

^a Adapted with permission from American Academy of Pediatrics Subcommittee on Management of Acute Otitis Media. Diagnosis and management of acute otitis media. *Pediatrics*. 2004;113:1451–1465.

non-suppurative OM, mucoid OM, glue ear OM) is a chronic condition characterized by persistence of fluid in the middle ear for 3 months or longer. The TM is retracted or concave with impaired mobility and without signs of acute inflammation. Affected children may be asymptomatic. These children are at greater risk for developing hearing deficits and speech delay. Chronic suppurative OM implies a non-intact TM (perforation or tympanostomy tube present) with 6 or more weeks of middle-ear drainage.

Epidemiology

The overall prevalence of OM is 15% to 20%, with the highest peak in children 6 to 36 months of age. An additional smaller peak occurs at about 4 to 6 years. Otitis media is relatively uncommon in older children and adolescents. The condition is more common in boys than girls.

Several epidemiological risk factors for OM have been identified, including age younger than 2 years; first episode of AOM when younger than 6 months; familial predisposition; siblings in the household; low socioeconomic status; non-breastfed infant; altered host defenses (acquired or congenital immunodeficiencies); environmental factors, such as child care attendance; and the presence of an underlying condition, such as allergic disease of the upper airway, chronic sinusitis, a cleft palate, or other craniofacial anomalies. Children with Down, Goldenhar, and Treacher Collins syndromes and ciliary dysfunction also have an increased risk of OM. Race, bottle feeding, use of pacifier, and exposure to cigarette smoke have not been identified consistently as risk factors for AOM. As one might expect, the highest rate of OM occurs during the winter months and in early spring, coinciding with peaks in the incidence of upper respiratory infections (URIs).

Worldwide OM leads to an estimated 50,000 deaths per year in children younger than 5 years because of the complications of CSOM. It is estimated to affect 65 million to 33 million people worldwide, 60% of whom suffer significant hearing loss. Chronic suppurative OM is a rare entity in developed countries where most otitis media is AOM or OME.

Etiology

In general 50% to 90% of cases of AOM culture are bacterial, 20% to 50% are viruses and 20% to 30% no growth. Up until the widespread immunization of children with pneumococcal vaccine, the causative microorganisms for AOM were *Streptococcus pneumoniae* (25%–50%), *Haemophilus influenzae* (15%–30% most non-typeable strains), and *Moraxella catarrhalis* (3%–20%). Since vaccine licensure, there has been an overall decrease in the incidence of AOM, especially noted in children who are completely immunized. Group A streptococcus, *Staphylococcus aureus*, alpha-hemolytic *Streptococcus*, *Pseudomonas aeruginosa*, and anaerobic bacteria are other less common causative organisms. Other uncommon organisms such as *Mycoplasma pneumoniae*, chlamydia, and *Mycobacterium tuberculosis* have also been isolated. Respiratory viruses such as respiratory syncytial virus, adenovirus, rhinovirus, parainfluenza, coronavirus,

and influenza (A and B) also play a role. Respiratory syncytial virus, adenovirus, and coronavirus are associated with a higher rate of AOM, with 50% of children who have URIs caused by these viruses developing AOM compared with only 33% of patients who have URIs caused by rhinovirus, influenza, parainfluenza, or enterovirus. The bacterial pathogens causing AOM in the first 6 weeks after birth are essentially the same as those in older children. However, in a recent study, 10.5% of neonates who had AOM had gram-negative bacilli.

Currently approximately 50% of *H influenzae* and 100% of *M catarrhalis* isolated from the upper respiratory tract are β -lactamase positive and 15% to 50% (average 30%) of *S pneumoniae* are not susceptible to penicillin. The mechanism of penicillin resistance among isolates of *S pneumoniae* is not associated with β -lactamase production but related to an alteration of penicillin-binding proteins. This effect varies widely by geographic location and results in resistance to both penicillins and *cephalosporins*.

Clinical Presentation

Children with AOM often have a history of fever and ear pain. Associated symptoms include URI, cough, vomiting, diarrhea, and nonspecific complaints such as decreased appetite, waking at night, generalized malaise, lethargy, or irritability. Purulent otorrhea with minimal ear pain and hearing loss may also occur. Fever occurs in approximately 30% to 50% of patients. Temperatures exceeding 40°C are uncommon and suggest bacteremia or another complication. Older children may complain of tinnitus, vertigo, and hearing loss. Younger children are not able to express such complaints but may appear ataxic.

Pathophysiology

The most important factor in the pathogenesis of OM is abnormal function of the eustachian tube (Figure 72-1). Eustachian tube dysfunction occurs for 2 main reasons: abnormal patency and obstruction of the tube. Obstruction is either functional (secondary to collapse of the tube), mechanical (from intrinsic or extrinsic causes), or both. Functional obstruction or collapse of the eustachian tube occurs commonly in infants and young children because the tube

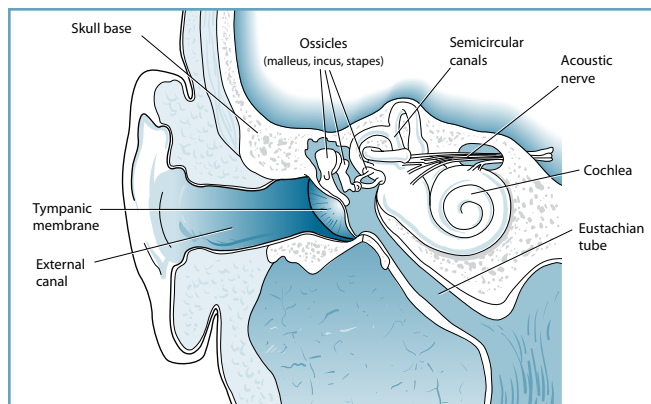

Figure 72-1. Relationship of middle ear to external and internal ears.

is less cartilaginous and therefore less stiff than in adults, as well as more horizontal and shorter. In addition, the tensor veli palatini muscle is less efficient in this age group. Extrinsically, the presence of lymphoid follicles (adenoidal enlargement) or tumors (rare) surrounding the opening of the tube contributes to reflux, aspiration, or insufflation of nasopharyngeal bacteria into the middle ear. Intrinsic mechanical obstruction of the eustachian tube occurs as the result of inflammation secondary to a URI or allergy in patients older than 5 years. In addition, viral infections may occur up to 6 to 12 times per year in children younger than 3 years. Subsequently this causes eustachian tube dysfunction leading to negative middle ear pressure, which occurs in 75% of children who have viral URIs. The presence of a viral URI enhances the ability of bacterial pathogens to adhere and ascend from the nasopharynx to the middle ear via the eustachian tube. In addition, viruses can affect the local host immune response by impairing leukocyte function, exposing receptors for bacteria, and decreasing the effectiveness of the mucociliary escalator (see Figure 72-1).

Hematogenous spread of microorganisms also can lead to infection. Less often, primary mucosal disease of the middle ear from allergies or abnormal cilia contributes to OM.

Differential Diagnosis

The most common cause of otalgia, or ear pain, is AOM. Other causes include mastoiditis, which is almost always accompanied by OM; otitis externa; and referred pain from the oropharynx, teeth, adenoids, or posterior auricular lymph nodes. A foreign body in the canal can produce similar symptoms. In children with ear pain, a search for any of these other conditions must be undertaken if the TM appears completely normal.

Evaluation

History

The history should carefully delineate the symptoms of OM and differentiate from those indicating a more serious condition such as meningitis (Questions Box).

Otitis Media

- Does the infant or child have fever, ear pain, hearing loss, or otorrhea?
- Is the infant or child inconsolable or lethargic?
- Has the infant or child had a previous ear infection? If so, when?
- Did the child complete the course of prescribed antibiotics?
- How many ear infections has the child had in the past year?
- Is the child taking any medication to prevent recurrent otitis media?
- Does the child attend child care?
- Does the child attend day care?
- Is the child exposed to passive smoke?
- Is the infant breastfed?
- Does the child seem to hear?
- Is the child's speech development normal?

Questions

For infants or children with a history of persistent or recurrent OM, it is important to find out when they had their last documented infection and what treatment they received. It is also critical to monitor development, particularly speech.

Physical Examination

To diagnose OM, the TM must be completely visualized and its mobility assessed. Occasionally this may be difficult because of the presence of cerumen or otorrhea. The diagnosis is then made on the basis of the history, and treatment may be initiated without confirmation by physical assessment. In all other cases, the position, color, degree of translucency, and mobility of the TM are evaluated. Classically, in AOM the TM is full, bulging, hyperemic, opaque, and/or has an air fluid level, with limited or no mobility. In addition, the light reflex is usually distorted or absent. In the case of persistent or chronic OM, signs of inflammation are usually absent, and the TM may be retracted, with limited or no mobility.

Associated physical findings with an uncomplicated middle-ear infection may include posterior auricular and cervical adenopathy. Other significant findings on physical examination are pain on movement of the pinna, anterior ear displacement, posterior auricular pain and, rarely, evidence of peripheral facial nerve (cranial nerve VII) paralysis. The presence of these findings suggests other diagnoses such as an associated otitis externa or mastoiditis.

Positioning of infants or young children for examination of the ear is critical for an adequate examination. Several methods have been described, including allowing parents to hold the child in their arms or on their laps or restraining the child on the examination table with or without a papoose board (Figure 72-2). In addition, it may be difficult to visualize the TM in infants because the external auditory canal is slightly angulated. Lateral retraction of the pinna may help correct this problem.

Figure 72-2. Three ways to position the infant or child for examination of the ear.

Laboratory Tests

Although the diagnosis of OM is suspected on the basis of the history and then verified on physical examination, tympanometry may be helpful in distinguishing the normal ear from one with an effusion. In acute cases, audiometry is of limited diagnostic value, but it is helpful in evaluating the effects of a persistent, recurrent, or chronic middle-ear effusion on hearing.

Tympanocentesis is the most definitive method of verifying the presence of middle-ear fluid and of recovering the organism responsible for the infection. Indications for tympanocentesis or myringotomy are listed in Box 72-2. Nasopharyngeal cultures are not helpful because they do not seem to correlate highly with middle-ear fluid cultures.

Box 72-2. Indications for Tympanocentesis or Myringotomy in Children With Otitis Media (OM)

- OM in patients with severe ear pain, serious illness, or appearance of toxicity
- Onset of OM in children receiving appropriate and adequate antimicrobial therapy
- OM associated with confirmed or potential suppurative complications, such as facial paralysis, mastoiditis, or meningitis
- OM in newborns, sick neonates, or immunodeficient patients, in each of whom an unusual organism may be present
- OM in patients with severe illness who have failed second-line antibiotic management.
- OM in patients with penicillin allergy who have failed first-line agent

Prevention

During infancy and early childhood, the incidence of respiratory tract infections and recurrent OM can be reduced by altering child care center attendance patterns.

Immunoprophylaxis with influenza vaccine and pneumococcal conjugate vaccine has proven effective in preventing OM. Avoiding supine bottle-feeding (bottle propping) decreases the incidence of AOM.

Breastfeeding, which provides infants with immunologic protection against URIs, other viral and bacterial infections, and allergies, also has a protective effect. Facial musculature may mature differently in breastfed infants, thus influencing eustachian tube function and reducing the risk of aspiration of fluid into the middle ear. Positioning during breastfeeding also has some protective effect, although immune factors in breast milk may serve as the most important mechanism for the reduced prevalence of OM.

Increased antibiotic resistance has eliminated the utility of routine antibiotic prophylaxis for recurrent AOM as a means of disease prevention.

Management

Current guidelines regarding the treatment of AOM confine the use of antibiotics to young children (<2 years old) or older ones with severe symptoms (Box 72-3). Otherwise, observation without the use of antibacterial agents in a child with uncomplicated AOM is recommended. Antibacterial treatment is deferred in these other children for 48 to 72 hours and management is limited to symptomatic relief. In an era of conjugated pneumococcal vaccine, the likelihood of bacteremia accompanying AOM is remote. Parents may be provided with a prescription to fill without recontacting the physician if the child remains symptomatic. This option is also recommended

Box 72-3. Indications for Antibiotics in the Treatment of Otitis Media^a

Criteria for antibacterial treatment or observation in children with non-severe illness

1. Younger than 6 months: antibacterial treatment
2. 6 months to 2 years: antibacterial treatment with certain diagnosis or severe illness or observation with uncertain diagnosis or non-severe illness
3. 2 years and older: antibacterial treatment with severe or observe with non-severe illness with certain diagnosis; observation for uncertain diagnosis

Observation is an appropriate option if

- A. Caregiver is informed and agrees.
- B. Caregiver is able to monitor the child and return should condition worsen.
- C. Systems are in place for ready communication with the clinician, reevaluation, and obtaining medication if necessary.

^a Adapted with permission from American Academy of Pediatrics Subcommittee on Management of Acute Otitis Media. Diagnosis and management of acute otitis media. *Pediatrics*. 2004;113:1451–1465.

to otherwise healthy children 6 months to 2 years of age with non-severe illness at presentation *and* an uncertain diagnosis. Among children 6 to 23 months of age with AOM antibiotic treatment affords a measurable short-term benefit and decreased risk of failure of a watchful waiting strategy. Concern for serious infection among children younger than 6 months influences the decision for immediate antibacterial therapy in this age group. The recommended antibiotic therapy is noted in Table 72-1.

Tympanocentesis is rarely performed nowadays prior to the initiation of antibiotics. Indications for tympanocentesis include severe ear pain (provides relief through decompression) or toxic appearance. Tympanocentesis is occasionally carried out in a child who has been receiving appropriate and adequate antimicrobial therapy but fails to improve; or in the face of confirmed or potential suppurative complications, such as facial paralysis, mastoiditis, or meningitis; or in newborns, sick neonates, or immunodeficient patients, in whom an unusual organism may be present (see Box 72-2).

Adjunctive medications such as topical analgesics and antipyretics are important therapeutic options and should be prescribed for children with significant pain or fever. Antihistamines, decongestants, or steroids play no documented role in the treatment of OME. Most resolving middle-ear effusions seen after AOM in otherwise healthy children do not need to be treated and the “wait-and-watch” approach is recommended.

Failure of antibiotic treatment and chronic effusions warrant a referral to an otolaryngologist for further evaluation for pressure equalization tubes or, if the patient is older than 4 years, a possible adenoidectomy. Other reasons for consultation include evidence of hearing loss; the presence of any anatomical abnormality, such as a defect of the TM (perforations, cholesteatomas) or intranasal problems (deviated septum, polyp); signs and symptoms of an OM but normal physical examination; and a predisposition to chronic recurrent OM (eg, children with a cleft palate or Down syndrome).

Table 72-1. Recommended Antibacterial Agents for Patients Who Have Failed 48 to 72 Hours of Observation or Initial Management With Antibacterial Agents^a

1.	<i>At diagnosis for patients being treated initially with antibacterial agents</i>			
	<i>Clinically Defined Treatment Failure at 48–72 Hours After Initial Management With Observation Option</i>		<i>Clinically Defined Treatment Failure 48–72 Hours After Initial Management With Antibacterial Agents</i>	
<i>Temperature ≥39°C (102.2°F) and/or Severe Otolgia</i>	<i>Recommended</i>	<i>Alternative for Penicillin Allergy</i>	<i>Recommended</i>	<i>Alternative for Penicillin Allergy</i>
No	Amoxicillin, 80–90 mg/kg/d	Non–type I: cefdinir, cefuroxime, cefpodoxime; type I: azithromycin, clarithromycin	Amoxicillin-clavulanate, 90 mg/kg/d of amoxicillin component, with 6.4 mg/kg/d of clavulanate	Non–type I: ceftriaxone, 3 days; type I: clindamycin
Yes	Amoxicillin, clavulanate, 90 mg/kg/d of amoxicillin, with 6.4 mg/kg/d of clavulanate	Ceftriaxone, 1 or 3 days	Ceftriaxone, 3 days	Tympanocentesis, clindamycin

^a Adapted with permission from American Academy of Pediatrics Subcommittee on Management of Acute Otitis Media. Diagnosis and management of acute otitis media. *Pediatrics*. 2004;113:1451–1465.

Complications

Complications associated with OM are much less common with appropriate antibiotic therapy and follow-up, but occasionally occur. They can be divided into 2 categories: extracranial and intracranial. Extracranial complications include perforation of the TM, conductive and sensorineural hearing loss, cholesteatoma, mastoiditis, facial nerve (cranial nerve VII) paralysis, osteomyelitis of the temporal bone, and Bezold abscess. Intracranial complications are meningitis, extradural as well as subdural abscesses, lateral venous sinus thrombosis, brain abscess, and hydrocephalus.

CASE RESOLUTION

In the case presented at the beginning of the chapter, the child displays the classic signs and symptoms of AOM: fever, upper respiratory infection, decreased appetite, and an abnormal tympanic membrane on physical examination. Because of his age, fever, and the certainty of diagnosis, he should be treated for 10 days with oral amoxicillin. The prognosis is good given his normal speech development.

Hearing Impairments

Julie E. Noble, MD

CASE STUDY

A 15-month-old girl is brought to the office because the parents are concerned that she has not yet begun to speak. The child was the full-term product of an uncomplicated pregnancy. Her 25-year-old mother, who began to receive regular prenatal care during the second month of gestation, had no documented infections during the pregnancy, took no medications, and has denied using illicit drugs or alcohol. The infant was delivered at home by a mid-wife and a newborn hearing screening was never done. The 27-year-old father is reportedly healthy. There is no family history of deafness, mental retardation, or consanguinity.

The girl, who is otherwise healthy, has never been hospitalized, but she has had 3 documented ear infections. She rolled over at 4 to 5 months of age, sat at 7 months, and walked at 13 months. She is able to scribble. The parents report that their daughter smiles appropriately, laughs occasionally, and plays well with other children. As an infant, the girl cooed and babbled, but she now points and grunts to indicate her needs. She does not respond to loud noises by turning her head.

The child's growth parameters, including head circumference, are normal for age. The rest of the physical examination is unremarkable.

Questions

1. When should deafness be suspected in infants or children?
2. What is the relationship between hearing loss and language development?
3. What are the major causes of deafness in children?
4. What neonates are at risk for the development of hearing deficits?
5. What methods are currently available to evaluate hearing in infants and children?
6. What are the important issues to address with families who have infants or children with suspected hearing impairment?

Hearing loss, even in a mild degree, is a significant childhood disability that can compromise speech and language development, academic performance, and psychosocial behavior. It is essential to identify hearing loss as soon as possible to implement early intervention, which has been shown to prevent many adverse consequences. Children may either be born with a hearing deficit, termed *congenital deafness*, or may acquire the condition during childhood, termed *progressive* or *late-onset*. A mild hearing deficit occurs with a 26 to 40 decibel (dB) loss. Severe hearing loss, on the other hand, is defined as 71 to 90 dB, and profound loss is 90 dB or greater. The most important period for speech and language development is from birth to 3 years of age. Reduced hearing acuity in both or even one ear during this time can significantly interfere with this important process (see Chapter 28). Therefore, primary care physicians must have a clear understanding of when to suspect impaired hearing in infancy and early childhood and must be familiar with the identification, evaluation methods, and treatment of hearing loss.

Epidemiology

The prevalence of congenital deafness in children is approximately 0.1%. In other words, 1 in 1,000 children is born severely to profoundly deaf. It has been estimated, however, that 3 to 5 in 1,000

children have mild to moderate hearing loss. The average age at diagnosis of most children who were born deaf was 2 to 3 years of age prior to the initiation of newborn hearing screening. Since its advent, the average age of diagnosis has dropped to 2 to 3 months of age. At this time in the United States, all 50 states have mandated universal newborn hearing screening programs. But as with any screening program, some infants may get missed, especially with at-home births; some infants may be lost to follow-up; and some forms of early-onset hearing loss are not apparent at birth. Therefore, careful assessment of hearing and language development by the pediatrician is essential at each patient encounter.

An estimated 20% to 30% of children who are hearing impaired develop the condition during childhood. Of these, 70% of children with acquired hearing loss are initially identified by the parents rather than physicians. Any concern by the parent that their child might have a hearing problem should be taken seriously by the physician and objective testing performed. Risk factors for acquired hearing loss in childhood include persistent otitis media with effusion, history of head trauma, bacterial meningitis, and the identification of syndromes or neurologic disorders associated with hearing loss.

Graduates of the neonatal intensive care unit have a significant increased risk of bilateral sensorineural hearing loss (1%–3%)

termed auditory neuropathy/dyssynchrony. Associated factors such as prematurity (birth weight <1,500 g), hyperbilirubinemia, prolonged mechanical ventilation, extracorporeal membrane oxygenation treatment, perinatal asphyxia, exposure to ototoxic drugs, and neonatal sepsis increase this risk. Other factors associated with deafness in childhood include meningitis, parental consanguinity, craniofacial malformations, congenital viral infections, exposure to chemotherapy, and a family history of deafness.

Clinical Presentation

Newborns might present to their pediatrician having had an abnormal newborn hearing screening test. The initial newborn screen is mandated by 1 month of age with definite testing by an audiologist for abnormal tests by 3 months of age. Therapy should begin by 6 months. If infants pass hearing testing but have positive risk factors they should have communication skills assessed at every well-child visit and diagnostic audiological assessment by 24 to 30 months of age.

Children with hearing impairments frequently present to physicians with delayed speech. Parents may be concerned that the toddler is indicating his needs by grunting and pointing rather than by using words. Children also may display behavioral problems, such as inattention, temper tantrums, or aggressive play with other children (Dx Box).

Dx

Hearing Impairment

- Parental concern or suspicion of hearing loss
- Delayed speech and language development
- Associated risk factors including prematurity, exposure to ototoxic drugs, congenital or acquired central nervous system infections, family history of hearing loss and craniofacial abnormalities
- History of behavioral problems and/or poor school performance
- Abnormal hearing test

Hearing impairment can be more difficult to recognize in infants younger than 6 months because they may have no obvious symptoms of a hearing deficit. They may startle to moderately loud noises and begin to vocalize just as other infants (Figure 73-1). If the history is suggestive of a hearing deficit, audiological testing should be performed.

Pathophysiology

Mechanism of Hearing

Sounds in the form of pressure waves are carried from the environment through the external auditory canal to the tympanic membrane (TM). These waves are then converted to mechanical vibrations by the ossicles, and the mechanical vibrations are then transmitted from the TM to the inner ear, where they are transformed to fluid vibrations. Finally, these fluid vibrations are converted into nerve impulses by nerve endings within the organ of Corti located in the cochlea in

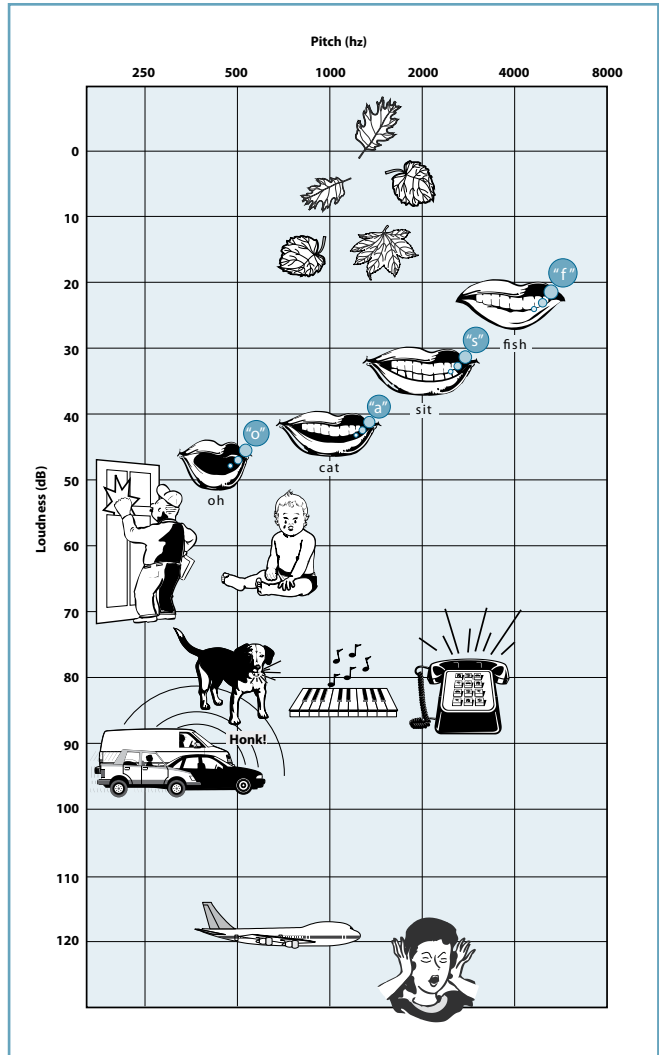

Figure 73-1. Loudness of everyday sounds. (Reproduced with permission from Northern J, Downs M. *Hearing in Children*. 4th ed. Baltimore, MD: Williams & Wilkins; 1991.)

Figure 73-2. Sound waves passing through the external ear into the middle ear.

the inner ear. These impulses are conducted via the auditory nerve to the auditory cortex (Figure 73-2).

Hearing impairments can be classified either according to the part of the auditory system affected or by the cause of the hearing loss.

Types of Hearing Loss

A **conductive hearing loss** denotes an abnormality in the outer ear, the TM, or middle-ear ossicles. Cerumen impaction, otitis externa, serous otitis, recurrent otitis media, TM perforation, and ossicular discontinuity are examples of this type of hearing loss. Middle-ear effusions rarely cause more than a 20- to 30-dB loss.

The cochlea or inner ear or auditory nerve is affected in **sensorineural hearing loss (SNHL)**. Congenital infections, anomalies, and genetic disorders lead to this type of loss. The loss of cochlear function is the main cause of permanent childhood hearing loss. A **mixed disorder** has characteristics of both conductive and sensorineural losses. In a **retrocochlear hearing loss**, the auditory nerve, brain stem, or cortex is affected. This includes auditory neuropathy noted in infants following neonatal intensive care unit stays.

Etiology of Hearing Impairment (Box 73-1)

Severe to profound hearing loss has 2 main causes: genetic and acquired environmental. Genetic causes account for approximately 68% of cases. There are more than 500 forms of syndromic hearing loss with associated clinical features. An autosomal-recessive syndrome, Pendred syndrome with thyromegaly is a more common example. Down syndrome and Goldenhar syndrome both have frequently associated hearing impairment. Alport syndrome with progressive SNHL and nephritis is also well recognized. But most cases of genetic hearing loss are non-syndromic and result from a single gene defect encoding connexin, 26(CX26) protein. This recessive disorder with mutations in the *GJB2* gene account for 30% to 50% of all cases in many populations. Genetic malformations of the ear pinnae or ossicles do occur but are the least common cause of hearing loss. Genetic mutations may result in different types of deafness with various presentations and outcomes (ie, hearing loss may be conductive, sensorineural, or mixed, and may be static or progressive with the initial presentation either in infancy or later childhood).

Acquired environmental causes include prenatal, perinatal, or postnatal events and exposures such as congenital infections, bacterial meningitis, hyperbilirubinemia, complications of prematurity, and exposure to ototoxic medications. Cytomegalovirus (CMV) is probably the most frequently unrecognized congenital infection causing deafness. Ten percent of infants with congenital hearing loss are infected with CMV. However, toxoplasmosis, rubella, herpes simplex virus, HIV, and syphilis can also be implicated. Hearing loss associated with bacterial meningitis accounted for as many as 20% of cases, with *Streptococcus pneumoniae* as the prevalent responsible organism. The incidence of both *S pneumoniae* and *Haemophilus influenzae* meningitis have decreased tremendously in young children following the advent of conjugate vaccine, and the prevalence of post-meningitic hearing loss has similarly declined. The role of steroids in the treatment of bacterial meningitis has also contributed to the decrease in sensorineural hearing loss in survivors.

Box 73-1. Major Causes of Childhood Deafness^a

Conductive Hearing Loss	Sensorineural Hearing Loss
Congenital <ul style="list-style-type: none"> • Microtia/atresia • Tympanic membrane abnormalities • Ossicular malformations 	<ul style="list-style-type: none"> • Genetic disorders (syndromic, connexin 26, mitochondrial) • In utero infections (cytomegalovirus, measles, mumps, rubella, varicella, syphilis) • Anatomical abnormalities of the cochlea or temporal bone • Exposure to ototoxic drugs during pregnancy (alcohol, isotretinoin, cisplatinum) • Hyperbilirubinemia
Acquired <ul style="list-style-type: none"> • Infection (acute otitis media, otitis externa, ossicular erosion) • Otitis media with effusion • Foreign body (including cerumen) • Cholesteatoma • Trauma (ossicular disruption, tympanic membrane perforation) 	<ul style="list-style-type: none"> • Infections (bacterial meningitis, measles, mumps, rubella, Lyme disease) • Trauma (physical or acoustic) • Radiation therapy for head and neck tumors • Neurodegenerative or demyelinating disorders (Alport, Cogan syndromes)

^a Adapted from Gifford KA, Holmes MG, Bernstein HH. Hearing loss in children. *Pediatr Rev.* 2009;30:207–216.

With the recognition and treatment of hyperbilirubinemia in term newborns, this as a cause of hearing loss is now rare in the United States and other developed countries. Prematurity as a cause of hearing loss is, however, not uncommon. Because of associated complications, premature infants have higher rates of severe hearing loss than do full-term infants. Some antibiotics, such as the aminoglycosides, and other medications like furosemide can be irreversibly ototoxic; other drugs may cause only transient effects.

Any head injury causing significant middle-ear trauma may also cause deafness in children. Repeated acoustic trauma from continuous or significant exposure to loud noise can also cause irreversible hearing loss. With children's use of personal listening devices, this cause of hearing loss is increasing.

Differential Diagnosis

In addition to hearing loss, communication disorders should be considered in infants or children with delayed speech and language development. These include problems with speech perception, language comprehension, formulation of language output, and speech production. Unrecognized conditions such as mental retardation or autism can be responsible for some of these disorders. Other etiologies include specific central nervous system deficits as well as impairments of fine motor control of the oropharynx.

Evaluation

Newborn Hearing Screening

In 1994 the Joint Committee on Infant Hearing (JCIH), composed of representatives from several professional organizations, endorsed universal newborn hearing screening. Their goal was the early identification of hearing loss in infants before age 3 months and the implementation of intervention services by 6 months of age. As a result of these recommendations, states have implemented legislation mandating newborn hearing screening and intervention programs. A subsequent position statement was issued in 2000 titled Principles and Guidelines for Early Hearing Detection and Intervention Programs (EHDI). The American Academy of Pediatrics endorsed this statement and promoted newborn hearing screening as well as periodic hearing assessment for every child. The JCIH policy statement was most recently updated in 2007 and includes more specific guidelines for diagnostic audiological evaluation, medical evaluation, and surveillance screening in the medical home. The policy notes that all infants and children regardless of hearing screening results should have ongoing assessment of communication skills beginning at 2 months of age. Any child with evidence of hearing loss in one or both ears should be offered early intervention.

History

Because the primary symptom of deafness is failure to learn to speak at the appropriate age, the most important aspect of the history in children with possible hearing loss is determining whether speech is developing normally. Even deaf infants may begin cooing and babbling in infancy, and these early attempts at verbalization are not useful milestones for assessment of hearing deficits. It helps to ask parents whether they are at all suspicious or concerned about their children's speech or hearing. Guidelines to assess language development are found in Table 73-1 (see Chapter 28). An assessment of risk factors for deafness, such as a positive family history, infection during gestation, history of prematurity, hyperbilirubinemia, neonatal sepsis, and asphyxia, is also important (Questions Box).

Physical Examination

A complete physical examination should be performed on all children. In particular, any dysmorphic facial features that may suggest the presence of a syndrome with an associated hearing deficit should be noted. Other anomalies of the head and neck should be noted as well. Abnormal pigmentary conditions may be important clues. The eyes should be evaluated for heterochromia and hypertelorism findings seen in Waardenburg syndrome, which also includes SNHL. The size and shape of the pinnae and external ear canals should be carefully inspected for abnormalities and patency, respectively. Preauricular pits or tags may be apparent. In addition, the TMs should also be visualized and assessed for the presence of a middle-ear effusion that may influence subsequent audiological tests. Insufflation may be helpful to assess middle-ear effusion. The oropharynx should be examined for a cleft palate or a bifid uvula, which

Table 73-1. Expected Speech-Language-Auditory Milestone^a

Age	Receptive Skills	Expressive Skills
Birth	Turns to source of sound Shows preference for voices Shows interest in faces	Cries
2–4 months		Coos Takes turns cooing
6 months	Responds to name	
9 months	Understands verbal routines (wave bye-bye)	Babbles Points Says ma-ma, da-da
12 months	Follows a verbal command	Uses jargon Says first words
15 months	Points to body parts by name	Learns words slowly
18–24 months	Understands sentences	Learns words quickly Uses 2-word phrases
24–36 months	Answers questions Follows 2-step commands	Phrases 50% intelligible Builds 3- (or more) word sentences Asks "what" questions
36–48 months	Understands much of what is said	Asks "why" questions Sentences 75% intelligible Masters the early acquired speech sounds: m, b, y, n, w, d, p, and h
48–60 months	Understands much of what is said, commensurate with cognitive level	Creates well-formed sentences Tells stories 100% intelligible
6 years		Pronounces most speech sounds correctly; may have difficulty with sh, th as in think, s, z, th as in the, l, r, and the s in treasure
7 years		Pronounces speech sounds correctly, including consonant blends such as sp, tr, bl

^a Adapted from Feldman HM. Evaluation and management of language and speech disorders in preschool children. *Pediatr Rev.* 2005;26:131–142.

may be associated with a submucous cleft. The manner in which children communicate with parents should be noted, if possible, and the child assessed for response to sound.

Questions

Hearing Impairment

- Does the infant seem to respond to sounds?
- Does the infant attempt to repeat sounds?
- How does the young child indicate his or her desires or needs?
- How are the parents currently communicating with the child?
- Is there any evidence of a congenital infection, structural anomaly of the head and neck, or syndrome?
- Is there a history of prematurity or other prenatal or perinatal problem?
- Have there been any serious bacterial infections such as meningitis?
- Has the child had a history of repeated ear infections or exposure to ototoxic drugs?
- Aside from the hearing problem, is the child developmentally normal?
- Is there a family history of deafness, consanguinity, or multiple miscarriages or stillbirths?

Laboratory Tests

Tympanometry does not measure hearing, but is useful in assessing the presence of middle-ear fluid and the mobility of the TM. Tympanometry can be particularly helpful with uncooperative, crying children in whom assessing the appearance of the TM and insufflation is difficult. Different types of hearing tests for evaluating infants and children for possible hearing deficits are available to general pediatricians (Box 73-2). **Automated auditory brain stem response (ABR)** and **brain stem auditory evoked response (BAER)** are electrophysiological measurements of activity in the auditory nerve and brain stem pathways. Electrodes are placed on the infant or child's head to record brain wave activity while a specific auditory stimulus is presented through earphones to one ear at a time. Auditory thresholds can be estimated. The ABR is used for newborn hearing screening and only takes approximately 10 minutes, whereas the BAER is more comprehensive, requiring up to 90 minutes to perform. **Behavioral observation audiometry** measures a child's response to speech and frequency-specific stimuli presented through speakers in a soundproof room. This method of testing can only assess hearing in the better ear and cannot detect unilateral hearing loss. It is used with children at younger than 6 months' developmental age. **Evoked otoacoustic emissions** can be performed on children of all ages. It measures cochlear function in response to a specific stimulus via a small probe that contains a microphone that is placed in the ear canal. This test can be used for newborn hearing screening in low-risk newborns and also can be performed in approximately 10 minutes. **Conditioned play audiometry** like **conventional audiometric testing** measures auditory thresholds in response to frequency-specific stimuli presented through earphones to one ear at a time. The patient is instructed to perform a particular task, such as put a block in a container versus raise his or her hand, when the stimulus is heard. Children as young as 3 years can be tested by conditioned play audiometry and 4 or 5 years of age via

Box 73-2. Tests to Evaluate Hearing

- Automated auditory brain stem response: used for newborn - hearing screening
- Behavioral observation audiometry
- Brain stem auditory evoked response
- Evoked otoacoustic emissions: newer type of newborn hearing screening
- Conditioned play audiometry
- Conventional audiometric testing

conventional audiometric testing. These tests should be used in conjunction with evaluations from audiological and otolaryngologic consultations. In the case of high-risk infants, testing should be repeated at least every 6 months until 3 years of age, and at appropriate intervals thereafter depending on the etiology of the suspected hearing loss and the hearing test results.

Diagnostic tests to consider in evaluating the cause of deafness include titers for congenital infections such as CMV, toxoplasmosis, HIV, and rubella and fluorescent treponemal antibody absorption tests for syphilis. In the newborn period, a CMV culture may be helpful. Testing for the *GJB2* gene, the mitochondrial A1555G mutation that predisposes one to ototoxicity from drugs, and the *SLC26A4* gene for Pendred syndrome along with CMV testing would reveal an etiology for 40% of congenital hearing loss and for 60% of late-onset hearing loss. Thyroid function tests are necessary if Pendred syndrome is suspected, especially in school-aged children with goiters. Proteinuria and hematuria should also be ruled out by urine dipstick, especially in boys with a positive family history of deafness and renal failure, findings suggestive of Alport syndrome. An electrocardiogram is recommended to detect conduction defects such as QT prolongation in Jervell and Lange-Nielsen syndrome.

Imaging Studies

Occasionally, a computed tomography or magnetic resonance imaging scan of the temporal bone may be used to view the anatomy of the middle and inner ear, particularly in cases of a suspected cochlear/vestibular malformation or fistula. Necessity for such studies should be determined by the audiologist or otolaryngologist.

Management

Studies have shown that the earlier the hearing deficit is detected and remediation begun in an otherwise normal infant, the greater the likelihood the child will have language development close to that of a hearing infant. Initiation of intervention prior to 6 months of age produces infants who are able to develop language, as well as social and emotional skills appropriate for their age. School performance and communication skills also have been shown to be better in those identified at a younger age. All infants and children identified with a hearing deficit should be referred to an otolaryngologist and audiologist for immediate assessment and recommendation for assistive devices.

Additional assessment includes an ophthalmologic evaluation and referral to a geneticist. Once infants or children are found to have a hearing impairment, careful follow-up is necessary so that any further reduction in hearing is promptly identified. The role of primary care providers thus becomes even more crucial. Coordination of care with speech and language specialists as well as educators that have experience with working with deaf children is essential. Both parents and other family members may initially be devastated by the diagnosis of a hearing impairment, especially if the deficit is severe to profound. They often have multiple questions about children's medical prognosis and educational future. The possibility of further speech and language development may also be a foremost concern in their minds. In addition to providing patients with comprehensive care, all of the parents' questions and concerns must be addressed and anticipated.

Future Audiological Evaluations

In newly diagnosed patients with sensorineural hearing loss, **audiology testing** should be repeated every 3 months in the first year and then every 6 months when children are in preschool. The test should be repeated at least annually after children have begun school. Continued monitoring is essential to detect any progression of the hearing deficit.

Assistive Devices

Although **hearing aids** may not restore normal hearing, all children with conductive as well as sensorineural hearing loss benefit from amplification. Several different types of hearing aids are available for children; these devices should be fitted appropriately and adjusted regularly. In addition, it is also recommended that all patients receive bilateral hearing aids to improve auditory localization and training, particularly in the context of different learning situations.

An **FM system** is an additional assistive listening device that can be used in a classroom. A speaker uses a microphone to transmit to a receiver the child wears to improve reception. **Closed-caption television** (signed or subtitled) is another method of auditory training. In addition, **teletype telephone systems** are available for children who can read.

Cochlear implants may be surgically placed in the cochlea to improve hearing. Implants were first approved by the US Food and Drug Administration in 1990 for use in children. The implant consists of an electrode array that responds to an external microphone and speech processor and produces an electrical discharge within the cochlea. These electrical pulses effectively stimulate the auditory system. The implant can be used in children at 12 months of age or older with profound sensorineural hearing loss. There are ongoing improvements in technology with improving results. Speech, language, and special education resources should also be provided. Most patients with implants show significant improvement in communication skills. Children with cochlear implants are at increased risk for meningitis, therefore pneumococcal vaccine is recommended.

Education and Communication

Much controversy exists regarding the optimal method of communication for deaf children. **Oral communication (lip reading)** and **sign language** each have their advantages as well as disadvantages depending on children's age, the type of deafness, and whether the deficit is congenital or acquired. Whether the children already know a language is also important to consider. The preferred methods seem to vary from region to region; therefore, schools, other institutions, and resource groups often use the most popular communication method in a particular area. In general, some authors recommend that children with minimal hearing loss may do better with lip reading than those with greater hearing loss, who will most likely benefit more from sign language. Early intervention and education programs can be home-based or in a group setting. But it is recommended that the educators be familiar with working with hearing impaired children.

Whether to "mainstream" children with severe hearing loss in a regular classroom with an interpreter or place them in a school for deaf children is another controversial issue. Parents should be encouraged to explore the possibilities of each option and to make a decision based on the individual needs of their children and not current trends. The expertise of an educator who is knowledgeable in this field can also be helpful when making this decision.

Outside Resources and Referrals

As previously mentioned it takes a team to properly evaluate a child with hearing loss. Newly diagnosed children should be evaluated by **otolaryngologists** with pediatric expertise, **audiologists**, pediatric **ophthalmologists**, and medical **geneticists**. Any refractory error should be treated and followed closely because children with severe hearing difficulties are more dependent on vision. A genetics evaluation is important for diagnostic reasons as well as for providing families with information and counseling about the risk of recurrence.

Speech assessment and therapy are an essential part of long-term management as are special education resources. Support groups and referrals to national organizations for hearing impaired individuals can be valuable for parents and families. Resources for financial support should also be explored. Agencies with multidisciplinary teams are particularly important for infants or children with other associated disabilities.

Prognosis

The goals of early recognition and treatment of infants and children with hearing deficits is to minimize the possible long-term sequelae of persistent speech and language problems and to maximize cognitive development. An additional goal is to prevent the development of learning disabilities with subsequent educational failure. The earlier the intervention, the more likely children succeed and maximize their potential. With appropriate treatment the child should be able to lead a normal life.

CASE RESOLUTION

In the opening case, the child has a history classic for a hearing deficit. She does not turn to loud noises, she has not developed any specific words, and she indicates her needs nonverbally. Although there are no obvious historical risk factors for hearing loss, a behavioral audiogram or **BAER** should be performed. The physician's suspicion should be discussed with the family, and a follow-up visit should be arranged to review the hearing test results as soon as possible.

Sore Throat

Stanley H. Inkelis, MD, and Casey Buitenhuys, MD

CASE STUDY

An 8-year-old girl has had a sore throat and fever for 2 days. She also has pain on swallowing, a headache, and a feeling of general malaise but no stridor, drooling, breathing difficulty, or rash. Other than the current illness, the girl is in good health. Although she has had sore throats in the past, she has never had one this severe. One week ago both her mother and father had a sore throat and fever that resolved after 5 days with no medication.

The child has a temperature of 102.2°F (39.0°C). The physical examination is normal except for red tonsils with exudate bilaterally, palatal petechiae, and tender cervical lymphadenopathy.

Questions

1. What are the causes of sore throat in children?
2. What is the appropriate evaluation of children with sore throat? What laboratory tests are necessary?
3. What is the appropriate management for children with sore throat?
4. When should otolaryngologic consultation be obtained?

Sore throat, one of the most common illnesses seen by the primary care physician, is a painful inflammation of the pharynx, tonsils, or surrounding areas. In most cases, children with sore throat have mild symptoms that require little or no treatment. However, sore throat may be the presenting complaint of a severe illness such as epiglottitis or retropharyngeal abscess. Small children are not able to define their complaints very well, which makes a careful history from parents or other caregivers and a good physical examination essential for correct diagnosis. Optimal management of sore throat, especially if group A beta-hemolytic streptococcus (GABHS) is suspected, is still very controversial.

Epidemiology

Sore throat accounts for approximately 7.3 million outpatient physician visits each year and approximately 5% of all pediatric emergency department visits are for pharyngitis. Sore throats are most common in children 5 to 8 years of age, and they continue to occur during later childhood. They are uncommon in children younger than 1 year. Like other respiratory infections, sore throats occur most often in the late fall and winter months. Approximately 11% of all school-aged children receive medical care for pharyngitis. Fifteen percent to 30% or more of cases of pharyngitis in these children are caused by GABHS. The estimated medical and nonmedical costs for GABHS pharyngitis are \$205 per visit or approximately \$224 to \$539 million per year.

The organisms that cause bacterial and viral pharyngitis are present in saliva and nasal secretions and are almost always transmitted by close contact. Spread from child to child in school is the common mode of transmission.

Clinical Presentation

The clinical presentation of sore throat is variable and often depends on etiology (Dx Box and see Differential Diagnosis). Most children with sore throat present with sudden onset of pain and fever. The height of the fever is variable and is typically higher in younger children. In older children, especially if the sore throat is associated

Dx Sore Throat

Viral

- Pain in throat
- Fever (variable)^a
- Rhinorrhea (common)
- Cough (common)
- Erythema of pharynx or tonsils
- Follicular, ulcerative, exudative lesions of pharynx or tonsils^a
- Conjunctivitis

Bacterial

- Pain in throat, usually sudden onset
- Fever
- Marked erythema of pharynx, tonsils, or uvula
- Headache, nausea, vomiting, abdominal pain
- Tonsillar and posterior pharyngeal wall exudate
- Tender, swollen cervical lymphadenopathy
- Scarletiform rash
- Absence of rhinorrhea or cough
- Positive rapid antigen test or throat culture

^a Dependent on etiology (see Differential Diagnosis).

with a common cold, fever is minimal or absent. The throat or tonsils are red, and the breath may be malodorous. Headache, nausea, vomiting, and abdominal pain may occur, especially if children are febrile. The appetite may be decreased and children may be less active than usual.

In children with the common cold, rhinorrhea and postnasal discharge are present. A pharyngeal and tonsillar exudate is not typical. Although the cervical lymph nodes may be enlarged, they are usually not very tender. In contrast, children with streptococcal pharyngitis typically have high fever, pharyngeal and tonsillar exudate, and tender cervical lymph nodes.

Pathophysiology

Various bacteria and viruses produce sore throat symptoms by causing inflammation in the ring of posterior pharyngeal lymphoid tissue that consists of the tonsils, adenoids, and surrounding lymphoid tissue. This ring of tissue, called Waldeyer ring, drains the oral and pharyngeal cavity and defends against infection of the mouth and throat. Other host defenses that protect against infection include the sneeze, gag, and cough reflexes; secretory immunoglobulin A; and a rich blood supply.

Viral sore throats may be acquired by inhalation or self-inoculation from the nasal mucosa or conjunctiva. The local respiratory epithelium becomes infected with the virus, and inflammation occurs. In some instances, inflammatory mediators may be responsible for the pain of sore throat. Group A streptococcus and other bacterial organisms directly invade the mucous membranes. Enzymes produced by this organism, streptolysin O and hyaluronidase, aid in the spread of infection.

Differential Diagnosis

Although most children who present with sore throat have common viral or bacterial pharyngitis, other less common disorders such as infectious mononucleosis, acute HIV seroconversion syndrome, epiglottitis, retropharyngeal abscess, or peritonsillar abscess should be considered.

Viral Infection

Viral infection, the most common cause of sore throat in children, is most often associated with an upper respiratory infection caused by a rhinovirus. Cough and rhinorrhea associated with a sore throat suggest this etiology. Influenza virus infections may present with sudden onset of high fever, headache, cough, sore throat, and myalgias.

Adenovirus often leads to exudative pharyngitis, frequently in children younger than 3 years. Pharyngoconjunctival fever, caused by adenovirus 3, is characterized by a high fever (temperature: $>102.2^{\circ}\text{F}$ [39.0°C]) for several days, conjunctivitis, and exudative tonsillitis.

Coxsackievirus and echovirus (enteroviruses) are the usual cause of herpangina. Vesicles and ulcers are generally apparent on the anterior tonsillar pillars and soft palate. They may also be found on the tonsils, pharynx, or posterior buccal mucosa. Children may have a high fever (temperature: $>102.2^{\circ}\text{F}$ [39.0°C]), be irritable, and

refuse to eat or drink; dehydration may result. Coxsackievirus A16 and enterovirus 71 cause hand-foot-and-mouth disease, which is characterized by ulcerative oral lesions on the tongue and buccal mucosa and, less frequently, on the palate and anterior tonsillar pillars. Vesicular and papulovesicular lesions are evident on the hands and feet and occasionally on other parts of the body, most commonly the knees and buttocks. Enteroviral infections typically occur in the late spring, summer, and early fall.

Herpes simplex virus (HSV) may lead to pharyngotonsillitis but can be distinguished from most of the enteroviral infections because HSV almost always involves the anterior portion of the mouth and lips and is associated with gingivitis (herpes gingivostomatitis). The lesions often appear as whitish-yellow plaques with an erythematous base and are sometimes ulcerative. This illness is characterized by a high fever (temperature: 102.2°F [39.0°C]) for up to 7 to 10 days and frequent refusal to eat or drink because of the painful lesions. Dehydration may occur.

Epstein-Barr virus (EBV) may cause exudative pharyngotonsillitis either alone or as part of the infectious mononucleosis syndrome that includes fever, malaise, lymphadenopathy, palatal petechiae, and hepatosplenomegaly. Fatigue, malaise, eyelid edema, organomegaly, and a maculopapular rash without the other characteristics of a scarlet fever rash help distinguish between infectious mononucleosis and GABHS infection.

Cytomegalovirus may cause an infectious mononucleosis syndrome similar to EBV but is not as commonly associated with pharyngitis and splenomegaly.

HIV seroconversion syndrome may present with low-grade fevers, myalgias, nonexudative pharyngitis, diffuse adenopathy, anorexia, and weight loss. Usually this constellation of symptoms is attributed to an influenza-like illness. Generally, onset of symptoms is about 1 week after exposure but may be within the first month after exposure.

Bacterial Infection

Group A beta-hemolytic streptococcus is the most common cause of bacterial sore throat in children older than 3 years. The pharynx is typically very red and sometimes edematous, and the tonsils are red, enlarged, and covered with exudate. Occasionally, the uvula is very inflamed as well. Children may also have dysphagia, fever, vomiting, headache, malaise, and abdominal pain. Swollen anterior cervical lymphadenopathy and petechiae on the soft palate and uvula are usually apparent. In addition, the occurrence of a scarlatiniform rash, “strawberry tongue,” and Pastia lines (petechiae in the flexor skin creases of joints) indicates scarlet fever, which is diagnostic of group A streptococcal infection (see Chapter 122). Sore throat from GABHS typically occurs in the winter and spring. Rheumatic fever and glomerulonephritis are non-suppurative complications of group A streptococcal infection.

Peritonsillar abscess or cellulitis and cervical lymphadenitis are suppurative complications of GABHS. Children with peritonsillar abscess often experience trismus and drooling and speak with a “hot potato” voice. The abscess in the affected tonsil causes a bulge in the

posterior soft palate and pushes the uvula away from the midline to the unaffected side of the pharynx. On palpation, the abscess may feel fluctuant. Peritonsillar cellulitis typically produces a bulge in the soft palate but does not cause deviation of the uvula.

Parapharyngeal and retropharyngeal abscesses that typically occur in children younger than 6 are additional life-threatening complications of GABHS. Sore throat is associated with these conditions, but dysphagia is usually more evident when the child swallows. Children with a retropharyngeal or parapharyngeal abscess are toxic-appearing, also complain of trismus, have a fever, refuse to swallow, drool, have neck pain and rigidity, have dysphonia, or have shortness of breath. A fluctuant mass may be palpated deep to the tonsils. The patient may have pain when the trachea is manipulated in a lateral direction. The neck may be stiff and the patient may resist passive neck movements. Stridor may be present but usually is an ominous sign of impending airway compromise.

Group B, C, and G beta-hemolytic streptococci (non-GABHS) have all been isolated from children with pharyngitis. *Streptococcus pneumoniae* and *Arcanobacterium haemolyticum* infrequently cause pharyngitis in children. The latter organism is associated with a scarlatiniform rash in some patients and is most common in adolescents and young adults. In contrast to scarlet fever, palatal petechiae and strawberry tongue are not present with the pharyngitis caused by this bacterium. Although *Corynebacterium diphtheriae* (diphtheria) rarely causes sore throat in immunized children, this organism should be considered in non-immunized children who have exudative pharyngotonsillitis and a grayish pseudomembrane that bleeds when removal is attempted.

Chlamydia trachomatis may lead to pharyngitis and tonsillitis in adolescents and young adults through sexual transmission. The role of *Chlamydia pneumoniae* as a cause of sore throat in children remains unclear. *Mycoplasma pneumoniae* does not usually produce sore throat in children unless they have lower respiratory tract disease. *Neisseria gonorrhoeae* may lead to sore throat in sexually active adolescents. Its occurrence in prepubertal children is often secondary to sexual abuse. The appearance of the throat is not characteristic, and diagnosis is made by cultures when the degree of suspicion is high. **Tularemia** is a rare cause of exudative pharyngitis in children but should be suspected if contact with wild animals has occurred.

Fusobacterium necrophorum is a gram-negative anaerobe that may cause an exudative pharyngitis, tender adenopathy, and fever. Untreated, it may progress to Lemierre syndrome or septic thrombosis of the internal jugular vein. Direct extension of the bacterial pharyngitis leads to perivenular inflammation and septic thrombosis of the internal jugular vein. Patients may present with fever, severe lateral neck pain, torticollis, and prominent internal and external jugular veins with erythema and induration. Patients may present with additional signs and symptoms if septic emboli propagate, including acute neurologic signs (central nervous system retrograde propagation) and shortness of breath and multilobar pneumonia with or without cavitation (pulmonary propagation). Paradoxical septic emboli may cause other symptoms if a right-to-left cardiac shunt is present.

Other Causes

Candida albicans may be responsible for sore throat in infants and in children who are immunocompromised or taking antibiotics. Children with oral candidiasis usually present with whitish plaques on the labial or buccal mucosa that do not wipe off easily. When the pharynx and tonsils are involved, some discomfort or dysphagia, but usually not significant pain, may occur.

Epiglottitis (supraglottitis) may present as sore throat. Prior to the *Haemophilus influenzae* type B (Hib) conjugate vaccine, epiglottitis typically affected children 2 to 7 years of age who would present with signs of toxicity, stridor, difficulty swallowing, and drooling. In relatively well-appearing children with sore throat but no stridor, neither epiglottitis nor retropharyngeal abscess is a likely cause of sore throat. In the past, epiglottitis was almost always caused by Hib. With the widespread use of the Hib conjugate vaccine, this organism is now rarely the etiology, thus diminishing the prevalence of epiglottitis and making this entity an uncommon cause of sore throat in children. Although rare in adolescents, epiglottitis may present with severe sore throat out of proportion to clinical findings. Other signs and symptoms include dysphagia, odynophagia, a muffled voice, and pain on palpation of the anterior neck around the hyoid bone. *Streptococcus pneumoniae*; *Staphylococcus aureus*; and group A, B, and C beta-hemolytic streptococci are unusual but reported causative agents of epiglottitis.

Children with croup may have sore throat and stridor, but they do not usually appear toxic and do not have difficulty swallowing. Affected children are usually between 6 months and 3 years of age (see Chapter 58).

Trauma from penetrating objects, burns, or exposure to caustic materials may cause sore throat in children. Household smoking may also lead to pharyngeal irritation. In addition, allergic rhinitis with postnasal drip may result in sore throat. Tumor rarely causes sore throat in children but should be considered if a mass is present or pharyngeal inflammation persists. Persistent sore throat may also be a symptom of Kawasaki disease.

Evaluation

History

A thorough history often reveals the etiology of the sore throat (Questions Box). Questions regarding duration, fever, headache, vomiting, pain on swallowing, rash, oral lesions, abdominal pain, and history of contact with other family members or classmates with similar symptoms suggest the most common causes of sore throat (infections with viruses and GABHS). A history of rapid onset of fever, toxicity, difficulty swallowing, drooling, and respiratory distress suggest epiglottitis and retropharyngeal abscess. Voice changes suggest peritonsillar abscess or tonsillar hypertrophy associated with infectious mononucleosis (EBV). Immunization history or history of immigration from a developing country helps assess the risk of diphtheria. Oral sexual activity suggests the possibility of a sexually transmitted infection. A history of allergies, trauma, and

Questions

Sore Throat

- How long has the child had a sore throat?
- Does the child have fever, headache, or vomiting?
- How rapid was the onset of fever?
- Does the child have pain on swallowing?
- Are there any voice changes?
- Does the child have a rash or oral lesions?
- Does the child have abdominal pain?
- Does the child have any ill contacts?
- Are the child's immunizations up to date?
- Is the child having any difficulty breathing?
- Does the child have a history of allergies?
- Has the child suffered any trauma to the throat or neck?
- Has the child been exposed to environmental smoke?
- For sexually active adolescents or children with a history of sexual abuse with non-responding sore throats: Has there been any oral sexual activity? Any other risk-taking behavior?

environmental smoke may help diagnose other causes of sore throat. Red eye or pinkeye with a rash, persistent fever (>5 days), and sore throat suggest Kawasaki disease. A teenager with at-risk behavior and an influenza-like illness may be presenting with HIV seroconversion syndrome.

Physical Examination

A general physical examination should be performed. It is important to note whether children appear toxic. The skin should be examined for a scarlatiniform, sandpaper-like rash; a vesicular rash involving the hands and feet; or a generalized maculopapular rash. The eyes should be evaluated for conjunctivitis and the nose for rhinorrhea (serous or purulent). The mouth, pharynx, and tonsils should be examined for vesicular lesions, ulcers, and gingivitis. The pharynx should be checked for redness, exudate, vesicles, edema, and foreign bodies. The tonsils and uvula should be examined for these same findings as well as asymmetry, and the neck should be checked for nuchal rigidity. The lymph nodes should be evaluated for enlargement (adenopathy) and inflammation (adenitis). The abdomen should be examined for hepatosplenomegaly.

Laboratory Tests

Although many signs and symptoms may suggest streptococcal pharyngitis, diagnosis can be confirmed only with laboratory tests. The **throat culture** is the gold standard for diagnosis. When done correctly, throat culture has a sensitivity of 90% to 95% in detecting pharyngeal GABHS. Specimens should be obtained from the surfaces of both tonsils and posterior pharynx without touching other parts of the pharynx or the mouth. The main disadvantage of throat culture is that the results are not available for a day or more after the specimen is obtained. Nevertheless, throat culture is the most reliable way to confirm streptococcal infection.

Rapid antigen detection tests (RADTs) are available for on-the-spot diagnosis. False-positive results are uncommon (specificity: $\geq 95\%$), but false-negative results for most RADTs occur commonly (sensitivity: 80%–90%). Because a negative test may not exclude a streptococcal infection, it is currently recommended that this result should be confirmed by throat culture. However, newer RADTs using optical immunoassay (OIA) and chemiluminescent DNA probes boast sensitivities of over 99%. Recent data suggest that a negative OIA RADT may not always need routine confirmation with a throat culture, especially if physicians confirm in their practice setting that the newer RADT has a sensitivity comparable to the sensitivity of throat culture. In one study of more than 30,000 patients comparing those managed with throat cultures alone to those managed with a high-sensitivity RADT without throat culture confirmation, it was determined that throat culture confirmation of a high-sensitivity RADT is not necessary to prevent suppurative or non-suppurative complications of group A streptococcal pharyngitis. In addition, it has been suggested in several studies that the recommendation to obtain a backup throat culture in all patients with a negative RADT is not a cost-effective approach. Rapid and sensitive OIA RADTs reduce antibiotic prescription rates by 50% in pediatric emergency care visits related to sore throat. An antistreptolysin-O titer and an anti-DNase-B titer may help confirm a prior streptococcal infection if the throat culture is negative, particularly in children in whom there is a high suspicion of acute rheumatic fever or acute post-streptococcal glomerulonephritis.

Differentiating between viral and bacterial pharyngitis is often difficult, and the rapid streptococcal antigen tests and throat cultures should be reserved for patients who have signs and symptoms common for both illnesses. There are some children whose clinical findings are not consistent with bacterial pharyngitis. For example, afebrile children with a sore throat, runny nose, and cough who have slight pharyngeal erythema almost certainly have viral pharyngitis and do not need further workup. However, children with a constellation of signs and symptoms suggesting bacterial pharyngitis, such as sudden onset of sore throat, fever, headache, swollen and erythematous tonsils, tonsillar or posterior pharyngeal wall exudate, uvulitis, tender and enlarged cervical lymphadenopathy, absence of runny nose or cough, or exposure to an individual with streptococcal pharyngitis may need further testing with RADT or throat culture to confirm group A streptococcal pharyngitis because an accurate diagnosis cannot be made on clinical grounds alone. Approximately 12% of all children are asymptomatic carriers of GABHS in the pharynx. Guidelines for clinical prediction have been evaluated and have suggested different approaches to the need for RADT or throat culture and antibiotic management. The Centor criteria were derived and validated in adult patients and overestimate the likelihood of GABHS pharyngitis in children. A modified McIsaac score predicts better in children but is still neither sensitive nor specific enough to rely on alone. In a meta-analysis of signs and symptoms predicting GABHS, presence of a tonsillar exudate, pharyngeal exudate, or exposure to strep infection in the previous 2 weeks (positive likelihood

ratios 3.4, 2.1, and 1.9, respectively) and the absence of tender anterior cervical nodes, tonsillar enlargement, or exudate (negative likelihood ratios of 0.6, 0.63, and 0.74), were most predictive. Guidelines that recommend identifying patients who are likely to have group A streptococcal pharyngitis based on clinical or epidemiological findings and providing antibiotics for only those confirmed by RADT or throat culture decrease the unnecessary overuse of antibiotics.

Viral throat cultures and acute and convalescent titers to determine viral pharyngitis are rarely indicated unless systemic infection occurs (eg, herpes encephalitis). Epstein-Barr virus infection can be determined by specific serologic antibody assays, but nonspecific tests for heterophil antibody (eg, monospot test) are most available and are usually the tests of choice for diagnosing infectious mononucleosis. However, it may be negative in children younger than 4 years or early in the course of the infection. Only 75% of infected children between 2 and 4 years of age, and less than 30% of children younger than 2 years, are identified by this test. The monospot test, a rapid slide test for heterophil antibodies, may remain positive for months after the infection and incorrectly may suggest the diagnosis of infectious mononucleosis in children who do not have this disorder. A complete blood cell count with more than 50% to 60% lymphocytes or more than 10% atypical lymphocytes is suggestive of mononucleosis. When these tests are inconclusive, the specific serologic antibody tests for EBV infection are helpful in establishing the diagnosis. Cytomegalovirus-specific antibody tests should be considered in the patient with a mononucleosis syndrome and negative laboratory tests for EBV. Culture or fluorescent antibody evaluation of the pseudo-membrane may be used to diagnose diphtheria. Culture or presence of serum agglutinins confirms tularemia. Thayer-Martin culture plates should be used to diagnose suspected gonorrheal sore throat. HIV antibody tests are of little use in the evaluation of acute seroconversion syndrome as antibody titers take 4 to 6 weeks to become detectable. If acute seroconversion is suspected, quantitative RNA polymerase chain reaction should be undertaken.

Imaging Studies

If epiglottitis or retropharyngeal abscess is suspected but is not clinically apparent, a lateral neck radiograph may be obtained. The radiograph should be performed with a physician in attendance that is capable of performing endotracheal intubation in case the child has respiratory difficulties (see Chapter 58). Computed tomography of the neck is indicated in the stable patient with suspected deep parapharyngeal or retropharyngeal infection. Emergency bedside ultrasound is an effective and sensitive tool for differentiating between peritonsillar cellulitis and a peritonsillar abscess.

Management

The management of children with sore throat is based on the etiology of the condition. The early recognition of potentially serious conditions based on history and physical examination is essential to providing optimal care. **Otolaryngological consultation**

should be obtained in children with peritonsillar abscess, retropharyngeal abscess, parapharyngeal abscess, epiglottitis, significant pharyngeal trauma, or pharyngeal tumor. Recurrent tonsillitis, especially in children who miss school, may be a reason for referral to an otolaryngologist.

Outpatient Treatment

For most children with sore throat, the physician must differentiate between viral and streptococcal pharyngitis. Viral sore throat can be managed symptomatically. Treatment of pain and discomfort with **analgesics such as acetaminophen or ibuprofen to relieve pain and maintaining hydration** are the mainstays of therapy for young children with viral or bacterial sore throat. Gargling with warm water and sucking on hard candy may provide additional symptomatic relief for older children. The use of steroids for reducing pain for pharyngitis is controversial. A recent systematic review demonstrated a relatively small reduction in time to significant pain relief of 4.5 hours and a negligible reduction in pain in 24 hours when a single dose of dexamethasone (0.6 mg/kg, maximum 10 mg) is given. The decision to administer steroids should be made on a case-by-case basis.

The pain from lesions of herpes stomatitis sometimes responds to acetaminophen or ibuprofen. For those children with persistent pain, acetaminophen with codeine or hydrocodone may be helpful. **Anesthetics** such as lidocaine may also decrease the pain. A convenient way of delivering lidocaine is in a mixture (1 part each) of lidocaine, diphenhydramine (Benadryl), and a liquid antacid. This mixture (called “magic mouth wash” by some) may be inserted into each side of the mouth, gargled, or placed on a gloved finger and applied directly on the oral lesions of the tongue and labial and buccal mucosa. It is best used about 15 to 30 minutes before feeding or drinking, especially in children who refuse to drink. Lidocaine should be used cautiously because it can suppress the gag reflex. The dose should never exceed 3 mg/kg/dose. Too much lidocaine may result in seizures. Parents should also be given instruction on how to monitor fluid intake and of the signs of dehydration.

In children without clear-cut evidence of streptococcal pharyngitis, a positive rapid streptococcal antigen test helps direct antibiotic treatment. A negative test in the presence of positive symptoms should be accompanied by a throat culture. However, the OIA rapid test may preclude the need for culture confirmation. Patients can await the results of culture before beginning antibiotic therapy. **Antibiotics** without confirmation from rapid streptococcal tests or cultures are indicated in children who appear toxic, who have scarlet fever or peritonsillar cellulitis/abscess, or who have a history of rheumatic fever. Most evidence suggests that early treatment results in more rapid clinical improvement, although this is controversial. Rheumatic fever can be prevented if treatment is started within 9 days of sore throat symptom development. Glomerulonephritis probably is not affected by antibiotic therapy.

Evidence suggests that children with streptococcal pharyngitis should be treated with antibiotics to relieve symptoms; shorten the course of their illness; and prevent disease dissemination,

suppurative complications, and rheumatic fever. Penicillin is the antibiotic of choice. It may be administered orally as penicillin V (phenoxymethyl penicillin) in a dose of 250 mg 2 to 3 times a day for 10 days for children and 500 mg 2 to 3 times a day for adolescents and adults. Most patients will feel better after 2 to 3 days, but it is important to stress to parents that their children need to complete the full 10-day course. Amoxicillin, which tastes better, given once a day (50mg/kg, maximum 1,000 mg) for 10 days is as effective as penicillin V given 2 to 3 times a day for 10 days, making compliance more likely. (See Table 74-1 for dosages.) “Magic mouthwash” can also be prepared without lidocaine, especially for younger children.

If the risk of noncompliance is high or if the risk of complication is great (eg, children have a history of rheumatic fever), the penicillin should be administered intramuscularly. Intramuscular penicillin has 2 disadvantages: (1) pain associated with the injection and (2) increased incidence of a potentially more severe allergic reaction. The dose of benzathine penicillin for children weighing less than 27 kg (60 lb) is 600,000 U. The dose for larger children and adults is 1.2 million U. Bicillin CR, which contains 900,000 U of benzathine penicillin and 300,000 U of procaine penicillin, is a satisfactory alternative form of delivering penicillin intramuscularly in children and may be preferable because it causes less pain and less severe local reaction. This preparation has not been determined to be effective in heavier patients (adolescents and adults) and therefore the benzathine preparation noted previously is recommended. The injection of benzathine penicillin is less painful if it is given after it

reaches room temperature. (See Table 74-1 for dosage information.) Macrolides such as azithromycin or clarithromycin may be substituted in children who are allergic to penicillin. They are preferred to erythromycin because they are associated with fewer gastrointestinal side effects. Azithromycin has the added advantage of once-a-day dosing and a shortened course of therapy of only 5 days. A first-generation oral cephalosporin is also an acceptable alternative, but should not be used in children with an immediate or Type I hypersensitivity to penicillin. Clindamycin may also be used for penicillin allergic patients; however, the liquid preparation is not palatable and compliance may be poor. Tetracyclines; sulfonamides, including trimethoprim-sulfamethoxazole; and fluoroquinolones are not recommended for the treatment of streptococcal pharyngitis.

If children continue to be symptomatic and have a persistently positive throat culture after completing a course of therapy, they may be re-treated with the same antibiotic, given another oral antibiotic (as noted previously and in Table 74-1), or given an intramuscular dose of penicillin, especially if compliance is in question.

Approximately 12% of children are asymptomatic carriers of group A streptococci. In general, these children do well, and eradication of the bacteria is not necessary. Cultures after treatment are generally not recommended, except for children with recurring or persistent symptoms or those with a previous history of rheumatic fever. In selected cases of children whose throat cultures remain positive, eradication of the pharyngeal carriage should be strongly considered. These indications are as follows: if there is an outbreak of

Table 74-1. Antibiotics Used in the Management of Sore Throat in Children

Drug (for Streptococcal Pharyngitis)	Dosage
Penicillin V	250 mg x 2–3/d for children and 500 mg x 2–3/d for adolescents orally for 10 days
Amoxicillin	50 mg/kg once a day orally for 10 days (maximum 1,000 mg)
Azithromycin	12 mg/kg/d, once a day orally for 5 days (maximum 500 mg)
Clarithromycin	15 mg/kg/d every 12 hours orally for 10 days
Cephalexin	25–50 mg/kg/d every 12 hours orally for 10 days (maximum 500 mg every 12 hours)
Benzathine penicillin	600,000 U (<27 kg or 60 lb); 1.2 million U (>27 kg or 60 lb) as single intramuscular injection
Bicillin CR	900,000 U benzathine penicillin and 300,000 U procaine penicillin for children as single intramuscular injection
Rifampin	10 mg/kg/dose orally every 12 hours for 4 days (given last 4 days of treatment with penicillin V or benzathine penicillin for chronic streptococcal carriers)
Clindamycin	20 mg/kg/d in 3 divided doses (maximum 1.8 g/d) orally for 10 days (for chronic streptococcal carriers or suspected <i>Fusobacterium necrophorum</i>)
Drug (for Gonococcal Pharyngitis)	Dosage
Ceftriaxone	125 mg intramuscularly in a single dose if <45 kg, 250 mg intramuscularly in a single dose if >45 kg
Plus Azithromycin	20 mg/kg (maximum 1 g) orally in a single dose
or Erythromycin	50 mg/kg/d (maximum 2 g/d) orally every 6 hours for 14 days
or (if ≥9 y) Doxycycline	100 mg orally 2 times a day for 7 days

acute rheumatic fever or post-streptococcal glomerulonephritis, if there is an outbreak of group A streptococcal pharyngitis in a closed or semiclosed community, if there is a family history of rheumatic fever, or if repeated episodes of documented symptomatic group A streptococcal pharyngitis recur within a family over several weeks despite appropriate therapy. If cultures remain positive, these children may be treated with benzathine penicillin and oral rifampin for 4 days in an attempt to eradicate the organism. (See Table 74-1 for dosages.) Clindamycin is reportedly more effective in eradication of the organism from symptom-free carriers. (See Table 74-1 for dosages.)

Mycoplasma pneumoniae pharyngitis is usually associated with a generalized infection. Because it is often a self-limited illness, it does not require antibiotic therapy unless symptoms persist. Treatment with any of the macrolide antibiotics may be helpful. However, clarithromycin and azithromycin have fewer side effects and are likely to produce better compliance. Macrolides are also the drugs of choice for children with *Arcanobacterium haemolyticum* pharyngitis.

Diphtheria, seen almost exclusively in less advantaged countries, is a life-threatening infection that requires prompt diagnosis and treatment. Penicillin G or erythromycin must be given to kill *C diphtheriae* and, in addition, equine antitoxin must be administered to neutralize the exotoxin. Tularemia pharyngitis is unusual, but if suspected is treated with gentamicin.

For gonococcal pharyngitis caused by *N gonorrhoeae*, intramuscular ceftriaxone is the drug of choice. (See Table 74-1 for dosages.) Additional antibiotic coverage for associated *C trachomatis* infection should be administered. Oral azithromycin or doxycycline should also be given to children 9 years of age or older. (See Table 74-1 for dosages.) Azithromycin or erythromycin may be used for younger children. Children should be examined and cultured for sexually transmitted infections in other sites and should have a serological test for syphilis at the first visit and have a repeat test 6 to 8 weeks later. They should also be evaluated for concurrent hepatitis B and HIV infection. Sexual abuse should be considered in all cases of gonococcal pharyngitis, particularly in prepubertal children (see Chapters 97 and 128).

Patients with Lemierre syndrome should be admitted and started on intravenous (IV) antibiotics covering polymicrobial organisms, including anaerobic organisms. If simple *Fusobacterium necrophorum* pharyngitis is suspected, antibiotics covering anaerobes are indicated, such as clindamycin.

Children with croup usually respond to steroids. Oral nystatin can be used in children with oral candidiasis. Adolescents with uncomplicated peritonsillar abscess may be managed as outpatients in selected cases with needle aspiration and oral antibiotics.

Inpatient Treatment

Children with sore throat should be admitted to the hospital if they have airway obstruction or need IV hydration or antibiotics. Children with retropharyngeal abscess and epiglottitis require IV

antibiotics and should be managed in consultation with an otolaryngologist. Preadolescent children or adolescents with complicated peritonsillar abscess also require IV antibiotics. Surgical intervention is indicated if the abscess is fluctuant, the child is toxic or has severe trismus or airway compromise, or if there is no resolution within 24 hours. Needle aspiration may be acceptable in selected cases. Intravenous hydration is occasionally needed for patients with severe herpes stomatitis who will not drink because of pain and who become dehydrated.

The role of tonsillectomy or adenotonsillectomy for children with recurrent sore throat is still controversial. However, The American Academy of Otolaryngology–Head and Neck Surgery convened a panel of clinicians from various disciplines to develop evidence-based guidelines to identify children who are most likely to benefit from tonsillectomy. These guidelines, containing content based on previous work done by Paradise about children with recurrent sore throats, have been recently published. Most children with sore throat improve on their own, and recommendations are therefore for watchful waiting if there are less than 7 documented sore throat episodes in the past year, less than 5 per year over the past 2 years, and less than 3 per year over the past 3 years. Parental report does not qualify as documentation. If the number of documented sore throats meets or exceeds these numbers, and there are associated findings (temperature of $>38.3^{\circ}\text{C}$, cervical lymphadenopathy, tonsillar exudate or a positive test for GABHS), the clinician may recommend tonsillectomy. Consultation with an otolaryngologist and a period of watchful waiting should be considered. If the child with recurrent sore throat does not meet these criteria, the child should be assessed for other factors that may favor tonsillectomy over observation. These may include but are not limited to multiple antibiotic allergy/intolerance, PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, and adenitis) or a history of peritonsillar abscess. Although these guidelines are evidence-based and the recommendations are better defined than previously, each case should be individualized. As with all clinical decisions, there is a role for shared decision-making with the child's caregiver and primary care physician regarding the need for tonsillectomy.

Education

Both patients and families should receive general education about sore throats. Medication for pain with drugs such as acetaminophen or ibuprofen is useful, especially if children are having difficulty swallowing. Gargling with warm salt water or sucking on hard candy may soothe the pain of sore throat. Children with bacterial pharyngitis may return to school after 24 hours of antibiotic therapy and the disappearance of fever. The practitioner should recommend that symptomatic family members see a physician. Parents should call or return to the physician if their children have respiratory or swallowing difficulties, drooling, severe pain, or fever (temperature: $>101.0^{\circ}\text{F}$ [38.3°C]) for more than 48 hours after the initiation of appropriate antibiotics.

Prognosis

The prognosis for children with viral sore throat is excellent because of its self-limited nature. The outlook for children with streptococcal sore throat is also excellent. If the infection is not diagnosed and treated appropriately, however, suppurative (eg, peritonsillar abscess) and non-suppurative complications (eg, rheumatic fever, acute glomerulonephritis) may occur. With early diagnosis and prompt treatment, the prognosis for unusual, life-threatening causes of sore throat is also very good. In addition, research in the development of a polyvalent synthetic oligosaccharide vaccine to decrease the suppurative and non-suppurative complications of GABHS is underway.

CASE RESOLUTION

In the case presented, the child has palatal petechiae and tonsillar exudate, which are signs and symptoms consistent with streptococcal pharyngitis. A streptococcal rapid antigen detection test is performed, and is positive. The child is treated with oral penicillin. Neither of her parents have sore throat symptoms.

Nosebleeds

Stanley H. Inkelis, MD, and Katherine E. Remick, MD

CASE STUDY

A 3-year-old boy is brought to the office one winter day. He has had 4 nosebleeds in the past week as well as a cold with a runny nose and cough, which began the day before the first nosebleed. The nosebleeds occurred either at night or during sleep and stopped spontaneously or with gentle pressure. Other than the cold and nosebleeds, the boy is in good health. He is active, with bruises over both tibias but none elsewhere. The many cuts and scrapes he has had in the past resulted in minimal bleeding. His family has no history of a bleeding disorder or easy bruisability.

The child's physical examination is entirely normal except for a small amount of blood in the left anterior nares.

Questions

1. What are the common causes of nosebleeds in children?
2. What systemic diseases are associated with nosebleeds?
3. How should nosebleeds be evaluated in children?
4. How should minor and severe nosebleeds be managed in children?

Nosebleed, or epistaxis, occurs commonly in children, especially in those between the ages of 2 and 10 years. In most cases, nosebleeds are secondary to local trauma and can be cared for by primary care physicians. In rare instances, however, a nosebleed may be difficult to control or may be a manifestation of a serious systemic illness. Referral to an otolaryngologist or a hematologist/oncologist is usually not required except in these situations, and hospitalization is generally unnecessary. Parents and children, who are often frightened by nosebleeds, frequently overestimate the amount of blood lost. Understanding and reassurance are important in allaying anxiety.

Epidemiology

Thirty percent of children have one nosebleed by the time they are 5 years of age. In children between the ages of 6 and 10, the frequency increases to 56%. Nosebleeds are rare in infancy and infrequent after puberty. They occur much more frequently in the late fall and winter months, when upper respiratory infections (URIs) are common, environmental humidity is relatively low, and the use of heating systems results in dryness. Nosebleeds are also more common in children who live in dry climates, especially if they have a URI or allergic rhinitis.

Clinical Presentation

Most children with nosebleeds have a history of bleeding at home and have minimal or no bleeding at the time of presentation (Dx Box). With anterior nosebleeds, blood exits almost entirely from the anterior portion of the nose. With posterior nosebleeds, most of the bleeding occurs into the nasopharynx and mouth, although

some blood exits through the nose as well. Posterior nosebleeds are heavier and more difficult to control, and children may present in a hemodynamically unstable condition.

Dx Nosebleeds

- Blood in anterior nares, nasopharynx, or mouth
- History of any of the following:
 - Frequent digital manipulation (nose picking)
 - Upper respiratory infection (recent)
 - Allergic rhinitis
 - Dry climate
 - Foreign body in nose
 - Trauma to nose
 - Prolonged or difficult-to-stop bleeding or easy bruisability
- Physical examination consistent with any of the following:
 - Rhinorrhea
 - Dry, cracked nasal mucosa
 - Foreign body in nose
 - Trauma to nose
 - Multiple bruises

Children with bleeding disorders may have recurrent nosebleeds and a history of prolonged bleeding, easy bruisability, or multiple bruises in unlikely locations. In unusual situations, children with gastrointestinal or respiratory tract bleeding may present with blood exiting through the nose. Alternatively, some children with nosebleeds may present with hematemesis, hemoptysis, melena, or anemia. In these cases a nasal source should be considered.

Pathophysiology

Nosebleeds may be either anterior or posterior in origin. Most nosebleeds in children (>90%) are anterior and are more easily controlled than posterior nosebleeds. The anterior portion of the nasal septum, about 0.5 cm from the tip of the nose, known as Kiesselbach plexus located in Little's area, is the most common part of the nose involved in anterior nosebleeds. This area is supplied by the anterior and posterior ethmoidal arteries, the sphenopalatine artery, and the septal branches of the superior labial artery (Figure 75-1). The mucosa covering the area is thin and friable, and the small vessels supplying the nasal mucous membrane have little structural support. Congestion of the vessels caused by conditions such as a URI or drying of the mucosa from low environmental humidity makes this area susceptible to bleeding.

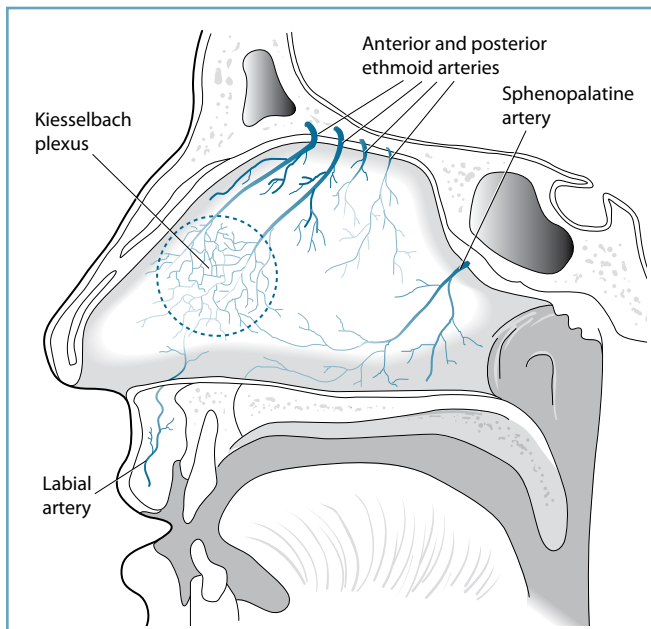

Figure 75-1. Vascular supply of nasal septum. Note the confluence of vessels that forms the Kiesselbach plexus.

Posterior nosebleeds are unusual in children. If bleeding is vigorous, poorly controlled with anterior nasal packing, or involving both nares, a posterior source is likely to be identified. Posterior nosebleeds generally arise from the turbinate or nasal wall. Significant bleeding, usually from a branch of the sphenopalatine artery, may occur. Because of the posterior location, children often present with symptoms other than frank epistaxis (eg, hematemesis, hemoptysis, melena, or anemia).

Differential Diagnosis

Trauma from nose picking and **inflammation** of the nasal mucosa from a URI are by far the most common causes of nosebleeds in children. Repetitive, habitual nose picking results in the formation of friable granulation tissue that bleeds when congested blood vessels are traumatized (epistaxis digitorum). As the nasal mucosa dries, it may lead to crust formation and cracking. Bleeding may occur

spontaneously, but more often it results from forceful nose blowing and sneezing that increases venous pressure in the more vascularized nasal septum. Nosebleeds occur more commonly in children who have nasal colonization with *Staphylococcus aureus*. It is postulated that *S aureus* replaces existing flora and leads to inflammation and new vessel formation.

Other viral respiratory infections, such as infectious mononucleosis and influenza, may also predispose children to nosebleeds because of their local inflammatory effect. Nosebleeds in children with these infections are more common in areas of low environmental humidity. Many children with no URI-like symptoms also suffer from nosebleeds in such environments, usually in winter, when inhaling dry, hot air from heating systems causes desiccation of the nasal mucosa (rhinitis sicca). **Allergic rhinitis** with inflammation and subsequent drying may also lead to nosebleeds. Children with allergic rhinitis who take decongestants or use topical nasal decongestants or topical nasal steroid sprays may be more likely to suffer from nosebleeds. In addition, the dispenser tip of these sprays may traumatize the already dry and friable mucosa causing the nose to bleed.

Foreign bodies may cause direct trauma or pressure necrosis to the vessels of the nasal mucosa. **External trauma** can cause either tears to the nasal mucosa or nasal fractures. If bleeding from mucosal vessels occurs but the mucosa remains intact, a septal hematoma may develop. Abscess formation or septal perforation may occur if the septal hematoma is not drained. **Non-accidental** trauma should be considered in the young child (younger than 2) with a nosebleed.

Although nosebleeds are usually benign conditions, they may be the first sign of serious illness. Persistent or recurrent nosebleeds with no obvious cause should raise the suspicion of **bleeding disorders**. Thrombocytopenia is the most common coagulation defect causing nosebleeds. Idiopathic thrombocytopenic purpura is the most frequent thrombocytopenic disorder associated with nosebleeds. Leukemia, aplastic anemia, and HIV infection must be strongly considered and ruled out in children with nosebleeds and thrombocytopenia. Platelet aggregation disorders may also be a cause of recurrent nosebleeds.

The most commonly inherited bleeding disorder associated with nosebleeds is von Willebrand disease, an autosomal-dominant bleeding disorder characterized by varying degrees of factor VIII deficiency and platelet dysfunction (decreased platelet adhesiveness). Hemophilia (factor VIII, IX, or XI) deficiency, factor VII deficiency, Glanzmann thrombasthenia, and Bernard-Soulier syndrome are other inherited bleeding disorders that may lead to nosebleeds. Hepatic disease, severe vitamin K deficiency, or malabsorption syndrome is associated with an acquired coagulopathy, which may present with nosebleed. Valproic acid administration has been associated with acquired von Willebrand disease and nosebleeds.

Nosebleeds may be a manifestation of **blood vessel disorders**, either hereditary or acquired. Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia) is an inherited autosomal-dominant disease with multiple mucosal telangiectasias, especially in

the nose. Because telangiectasias are deficient in muscular and connective tissue, these telangiectasias may rupture spontaneously and bleed profusely. An association between migraine headaches and recurrent nosebleeds has also been reported.

Neoplasms, particularly malignancies, are uncommon causes of nosebleeds in children. Nasal polyps are usually present in association with cystic fibrosis or allergies. Capillary, cavernous, and mixed hemangiomas may occur in the nose. Juvenile nasopharyngeal angiofibroma occurs almost exclusively in adolescent males who present with nasal obstruction and bleeding. Rhabdomyosarcomas, lymphomas, and squamous cell carcinomas of the nose, sinuses, or nasopharynx are rare causes of nosebleeds.

Drugs such as aspirin and nonsteroidal anti-inflammatory drugs, which interfere with platelet function, and warfarin and heparin, which inhibit clotting factors, increase the risk of nasal hemorrhage with minor trauma, infection, or inflammation. Accidental ingestion of these medications should be suspected if they are available. Cocaine or heroin snorting may cause nasal septal perforation and nosebleeds.

Hypertension is rarely associated with nosebleeds in children. Wegener granulomatosis and lethal midline granuloma are rare idiopathic inflammatory diseases in children that lead to nasal tissue destruction and bleeding. Nosebleeds during menstruation, known as vicarious menstruation, may be secondary to hormonal changes causing vascular congestion of the nasal mucosa.

Evaluation

History

A thorough history often reveals the etiology of the nosebleed (Questions Box). Information concerning the side of the nose from which the bleeding occurred, the amount of bleeding, the measures used to stop the bleeding, and the time required to stop the bleeding may be helpful to quickly assess the severity of the nosebleed.

Physical Examination

A general physical examination should be performed. In children with significant blood loss, particular attention should be directed toward the mental status and vital signs to determine hemodynamic stability. If vital signs are normal, these children should also be evaluated for orthostatic changes. If the blood pressure is elevated, it should be reassessed at a time when the anxiety related to the nosebleed has dissipated.

In addition, the skin and mucous membranes should be checked carefully for petechiae, purpura, and ecchymoses, which are signs of easy bruisability. The abdomen should be examined for hepatosplenomegaly, and the child should be evaluated for lymphadenopathy. Telangiectasias in the oropharynx or mucous membranes suggest Osler-Weber-Rendu syndrome. The oropharynx and nasopharynx should be examined for masses and blood dripping downward from a posterior bleed. The nose should then be inspected for the site of bleeding, with special attention directed toward Kiesselbach plexus

Questions

Nosebleeds

- Does the child pick his or her nose?
- Has the child suffered any trauma recently?
- Is there suspicion of non-accidental trauma?
- Has the child recently had an upper respiratory infection?
- Has the child recently had any systemic viral or bacterial illness?
- Does the child have any allergies?
- Is the child exposed to dry conditions (eg, dry climate, dry heat, dehumidified air)?
- Has the child put or tried to put foreign objects in his or her nose?
- Is there a history of easy bruisability or prolonged, difficult-to-stop bleeding in the child or family?
- Does the child or anyone in the family use any aspirin, aspirin-containing medications, nonsteroidal anti-inflammatory drugs, or warfarin?
- Which side of the nose was bleeding?
- How extensive was the bleeding?
- Did the child spit out or swallow blood? Was there blood in the mouth?
- What measures were used to stop the bleeding? How long did it take to stop the bleeding?
- Was this the first nosebleed? If the nosebleeds are recurrent, how often do they occur and how long do they last?

in the anterior septum. In children younger than 2 with nosebleeds, suspicion of non-accidental trauma should be considered, especially if nosebleeds are recurrent, the event is not witnessed, or the story given by the caretaker changes.

Diagnostic Studies

Laboratory tests are rarely indicated in most children with nosebleeds. A hematocrit/hemoglobin should be obtained if the nosebleeds are severe or recur frequently. Blood for type and crossmatch should be sent in children who have signs or symptoms of hypovolemia (increased pulse; cool, clammy skin; increased capillary refill; decreased blood pressure; etc) or a marked drop in hematocrit. If the history or physical examination suggests that a coagulopathy may be present, a complete blood cell count with platelet count, prothrombin time, and partial thromboplastin time should be obtained and screening for vonWillebrand disease considered if the other laboratory tests are negative.

Radiographs and other imaging studies are rarely necessary in children with nosebleeds.

Management

Children who present to primary care physicians with a history of a nosebleed or nosebleeds that have resolved spontaneously or with application of pressure to the nose need no further treatment in the office or emergency department setting, provided that the history and physical examination are consistent with a benign cause of the

nosebleed. These children or their parents should be instructed to apply **petroleum jelly** or an antibiotic ointment inside the septal portion of the involved naris twice a day for 3 to 5 days with a cotton-tipped swab or with the little finger. Often the child's little finger is used because it is nonthreatening and it "knows where to go." Further nose picking should be discouraged, and fingernails should be trimmed to minimize trauma. In addition, a bedside **humidifier** helps to moisturize the air, especially in dry climates or during the winter when forced hot-air heat is used. Children whose nares moisten from rhinorrhea and then dry and crack also benefit from humidified air. Buffered saline nasal spray may also be helpful in humidifying the nose. Those children who are prone to recurrent nosebleeds in whom serious causes have been ruled out may benefit from regular use of some of the mentioned measures when they have URIs or allergic manifestations, or are in a dry season or environment. In addition, for children with *S aureus* nasal colonization, eradication should be considered.

Children or parents should be given advice about how to care for nosebleeds at home. These instructions can also be given to parents who seek advice over the telephone about how to stop children's nosebleeds. Practitioners should reassure parents and children that most nosebleeds are easily controlled. Children should sit upright and lean forward slightly while **direct pressure** is applied to the nose. External compression of the nares between 2 fingers for 5 to 10 minutes should be sufficient. Pressure applied to the anterior and mid-portion of the nose rather than at the base is more effective in stopping the bleeding because most nosebleeds occur in these parts of the nose.

Children who are actively bleeding through the nose when seen by primary care physicians should be positioned sitting upright and leaning forward slightly, and they should be given a basin and facial tissue. Direct pressure should be applied by a nurse or physician to the anterior and mid-portion of the nose while following universal precautions. A cotton dental roll may be placed under the upper lip to compress the labial artery in older children in whom concern about displacement and possible aspiration of the cotton is minimal. If the bleeding continues after external compression, children should be instructed to blow their noses to remove as much clot as possible. Fresh blood should be removed with suction. Cotton pledgets moistened with a few drops of a topical **vasoconstrictor**, such as 0.05% oxymetazoline (Afrin), 0.25% phenylephrine (Neo-Syneprine) or epinephrine (1:1,000) mixed with 4% lidocaine for local anesthesia, or topical thrombin, should be inserted into the side of the nose involved. Pressure should then be applied for an additional 10 minutes.

If the bleeding persists, **cauterization** of the bleeding site with a silver nitrate stick is indicated. If not already applied, topical anesthesia with 2% to 4% lidocaine should be applied before cauterization. Continued bleeding is slowed by first cauterizing a small ring around the bleeding point to interrupt flow from surrounding vessels and then rolling the tip of the applicator onto the bleeding site for 5 to 10 seconds. Cauterization is often difficult in children, and consultation

with an otolaryngologist is advisable. Cauterization should not be performed in children with a bleeding diathesis. In addition, cauterizing both sides of the nasal septum can result in septal ischemia and possible necrosis and ultimately septal perforation.

If the bleeding continues, or as a modality to attempt prior to cauterization, an absorbable **nasal sponge** made from oxidized cellulose (Oxigel, Surgicel) or gelatin (Gelfoam) may be directly applied to the bleeding site to form an artificial clot. Alternatively, a **nasal tampon** (Merocel), made from a dehydrated material that expands when it becomes moist, may be inserted to tamponade the area of bleeding. Applying antibiotic ointment, preferably mupirocin, to the tampon allows for easier insertion and removal as well as potentially preventing *Staphylococcus aureus* infection that may lead to toxic shock syndrome. Avitene, a microfibrillar collagen material, provides for platelet aggregation and clot formation when applied to the bleeding site. Continued uncontrolled bleeding requires anterior **nasal packing** with antibiotic-impregnated, preferably mupirocin, 1-inch petrolatum gauze strips, which should remain in place for approximately 2 to 3 days. Prophylactic **antibiotics** should be started because sinusitis is a complication of anterior nasal packing. Antibiotics providing coverage for staphylococcal organisms, in particular methicillin-resistant *S aureus*, and sinusitis should be strongly considered.

Posterior nosebleeds, which are more difficult to control, should be suspected if (1) the measures described previously are ineffective, (2) bleeding is vigorous and the cause cannot be identified, or (3) most of the bleeding is into the nasopharynx and mouth. A posterior nasal pack can be created using rolled gauze or a nasal tampon. Alternatively, a Foley catheter or an Epistat inflatable nasal balloon catheter may be used to control posterior nosebleeds. Posterior packs should never be used without the presence of a concurrent anterior nasal pack. Thus, double-balloon catheters are now available (eg, Gottschalk Nasostat, Xomed Epistat) such that 2 separate packing mechanisms can be avoided. Posterior packing can result in significant discomfort for the patient and appropriate analgesia should be provided. However, significant pain with balloon inflation should not occur and overinflation may result in ischemia if the balloon is not slightly deflated. Posterior packing should be left in place for 2 to 3 days and antibiotics initiated to prevent sinusitis. In addition, posterior packing can result in hypoventilation and hypoxia. Therefore, all patients with posterior packing should be admitted and placed on a cardiorespiratory monitor. This also allows for monitoring of potential complications, namely aspiration due to accidental dislodgement; septal ischemia secondary to packing; and development of hypotension, bradycardia, or apnea secondary to a pronounced nasal-vagal response.

The need for **otolaryngological consultation** depends on the experience of the individual physician and the availability of consultation. Prompt consultation, if available, should be obtained for children with severe nosebleeds who need volume replacement; with nosebleeds that do not stop or recur after the mentioned measures have been taken; children who may need anterior or posterior nasal

packing; and with recurrent, difficult-to-stop nosebleeds. Surgical consultation should be sought in patients with suspected nasal fractures prior to the placement of nasal packing. In some cases, obtaining consultation before cauterization with silver nitrate is advisable, particularly in those patients with known bleeding disorders. Children with septal hematomas, tumors, polyps, telangiectasias, and intractable bleeding should be referred to an otolaryngologist for further care and possible surgical intervention. Children with a documented or suspected bleeding disorder should be referred to a hematologist. Selective angiographic embolization by an interventional radiologist may be indicated for patients with persistent, intractable nosebleeds. Endonasal laser surgery may be indicated in patients with recurrent nosebleeds from abnormal vascular malformations such as Osler-Weber-Rendu syndrome.

Children with severe nosebleeds should have an intravenous line started early; blood sent for type and crossmatch; and fluids replaced, depending on the amount of blood loss and physical evidence of hypovolemia. In children who are frightened or in whom certain procedures (eg, cauterization of bleeding site, drainage of septal hematoma) are performed, procedural sedation should be strongly considered. Intravenous pain medication should be used in children who need anterior or posterior packing. If procedures that cause undue pain or discomfort are necessary, general anesthesia in an operating room setting may be indicated.

Hospitalization is rarely necessary for children with nosebleeds. However, children who are hemodynamically unstable on presentation usually require inpatient treatment. As mentioned previously, children who need placement of a posterior nasal pack should be admitted to the hospital for close airway observation. Hospitalization may be necessary for children with difficult-to-stop bleeds who need an anterior nasal pack or who have a bleeding disorder or underlying chronic illness such as leukemia, aplastic anemia, or HIV infection.

Prognosis

The prognosis for nosebleeds in children is excellent. Almost all nosebleeds are easily controlled with a minimal amount of home care or medical management. Surgery is rarely indicated. Complications associated with significant nosebleeds include hypovolemia from blood loss, and sinusitis and toxic shock syndrome from anterior or posterior nasal packs. Even for rare causes of nosebleeds, the prognosis is very good with prompt diagnosis and treatment.

CASE RESOLUTION

In the case presented, the boy has experienced several nosebleeds of short duration associated with an upper respiratory infection and winter dryness. His history and physical examination are unremarkable for a bleeding disorder or chronic illness. The small amount of blood in his nose is consistent with an anterior nosebleed originating from Kiesselbach plexus with inflammation and drying of the nasal mucosa. Laboratory tests are not indicated. The parents should be instructed to apply petroleum jelly to the septal portion of the left side of the child's nose twice a day for 3 to 5 days and to humidify the child's bedroom. They should also be reassured that their child has a common condition that he will outgrow.

Strabismus

Teresa Rosales, MD

CASE STUDY

The mother of an 8-month-old infant complains that every time her son looks to either side his eyes seem crossed. Otherwise, he is growing and developing normally. A symmetrical pupillary light reflex, bilateral red reflex, and normal extraocular eye movements in all directions are noted on physical examination of the eyes.

Questions

1. What is strabismus?
2. What conditions make infants' eyes appear crossed? What is the differential diagnosis?
3. What tests are used in the office evaluation of children suspected of having strabismus?
4. Which infants with crossed eyes require referral for further evaluation and treatment?
