Strabismus refers to any abnormality in ocular alignment, whether the eyes go in or out or one eye is higher than the other. It is one of the most common eye problems observed in infants and children. The pediatrician plays an important role in the early detection and prompt referral of children with suspected ocular alignment abnormalities.

Epidemiology

Strabismus affects approximately 3% of the population, and the condition is seen most commonly in children younger than 6 years. About 50% of all affected children have a positive family history of strabismus, although the exact genetic mode of inheritance is unclear. Up to 75% of normal infants have transient intermittent strabismus during the first 3 months of life.

Clinical Presentation

Children with ocular misalignment have an asymmetrical corneal light reflex test. Eye movement is noted with cover testing. Children with paralytic strabismus may present with torticollis or head tilting in an effort to avoid diplopia (Dx Box).

Dx

Strabismus

- Head tilt
- Double vision (diplopia)
- Squint
- Asymmetrical corneal light reflex
- Eye movement with cover testing

Pathophysiology

Normal binocular vision is the result of the fusion of images from both eyes working synchronously across the visual field. Six extraocular muscles control all eye movements. Orthophoria is proper alignment of the eyes, and strabismus results from an imbalance in muscle movements.

Strabismus

The classification of strabismus is complex. Based on etiology, it may be considered non-paralytic (comitant) or paralytic (non-comitant). Strabismus may also be classified as congenital or acquired, intermittent or constant, and alternating or unilateral. In **non-paralytic strabismus**, the extraocular muscles and the nerves that control them are normal. The degree of deviation is constant or nearly constant in all directions of gaze. Non-paralytic strabismus is the most common type of strabismus seen in children, and congenital or infantile esotropia is usually of this kind. Ocular or visual defects such as cataracts or high refractive errors occasionally cause non-paralytic strabismus.

In **paralytic strabismus**, paralysis or paresis of one or more of the extraocular muscles produces a muscle imbalance. The deviation is asymmetrical, and characteristically the degree of deviation is worse when gazing in the direction of the affected muscle. Paralytic strabismus may be congenital or acquired. **Congenital paralytic strabismus** may result from birth trauma, muscle anomalies, abnormal development of the cranial nerve nuclei, or congenital infections affecting the eyes. Congenital strabismus may be seen in association with neurodevelopmental disorders such as cerebral palsy. **Acquired paralytic strabismus** due to extraocular muscle palsies usually indicates the presence of a serious underlying condition, such as an intracranial tumor, a demyelinating or neurodegenerative

disease, myasthenia gravis, a progressive myopathy, or a central nervous system (CNS) infection. Children may present with a complaint of double vision or a compensatory torticollis (head tilt) to avoid double vision (diplopia).

Intermittent (latent) misalignment of the eyes is referred to as a **phoria**. Under normal conditions, the fusional mechanisms of the CNS maintain eye alignment. Eye deviation is appreciated only under certain conditions, such as illness, fatigue, stress, or when fusion is interrupted by occluding one eye (eg, during cover testing). Some degree of phoria may be found in almost all individuals and it is usually asymptomatic. Larger degrees of phoria may give rise to troublesome symptoms such as headaches, transient diplopia, or asthenopia (eye strain).

Constant misalignment of the eyes is referred to as **heterotropia**. This condition occurs because normal fusional mechanisms are unable to control eye deviation; children are unable to use both eyes together to fixate on an object. In alternating heterotropias, both eyes appear to deviate equally, and vision generally develops normally in each eye because children have no preference for fixation. If strabismus affects only one eye, the other eye is always used for fixation, and there is a danger of developing amblyopia or loss of vision in the deviating eye.

Convergent deviation, a turning in or crossing of the eyes, is called an esodeviation (eg, esotropia or esophoria). Divergent deviation, a turning out of the eyes, is an exodeviation. Hypertropia is used for upward vertical deviations. Esodeviations are the most common type of ocular misalignment, accounting for 50% to 75% of all cases of strabismus. Vertical deviations represent less than 5% of all cases of strabismus.

Amblyopia

Amblyopia is a potential complication if strabismus is not corrected in a timely manner. It refers to poor vision in one eye or, rarely, both despite correction of any refractive errors. If children have no significant refractive error and the visual acuity of one eye is worse than the other, they have amblyopia. To be considered amblyopia, visual acuity, as measured by reading an eye chart, should differ by at least 2 lines (eg, 20/20 in one eye and 20/40 in the other). It is the leading cause of preventable visual loss in children.

Amblyopia may be classified into 3 major categories. **Deprivational amblyopia** generally results when a unilateral lesion or developmental defect in one of the structures of the eye or its visual pathways obstructs vision. Causes of deprivational amblyopia include congenital cataract, ptosis, corneal opacity, retinal detachment, retinoblastoma, colobomas, optic nerve defects (eg, optic nerve hypoplasia), or orbital tumors. These conditions cause a lack of formation of a retinal image or a blurred retinal image, usually in one eye. **Refractive amblyopia** refers to a blurring of the retinal image due to large or asymmetrical refractive errors. Amblyopia is usually considered a unilateral abnormality, but may be bilateral in cases of large refractive errors (usually astigmatism or hyperopia). In **strabismic amblyopia**, the immature or developing brain suppresses images from the deviating eye to prevent diplopia. Strabismic

amblyopia is most commonly associated with strabismus that develops in children who are younger than 4 years. If the condition leading to the amblyopia is not corrected while the brain's visual pathways are still malleable (eg, before approximately 6–7 years of age), children may have some degree of permanent visual loss.

Differential Diagnosis

The differential diagnosis of strabismus may be divided into 3 categories: transient neonatal strabismus, congenital or infantile strabismus, and acquired strabismus. True strabismus must be differentiated from the illusion of deviation created by facial asymmetry or anatomical variations (ie, pseudostrabismus).

Transient Neonatal Strabismus

Eye alignment in normal infants during the first 2 to 3 months of life may vary from normal to intermittent esotropia or exotropia. These deviations are believed to result from CNS immaturity and resolve spontaneously in most children by 4 months of age. If such deviations are constant or persist beyond this age, children should be referred to an ophthalmologist for further evaluation.

Congenital or Infantile Strabismus

This type of strabismus is defined as a deviation that occurs during the first 6 months of life. Because the deviation may not always be present at birth, the term *infantile* may be more accurate. The differential diagnosis of infantile strabismus is presented in Box 76-1. **Pseudoesotropia** is an illusion or apparent deviation and not a true deviation. In many infants, the broad, flat nasal bridge and prominent epicanthal folds may obscure a portion of the sclera near the nose and create the appearance of esotropia (Figure 76-1). This illusion resolves as children mature. Symmetrical corneal light reflexes or normal cover tests differentiate pseudoesotropia from true esotropia.

Esotropia is one of the more common types of childhood strabismus. The constant deviation of infantile esotropia is usually readily apparent because of the large angle of deviation. Affected children usually have good bilateral vision because of the alternation of fixation from one eye to the other. Cross-fixation, in which children look to the left with the adducted right eye and to the right with the adducted left eye, may be evident because of the large angle of deviation. Rarely, esotropia may be due to palsy of the sixth cranial nerve either in isolation or in association with other cranial nerve palsies (Möbius syndrome).

Infantile exotropia is less common than esotropia. Like esotropia, exotropia develops within the first 6 months of life and is characterized by a large angle of deviation. Other causes of infantile exotropia include congenital third nerve palsy (paralytic strabismus) and abnormalities of the bones of the orbit (eg, Crouzon disease).

Acquired Strabismus

Acquired strabismus may result from a variety of causes (Box 76-1). Accommodative esotropia and intermittent exotropia are the 2 most common types of acquired strabismus. **Accommodative**

Box 76-1. Differential Diagnosis of Strabismus**Congenital or Infantile Strabismus****Esodeviations**

Infantile esotropia
 Pseudoesotropia
 Möbius syndrome
 Congenital sixth nerve palsy
 Duane syndrome

Exodeviations

Congenital exotropia
 Congenital third nerve palsy
 Abnormalities of the bony orbit (Crouzon disease)
 Both esodeviations and exodeviations
 Duane syndrome (esotropia more common than exotropia)

Acquired Strabismus**Esodeviations**

Accommodative esotropia
 Benign sixth cranial nerve palsy

Exodeviations

Intermittent exotropia
 Overcorrection after surgery for esotropia

Both Esodeviations and Exodeviations

Poor vision
 Orbital trauma causing entrapment of extraocular muscles
 Intracranial tumors or tumors involving the orbit (eg, retinoblastoma)
 Myasthenia gravis
 Central nervous system (CNS) infection (eg, meningitis)
 CNS tumor
 Orbital cellulitis

Figure 76-1. Child with pseudoesotropia. Note the wide nasal bridge and prominent epicanthal folds.

esotropia typically develops in children between 2 to 4 years of age but may appear as early as 6 months or as late as 8 years. Children with hyperopia use accommodation (attempts to focus) to see clearly. The accommodative reflex is closely linked to convergence; when accommodation occurs, so does convergence. If children have severe hyperopia (farsightedness), the amount of convergence that occurs with accommodation may be severe and lead to the development of esotropia. Such esotropia is usually intermittent initially and only gradually becomes constant. The deviating eye frequently becomes amblyopic.

Intermittent exotropia, the most common form of exodeviation seen in children, develops between birth and 4 years of age. Although it begins as an intermittent condition in which children's eyes appear to deviate outward, especially when they are tired, ill, or fixating at a distance, the exotropia can become constant with time. Children may also close one eye in bright sunlight, presumably in an effort to prevent diplopia.

Evaluation**History**

The evaluation of infants or children suspected of having strabismus should begin with a thorough family history because strabismus often runs in families (Questions Box). Parental description of the ocular deviation is useful because misalignments, especially intermittent deviations that may only become manifest when children are tired, may not always be evident during the office visit. A history of head or orbital trauma may help in the evaluation of acquired strabismus.

Questions**Strabismus**

- Does the child have a family history of strabismus?
- Does the child constantly tilt the head toward one side?
- Does the child squint?
- Has the child complained of blurred or double vision?
- Does the child close one eye in bright sunlight?
- Has the child had any recent trauma to the eyes or head?

Physical Examination

On physical examination, the presence of any dysmorphic features and structural abnormalities of the face or neck (eg, torticollis) should be noted. Children with paralytic strabismus (eg, fourth nerve palsy or superior oblique palsy) may compensate for their paralytic lesion by tilting their head to avoid diplopia. It is important that visual screening of children begin during the neonatal period. Newborn screening should emphasize the presence of a bilateral red reflex. An abnormal red reflex or a white reflex may indicate

the presence of a cataract or retinoblastoma. These require immediate referral to an ophthalmologist. Evaluation for ocular alignment should begin at the 4-month health maintenance visit. Intermittent misalignment of the eyes is often seen in normal infants who are younger than 4 months. However, constant misalignment requires immediate attention at any age.

Vision Testing

Testing visual acuity is essential in the evaluation of children with suspected strabismus. Such testing may be performed as early as 3 years of age if children are cooperative. Charts with symbols, figures, or letters can be used. The traditional Snellen eye chart with letters can generally be used in children who are 4 years of age. Decreased vision in one eye may be indicative of ocular abnormalities, including ocular deviations.

The 2 basic tests for strabismus that can be easily performed in the office are the corneal light reflex test, or Hirschberg test, and the cover test. The pediatrician should be comfortable performing both tests.

The **corneal light reflex test** is the simplest and quickest test for the evaluation of strabismus. In this test, a penlight is projected simultaneously onto the corneas of both eyes as the child looks straight ahead. The examiner compares the placement of the corneal light reflex in each eye with respect to the center of the pupil. If the eyes are straight, the reflection appears symmetrically in the center of both pupils or on the same point on each cornea. If the light reflex appears off center in one eye compared with the other, an ocular deviation or heterotropia is present. Nasal deviation of the light reflex on the cornea indicates exotropia on that side, temporal deviation signifies esotropia, and inferior deviation indicates hypertropia.

Unlike the corneal light reflex test, which may be performed even in uncooperative children, the **cover tests** require a child's cooperation and ability to fixate on a specified object. These tests are used

to detect heterophorias. Two types of cover tests, alternate cover and cover-uncover, are used. Only the alternate cover test detects both heterophorias and heterotropias. This test may be preferred by the primary care physician as a screening tool. The cover-uncover test detects only manifest deviations or heterotropias. In the alternate cover test, one eye and then the other is covered as the child fixates on an object at a distance. If neither eye moves as the cover is moved rapidly between the eyes, the eyes are in alignment or orthophoric. With heterotropia, the deviating eye moves when the fixating eye is occluded; in heterophoria, the deviating eye moves when it is uncovered (Figure 76-2).

The alternate cover test may be illustrated with the following example. A child presents with constant esotropia of the left eye. When the right or fixating eye is occluded, the left eye is forced to fixate so that the child can see, and the left eye moves outward as the right eye is occluded. In the case of a child with an esophoria or latent deviation of the left eye, the eye deviates inward when it is occluded because it is not being forced to fixate. As the occluder is moved from the left eye to the right, the left eye moves outward and returns to a position of fixation.

The alternate cover test may be more difficult to interpret in children with bilateral or alternating strabismus who use both eyes in turn for fixation. It is not necessary for the pediatrician to identify exactly what type of strabismus is present; abnormal movement should be noted and children should be referred for further evaluation. An ophthalmologist is able to perform a more detailed examination.

Management

The goals of management are the attainment of the best possible vision in each eye, straight eyes cosmetically, and fusion. The sooner deviations are corrected, the better the child's chances for equal bilateral vision. Treatment includes correction of any underlying

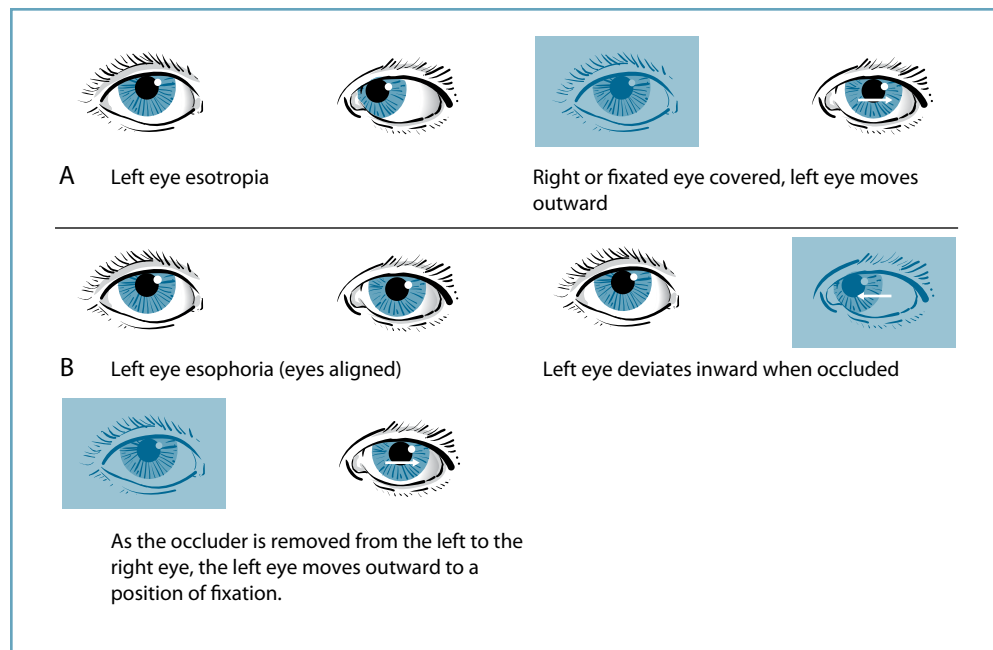

Figure 76-2. Alternate cover test in the detection of strabismus. Normally, both eyes appear to be aligned and centrally fixed. **A.** Detection of esotropia. The right eye is fixating and a left esotropia is present. When the right or fixating eye is covered, the left eye moves outward (away from the nose). **B.** Detection of esophoria. The eyes are aligned with a left esophoria. When the left eye is covered, it deviates inward. As the occluder is moved from the left eye to the right eye, the left eye moves outward to a position of fixation.

refractive error with **corrective lenses**. Such lenses, which remedy the refractive error and minimize the need for accommodation, are used to treat accommodative esotropia. Glasses are also used in anisometropic amblyopia in which one eye has a significantly different refractive error than the other.

Children who do not see equally well from both eyes may be at risk for amblyopia if they preferentially fixate with only one eye. If detected, amblyopia should be corrected with occlusion therapy of the fixating “good” eye. **Occlusion therapy** forces children to use the amblyopic eye. This treatment is best accomplished by constantly patching the eye with better vision during waking hours, or penalization with dilating drops in the better seeing eye. Children require repeat evaluations and close monitoring during this therapy.

If nonsurgical methods fail to align the eyes, surgical correction may be necessary. **Surgery** may be used to achieve the best possible ocular alignment and is usually required for treatment of infantile esotropia. It is generally performed in children between 6 months and 1 year of age, while the visual system is still pliable enough to allow for development of postsurgical binocular vision. Surgery also may be needed in children with intermittent exotropia if the frequency of the deviation is increasing.

Prognosis

Certain conditions, such as pseudoesotropia or infrequent intermittent exotropia, may resolve as children mature. Others, such as infantile esotropia, require early detection and treatment to achieve the best binocular vision. Amblyopia and permanent vision loss may result if correction of strabismus is delayed.

CASE RESOLUTION

The infant in the case history has pseudoesotropia. Although the boy's eyes appear to deviate, the corneal light reflex and cover tests are normal. Physical examination reveals prominent epicanthal folds and a broad, flat nasal bridge.

Infections of the Eye

Teresa Rosales, MD

CASE STUDY

A 10-day-old neonate has a 1-day history of red, watery eyes and nonproductive cough with no fever. The girl is breastfed and continues to eat well. She was the 7-lb, 2-oz (3,238-g) product of a term gestation, born via normal spontaneous vaginal delivery without complications to a 26-year-old woman. The pregnancy was also uncomplicated. No one at home is ill.

On examination, the infant is afebrile with normal vital signs. Examination of the eyes reveals bilateral conjunctival injection with only a mild amount of purulent

discharge. Bilateral red reflexes are present. The rest of the physical examination is within normal limits.

Questions

1. What is the differential diagnosis of conjunctivitis both during and following the neonatal period?
2. What laboratory tests, if any, should be performed?
3. When is a chest radiograph indicated in the evaluation of neonates with conjunctivitis?
4. What are management strategies for eye infections?

Infections of the eye and surrounding structures are commonly seen by pediatricians. Such infections range in severity from common problems such as blepharitis and conjunctivitis, which lack serious sequelae, to severe and less common infections such as periorbital and orbital cellulitis. The presenting complaint in many children with eye infections is a red-appearing eye. Familiarity with the common causes of a red eye makes prompt diagnosis and treatment possible.

Epidemiology

Conjunctivitis, which affects children of all ages, is perhaps the most common eye infection of childhood. The incidence of conjunctivitis in the newborn period is estimated to range from 1.6% to 12%. The incidence of chlamydial conjunctivitis is about 8 in 1,000 live births. About two-thirds of acute childhood conjunctivitis has a bacterial etiology, and one-third is viral. *Haemophilus influenzae* and *Streptococcus pneumoniae* are the most common bacterial agents and account for about 40% and 10% of culture-proven cases, respectively. The incidence of *H influenzae* is decreasing with the advent of the *H influenzae* type b vaccine. *Staphylococcus aureus* is isolated from the conjunctivae of children with acute conjunctivitis, but it is found with about the same frequency in the eyes of children without conjunctivitis. Adenovirus is the most common viral isolate. Most cases of acute conjunctivitis in young adults have a viral etiology. Serious eye infections such as periorbital and orbital cellulitis occur far less often.

Clinical Presentation

Red eyes and discharge are the common presenting signs of infections of the eyelids and conjunctivae. Eyelid edema and erythema surrounding the eye characterize periorbital and orbital cellulitis.

Proptosis, abnormal extraocular movement, or loss of visual acuity may signal spread of the infection beyond the orbital septum (orbital cellulitis) (Dx Box).

Pathophysiology

Eye infections may be divided into 2 types: those affecting the structures surrounding the orbit and those involving the orbital contents themselves (Figure 77-1). Although all structures surrounding the eye may potentially become inflamed or infected, the eyelids, nasolacrimal drainage system (dacryocystitis; see Chapter 78), conjunctiva, and cornea are most commonly involved. Orbital cellulitis is defined as an infection of the orbital structures posterior to the orbital septum. The orbital septum, an extension of the periosteum of the bones of the orbit, extends to the margins of both the upper and lower eyelids and provides an anatomical barrier to the spread of most infectious and inflammatory processes. Preseptal, or periorbital, cellulitis is localized to structures superficial to the orbital septum, whereas post-septal, or orbital, cellulitis implies that the disease process involves orbital structures extending beyond the septum.

Differential Diagnosis

Infections of the eye are included in the differential diagnosis of conditions presenting with red eye (Box 77-1). Also included in the differential diagnosis are congenital, inflammatory, traumatic, and systemic processes. Although infection and irritation are by far the most common causes of an acute onset of red eye, other possibilities, especially trauma, glaucoma, or underlying systemic disease, must be considered.

Dx Eye Infections

Eyelid Infections

- Redness
- Itching (blepharitis)
- Burning (blepharitis)
- Scales at the base of the lashes (seborrheic blepharitis)
- Swelling (hordeolum or chalazion)
- Pain (hordeolum)

Conjunctivitis

- Conjunctival injection and edema
- Excessive tearing
- Discharge or crusting
- Itching (allergic conjunctivitis)

Uveitis

- Conjunctival injection
- Pain
- Blurred vision
- Photophobia
- Headache

Periorbital Cellulitis

- Unilateral eyelid edema
- Erythema surrounding the eye
- Pain
- Fever

Orbital Cellulitis

- Eyelid edema
- Proptosis
- Decreased extraocular movements
- Loss of visual acuity
- Fever
- Ill appearance
- Associated sinusitis

Eyelid Infections

Common conditions affecting the eyelid and its related structures are blepharitis, hordeolum, and chalazion.

Blepharitis is an inflammation of the lid margins. This condition, which is often bilateral, may be chronic or recurrent. The 2 most common causes of blepharitis are staphylococcal infection and seborrheic dermatitis. Children with staphylococcal blepharitis often present with scales at the base of the lashes, ulceration of the lid margin, and loss of lashes. The infection may spread to the conjunctiva or cornea, producing conjunctivitis or keratitis. In contrast, seborrheic blepharitis is characterized by greasy, yellow scales attached to the base of the lashes. In addition, associated seborrhea of the scalp or eyebrows may be present. Mixed staphylococcal-seborrheic infections, which occur as staphylococcal superinfection, may complicate seborrheic blepharitis. Less commonly seen forms of blepharitis are parasitic blepharitis, which results from infestation of the lids by the head louse, *Pediculus capitis*, or crab louse, *Pediculus*

Figure 77-1. The eye and surrounding structures.

pubis, and primary or recurrent herpes simplex virus type 1 infections that may manifest as clusters of vesicles on the eyelids. Acne rosacea may rarely occur in childhood and can present very similarly to chronic blepharitis.

The glands of the eyelid can also be infected. *Staphylococcus aureus* is the most common organism. A **hordeolum**, or common stye, results from an infection of the meibomian glands located along

Box 77-1. Differential Diagnosis of Red Eye

Congenital Anomalies

- Nasolacrimal duct obstruction
- Congenital glaucoma

Infection

- Keratitis
- Conjunctivitis
- Dacryocystitis
- Corneal ulcer
- Periorbital and orbital cellulitis

Inflammation

- Blepharitis
- Hordeolum
- Chalazion

Trauma

- Corneal abrasion
- Foreign body
- Blunt trauma: hyphema
- Perforating injuries
- Exposure to chemicals or other noxious substances

Systemic Illnesses

- Kawasaki disease
- Varicella
- Measles
- Lyme disease
- Stevens-Johnson syndrome
- Ataxia-telangiectasia
- Juvenile rheumatoid arthritis

the lid margins. The glands become obstructed and an abscess can form. Affected children present with a well-circumscribed, painful swelling that may be at the lid margin or may be deeper in the lid tissue. These generally rupture or resolve without complications when treated aggressively with hot compresses.

A chalazion is a hordeolum that has not resolved over weeks to months. It is no longer an infectious process but has become a chronic granulomatous inflammation of the meibomian glands. The resulting firm, non-tender, slow-growing mass within the upper or lower eyelid may be painful if secondary infection is present.

Infections of the Conjunctiva

Conjunctivitis refers to any inflammation of the conjunctiva. The condition may be allergic, chemical, viral, or bacterial in etiology. In addition, it may be a sign of systemic disease such as Kawasaki disease or Stevens-Johnson syndrome.

Acute conjunctivitis, or pinkeye, is common during childhood and can be extremely contagious. The usual signs are conjunctival injection, tearing, discharge, crusting of the lashes, and conjunctival edema (chemosis). Pain and decreased vision are uncommon symptoms and may signal corneal involvement.

In general, it is difficult to distinguish bacterial conjunctivitis from viral conjunctivitis on clinical features alone. Certain clinical characteristics may guide the diagnosis. The average age of children affected with **bacterial conjunctivitis** tends to be younger than the age of those with viral conjunctivitis, which occurs more frequently in adolescents; however, considerable overlap occurs. Children with bacterial conjunctivitis typically present with an acute onset of unilateral or bilateral injection and edema of both the palpebral and bulbar conjunctiva, minimal to copious purulent discharge, and crusting of the eyelashes. Children may have difficulty opening their eyes on awakening in the morning because of the exudate. An association between conjunctivitis and concomitant otitis media has been well described. *Haemophilus influenzae*, which is often resistant to ampicillin, is the pathogen most commonly isolated from affected children.

The diagnosis of **viral conjunctivitis** is considered if signs of viral upper respiratory infection (eg, low-grade fever, cough, rhinorrhea) are evident. Viral infection is associated with conjunctival injection, watery or thin mucoid discharge, and only mild lid edema and erythema. Adenoviral infection is usually bilateral, with significant conjunctival injection and chemosis of the conjunctiva, and is often accompanied by a tender preauricular lymph node. Epidemic keratoconjunctivitis is a highly contagious form of adenoviral conjunctivitis. Affected children often complain of foreign body sensation beneath the lids or photophobia due to corneal involvement. Pharyngeal conjunctival fever, another presentation of adenoviral conjunctivitis, usually manifests as conjunctivitis in association with pharyngitis and fever.

Infants who suffer from **chronic or recurrent conjunctival discharge** may have an obstruction of the nasolacrimal duct, whereas older children with chronic conjunctivitis may have allergic

diseases, recurrent blepharitis, or chlamydial infections. Blepharitis is the most common cause of chronic conjunctivitis in older children. *Staphylococcus aureus* is frequently implicated in these infections.

Itching, tearing, and conjunctival edema are the hallmarks of **allergic conjunctivitis**, a noninfectious form of conjunctival inflammation often seen in children with other allergic disorders such as asthma or hay fever. Conjunctival injection tends to be mild, bilateral, and seasonal. The etiology is most often a hypersensitivity to pollens, dust, or animal dander. Vernal conjunctivitis is a bilateral, severe form of allergic conjunctivitis seen primarily during childhood. Most cases occur during the spring and summer. Severe itching and tearing are the most frequent complaints. The palpebral conjunctiva may have a cobblestone appearance due to the accumulation of inflammatory cells, or there may be small, elevated lesions of the bulbar conjunctiva at the corneal limbus. The pathogenesis is unclear, but atopy seems to play a role.

Chlamydial conjunctivitis frequently affects both neonates and adolescents. Inclusion conjunctivitis is an acute infection of the eyes caused by sexually transmitted *Chlamydia trachomatis* (usually serotypes D through K). This condition may be seen in neonates or sexually active adolescents. Trachoma, the most common cause of impaired vision and preventable blindness worldwide, is a chronic conjunctivitis usually caused by *C trachomatis* serotypes A, B, and C. Although this disease is rarely seen in North America, it is endemic among certain populations, especially Native Americans. Inclusion conjunctivitis and endemic trachoma are both characterized initially by conjunctivitis with small lymphoid follicles in the conjunctiva.

Neonatal conjunctivitis, or ophthalmia neonatorum, occurs during the first month of life. The major causes of neonatal conjunctivitis are chemical, chlamydial, and bacterial (in decreasing order of frequency). Ophthalmia neonatorum may be produced by the same bacteria that cause childhood conjunctivitis but also results from organisms such as *C trachomatis* or *Neisseria gonorrhoeae*. Newborns may acquire these latter pathogens following premature rupture of membranes or passage through an infected or colonized birth canal. *Chlamydia trachomatis* is the organism most commonly identified. It has been isolated from 17% to 40% of neonates with conjunctivitis. Infants born to mothers with active cervical chlamydial infection have a 20% to 50% chance of developing chlamydial conjunctivitis. Viruses are uncommon causes of neonatal ocular infections. Herpes simplex virus (HSV) is the primary viral agent involved in neonatal conjunctivitis. The presence of characteristic vesicular skin lesions or corneal dendritic lesions helps in the diagnosis.

The time of onset of symptoms is related to the etiologic agent. Inflammation secondary to the **silver nitrate** drops instilled at birth to prevent gonococcal infection presents as mild conjunctivitis 12 to 24 hours after birth in 10% to 100% of treated newborns. This condition usually resolves spontaneously in 24 to 48 hours. This is more of historic interest because erythromycin ointment 0.5% has replaced silver nitrate in most hospitals. (Silver nitrate was ineffective against *C trachomatis*.) Conjunctivitis due to *N gonorrhoeae* appears 2 to 5

days after birth and is associated with copious purulent discharge. Conjunctivitis due to *C trachomatis* occurs at 5 to 14 days, a result of a longer incubation period. The time of onset and the severity of symptoms of these 2 conditions may overlap, however. The presentation of gonococcal infection may be delayed for 5 days or more because of the partial suppression of the infection by the prophylactic drops instilled at birth. Chlamydial infection can vary in severity from mild erythema of the eyelids to severe inflammation and copious purulent discharge. Chlamydial infection is primarily localized to the palpebral conjunctiva and only rarely affects the cornea. Gonococcal conjunctivitis is considered a medical emergency because the gonococcus can penetrate the cornea, resulting in corneal ulceration and perforation of the globe within 24 hours if untreated.

Concomitant nasopharyngeal chlamydial infection is commonly seen. Spread of the organism from the nasopharynx to the lungs is a sequela of colonization. Ten percent to 20% of infants with conjunctivitis have chlamydial pneumonia. It may occur either simultaneously with the conjunctivitis or up to 4 to 6 weeks later. Affected infants are usually afebrile and present with symptoms of increasing tachypnea and cough.

Anterior uveitis may be confused with conjunctivitis. The uvea consists of the iris, the ciliary body, the retina, and the choroid. Inflammation of the iris or ciliary body may produce conjunctival injection, which may be associated with decreased visual acuity, pain, headache, and photophobia. Systemic conditions associated with uveitis include Kawasaki disease, juvenile rheumatoid arthritis, Lyme disease, tuberculosis, sarcoidosis, toxocara infection, toxoplasmosis, and spondyloarthropathies.

Infections of the Eye and Surrounding Tissues

Preseptal cellulitis and **orbital cellulitis** are 2 serious infections of the eyelids and surrounding structures. Although these infections are not as frequent as those that are limited to the eye, they have serious sequelae. The preseptal space is defined by the skin of the eyelid on one side and the orbital septum on the other. Children with preseptal cellulitis, or **periorbital cellulitis**, usually present with acute onset, unilateral upper and lower eyelid edema, erythema, and pain. The condition is often associated with systemic signs and symptoms such as ill appearance, fever, and leukocytosis. The eye itself usually appears normal. Infection may follow hematogenous seeding of the preseptal space, most often with *H influenzae* type b or *S pneumoniae*, or after traumatic breaks in the skin that usually lead to *S aureus* infection.

Orbital cellulitis is an infection of the contents of the orbit posterior to the orbital septum. Usually an insidious onset of eyelid edema, proptosis, decreased extraocular movements, and loss of visual acuity occur. As with periorbital cellulitis, children are often febrile and ill-appearing. Contiguous spread of infection from adjacent sinusitis (most often ethmoid) is the most common cause. The organisms most often involved are the same as those in acute sinusitis (*S aureus*, *S pneumoniae*, non-typeable *H influenzae*, and

Staphylococcus pyogenes). Untreated, the infection may progress to orbital abscess formation or progress posteriorly in the orbit to the cavernous sinus and the brain.

Primary herpes simplex infection can affect the skin surrounding the eyes as well as the eye itself. Most of these infections are caused by HSV type 1, although type 2 infections may be seen in newborns. Children with **herpetic infections of the eye** usually present with unilateral skin vesicles and a mild conjunctivitis or keratitis. Herpetic keratoconjunctivitis can recur following fever, exposure to sunlight, or mild trauma. The characteristic corneal lesion of herpes keratitis is the dendritic corneal ulcer, which appears as a tree branch pattern on fluorescein staining of the cornea. Although this lesion may be seen with primary infection, it is more common in recurrent infections. Skin vesicles may not appear with a recurrence, which makes it difficult to distinguish herpetic infection from other causes of conjunctivitis. Steroids may lead to progression of the herpetic infection and permanent corneal scarring as well as cataracts and glaucoma. Empiric topical steroid treatment for presumed viral conjunctivitis should be avoided for this reason. Neonatal herpetic infections of the eye primarily result from HSV-2. Infections may be isolated to the eye or the eye may be infected secondarily due to central nervous system (CNS) or disseminated disease. Proper diagnosis is important because disseminated herpetic disease has a mortality of about 85%, and CNS disease has a mortality of 50%. Isolated herpetic eye disease is actually quite rare in neonates.

Evaluation

History

A careful history taken from the parent or primary caregiver as well as the child can guide the diagnosis (Questions Box). It is important to exclude the possibility of ocular trauma or exposure to noxious chemicals when evaluating children with red, irritated eyes.

Questions

Eye Infections

- How long has the child had symptoms?
- Is the child having any difficulty seeing clearly?
- Is he or she complaining of light sensitivity?
- Has the child had fever, cold symptoms, or purulent nasal discharge (eg, green or yellow)?
- Are the eyes pruritic (itchy) or painful?
- Does the child have difficulty opening the affected eye on awakening in the morning or after naps?
- Have the parents noticed any discharge from the eyes or crusting around the eyelids?
- Is the child complaining of earache or sore throat?
- Does the child have allergies, asthma, or hay fever?
- Has there been any trauma or bug bites?

Physical Examination

A thorough examination of the eyes should be performed. The eyelids, conjunctiva, and cornea should be inspected for evidence of inflammation or foreign bodies. The presence of any discharge or crusting of the eyelids as well as light sensitivity or pain should be noted. Extraocular movements should be checked, and their symmetry should be noted. Visual acuity should be determined, and an ophthalmoscopic examination of the retina should be performed whenever possible. A slit-lamp examination of the eye is indicated if uveitis is suspected. In addition, it is important to perform a thorough head and neck examination, noting the presence of associated sinusitis, otitis media, pharyngitis, or preauricular nodes.

Laboratory Tests

Laboratory assessment is guided by the history and physical examination. Although clinical differentiation between a bacterial and viral etiology is difficult, cultures are usually not required because acute conjunctivitis in children is a self-limited disease. In neonatal conjunctivitis, however, the time of onset of illness and the clinical findings overlap, and Gram stain and cultures are essential. Gonococcal infection is assessed by both Gram stain and culture. Treatment may be initiated on the basis of Gram stain alone because of the serious potential for corneal involvement and subsequent loss of visual acuity.

If HSV is suspected, viral cultures should be obtained. If chlamydial infection is suspected, a nasopharyngeal culture should be sent in addition to conjunctival scraping. Purulent material may be examined for gonococci, but conjunctival scrapings are required for chlamydia because chlamydia is an obligate intracellular organism. Laboratory assessment of periorbital cellulitis includes a complete blood cell count (CBC), blood culture, and a lumbar puncture in young infants or in children with signs of meningeal irritation. The reported prevalence of meningitis is 1% in children with periorbital cellulitis and 10% in children with bacteremia and periorbital cellulitis. As with periorbital cellulitis, laboratory assessment of orbital cellulitis includes a CBC and blood culture.

Imaging Studies

Imaging studies are required infrequently in the assessment of eye infections. A chest radiograph to detect pneumonia should be taken if infants with neonatal conjunctivitis have respiratory symptoms. Characteristic features on chest radiograph include hyperinflation and diffuse or patchy interstitial infiltrates. In orbital cellulitis, a computed tomography scan of the orbit and sinuses may be useful for assessing the degree of involvement.

Management

Most common eye infections either resolve spontaneously or respond readily to **hygiene** and **topical antibiotics**. Treatment of both staphylococcal and seborrheic blepharitis consists of daily lid hygiene (usually at bedtime), including application of a warm compress and removal of the scales and crusts with a moistened, warm washcloth.

The eyelashes and lid margins may also be scrubbed with a washcloth soaked in a 50:50 mixture of baby shampoo and water. When staphylococcal blepharitis is present, an ointment containing an anti-staphylococcal antibiotic agent, such as erythromycin, may be applied to the eyelids after cleansing. Treatment of parasitic blepharitis consists of application of petrolatum ophthalmic ointment (to smother the nits) several times a day for 1 week, followed by removal of the remaining parasites and their ova with tweezers or forceps.

Treatment for hordeola consists of application of hot compresses several times a day. This usually causes the abscess to come to a point and drain. Occasionally, surgical excision and drainage may be required if the abscess does not resolve. Unlike the hordeolum, a chalazion generally requires surgical excision, because spontaneous resolution is uncommon.

Most cases of acute childhood conjunctivitis can be managed successfully by primary care physicians. Acute conjunctivitis in childhood is generally a self-limited disease. However, antibiotic treatment of bacterial conjunctivitis hastens recovery and may help prevent secondary cases by eradicating the bacterial pathogen. It is helpful to determine clinically whether the infection is bacterial and initiate empiric treatment with topical antibiotic preparations. Trimethoprim and polymyxin B sulfate (Polytrim), sodium sulfacetamide (Bleph-10), gentamicin (Garamycin), and tobramycin (Tobrex) are some of the commonly prescribed antibiotics. The newest antibiotic of choice is Vigamox (moxifloxacin). Avoid neomycin-containing products because sensitivity to neomycin occurs frequently. Antibiotic ointments may be easier to instill in infants and young children. Antibiotic drops should be used in older children during the day because the ointments can blur the vision. Ointments may be used at bedtime. Systemic therapy can be considered for concomitant conjunctivitis and otitis media. Good hygiene with special attention to hand washing is important to prevent the spread of the infection to the other eye and to family and friends. Children should not go to school until the discharge and drainage have resolved (even if on antibiotic drops). If symptoms persist for more than 7 to 10 days or if the diagnosis is in question, appropriate cultures should be taken. Complicated cases such as suspected herpetic or gonococcal infection, foreign bodies that cannot be removed easily, loss of visual acuity, presence of significant pain, those involving children with a history of recent penetrating ocular trauma or surgery, and those involving children who use contact lenses should be referred to an ophthalmologist immediately. Contact lens wearers with red eyes are at high risk for corneal ulcers. They should be instructed to leave their lenses out until seen by the ophthalmologist.

Allergic conjunctivitis can be managed with cool compresses. Topical decongestant drops may provide symptomatic relief if treatment is indicated. Vernal conjunctivitis may be treated with topical cromolyn sodium drops or medications designed to relieve redness and itching and stabilize mast cells, such as Patanol (olopatadine) or Acular (ketorolac). Caution should be used when prescribing corticosteroid preparations for the eye because they may lead to progression of an undiagnosed herpetic eye infection. Chronic use of topical steroids can cause cataracts and glaucoma.

Treatment of neonatal conjunctivitis depends on the diagnosis. If **gonococcal infection** is suspected and Gram stain is positive for gram-negative diplococci, immediate parenteral therapy with ceftriaxone should be initiated. **Chlamydial** conjunctivitis should be managed with systemic rather than topical treatment to prevent systemic disease. Oral erythromycin is the drug of choice. Although oral treatment provides adequate local antibiotic levels, topical erythromycin ointment may be used in conjunction with systemic therapy to provide more prompt relief of ophthalmic symptoms. The parents should also be treated.

Empiric parenteral antibiotic therapy (eg, cefuroxime) should be initiated for **periorbital cellulitis**. Repeat evaluations for signs of progression should be performed frequently during the initial 24 to 48 hours. If **orbital cellulitis** is suspected, an ophthalmologist should be consulted, and hospitalization and systemic antibiotics should be instituted. Surgical drainage of the sinuses or of an orbital abscess is sometimes necessary.

Children with suspected **herpetic infection** should be referred to an ophthalmologist. Intravenous acyclovir is often recommended for the treatment of isolated herpetic eye infections in neonates.

Prognosis

Most common eye infections such as blepharitis, hordeolum, and acute childhood conjunctivitis resolve without sequelae. Recurrence is common for hordeola, and periorbital cellulitis may be a potential complication in rare or untreated cases. Unlike acute conjunctivitis, chronic conjunctivitis may not be self-limited. Appropriate diagnosis and management are extremely important to prevent serious sequelae in some children. For example, endemic trachoma may progress to produce conjunctival scarring, pannus formation, and even blindness if not appropriately treated with systemic erythromycin or tetracycline. (In general, systemic tetracycline should not be used in children <8 years to avoid discoloration of the teeth.)

Periorbital cellulitis generally resolves without sequelae if treated promptly with systemic antibiotics. Orbital cellulitis should be considered a true ophthalmologic emergency because the potential for complications is high. The optic nerve may become involved, resulting in loss of vision or spread of the infection into the cranial cavity. This spreading may lead to meningitis, cavernous sinus thrombosis, or brain abscess.

CASE RESOLUTION

The infant presented in the case history has neonatal conjunctivitis. A Gram stain of the purulent discharge should be examined, and cultures should be taken from the eye and nasopharynx. If the Gram stain is negative for gonococci, empiric treatment may begin with oral erythromycin.

Excessive Tearing

Teresa Rosales, MD

CASE STUDY

A 4-week-old infant girl has had a persistent watery discharge from both eyes since birth. Her mother has noticed white, crusty material on her daughter's eyelids for the past few days. The infant's birth and medical history are unremarkable. Examination of the eyes, including bilateral red reflexes and symmetrical extraocular movements, is normal, except that the left eye appears "wetter" than the right.

Questions

1. What is the differential diagnosis of excessive tearing in infancy?
2. How do physical findings such as corneal enlargement and haziness influence the differential diagnosis?
3. How should infants with excessive tearing be managed?
4. When should a child with excessive tearing be referred to an ophthalmologist?

Infants or young children with excessive tearing or epiphora in one or both eyes are a common pediatric ophthalmologic concern. The pediatrician must be capable of differentiating benign causes of this common childhood condition from other more serious illnesses, such as glaucoma, that potentially threaten vision.

NASOLACRIMAL DUCT OBSTRUCTION

Epidemiology

Congenital obstruction of the nasolacrimal duct or dacryostenosis, which occurs in 1% to 6% of newborn infants, is the most common cause of excessive tearing in infancy. Eighty percent will resolve spontaneously by 6 months of age.

Clinical Presentation

Infants with dacryostenosis usually present with a history of a mucoid discharge and crusting along the eyelid margins. The affected eye appears "wetter" than the normal eye, and a small pool of tears may be noted along the lower eyelid. Frequent tearing is reported. Commonly, the patient has repeated episodes of infection with purulent discharge (Dx Box).

Pathophysiology

The lacrimal system (Figure 78-1) produces and drains tears away from the eyes and into the nose. Reflex tearing is usually present shortly after birth but may be delayed for several weeks to months until the lacrimal gland begins to function. Tears drain away from the eyes through the superior and inferior puncta into the superior and inferior canaliculi and finally into the nasolacrimal duct, which drains beneath the inferior turbinate into the nose.

Dx Excessive Tearing

- Conjunctival edema or injection
- Crusting of the eyelids
- Rhinorrhea
- Photophobia
- Corneal haziness
- Reflux of tears with gentle pressure on medial canthus
- Wetness of eye

Outflow obstruction, most often due to obstruction of the nasolacrimal duct or dacryostenosis, is the most common cause of excessive tearing in infancy. The obstruction is usually bilateral and occurs during fetal development. Most commonly a persistent, thin membrane (Hasner membrane) obstructs the opening of the sac in the nose. The membrane is usually located in the distal or nasal segment of the duct rather than in the proximal portion. The term *dacryocystitis* is used if acute infection or inflammation is associated with the obstruction. If both the canaliculi and the nasolacrimal duct are obstructed, a mucocele over the nasolacrimal sac may be noted at birth. This sac appears as a bluish, firm mass located over the lacrimal sac. Atresia of some portion of the drainage system may also occur, but this is extremely rare.

Differential Diagnosis

Box 78-1 outlines the differential diagnosis of excessive tearing in infancy. Although obstruction of the nasolacrimal duct is the most common cause of excessive tearing in infants, it is important to consider and rule out glaucoma when evaluating infants with this complaint. Infantile glaucoma may be unilateral or bilateral.

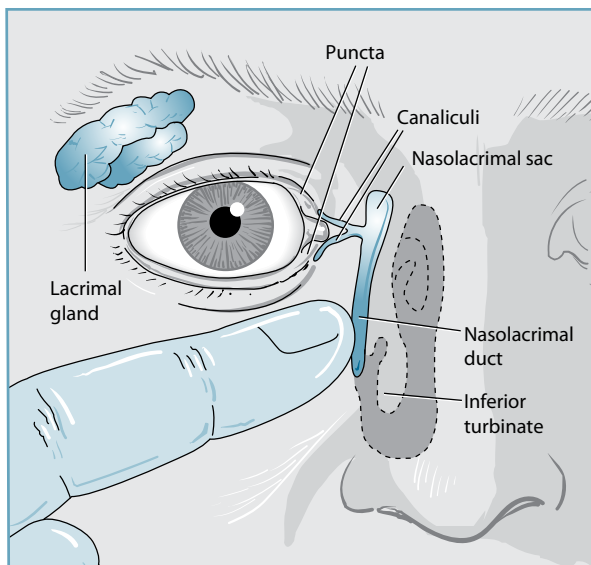

Figure 78-1. The lacrimal system, showing massage of the lacrimal sac.

Box 78-1. Differential Diagnosis of Excessive Tearing in Infants

Increased Production

- Infantile glaucoma
- Allergy
- Conjunctivitis
- Corneal abrasion
- Foreign body under the eyelid

Outflow Obstruction

- Nasolacrimal duct obstruction (dacryostenosis)
- Anomalies of the lacrimal drainage system
- Mucocele of the lacrimal sac
- Atresia of the lacrimal punctum or canaliculus
- Nasal congestion
- Craniofacial anomalies involving the midface

Acute onset of excessive tearing in older children is usually due to ocular irritation. Any irritation of the conjunctiva, cornea, or eyelids may produce tearing. Conjunctivitis and corneal abrasion, usually secondary to a retained foreign body or herpes simplex keratoconjunctivitis, are the 2 most common causes. Eye infections are discussed in Chapter 77.

Evaluation

History

Evaluation of excessive tearing should begin with a thorough history. The nature of any discharge (eg, watery, mucoid, or purulent) should be noted. Parents or other caregivers should be questioned about the appearance of the child's eyes (Questions Box). The excessive mucoid discharge in the medial canthal region and on the eyelashes is noticeable to the family, as is the increased tearing. Crusting

Questions

Excessive Tearing

- How old was the child when the excessive tearing appeared?
- Are one or both eyes affected?
- How does the eye appear? How has its appearance changed?
- Is there a family history of infantile glaucoma?
- Is the child photophobic or light sensitive (eg, closes the eyes in bright sunlight)?
- Has the child had any persistent, watery discharge?
- Does the child have difficulty opening the affected eye on awakening in the morning or after a nap?

along the eyelashes caused by drying of the mucoid material is usually noted when children awaken in the morning or after a nap. Mucopurulent discharge may be noted if an associated acute infection is present (dacryocystitis).

Physical Examination

A careful examination of the eyes in infants includes inspection, evaluation of extraocular movements, and funduscopic examination. Funduscopic examination may be difficult in this age group, but bilateral red reflexes should at least be elicited. Signs of **dacryostenosis**, which usually appear days to weeks after birth, include tearing, mucoid discharge, and crusting of the eyelids. Tearing may be as mild as an increased wetness of the affected eye; this is best evaluated prior to disturbing the child. Visible overflow of tears from the affected eye is not unusual, and is typically seen when the eye is irritated (eg, due to cold or wind). If dacryostenosis is present, there may be associated erythema and edema of the eyelids. Dacryocystitis may also spread to the surrounding tissues, producing a periorbital cellulitis; systemic signs of infection such as fever may be noted. Gentle pressure along the medial canthal region over the lacrimal sac may produce a reflux of tears or mucoid discharge onto the surface of the eye, thus confirming the diagnosis of obstruction.

Laboratory Tests

Routine laboratory assessment is generally not necessary.

Management

Spontaneous resolution of dacryostenosis is common by 6 to 8 months of age. The primary medical treatment of uncomplicated nasolacrimal duct obstruction consists of **local massage** and **cleansing** beginning when the symptoms are noted. Parents are instructed to massage the nasolacrimal duct several times a day by applying firm, downward pressure over the medial canthal region with their finger and then sliding the finger down toward the mouth (Crigler maneuver) (see Figure 78-1). This maneuver attempts to move fluid trapped within the nasolacrimal sac down through the duct in an attempt to break the obstruction with hydrostatic pressure. Parents may be asked to cleanse the eyes with warm water before performing this maneuver. Antibiotic ointments and drops should

be prescribed only if the discharge is purulent or associated conjunctivitis is evident.

Controversy exists regarding when probing of the nasolacrimal duct should be performed. Some ophthalmologists prefer probing the duct before children are 6 months of age because prior to this time the procedure may be performed in the office without general anesthesia. Others state that more than 80% of obstructions resolve with conservative medical management by 6 months of age and prefer to delay probing until the age of 9 to 12 months. At this age the procedure needs to be performed under general anesthesia. Deciding when to proceed with the probing depends on the standard of practice within the community, the severity of symptoms, the response to medical management, and the level of parental concern.

Ophthalmologic referral is necessary for affected infants by 6 months of age if the obstruction has not resolved. Referral should be made sooner if symptoms are severe or infections recur.

Prognosis

Most cases of dacryostenosis resolve spontaneously during the first year of life without further sequelae. If tear duct probing is necessary, it is 90% to 95% successful if performed before 13 months of age. The success rate drops to 70% between 13 to 15 months and 50% over 18 months.

CONGENITAL GLAUCOMA

Epidemiology

Congenital or infantile glaucoma, a serious cause of excessive tearing, is quite rare; the incidence is about 1 in 10,000 live births. Although glaucoma may be present at birth, onset during the first few weeks to months of life is more common. Approximately 25% of cases are diagnosed at birth and 80% by 1 year of age. The severity of the disease is worse with earlier onset. Most affected infants are male; the male-female ratio in older infants is 2:1. Infantile glaucoma seems to have a multifactorial inheritance pattern, but most cases are sporadic. In families with one affected child or a parental history of infantile glaucoma, the chance of having a child with glaucoma is about 5%. Although glaucoma may be unilateral or bilateral, most children (75%–90%) who present before 3 months of age have bilateral glaucoma.

Clinical Presentation

In addition to excessive tearing, other clinical signs of infantile glaucoma include blepharospasm (spasmodic blinking of the eyelids), photophobia, corneal enlargement and corneal haziness due to corneal edema, progressive enlargement of the eye (buphthalmos), and cupping and atrophy of the optic nerve (Dx Box).

Pathophysiology

Glaucoma is the most serious and potentially sight-threatening etiology for excessive production of tears. Glaucoma refers to an increase

in intraocular pressure that is severe enough to damage the eye and alter vision. In infants and children, glaucoma is usually a result of a developmental abnormality of the iridocorneal angle, interfering with drainage of aqueous humor from the anterior chamber. Young infants differ from adults in that the globe in infants' eyes is distensible; the increased intraocular pressure not only produces corneal enlargement and edema but also expands the globe itself. Breakdown of the corneal epithelium and resultant irritation of the eyes produce reflex tearing and photophobia. Untreated glaucoma may lead to optic nerve damage with resultant loss of visual acuity, decreased visual field, and even blindness. Glaucoma in children younger than 3 years is referred to broadly as infantile glaucoma, and glaucoma that occurs in children between 3 and 20 years of age is called juvenile glaucoma. Infantile glaucoma is further classified as being primary or secondary. Primary glaucoma refers to isolated abnormalities of the iridocorneal angle, whereas secondary glaucoma may be associated with other ocular or systemic diseases. Juvenile glaucoma is a form of open-angle glaucoma.

Differential Diagnosis

Excessive tearing may be due to increased production or to obstruction to outflow (see Box 78-1). Infants with increased production of tears will demonstrate rhinorrhea in association with epiphora, a finding that distinguishes glaucoma from dacryostenosis. Rhinorrhea is not associated with dacryostenosis because the nasolacrimal duct is obstructed and no tears drain out of the nose. Ocular irritation as occurs with conjunctivitis, corneal abrasion, or a foreign body under the eyelid can also produce excessive tearing, especially in older children. Allergies are also associated with excessive tearing due to overproduction.

Disorders associated with outflow obstruction include dacryostenosis, anomalies of the lacrimal drainage system (mucoceles of the lacrimal sac and atresia of the lacrimal punctum or canaliculus), nasal congestion, and craniofacial anomalies involving the midface.

Evaluation

A corneal diameter greater than 12 mm in infants is suggestive of infantile glaucoma. Corneal edema is more common in younger infants (<3 months of age) and may cause the red reflex to appear dull in the affected eye. The optic cup may be enlarged. A cup-to-disk ratio greater than 0.3 or an asymmetry of the ratio between the eyes may indicate glaucoma.

As in adults, loss of visual fields occurs in children with glaucoma. Visual fields are difficult to evaluate in young children because of their inability to cooperate with the examination.

Management

Suspected cases of glaucoma should be referred to an ophthalmologist immediately for further evaluation, including measurement of intraocular pressure. Pressures greater than 20 mm Hg are suggestive of glaucoma (normal pressures are 10–20 mm Hg in infants and young children as well as in adults).

Surgery is the primary treatment. The goal is to normalize intraocular pressure and minimize irreversible corneal and optic nerve damage.

Prognosis

Infantile glaucoma, if left untreated, may progress to blindness. The visual prognosis depends on several factors, including the age at onset of glaucoma (the earlier the onset, the worse the prognosis), the amount of optic nerve damage, and the degree of myopia caused by the enlargement of the eye. In addition, amblyopia, secondary to either deprivation due to corneal opacities or unequal refractive errors, is often seen (see Chapter 76).

CASE RESOLUTION

The infant presented in the case history at the beginning of the chapter has dacryostenosis. She can be managed with medical treatment such as local massage and cleansing at this stage. If her symptoms persist beyond the age of 6 months, consultation with an ophthalmologist is recommended.

Neck Masses

Stanley H. Inkelis, MD, and Casey Buitenhuis, MD

CASE STUDY

A 2-year-old boy is brought to the office with a 1-day history of an enlarging red, tender “bump” beneath his right mandible. He has a fever (temperature: 101.6°F [38.5°C]) and sores around his nose, upper lip, and cheek. These sores have been present for 3 days and have not responded to an over-the-counter antibiotic ointment. He had an upper respiratory tract infection 1 week ago, which has almost entirely resolved. He is otherwise in good health. The family has no history of tuberculosis or recent travel, and the child has not been playing with cats or other animals.

The physical examination is completely normal except for fever, mild rhinorrhea, honey-crusted lesions on the nares and upper lip, and a 4 × 5-cm, right submandibular neck mass that is erythematous, warm, and tender to palpation.

Questions

1. What are the common causes of neck masses in children?
2. What steps are involved in the evaluation of children with neck masses?
3. What clinical findings suggest that neck masses are neoplasms? When should neck masses be biopsied or removed?
4. What is involved in the treatment of the different types of neck masses in children?
5. When should children with neck masses be referred for further consultation?

Neck masses are any swellings or enlargements of the structures in the area between the inferior mandible and the clavicle. Normal variants, such as the angle of the mandible or tip of the mastoid, may occasionally appear as swellings, and parents sometimes confuse these with neck masses. If the swelling is not a normal structure, a well-directed history and physical examination usually determine the etiology.

Lymphadenopathy from viral or bacterial throat infections is the most common cause of neck **masses** in children. Therefore, neck masses are common because children frequently have sore throats. Most parents know about swollen lymph glands, and they usually do not seek medical advice unless the glands become very large or do not recede in a few days. Neck masses in children may have many other causes besides lymphadenopathy. Most of these masses may be categorized as inflammatory, neoplastic, traumatic, or congenital in origin. A well-described mnemonic in the adult literature, KITTENS, can summarize many of the causes of neck masses in children as well (Table 79-1).

Epidemiology

Most neck masses are benign. Almost 50% of all 2-year-old children and up to 90% of children between 4 and 8 years of age have palpable cervical lymph nodes. Although more than 25% of malignant tumors in children are found in the head and neck region (this is the primary site in only 5%), less than 2% of suspicious head and neck masses are malignant.

The epidemiology of neck masses of infectious origin depends on the infectious agent itself, geographic location of the child, and the child’s immediate environment. Neck masses of viral origin may be related to focal infection of the oropharynx or respiratory tract but are often associated with generalized adenopathy. Neck masses of bacterial origin typically occur from normal bacterial flora of the nose, mouth, pharynx, and skin that secondarily spreads to lymph nodes. These organisms are not usually transmitted from person to person. Pathogenic flora such as group A streptococcus and *Mycobacterium tuberculosis* that result in neck masses can spread by human-to-human contact, however. Additionally, cat scratch disease is caused by *Bartonella henselae*, a vector-borne pathogen.

Clinical Presentation

Children with neck masses present in a variety of ways depending on the etiology of the mass. Typically a swelling or enlargement in the neck, which parents often notice more than children, is evident. Associated signs and symptoms include fever, upper respiratory tract infection, sore throat, ear pain, pain or tenderness over the mass, changes in skin color over the mass, skin lesions of the head or neck, and dental caries or infections (Dx Box). Malignant tumors are usually slow-growing, firm, fixed, non-tender masses. Congenital neck masses and benign tumors, which have frequently been present since birth or early infancy, are soft, smooth, and cyst-like and may be recurrent. Neck masses associated with trauma are often rapidly evolving and may lead to airway obstruction. Temporal

development of neck masses is a helpful predictor of mass etiology. Skandalakis' rule of seven's may be applied and adapted to pediatric neck masses (Table 79- 2).

Pathophysiology

The pathophysiology of neck masses in children is dependent on etiology. Most neck masses are related to inflammation or infection of lymph nodes. Enlargement of lymph nodes usually results from proliferation of intrinsic lymphocytes or histiocytes already present in the lymph node (eg, lymphadenopathy caused by a viral

Dx Neck Masses

Inflammatory/Infectious

- Swelling or enlargement in the neck
- Fever
- Sore throat, dental infection, skin infection of head or neck
- Pain or tenderness over the mass (usually)

Neoplastic

- Slowly enlarging mass
- Unilateral, discrete
- Firm or rubbery
- Fixed to tissue
- Deep within the fascia
- Non-tender (usually)

Traumatic

- Rapidly enlarging mass
- Hematoma
- Acute airway obstruction

Congenital

- Enlargement in neck (usually present since birth or soon after)
- Soft, smooth, cyst-like
- Non-tender (unless infected)
- Recurrent

infection) or from infiltration of extrinsic cells (eg, lymphadenitis, metastatic tumor). Neck masses from trauma occur from leakage of fluid into the neck, and congenital anatomical abnormalities become apparent because of fluid collection or infection of the defect. The parotid gland may be enlarged from inflammation (eg, blocked salivary gland duct), infection (eg, mumps), or tumor (eg, pleomorphic adenoma), but the swelling primarily involves the face rather than the neck and obscures the angle of the jaw. Other salivary glands may be infected or obstructed and may cause submandibular swelling, erythema, and tenderness.

Differential Diagnosis

Neck masses in children are usually the result of inflammation or infection of lymph nodes, tumors of lymph nodes and other neck structures, trauma, and congenital lesions. The location of the mass is often a clue to its etiology (Figure 79-1).

Lymphadenopathy/Lymphadenitis

Lymphadenopathy is lymph node enlargement or hyperplasia secondary to localized infection or antigenic stimulation proximal to the involved node or nodes. Because lymphoid tissue steadily increases until puberty, palpable lymph nodes, including those in the cervical area, are a common, normal finding in children. Any lymph node in the neck larger than 10 mm qualifies as cervical lymphadenopathy.

The most common cause of cervical lymphadenopathy is a viral infection of the upper respiratory tract. Lymphadenopathy usually begins and resolves with the acute infection. Occasionally the swelling remains for several days or months, however, and children

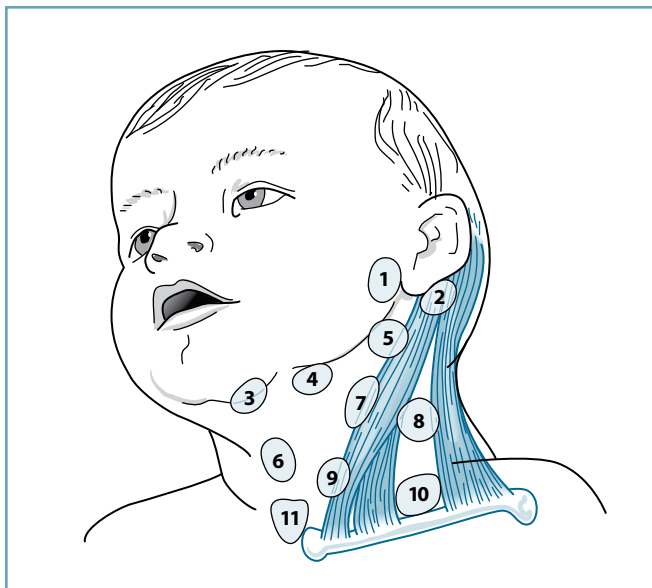

Figure 79-1. Differential diagnosis of neck mass by location. 1. Parotid—cystic hygroma, hemangioma, lymphadenitis, parotitis, Sjögren and Caffey-Silverman syndromes, lymphoma. 2. Postauricular—lymphadenitis, branchial cleft cyst (1st), squamous epithelial cyst. 3. Submental—lymphadenitis, cystic hygroma, thyroglossal duct cyst, dermoid, sialoadenitis. 4. Submandibular—lymphadenitis, cystic hygroma, sialoadenitis, tumor, cystic fibrosis. 5. Jugulodiagastic—lymphadenitis, squamous epithelial cyst, branchial cleft cyst (1st), parotid tumor, normal-transverse process C2, styloid process. 6. Midline neck—lymphadenitis, thyroglossal duct cyst, dermoid, laryngocele, normal hyoid, thyroid. 7. Sternomastoid (anterior)—lymphadenitis, branchial cleft cyst (2nd, 3rd) pilomatrixoma, rare tumors. 8. Spinal accessory—lymphadenitis, lymphoma, metastasis from nasopharynx. 9. Paratracheal—thyroid, parathyroid, esophageal diverticulum. 10. Supraclavicular—cystic hygroma, lipoma, lymphoma, metastasis, normal fat pad, pneumatocele of upper lobe. 11. Suprasternal—thyroid, lipoma, dermoid, thymus, mediastinal mass. (From May M. Neck masses in children: diagnosis and treatment. *Pediatr Ann.* 1976;5:518–535, with permission from SLACK Inc.)

present because of parental concern. Bacterial pharyngitis, usually from infection with group A beta-hemolytic streptococcus (GABHS), is often associated with cervical lymphadenopathy. Cervical as well as generalized lymphadenopathy may be seen in children with systemic illness (eg, Kawasaki disease, sarcoid, HIV). Cat-scratch disease, toxoplasmosis, fungal infection, and mycobacterial and atypical mycobacterial infections may be associated with lymphadenopathy that may later progress to lymphadenitis. Viral illnesses, including Epstein-Barr virus (EBV) (mononucleosis), adenovirus, enterovirus, herpes simplex virus, human herpesvirus 6 (HHV-6), and cytomegalovirus (CMV) commonly cause lymphadenopathy and lymphadenitis.

Lymphadenitis is infection or inflammation of the lymph node that occurs when microorganisms and neutrophils infiltrate the node, leading to necrosis and abscess formation. This condition is usually associated with proximal bacterial infection that drains to the affected nodes by connecting afferent lymphatic channels. Lymphadenitis is often a progression of disease, resulting in enlarged nodes that measure 2 to 6 cm. These nodes, which are typical of

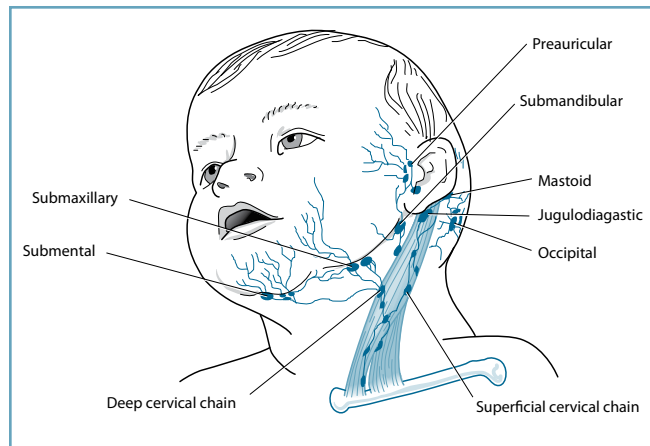

Figure 79-2. The lymphatic drainage and lymph nodes involved in infants and children with cervical lymphadenitis. (Reproduced with permission from Feigin RD, Cherry JD, eds. *Textbook of Pediatric Infectious Diseases*. 5th ed. Philadelphia, PA: Saunders; 2004:186.)

bacterial disease, are often termed hot nodes, and they are erythematous, warm, tender, and sometimes fluctuant. Cold nodes or cold lymphadenitis usually represents subacute or chronic inflammation of lymph nodes typical in illnesses such as cat-scratch disease, mycobacterial infection, or toxoplasmosis. Unlike hot nodes, cold nodes are not warm to the touch and are usually not as tender. They are typically not suppurative and may be difficult to distinguish from nodes that are simply enlarged (Figure 79-2).

Staphylococcus aureus and group A streptococcus are responsible for 50% to 90% of cases of acute unilateral cervical lymphadenitis. These organisms spread from a primary site to the lymph nodes draining those sites. Common primary sites of infection are the throat; teeth and gums; and skin (lesions), particularly on the scalp or ears. Infections at these sites may result from trauma, such as scratches or scabs, or from primary infection, such as impetigo. Anaerobic oral flora constitute a small portion of causes for bacterial cervical adenitis, especially in older children with poor dentition. *Staphylococcus aureus* or group B streptococcus usually causes cervical lymphadenitis in neonates or very young infants. Such staphylococcal infections, which are often nosocomially spread from contact in the newborn nursery, present as discrete masses. Group B streptococcus causes the “cellulitis-adenitis” syndrome, which presents as cervical adenitis associated with a facial cellulitis. *Pseudomonas aeruginosa* is an unusual cause of cervical adenitis in newborns.

Mycobacterial disease must always be considered in children of all ages who present with cervical adenitis particularly involving posterior cervical nodes. The child with *M tuberculosis* cervical adenitis often has multiple nodes, sometimes bilateral, usually non-tender, and usually not erythematous or warm. These children are typically older, commonly reside in an urban setting, have a history of tuberculosis exposure, and often have an abnormal chest radiograph. Intradermal placement of a purified protein derivative (PPD) often produces more than 15 mm of induration in most children with typical mycobacterial infection. A reaction of 5 to 14 mm may be caused by tuberculous or nontuberculous mycobacterial infection. Atypical

mycobacterial infection usually occurs in children between 1 and 6 years of age with unilateral rather than bilateral lymph node enlargement and a normal chest radiograph.

Cat-scratch disease should be considered in children who have cats or kittens or who play with them. The infection may result from a cat scratch or from a cat licking a child's broken skin. If the inoculum is near the head and neck area, cervical adenitis develops. Contact with the hand may result in axillary lymphadenitis. Occasionally generalized lymphadenopathy is present. An associated non-painful papule or papules where the cat scratch or lick occurred may be apparent. *Bartonella henselae* has been identified as the organism causing cat-scratch disease.

Toxoplasmosis may be accompanied by adenitis, usually in the posterior cervical area. Nodes are painless and may fluctuate in size, and children are often asymptomatic. Multiple lymph nodes are involved in about one-third to one-half of cases.

Children presenting with recurrent cervical adenitis and recurrent fevers may have PFAPA syndrome characterized by periodic fever, aphthous stomatitis, pharyngitis, and adenitis (cervical). This entity usually occurs in children younger than 5 years and can be aborted with steroids.

Kikuchi disease, or histiocytic necrotizing lymphadenitis, has an Asian and female predilection and is characterized by fever, leukopenia, and cervical lymphadenopathy. The illness is self-limited, and follow-up is recommended because of a possible association with systemic lupus erythematosus.

Less common bacterial, viral, and fungal causes of cervical adenitis are listed in Box 79-1.

Tumors

Compared with other neck masses, **malignant neck tumors** occur rarely; nevertheless, they should be considered in any children with rapidly enlarging or persistent neck masses. Hodgkin disease and non-Hodgkin lymphoma are the most frequent cause of head and neck malignancies in children, accounting for almost 60% of the cases. Rhabdomyosarcomas are the next most frequent head and neck malignancy followed by thyroid tumors, neuroblastoma, and nasopharyngeal carcinomas. Age is an important factor in determining the likelihood of specific tumors. Neuroblastoma and rhabdomyosarcoma are the most common tumor types in children younger than 6 years. Non-Hodgkin lymphoma typically occurs in preadolescence, and Hodgkin disease and thyroid carcinoma are the most common malignancies in adolescents.

Benign neck tumors, with the exception of those mentioned later in the discussion of congenital lesions, are uncommon. They include epidermoid inclusion cysts, lipomas, fibromas, neurofibromas, pilomatrixomas (benign skin neoplasms of hair follicle origin), keloids, goiters, and ranulas (intraoral mucocysts).

Trauma

Trauma to the neck may be associated with bleeding and edema. Large hematomas that affect vital structures are potentially life-threatening. Significant trauma and structural injury usually

accompany neck hematomas. In children with mild injuries and neck hematomas, bleeding disorders are a possible cause of the hematoma. Twisting injuries to the neck may lead to muscle spasm of the sternocleidomastoid muscle (torticollis) and an apparent mass that is the contracted muscle. Additionally, intramuscular hematoma and/or bleeding from vaginal delivery may cause torticollis in the neonatal period. The neck is bent toward the side of the affected sternocleidomastoid muscle. Child abuse should also be considered in children who have neck injuries that are not consistent with their histories.

A foreign body in the neck may present as a mass because of the foreign body itself (eg, piece of glass or metal, bullet) or surrounding inflammation. A crepitant neck mass following trauma to the neck or chest suggests subcutaneous emphysema from tracheal injury or a pneumomediastinum. Crepitant neck masses may also be seen secondary to pneumomediastinum in children with obstructive lung diseases such as asthma or cystic fibrosis.

Congenital Lesions

Children with congenital neck lesions can present with a neck mass in early infancy or later in childhood. Some congenital lesions are not discovered until adulthood. The most common of these benign lesions are thyroglossal duct cysts, branchial cleft cysts, lymphatic malformations (cystic hygromas/lymphangiomas), and hemangiomas (Figure 79-3).

Thyroglossal duct cysts are almost always midline in the neck and inferior to the hyoid bone. They usually move upward with

tongue protrusion or swallowing. Most branchial cleft cysts occur anterior to the middle one-third of the sternocleidomastoid muscle. Branchial cleft sinus tracts appear as slit-like openings anterior to the lower third of the sternocleidomastoid muscle and may present as neck masses if they become infected. Thyroglossal duct cysts and branchial cleft cysts may also present for the first time as infected neck masses.

Cystic hygromas are usually large, soft, easily compressible masses found in the posterior triangle behind the sternocleidomastoid muscle in the supraclavicular fossa. They transilluminate well. Two-thirds

of cystic hygromas are present at birth, and 80% to 90% are identified before 3 years of age. They are more common on the left side of the neck. Cystic hygromas occasionally become secondarily infected, with findings of erythema, warmth, and tenderness.

Hemangiomas are usually not present at birth but appear in early infancy and may enlarge rapidly. In most cases, they recede spontaneously by 9 years of age. They are usually much smaller than cystic hygromas, do not transilluminate, and may be recognized by their reddish color (capillary or strawberry hemangioma) or by a bluish hue of the overlying skin (cavernous hemangioma).

Small infants who present with torticollis should be examined for a sternocleidomastoid mass (“tumor”), which represents fibrosis and contracture of that sternocleidomastoid muscle so that the head tilts toward the affected side with the chin rotating to the opposite side. Contusion of the sternocleidomastoid muscle from traumatic extraction of the head during delivery with subsequent hemorrhage and healing has been implicated as the cause of the fibrotic mass. However, it is more likely that this mass occurs prior to birth because it contains mature fibrous tissue. In addition, the mass may be present following cesarean section and is associated with hip dysplasia and other congenital lesions, suggesting that the condition is related to abnormal positioning in utero. Venous occlusion of the sternocleidomastoid muscle either in utero or at the time of delivery has also been proposed as a cause.

Evaluation

History

A thorough history is important in establishing the etiology of the neck mass (Questions Box).

Questions

Neck Masses

- How old is the child?
- How long has the neck mass been present?
- What signs and symptoms are associated with the neck mass?
- Has the child been exposed to tuberculosis?
- Has the child ever drunk any unpasteurized cow’s milk?
- Has the child been in contact with any cats or kittens? Rabbits? Other animals?
- Has the child traveled to areas where endemic diseases such as histoplasmosis or coccidioidomycosis are prevalent?
- Has the child suffered any trauma recently?
- Does the child have any allergies?
- Does the child have any risk factors for HIV?

Physical Examination

A general physical examination should be performed. The neck mass should be examined for anatomical location, color, size, shape, consistency, tenderness, fluctuance, and mobility. The mass should also be measured. The head, neck, and face should be examined for lesions, most often infections, that drain into neck lymph nodes. Lesions can frequently be found on the scalp, neck, face, ears, mouth, teeth, tongue, gums, and throat. Hairstyles such as tight braids can sometimes provide ports of entry for bacteria. Occasionally, sinus tracts or fistulas may be the entry point of infection. In addition, other lymph node groups should be examined to determine if the lymphadenopathy is local or generalized. Particular attention should be paid to the supraclavicular area because enlarged supraclavicular nodes are more frequently associated with malignant pathology such as Hodgkin disease. The chest should be examined for use of

accessory muscles, equality of breath sounds, and wheezing. The abdomen should be examined for hepatosplenomegaly.

Laboratory Tests

Laboratory tests are rarely indicated in children with cervical lymphadenopathy or lymphadenitis of acute onset. Although a rapid streptococcal antigen detection test or throat culture is helpful in children with suspected streptococcal sore throat, it may be unnecessary if antibiotic therapy is empirically prescribed for the lymphadenitis. If the adenitis is fluctuant, aspiration and culture may be helpful in determining the specific bacteriologic diagnosis. Fine-needle aspiration cytology and polymerase chain reaction assays may help differentiate between tuberculous and nontuberculous mycobacterial disease. Superficial cervical nodes or axillary nodes, if enlarged, are appropriate first-line aspiration sites due to their superficial nature. In addition, a PPD test should be applied to all children who present with lymphadenitis.

If the adenitis does not resolve or improve after 2 to 3 days of observation or therapy, laboratory tests directed by the history and physical examination should be considered. A complete blood cell count (CBC) with differential and a monospot or serologic antibody tests for EBV may be helpful in the diagnosis of infectious mononucleosis. If the mass in the neck is a hematoma and a bleeding disorder is suspected, a CBC with platelet count, prothrombin time, and partial thromboplastin time should be obtained. Possible additional tests include an erythrocyte sedimentation rate, C-reactive protein and, if indicated, serologic tests for toxoplasmosis, CMV, HHV-6, coccidioidomycosis, histoplasmosis, tularemia, *B henselae*, and syphilis should be performed. Skin tests for fungi should be considered in those patients coming from endemic areas. These tests should be placed after serologic tests are performed so that false-positive serologic test results are not obtained.

Similar laboratory tests should be considered for children who present for the first time with enlarged or enlarging lymph nodes of long duration or those who do not respond after 2 weeks of antibiotic therapy. The physician may choose to do more of these laboratory tests at the initial evaluation or after a therapeutic trial because the likelihood of viral lymphadenopathy decreases and the possibility of a more unusual etiology increases. HIV testing should also be considered.

Thyroid function tests should be considered in children with a thyroid mass or suspected thyroglossal duct cyst. An ultrasound or a thyroid scan should be considered for the child with a thyroid mass.

Unless cat-scratch disease is very likely, immediate lymph node biopsy is indicated for enlarged supraclavicular nodes or lymph nodes in the lower half of the neck, rapidly progressive and enlarging nodes, fixed nodes, nodes deep within the fascia, or firm or hard nodes. Children who have a persistent fever or weight loss should have a biopsy at 1 week if a diagnosis has not been established. Asymptomatic children without an established diagnosis should have a biopsy at 2 weeks if the node increases in size, at 4 to 6 weeks if the node is not increased in size but is persistent, and at 8 to 12 weeks if the node has not regressed to a normal size. In some cases,

the initial biopsy is non-diagnostic but on subsequent biopsy a specific diagnosis may be made. Consequently, children with persistent adenopathy should be followed closely and be biopsied again if indicated. Fine-needle aspiration biopsy in children is controversial, but has some demonstrated benefits. It is being used more often to differentiate between benign and malignant disease and to potentially decrease the need for open biopsy. However, if malignancy is a consideration, consultation with an oncologist is advisable to determine the biopsy method of choice.

Imaging Studies

A chest radiograph should be obtained in all children with suspected tuberculosis or tumor (eg, enlarged supraclavicular nodes) as well as in children with crepitant neck masses or in those children in whom the diagnosis of the adenitis remains uncertain. If a foreign body in the neck is suspected, both anteroposterior and lateral neck radiographs should be obtained.

Almost all neck masses can be evaluated by ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI). Because there is no ionizing radiation associated with ultrasonography, it is quickly available, is noninvasive, and does not need sedation; it is considered by many to be the initial imaging study of choice, particularly for thyroid masses, thyroglossal duct cysts, branchial cleft cysts, and parotid masses. If malignancy is suspected or the mass cannot be delineated in the field of view, then MRI or CT may be more definitive studies. Ultrasonography with color Doppler is helpful in differentiating cystic from solid masses and determining if the mass is vascular. In addition, demonstration of a normal thyroid gland by ultrasound in patients with a thyroglossal duct cyst confirms a source of thyroid hormone. Consequently, a thyroid scan is not necessary.

Computed tomography and MRI scans provide better definition and extent of the mass. Computed tomography scan with contrast is the preferred method of imaging for deep neck abscesses that present with a neck mass and for enlarged salivary glands. Magnetic resonance imaging provides the best anatomical detail, and it is the preferred imaging study for children with vascular and lymphatic malformations and neoplasms; however, it is not as available as CT and often requires a greater degree of sedation.

Management

Neck masses are rarely acutely life-threatening. If neck masses impinge on the airway, children may experience stridor, hoarseness, drooling, increased

effort of breathing, unequal breath sounds, or evidence of shock. Resuscitation and stabilization should be initiated immediately. The algorithm in Figure 79-4 outlines the management of cervical lymphadenitis.

Children with lymphadenitis who do not appear toxic and have no evidence of sepsis may be treated empirically with **oral antibiotics** that cover *S aureus*, particularly methicillin-resistant *S aureus* (MRSA), and GABHS. Clindamycin or a combination of cephalexin

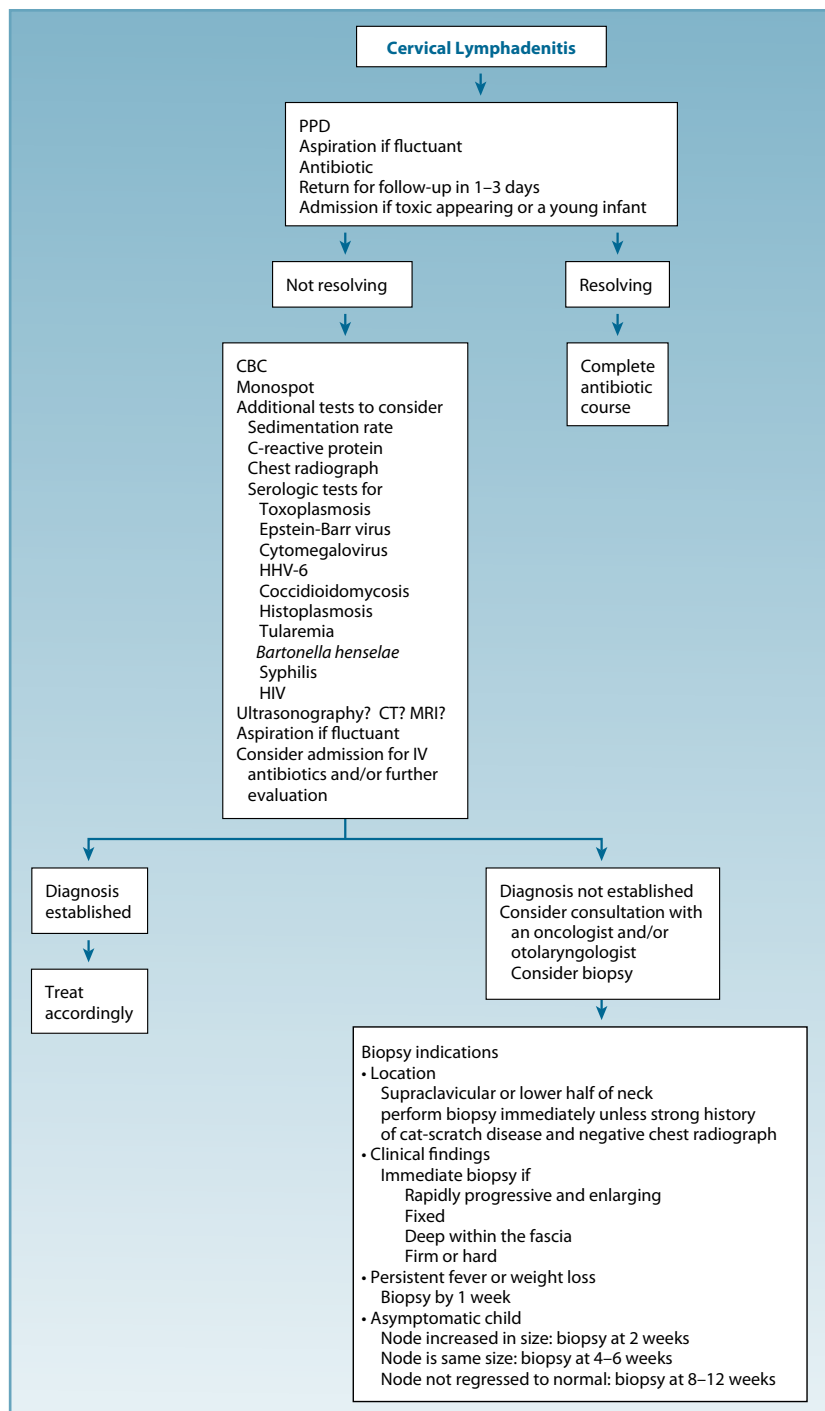

Figure 79-4. Management of cervical lymphadenitis. CBC, complete blood cell count; CT, computed tomography; HHV-6, human herpesvirus 6; HIV, human immunodeficiency virus; IV, intravenous; MRI, magnetic resonance imaging; PPD, purified protein derivative.

(administered until the culture from the lymph node, if available, for group A streptococcus is negative) and trimethoprim-sulfamethoxazole may be used to provide coverage for these organisms. If methicillin-susceptible *S aureus* (MSSA) is cultured and sensitivities are determined, a first-generation cephalosporin such as cephalexin (50 mg/kg/d, dicloxacillin (50 mg/kg/d), or amoxicillin/clavulanic acid (40 mg/kg/d [amoxicillin]) may provide satisfactory coverage. Treatment should be continued for a minimum of 10 days but for no less than 5 days after resolution of acute signs and symptoms. Lack of clinical improvement after 36 to 48 hours suggests that the diagnosis and proposed therapy need to be reevaluated.

Infants and small children, as well as those older children who do not respond to oral antibiotic therapy, may require admission for **intravenous antibiotics** such as clindamycin or vancomycin (especially for a potentially life-threatening infection) until culture results are available. If MSSA is cultured and sensitivities are determined, oxacillin or a cephalosporin may be satisfactory alternatives. Incision and drainage of large, fluctuant nodes that are clearly from bacterial disease should be done in consultation with an otolaryngologist or surgeon to promote resolution of the lymphadenitis. Alternatively, treatment by needle aspiration instead of incision and drainage has been advocated by some physicians. If *M tuberculosis*, atypical mycobacterial infection, or infection with *B henselae* is suspected, incision and drainage should not be done because persistent sinus tracts may result.

Atypical mycobacterial infection is generally unresponsive to treatment with antituberculous medications. **Surgical excision** of all visibly affected nodes, deep as well as superficial, is recommended. However, in cases where surgery is refused or is incomplete or disease is recurrent, macrolide monotherapy (clarithromycin or azithromycin) or a macrolide in combination with ethambutol or rifampin has been helpful in treating nontuberculous adenitis. Tuberculous mycobacterial adenitis usually responds to short-course medical therapy. Antituberculous medication for 6 to 9 months is recommended.

Lymphadenitis from cat-scratch disease usually resolves on its own. Antibiotic therapy is usually not indicated, but if children are severely ill or appear toxic with systemic cat-scratch disease, have hepatic or splenic involvement, are immunocompromised, develop meningoencephalitis, or are admitted for a suppurative adenitis, treatment with oral antibiotics such as azithromycin, rifampin, trimethoprim-sulfamethoxazole, or ciprofloxacin may be beneficial. If there is no improvement, the addition of parenteral gentamicin to the regimen may be considered. **Aspiration** is indicated to relieve symptoms in patients with fluctuant or painful suppurative nodes. Incision and drainage should not be done. Total removal of the node is sometimes necessary to effect a cure.

There is no specific therapy for lymphadenitis caused by *Toxoplasma gondii*. Excision of the affected node may be indicated if the diagnosis is questionable.

If a tumor is suspected, consultation with a pediatric oncologist is recommended. The mass should be biopsied for a definitive diag-

nosis. If it is malignant, a treatment plan should be generated with the appropriate consultants.

Congenital torticollis from fibrosis of the sternocleidomastoid muscle is best treated with nonoperative intervention. Repetitive passive range-of-motion exercises over several weeks usually result in loosening the tight muscle and increasing the range of motion.

Hemangiomas usually resolve by the time children are 9 years of age, and surgical intervention is rarely indicated. Recent literature has demonstrated a profound benefit with oral propranolol therapy in the management of hemangiomas. Oral propranolol therapy demonstrates a considerable flattening and effacement of both cutaneous and mucous membrane hemangiomas within 24 hours and marked improvement after weeks of propranolol therapy. While studies are still small and underpowered, recent evidence has supported a near 100% efficacy with oral propranolol for the treatment of life-threatening, vital-organ impairing (eg, vision loss), refractory, or disfiguring hemangiomas. Dosing is titrated up to 2mg/kg/day and continued for weeks until resolution of the hemangioma. Patients should be closely monitored for hypoglycemia, bradycardia, hypotension, and congestive heart failure during institution of therapy for adverse effects usually requiring consultation with a cardiologist and a short hospitalization. Corticosteroids, previously the mainline treatment modality for hemangiomas, are now considered an adjunctive treatment with propranolol. Additional therapies include interferon alfa-2a and various cytotoxic medications. Interferon alfa-2a has been associated with transient or permanent neurologic disabilities, so it is important to balance the benefits and risks of this medication.

Surgical excision is usually indicated for cystic hygromas (lymphangiomas), branchial cleft cysts, and thyroglossal duct cysts. A thyroid ultrasound should be performed before removal of a thyroglossal duct cyst to confirm that other thyroid tissue is not present. Endocrinologic consultation is recommended in these cases. Thyroid nodules in children may be cancerous, especially in children who have had irradiation to the head and neck region. Consultation with an endocrinologist and surgeon should be obtained. Goiters in children should be evaluated by an endocrinologist.

Prognosis

The prognosis for children with neck masses is generally excellent but differs depending on the cause. Children with an infectious etiology do very well if diagnosed and treated with appropriate antimicrobials. Mycobacterial lymphadenitis may result in sinus tract formation or disseminated disease. Surgical excision usually cures atypical mycobacterial infection. Cat-scratch disease is usually benign and self-limited. Encephalopathy is a rare complication of this disorder.

The prognosis for benign tumors of the neck is excellent. The outlook for children with malignant neck tumors depends on etiology of the tumor and the spread of the malignancy to other organs. Early diagnosis and treatment are clearly important in improving outcome.

Children with neck masses from trauma usually have had significant injury. The outcome often depends on establishment of an

airway, provision of ventilatory support, and management of hemodynamic instability. Availability of surgical support is often essential to a good outcome.

Children with congenital lesions of the neck usually have an excellent prognosis. Some lesions resolve spontaneously, while others require simple surgical excision. Cystic hygromas may require multiple operations for complete removal because of their diffuse nature.

CASE RESOLUTION

In the case presented, the boy has signs and symptoms consistent with submandibular bacterial cervical lymphadenitis. The location of the neck mass in relation to the honey-crusted lesions (non-bullous impetigo) implicates spread of bacteria from the primary site of infection to the lymph nodes. Laboratory tests are unnecessary because the child does not appear septic. Culture of the impetigo may be helpful in determining if the organism causing the infection is MRSA. If the affected lymph node is fluctuant, aspiration of fluid for culture is indicated and incision and drainage should be considered. The child should be treated as an outpatient with an oral antibiotic directed against MRSA and GABHS, such as clindamycin or a combination of cephalexin and trimethoprim-sulfamethoxazole, as well as an analgesic for pain as needed. If MSSA is cultured and sensitivities are determined, cephalexin, amoxicillin-clavulanate acid, or dicloxacillin may be administered. If the child appears toxic, or if there is marked lymph node enlargement, the child should be admitted for intravenous antibiotics. A PPD skin test should be placed. The child should be followed up in 1 to 3 days for clinical improvement depending on the severity of the infection.

Allergic Disease

Nasser Redjal, MD

CASE STUDY

A 3-year-old girl is rushed to the office by her mother after her daughter developed a pruritic rash, facial swelling, and hoarseness shortly after eating a peanut butter sandwich. Previously she has been well except for recurrent nasal congestion every spring that has responded to antihistamines. She has also had an intermittent skin rash that has been treated with topical steroid creams. She has never had an acute reaction before and has no history of asthma. Her father had asthma as a child.

Physical examination reveals a well-developed, 3-year-old girl with marked facial swelling and a **generalized rash** who is in mild respiratory distress. Vital signs, including blood pressure, are normal. Growth parameters are at the 50th percentile. The girl has a diffuse, blotchy,

erythematous rash with central wheals; a hoarse voice; and a mild expiratory wheeze on auscultation of her chest. The remainder of the examination is normal.

Questions

1. What are the various symptoms of allergic disease?
2. What is the appropriate evaluation of children with manifestations of allergic disease?
3. What allergens are common triggers for allergic symptoms?
4. What management is helpful in the treatment of children with manifestations of allergic disease?
5. Can allergic disease be prevented?

Allergic disease, which occurs frequently in the general population, is manifested in many ways. Asthma; atopic dermatitis; allergic rhinitis; allergic conjunctivitis; urticaria; angioedema; anaphylaxis; and food, insect, and drug allergies are all types of allergic diseases. Allergic symptoms result from the production of specific immunoglobulin E (IgE) antibody following exposure to a foreign antigen. The process has 2 steps. The first step is the sensitization or antibody induction stage. The individual develops IgE antibody against an inhaled, ingested, or injected substance. This newly formed IgE antibody adheres to circulating blood basophils or to tissue mast cells. The second step involves reexposure of a sensitized person to the allergen, which then binds to several specific IgE antibodies on the surface of immune cells. The release of inflammatory mediators causes the appearance of the characteristic features of allergic disease, which can range from rhinorrhea to sudden death. Similar non-IgE-mediated symptoms may occur, but these are not true allergic reactions. The reader should refer to Chapter 81 for details concerning asthma and Chapter 121 for a review of atopic dermatitis. This chapter focuses on the remaining manifestations of allergies, including food allergies.

Epidemiology

Allergic disease or some form of allergic symptoms is found in 12% to 20% of the general population. The prevalence of symptoms varies depending on the population being investigated. Factors such as age, genetic background, and place of residence are significant. Allergic rhinitis occurs in 10% of children, as does asthma. Up to 6% of chil-

dren younger than 3 years develop food allergies. Urticaria occurs at some time in about 10% to 20% of the population.

It is generally accepted that if neither parent is atopic (has the allergic tendency to manufacture IgE on antigen exposure), then the chance that children will develop allergic symptoms is less than 1 in 5. If one parent is atopic, the risk doubles. If both parents are atopic, the chance is greater than 3 in 5.

Clinical Presentation

Children with allergic disease frequently present with persistent, clear rhinorrhea; sneezing; postnasal drip; or injected pruritic conjunctiva. Skin manifestations include dry, scaling, erythematous rashes; wheals; or subcutaneous swelling (Dx Box). A recurrent cough or wheezing on chest examination is further evidence of allergic disease.

Pathophysiology

Allergic rhinitis, like all allergic manifestations, is caused primarily by an antigen-antibody reaction involving IgE. Antigen-specific IgE is produced by the B lymphocytes of allergic patients on exposure to a particular antigen, which attaches to immune cell receptors located on basophils in the circulation and mast cells in the tissue. On reexposure, the antigen reacts with this specific IgE on the mast cells, releasing vasoactive mediators including histamine, leukotrienes, kinins, and prostaglandins. These mediators produce vasodilation and edema, and they also stimulate neural reflexes to produce mucous hypersecretion and sneezing. Eosinophils, and

Dx Allergic Disease

- Chronic, clear rhinorrhea

- Conjunctival injection
- Wheezing
- Chronic cough
- Postnasal drip
- Repetitive sneezing
- Acute onset of symptoms following exposure to possible allergen

other inflammatory cells induced by chemotactic factors, enter the affected organ, releasing mediators, thereby worsening the inflammation and damaging tissues. Secretions and released tissue proteins worsen existing edema. Other immunologic mechanisms can also be involved.

Urticaria, the clinical rash produced by vasodilation and edema of the skin, is the allergic condition that occurs when histamine and other mediators such as prostaglandins and leukotrienes are released from the dermal mast cells. The antigen-specific IgE is located on these mast cells. Otherwise, the pathophysiology is similar to that of allergic rhinitis. Exposure to that antigen causes release of chemical mediators from the mast cells. Other mechanisms, including physical stimuli, can produce urticaria.

Angioedema is the extension of the urticarial process deeper into the dermis of the skin, producing circumscribed swelling. The mucous membranes may be affected. The pathophysiology is the same as for urticaria. A hereditary type of angioedema, which is not allergy related, is caused by the inherited deficiency of the C1 esterase inhibitor.

Anaphylaxis is an acute, systemic allergic reaction resulting from antigen-specific IgE on mast cells and basophils. The pathophysiology is similar to allergic rhinitis, but the reaction occurs in mast cells in many locations simultaneously, and prior sensitization to an allergen is essential. Anaphylactic reactions may be life-threatening. Vasodilation may be so severe that decreased venous return can lead to acute myocardial infarctions and arrhythmias. Reactions can occur in seconds or as late as 1 hour after exposure. Common antigens that precipitate anaphylactic reactions include injections of foreign serum, drugs, foods, and insect venom. Anaphylactoid reactions are clinically indistinguishable from anaphylaxis but are non-IgE-mediated, and include reactions to substances such as intravenous (IV) contrast media, opiates, and deferoxamine. The drug most frequently implicated in anaphylaxis is penicillin. Patients initially experience tightness and intense itching of the skin. Nausea, vomiting, and abdominal pain may ensue. Subsequently, the full spectrum of anaphylaxis appears.

A **food allergy** may produce any of the previously described allergic manifestations, including atopic dermatitis and asthma, as well as vomiting, diarrhea, and failure to thrive. Food intolerance, which has a non-immunologic pathogenesis, should be differentiated from food allergy, which is an IgE-mediated allergic reaction. The localization of the IgE-sensitized mast cells to that specific antigen determines the symptoms produced by the allergy. The antigen enters through the gastrointestinal (GI) mucosal barrier. Intact food proteins may enter the circulation, stimulating the production of antigen-specific IgE.

Major food allergens are usually glycoproteins (Box 80-1), but any food can be sensitizing. Sensitized GI mast cells release mediators, causing vomiting and diarrhea. As a result of the edema and vasodilation of the intestinal wall, the mucosa becomes more permeable to enteric antigens, resulting in more hypersensitivity and inflammation.

Differential Diagnosis

In evaluating children with possible allergic disease, other etiologies for the symptoms should be considered and explored. Allergic rhinitis is most often confused with an upper respiratory infection but may also resemble vasomotor rhinitis, nonallergic rhinitis with eosinophilia syndrome, cerebrospinal fluid rhinorrhea (usually associated with a basilar skull fracture), sinusitis, drug-induced rhinitis, cholinergic rhinitis (skier's/jogger's nose, gustatory rhinitis), or a nasal foreign body. Unlike allergic rhinitis, infectious etiologies of rhinitis result in inflammatory nasal mucosa and possible fever. Foreign bodies elicit a unilateral, purulent, often foul-smelling discharge. Vasomotor rhinitis is usually transient.

Urticaria can resemble insect bites, erythema multiforme, papular urticaria, mastocytosis, or contact dermatitis. Distinct features of urticaria include pruritus, raised erythematous lesions with pale centers and a transient nature, without any epidermal break. It may result from an allergic reaction to drugs, food and food additives, insect bites and stings, inhalant or systemic disease such as endocrine disease, collagen-vascular disease, malignancy, and vasculitis or may occur secondary to an infectious etiology. Parasitic, bacterial, fungal, and viral infections can all cause urticaria. Physical urticaria due to heat, vibration, pressure, ultraviolet light, exercise, or anxiety can also produce the reaction. In addition, a deficiency in factor I in the complement system may cause a genetic form of urticaria.

Anaphylaxis is usually associated with cutaneous, respiratory, cardiovascular, and systemic symptoms, such as skin rash, edema, wheezing, arrhythmia, occasionally fever, and shock. A history of an acute exposure is more likely to be seen with anaphylaxis.

Patients with food allergies may present with signs and symptoms of anaphylaxis or their symptoms may resemble those associated with food intolerances, which are nonallergenic. Food intolerances include toxic contamination (eg, scromboids), metabolic disorders (eg, lactose intolerance), and reactions to pharmacologic properties of the ingested food. Associated allergic findings (eg, asthma, atopic dermatitis) may be seen with true allergies. Specific testing of the food or stool, or allergy skin or blood testing, may be necessary to differentiate allergic reactions from food intolerance.

Evaluation: History and Physical Examination

Allergic Rhinitis and Conjunctivitis

Practitioners should determine if children with possible allergic rhinitis have a history of symptoms of sneezing, itching, nasal discharge, and nasal blockage. The eyes, ears, palate, and throat may itch. Children may also have a history of mouth breathing and snoring at night, sleep disturbances and daytime fatigue from nasal obstruction, or signs of complications such as sinusitis, postnasal drip, halitosis, cough, and morning sore throat. Symptoms may be seasonal or associated with a specific stimulus. In addition, systemic symptoms of fatigue, headache, anorexia, and irritability may be present.

The history should also include a search for other manifestations of allergies (eg, wheezing, atopic dermatitis) as well as a family history of atopy. An environmental history of allergen exposure, including pets, is also important to obtain.

The physical examination should be thorough. The skin should be inspected for atopic dermatitis and the lungs for evidence of asthma. The nasal mucosa should be examined with an otoscope. In children with allergic rhinitis, the nasal mucosa is swollen, pale, and sometimes cyanotic with copious clear discharge. Nasal polyps, if present,

should be noted. Although polyps are most often present on an allergic basis, they may occur with cystic fibrosis. A transverse crease across the nose (“allergic creases”) can occur from repeatedly using the palm of the hand in an upward thrust on the nares to relieve itching and open the nasal airway (“allergic salute”). Dark circles under the eyes (“allergic shiners”) may be present from chronic periorbital edema and venous stasis. Dennie sign (also called Morgan line), a wrinkle just beneath the lower eyelids, is present from early infancy and is associated with atopic dermatitis and allergic rhinitis. Allergic gape or adenoid facies is secondary to chronic mouth breathing during the first several years of life and results in a characteristic pattern of maldevelopment of facial bones, causing a high-arched palate, flat maxilla, and angulated mandible with a recessed chin and dental malocclusion. If affected, the conjunctivae are erythematous with a clear discharge and may have a follicular appearance. The mouth may reveal a high-arched palate from chronic mouth breathing, and hypertrophic lymphoid follicles in the oropharynx often can be seen (Figure 80-1).

Complications of chronic allergic rhinitis may be evident on examination. If children have one of these conditions, such as chronic serous otitis, recurrent otitis media, hearing loss secondary to otitis, sinusitis, nasal polyps, sleep apnea, or dental malocclusion, the possibility of allergic disease as a cause should be explored.

Urticaria and Angioedema

When children present with an acute rash, questions should focus on recent exposures to drugs, dietary changes, new soaps or detergents, and environmental agents. An urticarial rash is acute in onset, extremely pruritic, and typically evanescent. Evidence of infection and a history of chronic disease or any other allergic disease should be explored. The rash should be evaluated carefully. An urticarial rash appears as erythematous lesions of various sizes with pale,

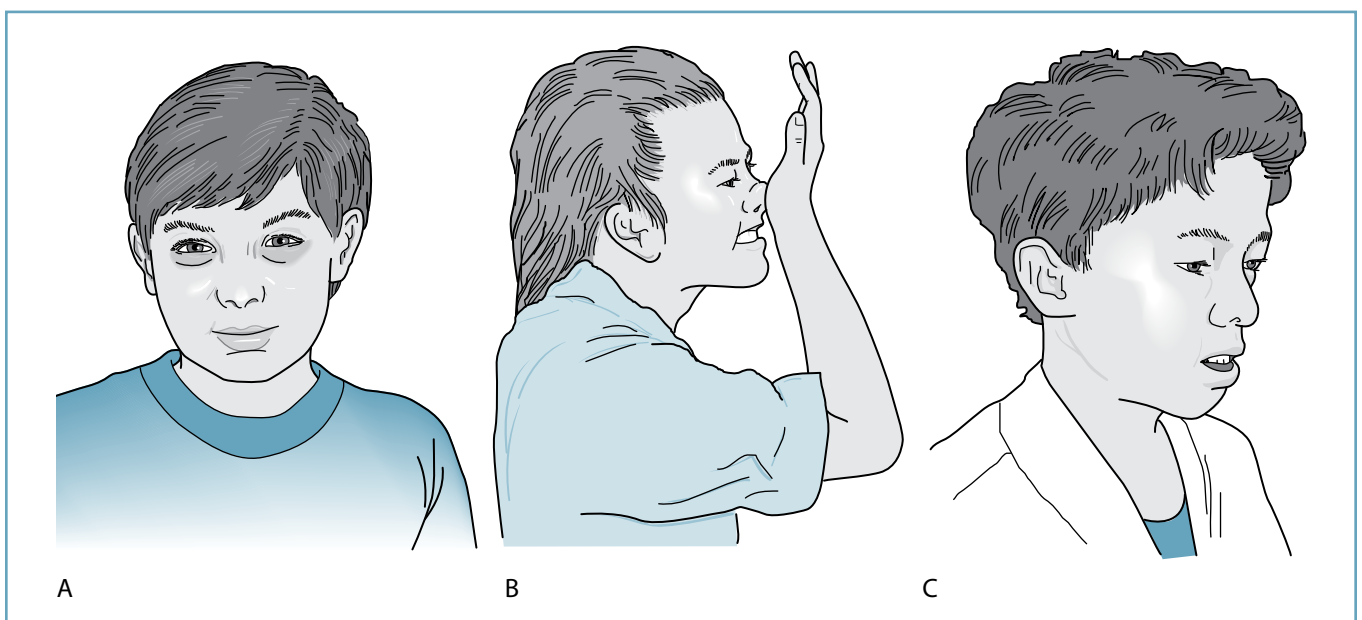

Figure 80-1. Characteristic facial features in children with allergic diseases. A. Allergic shiner. B. Allergic salute. C. Adenoid facies.

popular centers. Lesions may coalesce, the rash blanches on pressure, and the skin is intact.

The physical examination should also assess whether other contributing problems, such as infection, are present.

Anaphylaxis

An acute exposure to a foreign antigen (eg, medication, food, venom) should be elicited in the history of any patient who presents with anaphylaxis.

On physical examination, vital signs indicate hypotension and tachycardia. The skin is erythematous with diffuse edema. Airway edema may produce hoarseness with stridor and wheezing noted on auscultation of the chest. Patients may have severe difficulty breathing. Cardiac examination may reveal arrhythmias.

Food Allergies

An accurate diet diary is essential in diagnosing a food allergy. The timing of symptoms associated with a specific food must be obtained. Personal as well as family history of atopy is important. Allergy skin testing or an allergy blood testing and elimination diet followed by a challenge helps the diagnostic evaluation. The double-blind, placebo-controlled food challenge is the most accurate assessment for diagnosis.

Evaluation

Laboratory Tests

With allergic rhinitis, as with any allergic disease, the diagnosis can usually be made with a thorough history and physical examination. Frequently, therapy can be initiated with no laboratory data.

Screening tests may include a nasal smear for eosinophils. A result of greater than 10% eosinophils is considered confirmatory data for allergic rhinitis. Although serum IgE levels are elevated in 60% of patients with allergic rhinitis and asthma, they are not sensitive or specific and have limited value. A multi-allergen screening test, which gives reliable results when checking for the presence of allergic disease, is currently available.

Skin testing for specific antigens should be performed if desensitization shots or environmental changes are being considered in the management plan. Skin tests are sensitive and accurate. Positive tests indicate the presence of an antigen-specific IgE. Prick tests are used initially. They may be followed by intradermal tests for allergens that are negative on prick testing. Although skin testing may be less reliable in infants because their skin is less reactive, the tests have been performed in children as young as 4 months.

Radioallergosorbent testing (RAST) of sera, which is also available for the laboratory assessment of allergies, provides a semiquantitative measure of the amount of IgE specific for individual allergens. RAST is much more expensive than skin testing and has no advantage unless skin testing cannot be performed, such as in patients with a history of anaphylaxis, poor skin reactivity, current antihistamine use, or dermatographia.

Objective testing with skin tests by the prick method may be helpful in diagnosing food allergies. Negative tests are accurate for excluding food allergies, but positive tests may occur in patients without symptoms related to a particular food. Intradermal skin tests are not indicated. They do not give additional information, and they increase the risk of a serious reaction. RAST of sera may be used for specific foods.

Management

The first line of therapy for all allergic diseases is **avoidance of any precipitants**. For allergic rhinitis, this begins with environmental control, because the most frequent precipitants are inhalant allergens. Reducing exposure to the dust mite, a common allergen, can help control allergic rhinitis. Environmental humidity, which increases the dust mite population, should be decreased. Specifically, parents should be instructed to remove carpets, drapes, and upholstered furniture, which can harbor dust mites, from the house. They should cover mattresses with plastic covers and remove furry pets. Decreasing humidity also helps reduce mold counts, another important allergen, and air-conditioning units with a HEPA filter can lower pollen and mold counts as well. Nonspecific irritants such as smoke should be avoided because they can also precipitate any allergic symptom.

Anaphylaxis is considered a **medical emergency**. The first step in management is to establish an airway. Oxygen therapy should be instituted, and IV access established. Epinephrine is the drug of choice because of its potent vasoconstrictive and myocardial stimulating effects. The dose is 0.01 mL/kg of 1:1,000 aqueous solution, up to 0.5 mL, given subcutaneously. If the blood pressure is decreased, epinephrine may be given intravenously, with normal saline fluid boluses to expand intravascular volume. Intravenous administration of an antihistamine, such as diphenhydramine (5 mg/kg/24 hours) is used as well as a steroid, such as methylprednisolone (2 mg/kg).

The management of urticaria should begin with the **identification of the causal agent** and its elimination. Children who have experienced anaphylaxis should be instructed to avoid future exposure to the precipitating allergen. In addition, they should be instructed to wear a medical alert tag that notifies others of the potential for a severe allergic reaction and carry an epinephrine kit for immediate treatment.

A maintenance diet that does not contain the allergen is the basis for management of food allergies. It is essential that the prescribed diet be nutritionally sound. Families should be instructed by a nutritionist and taught to read food labels appropriately to avoid all exposure to the antigen. They should also be advised about what foods children can consume.

Medications should be used in allergic disease when additional management is indicated by persistent symptoms. Histamine H1 receptor antagonists or **antihistamines** are frequently indicated in the treatment of allergic rhinitis. Diphenhydramine, chlorpheniramine, and brompheniramine have all been useful in relieving symptoms but may be very sedating. The newer antagonists, desloratadine,

fexofenadine, cetirizine, and loratadine, do not readily cross the blood-brain barrier and are less sedating. Leukotriene inhibitors, such as montelukast as monotherapy or in combination with an antihistamine, provide effective symptom relief. Oral decongestants have been effective in decreasing nasal congestion. Pseudoephedrine has been used in children. Topical nasal decongestants, which can cause dependence and rebound swelling, should not be used on a long-term basis.

Antihistamines are also used in the symptomatic treatment of urticaria and angioedema. These agents can relieve the rash as well as the itching of the rash. Diphenhydramine (5 mg/kg/d in 4 doses) and hydroxyzine (2 mg/kg/d in 4 doses) are both used. If the urticaria is extensive or severe, epinephrine or Sus-Phrine (epinephrine in oil) may be used subcutaneously. This often provides immediate relief of symptoms and is diagnostic as well as therapeutic.

Cromolyn sodium nasal spray is the next line of treatment for allergic rhinitis in children older than 6 years. A very effective mast cell stabilizer, it suppresses mediator release. Cromolyn spray should be used prophylactically on a regular basis 2 to 4 times per day, one spray per nostril, to prevent symptoms.

Steroids have an anti-inflammatory effect and work well topically for allergic rhinitis. Mometasone, triamcinolone, and flunisolide are available as nasal sprays, and all 3 agents may cause stinging and nasal irritation. Topical antihistamines and mast cell stabilizer, such as azelastine or olopatadine nasal sprays alone or in combination with nasal steroid, are effective. Systemic steroids may also be used for treatment of urticaria, angioedema, and anaphylaxis.

Immunotherapy should be considered for children with allergic rhinitis when avoidance techniques and medications are not controlling symptoms or when there is a history of anaphylaxis, depending on the allergen. This treatment has been effective in relieving symptoms due to dust mites, pollens, animal dander, molds, insect stings, and drug reactions. Immunotherapy involves a series of injections with extracts of allergens specific for individual patients, producing tolerance to particular antigens. The mechanism of action of immunotherapy is related to the development of allergen-specific blocking antibody (IgG), increased allergen-specific suppressor T cells, decreased lymphocyte cytokine response to an allergen, and decreased basophil histamine release in response to an allergen. The results of skin testing dictate which allergens to use. Initially, injections are given weekly. Then they are tapered and given on a maintenance schedule. Although immunotherapy can be performed at any age, the injections are painful and expensive. They necessitate frequent visits. Patients risk an allergic reaction with each injection.

Prevention

The cost of medical care, lost school days and workdays, disability from complications, and actual lives lost from allergic disease take a great toll on the population. Evidence currently suggests that sensitization to foods is more likely to occur in the first 6 to 12 months of life. Avoidance of these allergens at this age may decrease the

subsequent development of allergic disease. For children at high risk for the development of allergic disease, which is usually determined by family history, the following steps are recommended:

- Keep the home free of allergens such as dust mites, pollen, etc.
- Keep humidity below 50% in the home to prevent mold and dust mite growth.
- Prevent smoking in the environment.

To reduce the incidence of food allergies, it is recommended that mothers breastfeed infants exclusively for at least the first 6 months of life. When infants are 6 months old, foods can gradually be introduced. Cow's milk, wheat, corn, and citrus should be avoided until after the age of 1 year. Peanuts, eggs, fish, and shellfish should be delayed until 24 months. Postponing the introduction of food allergens may reduce the rate of sensitization in high-risk infants, but this is a controversial issue. Studies have demonstrated that such postponement may only delay the sensitization, though a recent study showed that early food allergen exposure, rather than avoidance, might improve allergic outcome.

Prognosis

The prognosis for children with allergic disease is good when the diagnosis is made correctly. Some patients lose their allergy naturally or following immunotherapy. For others, allergic rhinitis, urticaria, and anaphylactic reactions persist throughout life on exposure to antigens. However, with appropriate management with medication and avoidance of allergens, children with allergic disease can thrive and live a normal life without restrictions on activity. Immunotherapy can be effective in alleviating the allergic response to inhalants in allergic rhinitis and to insect venoms. The chance for resolution of food allergies is very good. Many foods that initially elicit an allergenic reaction can be tolerated after the age of 3 to 4 years; 85% of children with cow's milk, egg, wheat, or soy allergy will experience remission by 5 years, presumably as a result of maturation of the GI mucosa. However, only 20% of young children outgrow peanut allergy.

CASE RESOLUTION

In the case presented at the beginning of the chapter, the girl's symptoms of rash, swelling, and wheezing after exposure to an antigen suggest a systemic allergic reaction with angioedema and asthma. Treatment with epinephrine and antihistamines is clearly indicated. Because of the presence of pulmonary symptoms, admission for observation is warranted. The child and family should be counseled to avoid any foods that contain peanuts in the future. The parents should read all food labels, and carry an epinephrine autoinjector (Epi-pen) at all times for emergency use. The patient should wear a medical alert bracelet indicating peanut allergy. The patient should be referred to an allergist for further evaluation.

Wheezing and Asthma

Nasser Redjal, MD

CASE STUDY

A 7-year-old boy is referred to the office after being seen in the emergency department (ED) for wheezing. He has been treated in the ED for wheezing 4 times in the past month and was once hospitalized for 3 days. The boy's father and paternal grandmother both have asthma.

The child's physical examination is remarkable for end-expiratory wheezing on forced expiration.

Questions

1. What are the most common causes of wheezing in infants and children?
2. What are the causes of reversible bronchospasm?
3. What is the pathophysiology of reversible bronchospasm?
4. How should children with asthma be managed?

Recurrent wheezing is a frequent symptom of obstructive airway disease in children that may be caused by intrinsic or extrinsic compression of the airway, bronchospasm, inflammation, or defective clearance of secretions. Ten percent to 15% of infants wheeze during their first year of life, and as many as 25% of children younger than 5 years present to their clinicians with wheezing during a respiratory illness. Most infants and young children with recurrent wheezing have asthma; however, a wide variety of congenital and acquired conditions can cause narrowing of the extrathoracic or intrathoracic airways, and may present with wheezing. Reactive airways disease is the most common cause of wheezing in childhood. Childhood asthma typically falls into 1 of 3 categories. **Transient wheezers** are infants who wheeze when ill with lower respiratory tract infections but experience no further wheezing after age 3 years. More than 80% of infants with a history of wheezing in their first 12 months fall into this category. **Nonatopic wheezers** are children with somewhat more reactive airways, a history of previous respiratory syncytial virus (RSV) infections, and persistent wheezing beyond 3 years of age, but symptoms may still resolve over time. **Atopic wheezers** are those children who are most likely to develop persistent asthma.

Wheezes can originate from airways of any size, from the large extrathoracic upper airway to the intrathoracic small airways. In addition to narrowing or compression of the airway, wheezing requires sufficient airflow to generate airway oscillation and produce sound. Thus the absence of wheezing in a patient who presents with acute asthma may be an ominous finding, suggesting impending respiratory failure. The audible "musical or squeaking sounds" noted with obstruction are caused by turbulence of the air as it is forced through a narrowed airway. Infants and young children are more prone to wheezing when they have airway obstruction because air forced through smaller airways is more turbulent than air forced through the larger airways of older children and adults. Infection-induced wheezing in children younger than 2 years is

associated with RSV, especially in infants with passive exposure to smoke, and with rhinovirus in children older than 2 years. The most common causes of wheezing in infants and children are asthma, bronchiolitis, and pneumonia. Less common causes include congenital structural anomalies, gastroesophageal reflux and aspiration, cardiac failure, cystic fibrosis, foreign bodies, and vocal cord dysfunction (Box 81-1).

The Modified Asthma Predictive Index (API) is a clinical instrument to predict persistence of asthma. Predictive factors include wheezing before 3 years of age and the presence of one major risk factor (parental history of asthma, a personal history of atopic dermatitis, or patient sensitized to aero-allergen) or 2 of 3 minor risk factors (patient sensitized to food, wheezing apart from colds, and/or eosinophilia). The API has a positive predictive value of 76% and a negative predictive value of 95%. More than 80% of infants who have a history of wheezing in the first postnatal years do not wheeze after 3 years of age.

Asthma is a common chronic disorder of the airways characterized by variable and recurring symptoms, airflow obstruction, bronchial hyperresponsiveness, and underlying inflammation. Bronchospasm is reversible either spontaneously or with treatment. In some patients permanent alterations in the airway structure, referred to as **airway remodeling**, develops and is not prevented by, or fully responsive to, currently available treatment. Clinically asthma is characterized by recurrent episodes of cough, chest tightness, dyspnea, prolonged expiration, wheezing, hyperinflation of the chest (air trappings), use of accessory chest muscles (retractions) and, in severe cases, cyanosis.

Epidemiology

Asthma is the most common chronic childhood illness. In 2007 the National Health Interview Survey noted that 9% of children 0 to 17 years of age (6.7 million) had asthma. Asthma is the leading cause

of ED visits, hospital admissions, and school absenteeism. Over the last several decades, the prevalence of asthma has increased worldwide, an increase that varies from 40% in some areas of the United Kingdom and Australia to 3% in Indonesia, China, and India. Asthma prevalence, mortality, and hospitalization rates are higher in blacks than in whites. One-third of patients initially experience symptoms in the first year of life, and 80% are diagnosed by the time they reach school age. In the United States, asthma is a leading diagnosis for children admitted to children's hospitals. Hospitalization rates have

remained relatively stable, with lower rates in some age groups but higher rates in children 0 to 4 years of age. In addition, asthma is a major cause of school absence; 23% of school days missed can be attributed to asthma. The male-female ratio is 2:1 until age 10 and is equal from ages 10 to 14; after puberty, asthma incidence is greater in girls and women.

In recent years, the incidence of more serious disease in younger children and adolescents has increased. Low socioeconomic status is associated with an increase in asthma prevalence, morbidity, and mortality. Inner-city African Americans are most at risk but studies suggest that socioeconomic class and health care disparities only partially account for these differences.

Clinical Presentation

Children with asthma may present with acute symptoms of cough, shortness of breath, prolonged expiration, use of accessory muscles of respiration, wheezing, complaints of chest tightness or congestion, hyperinflation of the chest, cyanosis, exercise intolerance, tachycardia, and abdominal pain.

Wheezing may be audible and detected by the parent or may not be appreciated until the child is examined by a physician. There may be no wheezing in children with severe bronchoconstriction because the flow of air is impeded, but wheezing may appear after bronchodilator treatment, owing to partial opening of the airway.

Some children have cough, which may be nocturnal or recurrent as a predominant symptom. Some pediatric patients have symptoms such as cough or wheezing that are precipitated or exacerbated by exercise (Dx Box).

Dx Asthma

- Recurrent wheezing
- Shortness of breath
- Exercise intolerance
- History of allergies
- History of atopic dermatitis
- Nasal polyps
- History of nighttime cough

Abdominal pain and vomiting also are common in younger children and may be followed by temporary relief of respiratory symptoms. During an acute asthma attack, a low-grade fever, profuse sweating, and fatigue from the hard work of breathing may be apparent.

Pathophysiology

Asthma is a chronic inflammatory disorder of the airways. The immunohistopathologic features of asthma includes alteration and denudation of the airway epithelium, thickening of the basement membrane, fibrotic changes in the sub-basement membrane, bronchial smooth muscle hypertrophy, edema and angiogenesis, mast cell activation, and inflammatory cell infiltration (neutrophils, lymphocytes,

eosinophils), which release mediators such as histamine, prostaglandin, leukotriene, major basic proteins, etc. These changes lead to airway hyperresponsiveness, airflow limitation, respiratory symptoms, and disease chronicity. The limitation to the flow of air results from acute bronchoconstriction, airway edema, mucus plug formation, and airway wall remodeling. The unique anatomy and physiology of the lung in infants compared with adults predisposes infants to obstructive airways disease. These anatomical differences include reduced number and size of the pores of Cohn and Lambert canals, causing deficient collateral ventilation and a predisposition to atelectasis distal to obstructed airway. Mucous gland hyperplasia favors increased intraluminal mucus production. Decreased smooth muscle in the peripheral airway results in less support and narrower airways. Decreased number of fatigue-resistant skeletal muscle fibers in the diaphragm, its horizontal insertion to the rib cage (versus oblique in adult), and a highly compliant rib cage increase the work of breathing in children. Decreased static elastic recoil predisposes to early airway closure during tidal breathing, resulting in mismatching of ventilation and perfusion and hypoxemia.

Atopy, the genetic predisposition to the development of immunoglobulin (Ig) E-mediated response to common aeroallergens, is a predisposing factor for developing asthma. There are at least 50 genes that influence susceptibility to asthma and its clinical expression. Sites located on chromosomes 6p, 12q, 5q, 11q, and 16p are known to be associated with allergic diseases and encoding for major histocompatibility complex, IgE, interferon, and cytokine.

Environmental changes such as wind; temperature fluctuations; and increased exposure to allergens or air pollutants, such as tobacco smoke, ozone, sulfur dioxide, and nitrogen dioxide, and particulate matter, such as diesel exhaust and biologic residues (eg, endotoxin), may precipitate clinical attacks. Inhalant allergens, particularly indoors, play an important role. The most important allergens are house dust mite feces (Der p1 and Der p2), cat dander (Feld 1), and cockroach saliva (Bla g2, Bla g4, and Bla g5). Other inhalant allergens, such as dog dander, and outdoor fungus (ie, *Alternaria*), and some pollens, also play a role. Infections, particularly respiratory ones, are implicated, influencing not only asthma's exacerbation, but also its inception and persistence. Viral infections, such as RSV, parainfluenza, and rhinovirus, are the most frequent precipitants of asthma exacerbations in infancy. The frequency of lower tract respiratory infection during early childhood with these viruses is a strong independent factor in development of asthma. *Mycoplasma* and *Chlamydia* infections can cause wheezing and persistence of asthma. Emotional stress may also play a role in the exacerbation of asthma.

The physiological changes involved in asthma occur in 2 phases. An immediate response ("early phase") to the offending agent causes edema and bronchial smooth muscle constriction that lead to narrowing of the airway and plugging with secretions. Air is trapped behind the narrowed airways, resulting in altered gas exchange, increased respiratory rate, decreased tidal volume, and increased work of breathing. The late response, which occurs 4 to 12 hours after the initial symptoms, primarily involves infiltration of the airways

with inflammatory cells. The end pathway in the disease process is obstruction to airflow. The pathophysiology of asthma is reviewed in Figure 81-1.

Differential Diagnosis

An extensive differential diagnosis is listed in Box 81-1. Most conditions are differentiated from asthma by the presence of associated symptoms or the child's response to bronchodilators.

Evaluation

History

A thorough history including how the child and family are coping with the asthma should be obtained (Questions Box). If acute respiratory distress is present, an abbreviated history focusing on potential precipitating factors and medication use should be obtained first and the more detailed history gotten at a later time.

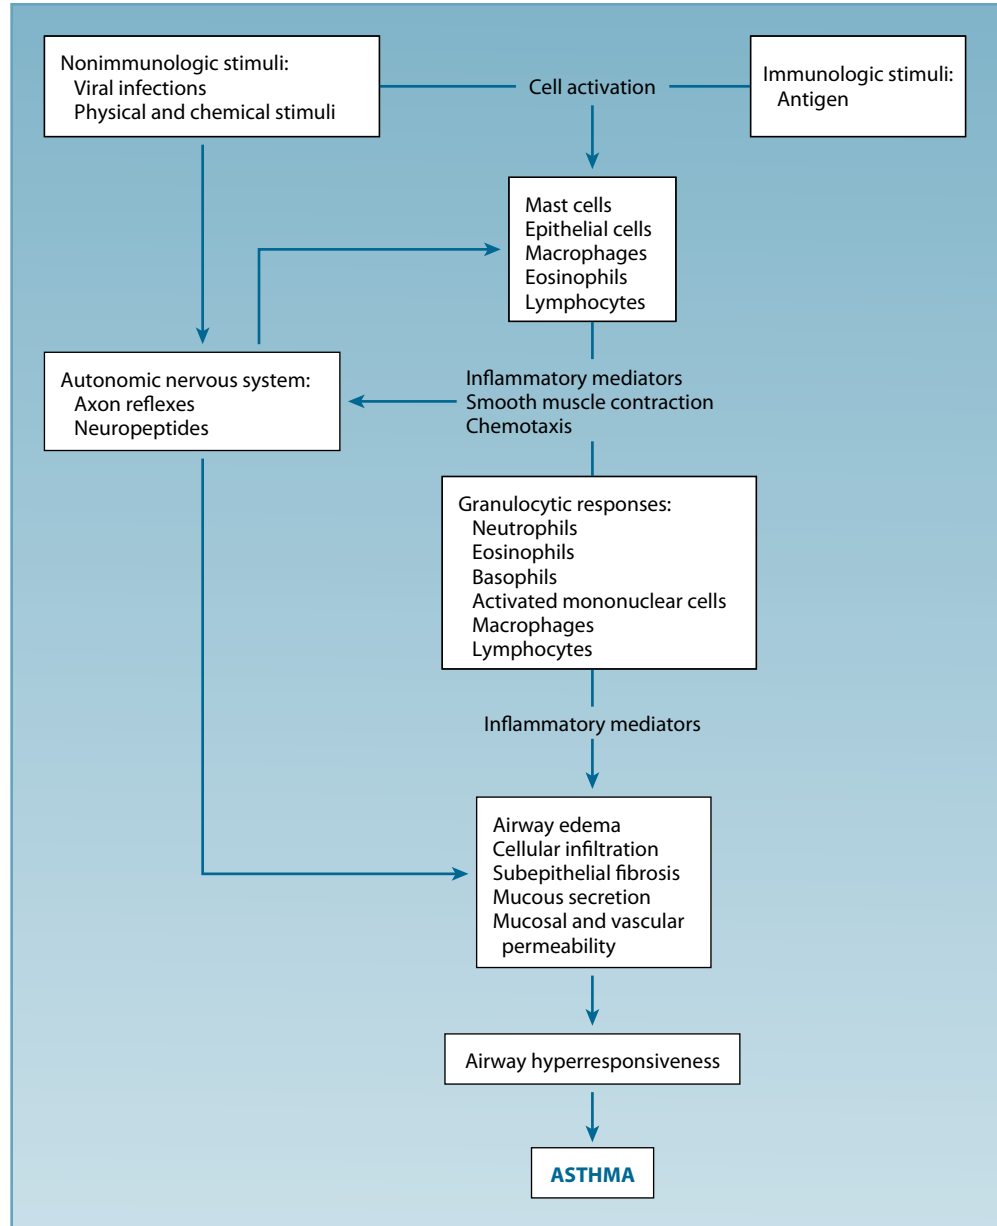

Physical Examination

Vital signs including pulse oximetry should be obtained. Objective determination of pulmonary function involves measuring the peak expiratory effort. Pulsus paradoxus, the difference between systolic arterial blood pressure during inspiration and expiration, is usually under 10 mm Hg. This difference may be increased during an acute asthma exacerbation, but the measurement is difficult in young children. Breath sounds, work of breathing, the inspiratory-expiratory ratio, use of accessory muscles, presence of retractions, quality of breath sounds (whether decreased), presence of prolonged expiration, and quality of wheezing should be carefully assessed (Table 81-1). Polyphonic wheezing (many different pitches, starting and stopping at varying points in the respiratory cycle) and cough are highly suggestive of asthma. Monophonic wheezing (a single, distinct noise of one pitch and starting and stopping at one discrete time) and cough should always raise suspicion of large airway obstruction caused by foreign body aspiration, vascular ring, or tracheomalacia. The nose and associated nasal passages should be examined for secretions, edema, pallor, and polyps. The skin should be assessed for eczema and other rashes. The chest should be carefully checked for increased anteroposterior diameter of the chest wall, a sign of air trapping. Fingers should be examined for signs of digital clubbing, which suggests a diagnosis other than asthma.

Laboratory Tests

The laboratory assessment of wheezing children is indicated if the diagnosis is unclear or to eliminate disorders that mimic asthma. Pulmonary function tests are noninvasive, objective, and cost-effective in the diagnosis and follow-up of patients with asthma. These tests can be performed in children older than 5 years with appropriate coaching. After the administration of an aerosolized bronchodilator, dynamic tests of airflow increase or return to normal. An improvement in forced expiratory volume in 1 second (FEV₁) greater than

Figure 81-1. Proposed pathways in the pathogenesis of bronchial inflammation and airway hyperresponsiveness. (Reproduced from the National Heart, Lung, and Blood Institute. *National Asthma Education Program Expert Panel Report: Guidelines for Diagnosis and Management of Asthma*. Bethesda, MD: National Institutes of Health; National Heart, Lung, and Blood Institute; 1991. NIH Publication No. 91-3042.)

12% is virtually diagnostic, but lack of improvement in FEV₁ does not preclude asthma. Exercise tolerance tests using a treadmill or free running followed by pulmonary function tests can be performed; a decrease greater than 12% in FEV₁ or 30% in forced expiratory flow is diagnostic of exercise-induced asthma. Peak flow meters, which measure forced peak expiratory flow (PEF), are useful in the office and at home to monitor expiratory flow rate. A decrease in PEF may predict the onset of an exacerbation and suggests the need for early intervention, using additional drug therapy. A complete blood cell count with a differential count may suggest infection or allergies. Peripheral eosinophil counts may be elevated in asthma. Pulse oximetry assesses the degree of oxygen saturation.

Sputum smear, stained with eosin-methylene blue, may show numerous eosinophils and granules from disrupted white blood cells, eosinophils, and epithelial cells. The presence of more than 5% to 10% eosinophils suggests allergic inflammatory disease. Other findings in the sputum include Curschmann spirals, which are threads

of glycoprotein; Creola bodies, which are clusters of epithelial cells; and Charcot-Leyden crystals, which are derived from eosinophils.

Total serum IgE is not as helpful as antigen-specific IgE, and is elevated in 80% of children with allergen-induced asthma. Allergy skin testing or serologic testing, such as radioallergosorbent testing, is indicated to identify potentially important environmental allergens. Allergens may play a significant role in asthma, and 85% of asthma patients have a positive skin test reaction to common aeroallergens. Extensive laboratory testing should be reserved for children with severe disease who may benefit from consultation with an allergy specialist.

Imaging Studies

Children suspected of having asthma rarely require a chest radiograph unless there is concern about other pathology. radiograph findings may range from normal to hyperinflation, increased bronchial

Asthma

Questions

- What symptoms (eg, wheezing, exercise intolerance) does the child experience?
- Does the child experience any nocturnal awakening or cough?
- What time of day and year do the symptoms occur?
- When did the symptoms begin? How old was the child?
- Are the symptoms associated with any particular activity? Does anything seem to trigger the symptoms?
- Are the child's activities limited in any way?
- How often do the asthma attacks occur?
- What is the child's living situation? Are there pets in the home?
- Does anyone smoke in the home?
- Do the asthma attacks cause the child to be absent from school?
- Does the child manage the condition at home with any particular treatments or medications?
- Has the child visited any urgent care and emergency departments for treatment for asthma or related episodes in the past? Has the child had any hospitalizations?
- Does the child have a history of allergies?

marking, and atelectasis, especially during acute exacerbation. Infiltration, pneumothorax, pneumomediastinum, and pneumonia are less common findings.

Management

The long-term goals of asthma therapy are as follows:

- Prevent chronic and disabling symptoms (eg, coughing, sleep disturbances, exercise intolerance, shortness of breath).
- Maintain normal or near-normal pulmonary function.
- Maintain normal activity levels.
- Prevent recurrent exacerbations and minimize the need for ED visits and admission to the hospital.
- Provide drug therapy that is effective with minimal side effects.
- Meet the expectations of the child and the family for the care of asthma.
- Encourage self-management of asthma.

Assessment measures for asthma should include monitoring of the following: signs and symptoms, pulmonary function through peak flow or respirometry, quality of life/functional status, acute disease exacerbations, pharmacologic therapy, and satisfaction of the child and family with their asthma care.

Selecting the appropriate therapy for an asthma patient depends on the age, disease severity, and developmental level of the child; the tolerance for a specific pharmacologic agent; and the routes of administration. The pharmacologic treatment for symptom control and reduction of inflammation is predicated on the severity of the asthma, as categorized, according to National Heart, Lung, and Blood Institute (NHLBI) guidelines. Box 81-2 contains an overview of these medications. Quick-relief medications ("rescue meds") are used for acute exacerbations and the long-term control medications for chronic therapy. Non-pharmacologic measures aim at prevention and serve as an adjunct to drug therapy.

Table 81-1. Parameters Used to Estimate the Severity of Acute Asthma

<i>Sign/Symptom</i>	<i>Mild</i>	<i>Moderate</i>	<i>Severe</i>
Respiratory rate	Normal	Increased	Increased >2 SD
Breath sounds	Normal (some end-expiratory wheezes)	Wheezing in inspiration and expiration	Decreased \pm wheezing
Shortness of breath	None (can speak in sentences)	Can speak in phrases	Speaks only single words
Skin color	Normal (pink)	Pale	Pale to cyanotic
Work of breathing	Normal	Moderate retractions; some use of accessory muscles	Severe retractions, nasal flaring, use of accessory muscles
Pulse	Normal	Normal or increased	Increased
Level of consciousness	Normal	Normal	Diminished; may be lethargic or combative
Pulsus paradoxus	<10 mm Hg	10–20 mm Hg	20–40 mm Hg
Oxygen saturation	>95%	90%–95%	<92%
Pulmonary function	80% of predicted	50%–70% of predicted	<50% of predicted

Abbreviation: SD, standard deviation.

Short-term Management

Acute attacks can be managed in the office if the staff is prepared to deal with children in respiratory distress. Otherwise children can be referred to the ED. Equipment and supplies for resuscitation of infants and children must be available in offices that care for children with asthma.

The goal of therapy is to relieve airflow obstruction and prevent respiratory failure. All children with moderate or severe asthma should be placed in a position of comfort and given oxygen by nasal prongs or mask as tolerated. Assessment of work of breathing and the use of pulse oximetry help guide oxygen therapy. Nebulized β_2 -agonists such as albuterol are used until symptoms subside. Children may require drug therapy every 20 to 30 minutes. Not only are nebulized β_2 -adrenergic agonists more effective than oral medications, they are associated with fewer side effects. Ipratropium bromide used in conjunction with a β -agonist in the urgent care setting has been shown to reduce risk of hospitalization. Systemic corticosteroids, which help reduce the inflammation associated with clinical attacks, are indicated in most moderate and severe cases. Response to therapy is determined by clinical assessment of work of breathing, respiratory rate, objective changes in pulmonary function, and pulse oximetry. Children with incomplete responses to initial therapy may require several hours of treatment or hospitalization.

Long-term Management

The goals of long-term management are shown in Box 81-3.

Continuous and longitudinal primary care of children with asthma can profoundly affect the course of their disease. Primary care practitioners, children, and their families must work together to achieve good control of symptoms. Prevention of exacerbations may be accomplished by removal of offending allergens. Minimization of exposure to known allergens and irritants has been shown to decrease symptoms and exacerbation. The most commonly implicated irritants are tobacco smoke; fumes from gas, oil, and kerosene stoves and wood-burning appliances; and sprays and strong odors. House dust mites are microscopic insects that feed on human scales, require humidity greater than 50%, and are found in stuffed furniture, carpets, and mattresses. House dust mite infestation can be reduced by encasing mattresses, blankets, and pillows in mite-proof covers; removing carpeting; and decreasing humidity to less than 50%.

Allergen immunotherapy may be considered for asthma patients when there is evidence of a clear relationship between symptom and exposure to an allergen, and symptoms are poorly controlled with pharmacologic management (medication ineffective, multiple medications are required, or patient does not accept or tolerate medication). Adherence with appropriate medications and in-home peak-flow measurement helps in prevention and control of asthma. Periodic assessment ensures appropriate therapy and compliance with treatment. Practitioners should make sure that families can afford the necessary medications. During routine visits, home monitoring and therapy as well as any diaries and records should be reviewed, children's and families' expectations about the course of the disease should be discussed, and all parties should be allowed to express their concerns regarding the development of a treatment plan. Other factors, such as rhinitis, sinusitis, and gastroesophageal reflux, which may influence the severity of asthma or a child's quality of life, should be assessed and treated appropriately.

Family members and children should be given a written action plan based on patients' personal best peak flow (Figure 81-2) and instructed in the use of peak flow meters to indicate when medical treatment is necessary. Some meters have 3 color zones: a green zone, which indicates good airflow; a yellow zone, which signals the need for treatment; and a red zone, which suggests that a visit to the ED may be indicated.

Pharmacologic Therapy

The 2007 NHLBI guidelines for asthma management are based on age group: children 0 to 4 years of age, children 5 to 11 years of age, children 12 years of age and older (Tables 81-2, 81-3, and 81-4).

Asthma severity is categorized by "impairment" and "risk." Impairment considers the frequency and severity of both daytime and nighttime asthma symptoms, use of short-acting β_2 -agonist for other than exercise-associated symptoms, impact on activities, and pulmonary function testing. Risk assesses the frequency of asthma exacerbations requiring the use of oral corticosteroids. The most

Box 81-2. Pharmacologic Therapy: An Overview of Medications Used to Treat Asthma

Long-term Control Medications (Controller Class)

Corticosteroids

Most potent and effective anti-inflammatory medication currently available. Inhaled form is used in the long-term control of asthma. Systemic corticosteroids are often used to gain prompt control of the disease when initiating long-term therapy.

Cromolyn Sodium and Nedocromil

Mild anti-inflammatory medication. May be used as monotherapy in mild persistent asthma. Can also be used as preventive treatment prior to exercise or unavoidable exposure to known allergens.

Long-Acting β_2 -Agonists

Long-acting bronchodilator used concomitantly with anti-inflammatory medications for long-term control of symptoms, especially nocturnal symptoms. Includes salmeterol and formoterol.

Methylxanthines

Sustained-release theophylline is a mild-to-moderate bronchodilator used principally as adjuvant to inhaled corticosteroids for prevention of nocturnal asthma symptoms. May have mild anti-inflammatory effect.

Leukotriene Modifiers

Montelukast, a leukotriene receptor antagonist, or zileuton, a 5-lipoxygenase inhibitor, may be considered an alternative therapy to low doses of inhaled corticosteroids, or cromolyn or nedocromil, in mild persistent asthma.

Systemic Corticosteroids

- Used for moderate-to-severe exacerbations to speed recovery and prevent recurrence of exacerbations.
- **Omalizumab** (anti-IgE) a recombinant DNA-derived humanized monoclonal antibody of the Fc portion of the IgE antibody, binds to that portion thereby preventing IgE binding to its high-affinity receptor (Fc ϵ R1) on mast cells and basophils, leads to a decrease in the release of mediators in response to allergen exposure.

Quick-Relief Medications (Reliever Class)

Short-Acting β_2 -Agonists

Albuterol and levalbuterol are therapy of choice for relief of acute symptoms and prevention of exercise-induced bronchoconstriction.

Anticholinergics

Ipratropium bromide provides additive benefit to inhaled β_2 -agonists in acute exacerbations. May be an alternative bronchodilator for patients who do not tolerate inhaled β_2 -agonists.

Box 81-3. Therapeutic Goals for Children With Chronic Asthma

- Maintain a normal, age-appropriate activity level.
- Maintain near-normal pulmonary function.
- Prevent symptoms such as exercise intolerance, chronic cough, and shortness of breath.
- Prevent acute exacerbations of the disease that require acute therapy.
- Minimize adverse effects of the drugs used to treat the disease.
- Promote self-esteem and a sense of well-being.

For: _____ Doctor: _____ Date: _____

GREEN ZONE

Doing Well Take these long-term control medicines each day (include an anti-inflammatory).

	Medicine	How much to take	When to take it
• No cough, wheeze, chest tightness, or shortness of breath during the day or night	_____ →	_____ →	_____
• Can do usual activities	_____ →	_____ →	_____

And, if a peak flow meter is used, **Identify and avoid and control the things that make your asthma worse, like (list here):**

Peak Flow: more than _____
(80% or more of my best peak flow) _____

My best peak flow is: _____

Before exercise, if prescribed, take: 2 or 4 puffs _____
5–60 minutes before exercise

YELLOW ZONE

Asthma is Getting Worse → First Add: quick-relief medicine and keep taking your GREEN ZONE medicine

_____ 2 or 4 puffs, every 20 minutes for up to 1 hour
(short-acting β_2 -agonist) Nebulizer once

• Cough, wheeze, chest tightness, or shortness of breath, or
• Waking at night due to asthma, or
• Can do some but not all usual activities

– Or –

Peak flow: _____
(50%–79% of my best peak flow)

If applicable, remove yourself from the thing that made your asthma worse.
→ **Second, if your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment:**

Continue monitoring to be sure you stay in the green zone

If your symptoms (and peak flow, if used) do not return to GREEN ZONE after 1 hour of above treatment:

Take: _____ 2 or 4 puffs or Nebulizer
(short-acting β_2 -agonist)

Add: _____ mg per day For _____ (3–10 days)
(oral corticosteroid)

Call the doctor _____ before/ within _____ hours after taking oral corticosteroid.

RED ZONE

Medical Alert!

• Very short of breath, or
• Quick-relief medicines have not helped, or
• Cannot do usual activities, or
• Symptoms are same or get worse

After 24 hours in Yellow Zone

– Or –

Peak flow: less than _____
(50% of my best peak flow)

Take this medicine:

_____ 4 or 6 puffs or Nebulizer
(short-acting β_2 -agonist)

_____ mg
(oral corticosteroid)

Then call your doctor NOW. Go to the hospital or call an ambulance if:

You are still in the Red Zone after 15 minutes AND
You have not reached your doctor.

DANGER SIGNS

• **Trouble walking and talking due to shortness of breath**
• **Lips or fingernails are blue**
• **Take 4 or 6 puffs of your quick-relief medicine AND**
• **Go to the hospital or call for an ambulance** _____

Table 81-4. Classifying Asthma Severity ≥ 12 Years^a

<i>Component of Severity</i>		<i>Classifying of Asthma Severity and Initiating Treatment (≥ 12 years of age)</i>			
		<i>Intermittent</i>	<i>Persistent</i>		
			<i>Mild</i>	<i>Moderate</i>	<i>Severe</i>
Impairment	Symptoms	≤ 2 days/week	> 2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤ 2 x/month	3–4x/month	> 1 x week, but not nightly	Often 7x/week
	Short-acting β_2 -agonist use for symptom control (not prevention of EIB)	≤ 2 days/week	> 2 days/week but not daily and more than 1x on any day	Daily	Several times per day
	Interference with normal activity	None	More limitation	Some limitation	Extremely limited
	Lung function	Normal FEV ₁ between exacerbations FEV ₁ $> 80\%$ predicted FEV ₁ /FVC $> 85\%$	FEV ₁ = $> 80\%$ predicted FEV ₁ /FVC normal	FEV ₁ > 60 , but $< 80\%$ predicted FEV ₁ /FVC = reduced 5%	FEV ₁ $< 60\%$ predicted FEV ₁ /FVC reduced $< 5\%$
Risk	Exacerbation requiring oral systemic corticosteroids	0–1/year	≥ 2 year		
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time. Exacerbations of any severity may occur in patients in any severity category.			
Recommended Step for Initiating Therapy		Step 1: SABA PRN	Step 2: Low-dose ICS	Step 3: Low-dose ICS + LABA	Step 4/5: Medium/High-dose ICS + LABA
(See Table 81-5 for treatment steps.)		Consider short course of OCS.			
In 2–6 weeks, depending on severity, evaluate level of asthma control that is achieved. If no clear benefit is observed in 4–6 weeks, consider adjusting therapy or alternative diagnoses.					

Abbreviations: EIB, exercise-induced bronchoconstriction; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroids; LABA, long-acting β_2 -agonist; OCS, oral corticosteroids; PRN, as needed; SABA, short-acting β_2 -agonist.

^aAdapted from the National Asthma Education and Prevention Program. *Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, 2007*. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH Publication No. 07-4052.

severe level of symptoms, medication use, and other factors defines the level of severity, which determines the long-term approach to management. Patients with intermittent asthma may respond to short-acting bronchodilator as needed, whereas children with persistent asthma require a controller medication such as inhaled corticosteroids (ICS) to reduce inflammation. The treatment of asthma is based on its severity and control. For **intermittent asthma only** short-acting β_2 -agonists are required on an as-needed basis to treat symptoms. Prophylactic use of β_2 -agonists, cromolyn, or nedocromil may be used for exercise-induced asthma before the onset of activity. For **mild persistent asthma**, daily anti-inflammatory medications (controllers) are required with low-dose ICS as recommended therapy or alternative monotherapy with cromolyn, nedocromil, or leukotriene modifier agents, such as montelukast. Use short-acting β_2 -agonists for acute exacerbations. For **moderate persistent asthma**, medium-dose ICS or low-dose ICS plus a second agent is recommended depending on the age group. Second agents include long-acting β_2 -agonists, leukotriene modifiers, and theophylline. For **severe persistent asthma**, usually high-dose ICS plus a second agent is required. Systemic corticosteroids may be required to gain asthma control in moderate to severe persistent asthma patients. In difficult to control patients, especially those experiencing severe exacerbations despite optimal controller therapy, omalizumab has

been shown to decrease risk of asthma attacks. Patients of all asthma severities require short-acting β_2 -agonists for quick relief of symptoms and prevention of exercise-induced asthma.

Inhaled corticosteroids act topically on lung epithelium, inhibiting cell migration and activation and reducing airway hyper-responsiveness. Inhaled corticosteroids are the most effective anti-inflammatory medication for asthma. Inhaled corticosteroids reduce asthma symptoms, improve lung function, reduce acute exacerbations of asthma, and reduce the risk of death from asthma. Recent data show that ICS are well-tolerated, safe medications at the recommended dosages.

Leukotriene modifiers interfere with the action of leukotrienes, inflammatory mediators released from mast cells, eosinophils, and basophils. Long-acting β_2 -agonists provide at least 12 hours of bronchodilation by stimulating β_2 receptors in the airway, which increases the concentration of cyclic adenosine monophosphate, causing relaxation of airway smooth muscle. Long-acting β_2 -agonists should never be used alone without concomitant use with ICS in treatment of asthma.

Patients may be started at a higher level of medications at the onset, to establish prompt control, and then step-down reduction should be implemented to reach the minimum medication necessary to maintain control (see Table 81-5).

Table 81-5. Stepwise Approach for Managing Asthma By Age Group^{a-d}

Age	Step 1	Step 2	Step 3	Step 4	Step 5	Step 6
0–4 y	SABA PRN	Low-dose ICS alternative: Cromolyn or montelukast	Medium-dose ICS	Medium-dose ICS + either LABA or montelukast	High-dose ICS + either LABA or montelukast	High-dose ICS + OCS + either LABA or montelukast
5–11 y	SABA PRN	Low-dose ICS alternative: Cromolyn, LTRA, or theophylline	Low-dose ICS + either LABA, LTRA, or theophylline OR Medium-dose ICS	Medium-dose ICS + LABA alternative: Medium-dose ICS + either LTRA OR theophylline	High-dose ICS + LABA alternative: High-dose ICS + either LTRA OR theophylline	High-dose ICS + LABA + OCS alternative: High-dose ICS + either LTRA OR theophylline + OCS
12 y–adult	SABA PRN	Low-dose ICS alternative: Cromolyn, LTRA, or theophylline	Low-dose ICS + LABA OR medium-dose ICS alternative: Low-dose ICS + either LTRA OR theophylline or zileuton	Medium-dose ICS + LABA alternative: Medium-dose ICS + either LTRA OR theophylline or zileuton	High-dose ICS + LABA AND Consider omalizumab for patients who have allergies	High-dose ICS + LABA + OCS AND Consider omalizumab for patients who have allergies

Abbreviations: ICS, inhaled corticosteroid; LABA, long-acting β_2 -agonist; LTRA, leukotriene receptor antagonist; OCS, oral corticosteroids; PRN, as needed; SABA, short-acting β_2 -agonist.

^aAdapted from the National Asthma Education and Prevention Program. *Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, 2007*. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH Publication No. 07-4051.

^bAll patients need quick-relief medication (SABA).

Each Step: Patient education, environmental control, and management of comorbidities.

^cSteps 2–4 (5 y–adult): Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma.

^dSteps 5–6 (12 y–adult): Consider omalizumab for patients who have allergies.

Prognosis

Asthma can result in significant morbidity and mortality if children are not managed appropriately. Children without longitudinal primary care generally require expensive therapy in EDs or inpatient settings. A significant number of individuals with asthma have fatal outcomes because of lack of timely and appropriate care. Virtually all of these deaths are preventable.

CASE RESOLUTION

The 7-year-old boy in the case scenario who visits the office for asthma requires not only medication but also education and longitudinal primary care. It is particularly important to assess possible environmental factors (eg, pets), exposure to smoke, and poor compliance with previous recommendations, which have contributed to his recurrent symptoms.

Cough

Nasser Redjal, MD

CASE STUDY

A 3-year-old boy presents with a cough that he has had for 4 weeks. In the past he has had coughs with colds, but this cough is persistent and deeper in quality. The cough seemed to develop suddenly when he was playing at a friend's house. It occurs all day and disrupts his sleep at night. The boy has had no nasal congestion, fever, or sore throat. No one at home is coughing, and the boy has not traveled recently. Neither the boy nor his family has a history of allergies or asthma. Over-the-counter cough preparations have not helped relieve his symptoms. On examination, growth parameters are normal. The child has a persistent cough with no respiratory distress. Chest examination reveals a normal respiratory rate,

no retractions, and no use of accessory muscles, but diffuse expiratory wheezing is noted in the right lower lobe. The remainder of the examination is normal.

Questions

1. What are common parental concerns regarding cough?
2. What diagnoses in children with persistent cough should be considered?
3. What historical factors and physical findings are important to determine the etiology of cough?
4. What diagnostic workup is appropriate?
5. How should children with chronic cough be managed?

Cough is an essential protective reflex that allows for clearance of secretions and particulates from the airways. Its persistence can be distressing to the patient and often causes parental anxiety due to the concern regarding its etiology and the frequent disruption of sleep. Cough may be acute, subacute, or chronic. Acute cough lasts less than 2 weeks and is often associated with respiratory tract infections in children. Cough lasting 2 to 4 weeks is subacute, and when cough lasts more than 4 weeks, it is persistent or chronic. Parental sensitivity as well as accessibility to medical care influence when in the course of disease children present with this problem.

Epidemiology

Cough is a very common complaint initiating pediatric office visits. In the National Ambulatory Medical Care Survey, 6.7% of pediatric office visits involved children who presented with cough. Typically, preschool children have up to 8 upper respiratory infections with associated cough in a winter season. Persistent cough is also very common, with an estimated prevalence of 5% to 7% in preschoolers and 12% to 15% in older children. Cough is more common among boys than girls up to 11 years of age, and may be less common in developing countries than in affluent countries. Many serious diseases, including cystic fibrosis, congenital heart disease, asthma, and immunodeficiency disorders, may result in cough.

Clinical Presentation

The presentation varies greatly depending on the etiology of the cough. Children may present in severe respiratory distress or have

no evidence of respiratory compromise. They may exhibit failure to thrive or appear totally healthy.

Pathophysiology

Coughing is a complicated reflex process that propels excess mucus up the airways at the pressures of up to 300 mm Hg and at flows of up to 5 to 6 L/sec. It is initiated through irritation of one of the multiple cough receptors (Figure 82-1). These receptors are located in the nose, paranasal sinuses, posterior pharynx, larynx, trachea, bronchi, and pleura. They can also be found outside of the respiratory tract in the ear canal, stomach, pericardium, and diaphragm. Stimulation of any of these receptors by an irritant, whether mechanical, chemical, thermal, or inflammatory, can initiate the cough reflex. The proximal airways (larynx and trachea) are more sensitive to mechanical stimulation, and the distal airways more sensitive to chemical stimulation. The lung parenchymal (bronchiolar and alveolar) tissue contains no cough receptors, so pneumonia may not produce a cough. Impulses from stimulated cough receptors traverse afferent nerves (vagus, glossopharyngeal, trigeminal, or phrenic) to a "cough center" in the medulla, which itself is under some control by higher cortical centers. The cough center generates an efferent signal that travels down the vagus, phrenic, and spinal motor nerves to expiratory musculature, thereby producing the cough. The cough center can be voluntarily stimulated or suppressed.

The actual cough experienced by patients may be broken down into 4 phases. First, the glottis opens with an inspiratory gasp. Second, the glottis closes with forceful contraction of the chest wall, diaphragm, and abdominal muscles. Third, the glottis again opens

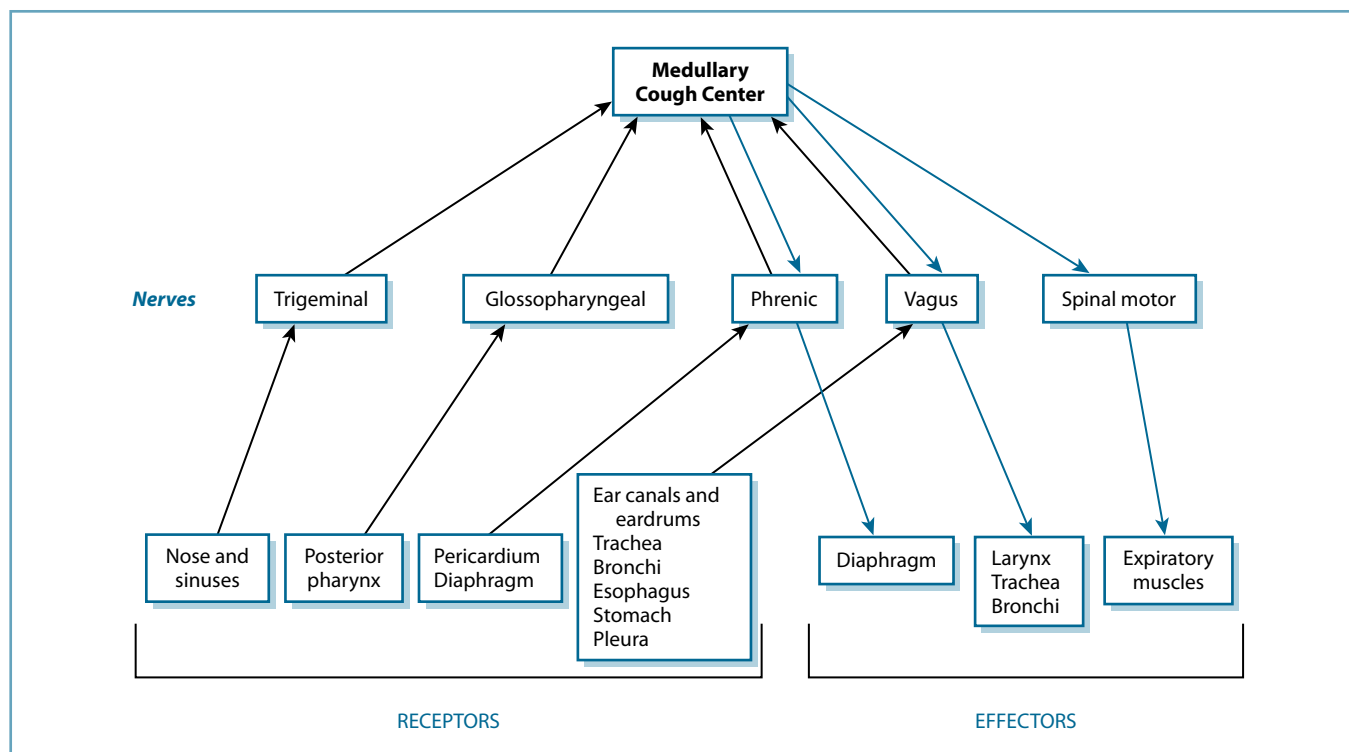

Figure 82-1. The cough reflex.

with release of airway pressure in an expiratory phase. The fourth phase involves relaxation in which the chest wall and abdominal muscles relax. This process expels mucus or irritants from the airways, helping maintain the health of the lungs. Children who do not cough effectively may be at risk for atelectasis, recurrent pneumonia, and chronic airway disease from aspiration and/or retention of secretions.

Differential Diagnosis

The list of differential diagnoses of cough is long (Box 82-1). Narrowing the list of causes can be accomplished by paying attention to several factors (Dx Box).

As with any pediatric symptom, the child's **age** influences the diagnostic possibilities and management of the cough. Congenital anomalies, which are most likely to present in the first few months of life, include tracheoesophageal fistula, laryngeal cleft, vocal cord paralysis, and tracheobronchomalacia. Congenital heart disease

can produce a cough from heart failure and pulmonary edema. Congenital mediastinal tumors cause infants to cough if the tumor presses on the bronchial tree. Many children with asthma experience cough and/or wheezing in infancy, often associated with an episode of bronchiolitis.

The **duration of the cough** also suggests its possible cause. Most acute coughs are infectious in origin. Upper respiratory infections can initiate an acute cough through stimulation of the cough receptors in the nose and posterior pharynx. If nasal congestion and cough persist, a diagnosis of allergic rhinitis or sinusitis should be considered. Serous otitis media can also cause a persistent cough and may occur in children with chronic congestion. Children with pneumonia may present with either acute or chronic cough.

The presence of a nighttime cough can be important. Pathologic coughs, including those caused by sinusitis with postnasal drip, gastroesophageal reflux, and asthma, are more likely to occur at night.

The character of the cough is another factor to consider in the differential diagnosis. Certain etiologies are associated with a very specific type of cough. A barking cough is consistent with laryngeal edema and croup. A stridorous cough may be seen with proximal airway disease, such as laryngomalacia or tracheomalacia, laryngotracheobronchitis, or a foreign body. An inspiratory whoop is characteristic of pertussis or parapertussis. Staccato cough in infants can be the result of infection with *Chlamydia trachomatis*. The psychogenic or habitual cough is a strange, honking sound (Canadian goose-like), disappears at night, and is typically at its worst and most disruptive during school classes. Chronic paroxysmal cough triggered by exercise, cold air, sleep, or allergens is often seen in patients with asthma.

Dx Cough

- Quality: dry, productive, brassy, honking
- Duration: acute, subacute, chronic, recurrent
- Timing: during day, at night, on awakening, with exercise
- Fever or upper respiratory infection associated with infectious origin
- Allergic findings of rhinorrhea, sneezing, wheezing, atopic dermatitis associated with asthma or allergic rhinitis
- Failure to thrive (indicates chronic disease)

Box 82-1. Causes of Cough

---	---	--

In contrast, a chronic productive (or “wet”) cough suggests a suppurative process, and may require further investigation to exclude bronchiectasis, cystic fibrosis, active infection, immune deficiency, or congenital malformation.

Pneumococcus is the most probable causal agent in acute cough with pneumonia, but when the cough becomes chronic, other infectious agents are more likely. Adenovirus and respiratory syncytial virus, which occur more commonly in infants, and influenza and parainfluenza, which affect children of all ages, are common viral agents that produce chronic cough. *Bordetella pertussis*, mycoplasma, and chlamydia also cause chronic cough. Other infections, such as tuberculosis and coccidioidomycosis, should also be considered in endemic areas or high-risk populations. Chronic infectious coughs, such as those associated with influenza and pertussis, can last up to 6 months. Host factors that may predispose to chronic cough should also be investigated. Children with cystic fibrosis, bronchopulmonary dysplasia, HIV and other immunodeficiency syndromes, and congenital pulmonary malformations may present with chronic, recurrent cough.

The most common triggers of chronic cough are persistent rhinitis and chronic sinusitis followed by gastroesophageal reflux disease and asthma. All of these contribute to the development of an irritable larynx, which causes cough. In fact, cough with no notable wheezing may be the only manifestation of asthma. In infants or neurologically impaired children, chronic cough may indicate gastroesophageal reflux or recurrent aspiration. An unexplained persistent cough, primarily in toddlers, may be the result of foreign body aspiration if the initial aspiration was not observed. In some studies a history of choking episodes is absent in approximately 50% and chest radiograph examination produces

normal results in approximately 20% to 40% of children who have foreign bodies present on bronchoscopy. The foreign object acts as a chronic airway irritant that stimulates coughing, and it may be the cause of recurrent infections. Other irritants that initiate cough include dust, allergens, wood- and gas-burning stoves, chemicals, and passive or active exposure to smoke from tobacco, marijuana, cocaine, or other substances. Drugs such as β -adrenergic receptor antagonists and angiotensin-converting enzyme inhibitors can also induce a chronic cough, probably by increasing the sensitivity of the cough reflex. Patients previously treated with cytotoxic drugs or thoracic radiation are at risk of interstitial lung disease. Cough along with symptoms of pancreatic insufficiency, recurrent bacterial pneumonia, and/or failure to thrive should raise suspicion of cystic fibrosis. Cough with a history of dyspnea or hemoptysis should trigger a search for organic lung disease. Hemoptysis should also raise concerns of bronchiectasis, cavitary lung disease (tuberculosis or bacterial abscesses), congestive heart failure, hemosiderosis, neoplasm, foreign bodies, vascular lesions, endobronchial lesions, catamenial (ectopic endometrial tissue) bleeding, and clotting disorders.

Evaluation

History

A complete history should be obtained when children present with cough (Questions Box). All symptoms should be noted. Vomiting with cough can indicate phlegm production and the accumulation of mucus in the stomach, with resultant delayed gastric emptying. In some children with a chief complaint of vomiting it is actually the cough that precipitates the vomiting. Post-tussive vomiting is characteristic of pertussis.

Cough

- How old is the child?
- How long has the child had the cough?
- How frequently does the child cough?
- Does the cough occur at night?
- Does exercise make the cough worse?
- Do any factors such as environmental irritants seem to precipitate the cough?
- Does the child have any related infectious symptoms, including fever and nasal congestion?
- Does the child have any other symptoms?
- Has the child had any previous episodes of coughing or associated symptoms?
- Has the child lost weight recently?
- What is the child's birth history?
- Has the child had any pulmonary injuries?
- What is the child's immunization status?
- Does the child have a history of recent travel?
- Has a family member had similar symptoms?
- Does the family have a history of pulmonary disease or allergies?
- Has the child been treated with any medications for the cough? Have they helped?
- Is the child taking any other medications?

Questions

Physical Examination

A complete physical examination should be performed on all children who present with cough. Growth parameters and vital signs should be assessed. Skin should be examined for evidence of cyanosis or atopy. Facial petechiae or subconjunctival hemorrhage indicates particularly forceful coughing. Extremities should be evaluated for fingernail clubbing, which is a sign of chronic pulmonary disease. The nose should be assessed for evidence of congestion. Allergic disease produces pale, edematous mucosa, whereas infection results in more inflammatory mucosa. Tympanic membranes should be examined and mobility tested; halitosis, tonsillar hypertrophy, pharyngeal cobblestoning, and tenderness on the sinus area suggest sinus disease.

The respiratory effort, including the use of accessory muscles, should also be noted. Careful attention should be paid to breath sounds; whether abnormal sounds are in the inspiratory or expiratory phase of respiration should be determined. Stridor is classically an inspiratory sound (see Chapter 58), whereas wheezing is usually an expiratory sound. Chronic cough and wheeze are often noted in combination. Even in the absence of a history of wheeze, clinicians should listen carefully for this finding during the physical examination. Wheezing that is characterized by many different pitches and starting and stopping at varying points in the respiratory cycle is termed *polyphonic* and in association with cough is highly suggestive of asthma. Other causes of polyphonic wheezing include viral bronchiolitis, obliterative bronchiolitis, bronchiectasis, bronchopulmonary dysplasia, congestive heart failure, immunodeficiency, bronchomalacia, and aspiration syndromes.

Monophonic wheezing (a single, distinct, one pitch that starts and stops at one discrete time) and cough should always raise suspicion of large airway obstruction caused by foreign body or by tracheomalacia. Extrinsic airway compression as occurs with vascular rings, lymphadenopathy, and mediastinal tumors is also associated with monophonic wheezing. Tuberculosis should also be considered in a child with a monophonic wheeze, particularly in areas where the disease is prevalent.

Prolongation of the expiratory phase also is associated with wheezing and also indicates airway obstruction. Abnormal breath sounds should be localized if possible. Because the character of the cough can establish the diagnosis, listening to the cough is probably the most important part of the physical examination. A parental description of the cough may be less diagnostic.

Laboratory Tests

After a thorough history and physical examination, laboratory data may not be necessary. Laboratory tests should be ordered when more information is needed to help make a reasonable diagnosis. The laboratory data should be directed at proving or disproving the most likely diagnosis in a specific patient.

If after the history, physical examination, and chest radiograph an infectious etiology for cough is suspected, a complete blood cell count with differential and a purified protein derivative skin test should be ordered. Appropriate cultures should be sent, if possible. Most children swallow their phlegm, so sputum cultures may be difficult to obtain. Gastric aspirates can sometimes yield a reasonable sputum specimen for culture. Nasopharyngeal cultures are useful for diagnosing pertussis and viruses.

If a specific diagnosis is suspected, laboratory tests (Table 82-1) should be directed toward that diagnosis (eg, sweat chloride to rule out cystic fibrosis or quantitative immunoglobulins to rule out immunodeficiency). Allergy skin test or radioallergosorbent testing may be indicated to exclude inhalant allergy.

Imaging Studies

The chest radiograph (anteroposterior and lateral views), the mainstay of the diagnostic evaluation of cough, should be the first test ordered in the evaluation of a chronic cough or if definite findings are evident on physical examination. A lateral decubitus film can provide additional information about pleural fluid or air trapping. Inspiratory and expiratory films can be obtained if a foreign body is suspected. An area of inflation that either fails to deflate on exhalation or remains present in the decubitus position is suggestive of a foreign body. Congenital lobar emphysema and unilateral hyperlucent lung (Swyer-James Macleod) syndrome are rare causes of focal or unilateral hyperinflation. If a nodular pulmonary lesion is found on radiograph, bronchoscopy may be the next step to further define the lesion. Bronchiectasis is a characteristic of cystic fibrosis, immune deficiency, primary ciliary dyskinesia, chronic aspiration, and previous history of severe infection (most commonly adenovirus and pertussis). If sinusitis is suspected, radiographs or a computed tomography scan of the sinuses can be performed. An upper

Table 82-1. Tests to Consider for Evaluation of Chronic Cough

Allergy	Allergy skin test or blood-specific immunoglobulin E test
Asthma	Pulmonary function test (PFT), bronchial hyperresponsiveness test such as methacholine challenge test, exhaled nitric oxide, trial of asthma treatments
Ciliary dyskinesia	Ciliary function tests
Congenital anomalies	Bronchoscopy, chest radiograph, computed tomography (CT)/magnetic resonance imaging, angiography
Fungal infections	Coccidiomycosis: antibody assay (precipitin, complement fixation) Histoplasmosis: antibody assay (complement fixation, immunoprecipitating) Serum and urine antigen detection
Cystic fibrosis	Sweat chloride test, genetic test
Fibrosing alveolitis, autoimmune disease	PFT and diffusion CT, autoantibodies
Foreign body	Chest radiograph, bronchoscopy
Gastroesophageal reflux	Barium swallow, 24-hour pH recording, and bronchoalveolar lavage (BAL)
Pertussis, chlamydia, or other infectious etiologies	Cultures, serology, polymerase chain reaction testing
Purulent infection	Cultures (sputum, BAL), chest radiograph, CT, microbiology immunology, sweat test
Sinusitis	Imaging of sinuses with radiograph or CT scan
Tuberculosis	Mantoux testing

gastrointestinal series of radiographs or a pH probe study would help to define gastroesophageal reflux if the cough occurs after recurrent episodes of vomiting or at night.

In children with asthma, the chest radiograph may be totally normal. Further diagnostic testing with peak flow measurements or pulmonary function tests in children older than 4 years can be done to demonstrate restriction or obstruction of the airway. The most helpful test to diagnose asthma may be a trial of a bronchodilator (see Chapter 81).

Management

Cough should not be treated until the cause has been identified by a thorough consideration of the differential diagnoses. Therapy should then be directed toward treating that etiology. However, many children do not have any evidence of chronic disease based on a detailed history, physical examination, radiography, and pulmonary function testing. When the initial evaluation outlined previously is unrevealing, cough-variant asthma, post-viral cough, increased cough receptor sensitivity, and functional disorders (including habit cough and tic disorders) should be considered. Empiric courses of therapy for asthma, rhinitis, sinusitis, or gastroesophageal reflux can be considered if suggestive findings exist. The external ear is innervated by the vagus nerve, and removal of irritants from the external auditory canal may reduce the coughing. Airflow obstruction may be apparent at the first visit, and a trial of asthma therapy is warranted, particularly if other signs of allergic disease are present or if the child's cough is precipitated by typical asthma triggers. A cough of an infectious etiology should be treated with the appropriate antibiotics. Expectorants and mucolytic agents in cough syrups have little effect on relieving coughs. Most over-the-counter children's

cough medications are marginally effective, provide no greater benefit compared with placebo, and may be associated with adverse or paradoxical reactions.

Prognosis

With thoughtful evaluation, it is usually possible to identify the causes of both acute and chronic cough. Most symptoms resolve with appropriate therapy. If the cough persists with treatment, then alternate diagnoses should be considered.

CASE RESOLUTION

In the case presented at the beginning of this chapter, the child's cough began acutely and developed into a chronic cough. The boy has no history of allergies or symptoms consistent with an infectious process. Physical examination reveals localized wheezing. A chest radiograph is ordered, which reveals hyperinflation of the right lung. His symptoms and presentation are most consistent with foreign body aspiration and he is admitted to the hospital for bronchoscopy.

Anemia

Wendy Y. Tcheng, MD

CASE STUDY

An 18-month-old girl is brought to the office with a 3-day history of cough, rhinorrhea, low-grade fever, mild scleral icterus and pallor. During her first week of life, the girl had hyperbilirubinemia of unknown etiology that required phototherapy. Her family history is significant for mild anemia in her father; the cause of his condition is unknown. A paternal aunt and grandfather had cholecystectomies while in their 30s.

On physical examination, the girl is tachycardic and tachypneic (no respiratory distress), with scleral icterus and pallor. Her spleen is palpable 3 cm below the midcostal margin. The remainder of her examination is normal.

Questions

1. What hemoglobin/hematocrit values are associated with anemia?
2. What is the appropriate initial evaluation of children with anemia?
3. What emergency situations in children who present with anemia should be recognized by the primary pediatrician?
4. When should a child with anemia be referred to a hematologist?
5. How is the family history relevant in the evaluation of anemia?

Anemia occurs when there is a reduction in hemoglobin concentration or red blood cell (RBC) number, leading to decreased oxygen-carrying capacity of blood. Anemia is defined as a hemoglobin or hematocrit value that is less than 2 SDs below the mean for age and gender. With this statistical definition, 2.5% of the healthy population will be categorized as having anemia. These values vary throughout infancy and childhood as hematopoiesis evolves from fetal to adult type, and it is important to reference normal age and gender-related values when interpreting a hemoglobin or hematocrit result. (See Table 83-1 for normal age-related values.) In addition, there is racial variation with African American children having lower average hemoglobin values when compared to Caucasian children. The cardiopulmonary status should also be considered as children with cyanotic heart disease or chronic respiratory insufficiency typically have hemoglobin values that are higher than the normal range and may be functionally anemic when the hemoglobin value falls even if it is within the lower range of normal.

Epidemiology

Iron deficiency is the most common cause of anemia in childhood, occurring most frequently during late infancy through the first few years of life and again during adolescence. This prevalence pattern corresponds to periods of rapid growth, and when combined with poor dietary intake can predispose to iron deficiency. Other contributing factors to iron deficiency include prematurity, blood loss (most commonly menstrual or gastrointestinal [GI]), and GI conditions associated with decreased iron absorption.

Other epidemiological factors that contribute to anemia are presented in Box 83-1. Anemias that have a genetic etiology, including

Table 83-1. Values (Mean and Lower Limits of Normal) for Hemoglobin, Hematocrit, and Mean Corpuscular Volume Determinations^a

hemoglobinopathies (eg, sickle cell disease, thalassemias), RBC enzyme deficiencies (eg, glucose-6-phosphate dehydrogenase [G6PD], pyruvate kinase), and RBC membrane disorders (eg, hereditary spherocytosis), are commonly diagnosed in childhood. The highest incidence of sickle cell disease, thalassemia, and G6PD deficiency is in individuals of African, Mediterranean, and Southeast Asian descent within the “malaria belt” near the equator, likely reflecting an advantage against malaria. Dietary factors can cause impaired hematopoiesis as in iron, folate, or vitamin B₁₂ deficiency. Ingestion of oxidants (eg, fava beans, medications) can trigger hemolysis in G6PD deficiency. Ingestion of toxins such as lead can also result in impaired hematopoiesis. Lead poisoning occurs more commonly in children who live in cities and older housing. In an otherwise healthy child, viral infections can cause a pure red cell aplasia (transient erythroblastopenia of childhood), an autoimmune hemolytic anemia, or an aplastic anemia. Children with congenital hemolytic anemias are at risk for hemolytic and aplastic crises associated with infectious illnesses.

Clinical Presentation

The clinical presentation of anemia depends on the age of the child, the severity and cause of the anemia, and the rapidity of onset (Dx Box). Most often anemia is detected on a routine screen or as part of an evaluation for an acute illness and the child is asymptomatic with no significant physical findings. Children who have developed anemia gradually may be relatively asymptomatic because time has afforded compensatory mechanisms. With severe anemia, easy fatigability and exercise intolerance can develop and pallor, fatigue, headache, dizziness, and irritability may occur. On examination, pallor, tachycardia, tachypnea, edema and, in severe cases, outright congestive heart failure (CHF) may be present. Children with an abrupt drop in hemoglobin due to blood loss or hemolysis will present more acutely with signs of tachycardia, tachypnea, and possible hypotension and shock. If the anemia is due to acute hemolysis, accompanying jaundice, icterus, and dark urine may be seen.

Pathophysiology

Erythrocytes develop from pluripotent stem cells within the bone marrow under the influence of various hematopoietic growth factors. Erythropoietin is the primary growth factor regulating RBC production and is produced primarily in the kidneys. The primary function of the erythrocyte is the delivery of oxygen to tissues for aerobic metabolism. To this end, hemoglobin is the main intracellular protein of the erythrocyte. Hemoglobin consists of 4 polypeptide chains, each containing an active heme group that is capable of binding to an oxygen molecule. A normal erythrocyte has a life span of approximately 120 days and is subsequently removed from circulation as it passes through the reticuloendothelial system. Under steady state conditions, the daily 1% loss of aged erythrocytes is compensated by a normal active erythropoiesis.

Anemia occurs when there is an imbalance between erythrocyte production and destruction. It can arise from conditions leading

Box 83-1. Epidemiological Factors Related to Anemia

Genetic

- Autosomal-dominant: hereditary spherocytosis
- Autosomal-recessive: most Embden-Meyerhof pathway enzyme deficiencies (pyruvate kinase deficiency), most hemoglobinopathies (sickle cell disease, β -thalassemia)
- X-linked: glucose-6-phosphate dehydrogenase (G6PD) deficiency

Ethnicity

- Northern European: hereditary spherocytosis, pyruvate kinase deficiency
- Mediterranean (Italian, Greek, North African): β -thalassemia, G6PD deficiency
- African: sickle cell disease, hemoglobin C, hemoglobin D, G6PD deficiency, α -thalassemia trait, hereditary elliptocytosis
- Southeast Asian: α -thalassemia, hemoglobin E, G6PD deficiency

Dietary

Poor dietary intake (iron, folate, or vitamin B₁₂ deficiency)

- Iron (excessive cow's milk intake)
- Folate (excessive goat's milk intake)
- Vitamin B₁₂ (vegan diet)

Poor gastrointestinal absorption

- Iron, absorbed in duodenum (small bowel disease)
- Folate, absorbed in duodenum and jejunum (small bowel disease)
- Vitamin B₁₂, absorbed in terminal ileum (surgical resection, pernicious anemia, small bowel disease)

Ingestion of oxidants (medications such as sulfa drugs, fava beans in G6PD deficiency)

Toxins (lead)

Socioeconomic

- Living near highways: increased incidence of lead poisoning
- Poverty: associated with pica and lead poisoning

Infectious

- Malaria: heterozygous form of sickle cell disease, thalassemia, G6PD-deficiency confer protection
- Viral infections: transient erythroblastopenia of childhood, autoimmune hemolytic anemias, hemolytic crisis in patients with congenital hemolytic anemias
- Parvovirus: aplastic crisis in patients with hemolytic anemias
- Viral hepatitis: aplastic anemia

Dx Anemia

- Pallor, fatigue
- Scleral icterus
- Hepatosplenomegaly
- Lymphadenopathy
- Weight loss
- Congestive heart failure

to **decreased production, increased destruction** (ie, hemolysis), or **blood loss**. Deficient production may be due to nutrient deficiency (iron, folate, vitamin B₁₂), bone marrow failure (acquired or inherited), or bone marrow infiltration (eg, malignancy). Increased destruction of erythrocytes can occur as a consequence of disorders intrinsic to the erythrocyte (eg, hemoglobinopathies, enzymopathies, membranopathies) or extrinsic factors (immune or nonimmune etiologies).

Differential Diagnosis

The differential diagnosis of anemia can be determined by considering both the underlying mechanism of anemia (decreased production/increased destruction/blood loss) and the size of the erythrocyte (mean corpuscular volume [MCV]). The differential diagnosis of anemia based on pathophysiology and erythrocyte size can be found in Table 83-2 and Box 83-2. In determining the cause of anemia, the reticulocyte count is the most useful test in ascertaining whether the anemia is due to decreased production or increased destruction. A reduced reticulocyte count indicates decreased marrow production, whereas an elevated reticulocyte count is highly suggestive of hemolysis. Anemia based on erythrocyte size can be classified as microcytic (low MCV), normocytic (normal MCV), or macrocytic (high MCV). Microcytic anemias reflect a defect in hemoglobin synthesis and are most commonly due to iron deficiency, thalassemia, lead poisoning, and chronic disease. Macrocytic anemias reflect a relative decrease in DNA synthesis during erythropoiesis and are usually of nutritional origin (vitamin B₁₂ or folate deficiency). The many other causes of anemia commonly fall into the normocytic category and can be further divided based on the reticulocyte count. Etiology and erythrocyte size, the 2 systems for classification of anemia, are not mutually exclusive—simultaneous application of these 2 systems will enable the pediatrician to make a primary diagnosis of anemia and determine its probable causes.

Microcytic Anemias

Iron deficiency is the most frequent cause of microcytic anemia in childhood and occurs as a result of (1) inadequate intake, (2) increased requirements due to growth, (3) blood loss, and (4) malabsorption of iron. As iron deficiency evolves, depletion of iron stores occurs first, then iron-deficient erythropoiesis without anemia and, finally, iron deficiency anemia. The combination of rapid growth and inadequate iron intake is responsible for the common occurrence of iron deficiency anemia in toddlers and adolescents. Most young infants are spared because of adequate iron stores acquired in utero and the ingestion of iron-fortified formulas. Premature infants are the exception as they have lower baseline iron stores (much of the iron stores are acquired by the fetus in the third trimester). As iron stores become depleted during late infancy and cow's milk is introduced into the diet, the ever-growing older infant/toddler becomes at risk for iron deficiency. Excessive cow's milk intake during the first few years of life predisposes to iron deficiency because cow's milk has minimal iron (<1 mg/L). Large intake of cow's milk results in early satiety and prevents adequate intake of other iron-containing

foods. The iron deficiency is often further compounded by trace amounts of GI blood loss due to lack of cytochrome iron and GI mucosal damage or cow's milk allergy enteropathy. Adolescents, particularly menstruating females, are also prone to iron deficiency because of the pubertal growth spurt and suboptimal dietary habits. In young infants and children older than 3 years, dietary iron deficiency is uncommon, and an evaluation for blood loss or malabsorption is warranted. Blood loss can occur as hematochezia or melena (inflammatory bowel disease, diarrhea, Meckel diverticulum, polyp, ulcer), menorrhagia, epistaxis, hematuria (intravascular hemolysis), or rarely as pulmonary bleeding (pulmonary hemosiderosis). Iron is absorbed primarily in the duodenum, and a number of dietary factors (coffee, tea) as well as primary intestinal disorders can impair absorption.

The **thalassemias** are a heterogeneous group of inherited anemias that are characterized by impaired or absent synthesis of either the α or β chains that make up the normal adult hemoglobin tetramer. The **β -thalassemias** are caused by a decrease in the production of β -globin chains. The anemia observed in the severe forms of β -thalassemia occurs as a result of ineffective erythropoiesis. This is due to the instability of the excess α chains, which precipitate and cause oxidative damage to the cell membrane leading to premature destruction of the erythrocyte within the bone marrow. The erythrocytes that do survive in the circulation have a shortened life span because of increased hemolysis. The severe forms (compound heterozygous or homozygous state) are classified as **β -thalassemia intermedia** or **β -thalassemia major** depending on the clinical presentation and degree of anemia. Individuals with β -thalassemia major develop a severe anemia during the first year of life because decreasing levels of fetal hemoglobin ($\alpha_2\gamma_2$) cannot be replaced by normal adult hemoglobin ($\alpha_2\beta_2$). Hemoglobin values fall in the range of 3 to 4 g/dL and regular transfusions are required. Individuals with β -thalassemia intermedia usually present later in life and do not require early intervention with blood transfusions. Hemoglobin values are in the 7 to 8 g/dL range, and individuals may be intermittently transfusion-dependent. Individuals with **β -thalassemia trait** (β -thalassemia minor), the heterozygous form, have a mild microcytic anemia with a hemoglobin that is approximately 2 g/dL below the normal mean for age. Clinically it is an asymptomatic anemia; however, it is of diagnostic relevance in that it must be distinguished from iron deficiency anemia.

The **α -thalassemias** are caused by a decrease in the production of α chains and are generally milder than the β -thalassemias. This reflects the fact that the excess of β chains that occurs in α -thalassemia is more stable, resulting in less membrane damage and intramedullary erythrocyte destruction. In humans, there are 4 α -globin genes. Individuals with a deletion of one α -globin gene are **silent carriers** and are asymptomatic with a normal hemoglobin value and MCV. Individuals with 2-gene deletions have **α -thalassemia trait** and have a very mild microcytic anemia that is asymptomatic. Three α -globin gene deletions causes **hemoglobin H disease**, a moderate chronic hemolytic anemia that may be intermittently transfusion-dependent. This occurs primarily in individuals of Southeast Asian descent.

Box 83-2. Differential Diagnosis of Childhood Anemias Based on Red Blood Cell Size

Hypochromic, Microcytic Anemia (Low MCV)

- Iron deficiency anemia
- Thalassemias
- Lead poisoning
- Anemia of inflammation or chronic disease

Normochromic, Normocytic Anemia (Normal MCV)

- High reticulocyte count
 - Intrinsic red cell disorders
- Hemoglobinopathies (hemoglobin SS disease)
- Enzymopathies (G6PD, PK)
- Membranopathies (HS)
 - Extrinsic red cell disorders
- Immune-mediated
- Non-immune (microangiopathic hemolytic anemia [eg, hemolytic uremic syndrome])
- Low reticulocyte count
 - Pure red cell aplasia (Diamond-Blackfan anemia, TEC)
 - Pancytopenia (marrow failure or infiltration)

Macrocytic Anemia (Increased MCV)

- Folate deficiency
- Vitamin B₁₂ deficiency
- Diamond-Blackfan anemia
- Myelodysplastic syndromes
- Chemotherapy agents

Abbreviations: G6PD, glucose-6-phosphate dehydrogenase; HS, hereditary spherocytosis; MCV, mean corpuscular volume; PK, pyruvate kinase; SS, 2 sickle β -globin genes; TEC, transient erythroblastopenia of childhood.

Four-gene deletion causes **hydrops fetalis**, an almost universally fatal condition.

Although **lead** inhibits heme synthesis and red cell function on many levels, microcytic anemia is a late finding of lead intoxication. Iron deficiency and lead poisoning often occur together with a complex relationship. In the presence of lead, iron uptake by the erythrocyte is diminished and iron deficiency increases lead retention and toxicity. Intestinal absorption and uptake of lead by red cells is decreased in the presence of iron. In addition, iron deficiency and lead poisoning tend to occur in the same lower socioeconomic population, and both are exacerbated by concomitant nutritional deficiencies.

Anemia of inflammation or chronic disease can be seen in children with chronic infections, generalized inflammatory disorders (rheumatoid arthritis), and some cancers. It is characterized by a decrease in serum iron and iron binding capacity, an increase in ferritin, and the presence of iron in bone marrow macrophages indicating impaired iron mobilization from storage sites. Increased synthesis of hepcidin, an iron regulatory hormone, under the influence of inflammatory cytokines seems to be responsible for the hypoferremia observed in anemia of inflammation. In general, the anemia of inflammation is mild and may be microcytic or normocytic.

Macrocytic Anemias

Both **folate** and **vitamin B₁₂ deficiency** cause a macrocytic anemia as a consequence of defective erythroid precursor nuclear maturation and megaloblastic changes in the bone marrow. Folate is absorbed in the duodenum and jejunum and is widely available in meats, green leafy vegetables, and cereals. Because of the ubiquity of folate, dietary deficiency is uncommon; however, infants fed exclusively goat's milk are at risk because of the exceedingly low levels of folate in goat's milk. Individuals with chronic hemolytic anemias may also become folate-deficient because of high bone marrow activity and increased demand.

Vitamin B₁₂ is available from animal sources and is actively absorbed in the terminal ileum in association with intrinsic factor. Vitamin B₁₂ deficiency can occur in individuals with a strict vegan diet (or in exclusively breastfed infants of women following a strict vegan diet); however, it usually occurs as a consequence of malabsorption. Decreased absorption can occur in the setting of pernicious anemia (decreased intrinsic factor), surgical resection, or GI disease.

Other causes of macrocytic anemias include congenital hypoplastic anemias (eg, Diamond-Blackfan anemia), myelodysplastic syndromes, and chemotherapeutic agents (eg, methotrexate).

Normocytic Anemias

Normocytic anemias can be classified as hemolytic anemias (associated with a reticulocytosis) and hypoplastic anemias (reticulocytopenic). **Hemolytic anemias** can be further divided into disorders that are intrinsic to the RBC or extrinsic to it. Intrinsic RBC disorders include hemoglobinopathies, enzymopathies, and membranopathies.

Sickle cell disease is most common in individuals of African or mixed African and Latino descent. Inheritance of 2 sickle β -globin genes (hemoglobin SS) is the most common form; however, other significant sickle syndromes include hemoglobin SC, S β^+ thalassemia, and S β^0 thalassemia. Hemolytic anemia and painful vaso-occlusive episodes are the hallmarks of sickle cell disease. The anemia is generally well tolerated with hemoglobin values in the 6.5 to 8.5 g/dL range with an associated reticulocytosis (5%–15%). The 2 most common hematologic complications in sickle cell disease are aplastic crises and splenic sequestration—both of which can cause an acute drop in hemoglobin. Aplastic crises are generally the result of infection with parvovirus, which temporarily causes the complete cessation of red cell production. Splenic sequestration occurs most commonly in infants and young children with sickle cell disease, often in association with a viral illness. Large amounts of blood can be quickly trapped in the spleen causing hypovolemia, shock, and massive splenomegaly.

Pyruvate kinase deficiency is the most common red cell enzyme defect causing a chronic congenital hemolytic anemia. The degree of hemolysis is variable, ranging from a mild fully compensated hemolytic process without anemia to a transfusion-dependent anemia. Individuals with severe hemolysis may be chronically jaundiced and may develop the clinical complications of chronic hemolytic states (gall stones, transient aplastic crises in association with infections,

folate deficiency and, infrequently, skin ulcers.) The enzymatic activity of G6PD is essential in protecting the red cell proteins from oxidative damage. **Glucose-6-phosphate dehydrogenase deficiency** renders the red cell susceptible to oxidant stress and hemolysis. A number of variants have been defined; however, the most common variants are those associated with acute intermittent hemolytic anemias with exposure to oxidant stresses (fava beans, medications). Variants associated with chronic hemolytic anemias are very rare.

Hereditary spherocytosis is the most common red cell membranopathy and is characterized by the presence of spherical-shaped erythrocytes on the peripheral blood smear. Increased membrane fragility due to defects in proteins of the red cell membrane (spectrin, ankyrin, band 3, protein 4.2) leads to membrane vesiculation and membrane loss and the assumption of a spheroidal shape. Hemolysis occurs as these spherocytes are then trapped within the spleen. Clinically, the degree of hemolysis varies from mild anemia to severe transfusion dependence. The complications of a chronic hemolytic state such as gallstones, aplastic crises, and folate deficiency can also be observed.

Hemolytic anemias that are due to factors extrinsic to the red cell can be further classified as immune-mediated or nonimmune. **Immune-mediated anemias** may be due to alloantibodies that occur in the setting of neonatal Rh or ABO incompatibility or transfusion reactions. Autoantibodies may occur in association with infection, autoimmune disorders, malignancy, or drugs. In children, autoantibodies (warm immunoglobulin G) are often seen in association with a viral illness. **Nonimmune hemolytic anemias** include microangiopathic and macroangiopathic hemolytic anemias due to a myriad of etiologies, including infections, drugs, toxins, burns, and heart valves.

Reticulocytopenic anemias can be congenital or acquired and can occur in isolation or in the setting of pancytopenia. **Diamond-Blackfan anemia** is a ribosomal disorder that causes a congenital pure red cell aplasia that presents early in infancy. The bone marrow typically shows red cell aplasia with a paucity of red cell precursors, and the red cells may be normocytic or macrocytic. Associated congenital anomalies, such as craniofacial anomalies, radial abnormalities, and renal and cardiac defects, are seen in approximately 25% of affected individuals. **Transient erythroblastopenia of childhood** is an acquired reticulocytopenic anemia that typically occurs following a viral illness. The usual age of presentation is between 2 to 3 years in an otherwise healthy child, and complete recovery is the natural course.

Evaluation

History

When evaluating an infant or child with anemia, the age, rapidity of onset of symptoms, MCV, and suspected underlying mechanism of anemia will direct the history (Questions Box). In most instances, it is important to inquire about dietary habits, with particular attention to the type and amount of milk ingested per day (number of bottles/ounces). Ingestion of more than 24 oz of cow's milk should raise

Questions

Anemia

- Does the child eat meat?
- Does the child drink too much milk (>24 oz/day)?
- Has the child had any bleeding recently?
- Has the child had a recent illness?
- Is the child taking any medications?
- Have the child's eyes appeared yellow?
- Does the child have a family history of anemia, jaundice, or gallstones?

the suspicion for iron deficiency anemia. Medication use, potential toxin ingestion (lead), or a history of pica should be determined as well. In addition, inquiries to potential sources of blood loss (hematochezia, melena, menorrhagia, hematuria, epistaxis, pulmonary) should be addressed. Acute onset of jaundice, icterus, or dark urine is suggestive of hemolysis and should elicit questions regarding possible triggers (fava beans, medications, illnesses). A personal history of neonatal hyperbilirubinemia or a family history of anemia, gallstones, cholecystectomy, or splenectomy is highly suggestive of a congenital hemolytic anemia. Acute onset of hemolysis with a viral illness is consistent with an autoimmune hemolytic anemia. Marrow failure syndromes often present with a prolonged history of increased fatigue and pallor, with occasional history of previous red cell transfusions prior to diagnosis. In acquired marrow failure states such as aplastic anemia, the history is occasionally consistent with antecedent hepatitis, a viral syndrome or, rarely, exposure to toxins such as benzene and toluene-containing compounds, or oral chloramphenicol use (commonly available over the counter in Latin America).

Physical Examination

Most children who present with anemia will have a normal physical examination. Depending on the degree of anemia, pallor, tachycardia, or tachypnea may be present. In severe cases of anemia (hemoglobin <3 g/dL) with chronic onset and moderate anemia (hemoglobin 3–7 g/dL) with acute onset (blood loss), CHF can occur. Other physical findings are unique to certain red cell disorders. Infants with sickle cell disease may present with dactylitis, a form of painful crisis that manifests as swelling of 1 to 4 digits associated with pain and sometimes fever. Splenomegaly can be seen in sickle cell disease (in younger children prior to autosplenectomy), β -thalassemia major and intermedia, and red cell membrane disorders, most commonly hereditary spherocytosis. In children with severe chronic hemolysis, regardless of etiology, classic facies (often called thalassemic facies) can develop, with frontal bossing and flattened nasal bridge, due to thinning of the facial bones from brisk intramedullary hematopoiesis. Children with Diamond-Blackfan anemia or Fanconi anemia may have physical anomalies, such as thumb or radial abnormalities, short stature, cardiac or renal anomalies, and developmental delay. Aplastic anemia or malignant infiltration of the bone marrow may present with concomitant neutropenia and thrombocytopenia. If neutropenic (absolute neutrophil count <1,000/mL), signs of fever or infection may be present. If thrombocytopenic, bruises; petechiae;

and mucosal bleeding from the mouth, nose, and GI tract may also be present. With malignancy, such as leukemia, lymphadenopathy and hepatosplenomegaly may also be observed.

Laboratory Tests

The complete **blood cell count (CBC)** and peripheral blood smear provide a wealth of information and should be evaluated closely to narrow the differential diagnosis. The first step is to determine if the child is truly anemic by referencing the normal **hemoglobin/hematocrit** values for the child's age and gender. The second step is to evaluate the red cell indices. The **MCV** is a direct measure of red cell size and allows for classification of the anemia as microcytic, normocytic, or macrocytic. The mean corpuscular hemoglobin (**MCH**) is a calculated value that typically parallels the MCV. The **MCH concentration** is a measure of the red cell hydration status and is useful when elevated as this reflects the presence of spherocytes. The red cell volume distribution width reflects the variation in red cell size (usually normal with thalassemia trait and elevated in iron deficiency). The RBC count can be useful because it is typically elevated (>5 million/mL) in a child with thalassemia trait and decreased in iron deficiency anemia. Review of the **white blood cell and platelet count** will provide information as to whether other cell lines are affected. The **peripheral blood smear** provides information regarding RBC morphology characteristic of different red cell disorders (sickle cells, spherocytes, elliptocytes, schistocytes). The presence of polychromasia is suggestive of a hemolytic process. White blood cell morphology can also suggest the etiology of the anemia (hypersegmented neutrophils in folate or vitamin B₁₂ deficiency). The **reticulocyte count** provides clues to the underlying mechanism of anemia. An elevated reticulocyte count is consistent with a hemolytic or blood loss picture whereas a reduced or normal reticulocyte count in the face of anemia suggests a production problem. If hemolysis is evident, a **Coombs test (direct antiglobulin test)** should be performed to determine if this is an immune-mediated process.

With the CBC, peripheral blood smear, and reticulocyte count, a focused differential diagnosis can be generated and more specific testing can be performed. Further studies specific for individual hemolytic diseases or particular diseases secondary to marrow failure are summarized in Table 83-2.

Imaging Studies

Few children routinely need imaging studies in the evaluation of their anemia. If performed in children with chronic hemolytic disorders, radiographs may reveal “hair-on-end” appearance of bones due to increased hematopoiesis. Patients who have anemia associated with lead poisoning may have lead deposition, referred to as **lead lines**, in their long bones.

Management

The treatment of anemia varies depending on the etiology. Nutritional anemias require dietary counseling and nutrient supplementation. With **iron deficiency anemia**, oral iron supplementation (3–6 mg/

kg/day divided into 2–3 doses) should generate a brisk reticulocytosis within 7 days, and the hemoglobin should increase by 1.0 g/dL/week thereafter. Therapy should be continued for an additional 6 to 8 weeks after the hemoglobin has normalized to replete iron stores. Dietary education is key to ensure that milk intake is reduced and that iron-rich foods are encouraged. Failure to respond to iron therapy is most commonly due to noncompliance; however, alternative diagnoses (thalassemia trait), ongoing blood loss, or malabsorption states should also be considered.

Patients with severe thalassemia syndromes (β -thalassemia major) are transfusion-dependent, often requiring transfusions every 3 to 4 weeks to maintain a hemoglobin level in the 9 to 10.5 g/dL range. With transfusion therapy, progressive iron deposition in tissues occurs leading to cardiac, hepatic, and endocrinologic complications, which can be fatal if not prevented. Iron chelation with deferoxamine or deferasirox has improved survival; however, compliance remains an issue. Bone marrow transplantation has been performed in patients with β -thalassemia major.

Depending on the degree of hemolysis and compensation, individuals with congenital hemolytic anemias may require no transfusions, intermittent transfusions (due to aplastic crises), or regular transfusions. Individuals may require folate supplementation and should be monitored for potential complications such as gallstones and aplastic crises. The more severely affected individuals may benefit from splenectomy. Individuals with G6PD deficiency should be counseled on the avoidance of potential triggers of hemolysis.

Two anemia-related conditions constitute emergencies. Prompt recognition of these conditions is vital if proper treatment is to be initiated. **Splenic sequestration** occurs in infants and young children with sickle cell disease who sequester large volumes of blood within the spleen over a period of hours. This results in a rapidly dropping hemoglobin, clinically resembling anemia due to massive blood loss. The blood pooled in the spleen is not available to the circulation, and affected children are subject to fatal splenic rupture. Treatment involves transfusion or exchange transfusion and early recognition is essential. **Severe autoimmune hemolytic anemia** is the second anemia-related emergency. Children with this disorder can occasionally present with severe Coombs-positive anemia and clinical evidence of rapid hemolysis; their hemoglobin may fall as much as 1 g/dL per hour. These patients generally require hospitalization, transfusion, and treatment with high-dose steroids.

The primary treatment for patients with Diamond-Blackfan anemia is steroids and RBC transfusions. Most patients will respond to steroids (50%–75%) and can be controlled at very low doses. For steroid-refractory patients, alternative immunosuppressive therapy and RBC transfusions are necessary. Bone marrow transplantation has been performed in steroid-refractory patients with Diamond-Blackfan anemia with success.

Prognosis

The prognosis for a child with anemia depends on the underlying cause. Children with anemia due to nutritional deficiencies that

are detected and appropriately treated have an excellent prognosis. Children with transient erythroblastopenia of childhood can expect complete recovery. Most immune-mediated anemias are responsive to therapy; however, if associated with an underlying autoimmune disorder, they may have a relapsing course. Children with chronic hemolytic disorders will have varying courses depending on the degree of hemolysis. Early diagnosis and intervention through newborn screening for children with sickle cell disease has significantly reduced early mortality for this disease. Children with β -thalassemia major or severe congenital hemolytic anemias will be transfusion-dependent and will be subject to the complications of iron overload, which can be addressed with chelation therapy. Some children with transfusion-dependent congenital hemolytic anemias may be candidates for splenectomy, with normalization of their hemoglobin values post-splenectomy. The prognosis for children with Diamond-Blackfan anemia depends on their responsiveness to steroid therapy and the need for transfusions. These individuals are also at risk for certain malignancies.

Children with anemia due to chronic inherited or acquired red cell disorders are at risk for complications during the course of their disease and are best served at a center that offers pediatric hematology expertise.

CASE RESOLUTION

The girl described in the case history at the beginning of the chapter has hereditary spherocytosis. Her history is highly suggestive of a hereditary hemolytic disorder, and the combination of spherocytes in the peripheral smear; a negative Coombs test; and a positive, incubated, osmotic fragility test are diagnostic of the condition. At the age of 9 years, she undergoes a splenectomy and has no more hemolytic episodes that require transfusions.

Bleeding Disorders

Wendy Y. Tcheng, MD

CASE STUDY

A 6-year-old girl presents with a several-month history of recurrent epistaxis. Episodes occur every 2 to 3 weeks and last 15 to 20 minutes at a time. Both nares are affected. Her mother also notes that the girl has always bruised easily. On physical examination, several 2- to 3-cm ecchymoses are noted on her lower extremities. Initial laboratory evaluation includes a complete blood cell count, which is normal (platelet count 300,000), a normal partial thromboplastin time of 30 seconds, and a normal prothrombin time of 12.5 seconds, with international normalized ratio (INR) 1:1.

Questions

1. What conditions should be considered when easy bruisability is the chief complaint?
2. What is the appropriate laboratory evaluation for children with clinical signs of bleeding?
3. What management is appropriate for the most common pediatric bleeding disorders?
4. What are the common medical complications that children with bleeding disorders face?
5. When is consultation with a hematologist appropriate in a child with easy bruisability?

When evaluating a child with bruising or bleeding symptoms, the major challenge facing the pediatrician is to ascertain whether the degree of bleeding is appropriate for the hemostatic stress or whether further evaluation for a potential bleeding disorder is warranted. Bruising and bleeding are common childhood complaints and usually follow minor injury or trauma. However, in the child with an underlying hemostatic disorder, non-accidental trauma, or both, the bruising or bleeding may be more extensive than expected. A thorough medical history and physical examination and an understanding of hemostasis will aid in focusing the laboratory evaluation and elucidating the underlying etiology.

Epidemiology

Bleeding disorders can be inherited or acquired. Of the inherited bleeding disorders, von Willebrand disease is the most common, with a reported incidence ranging between 1 in 100 and 1 in 1,000. Von Willebrand disease is autosomally inherited, affecting males and females equally; however, more females are diagnosed because of the inherent hemostatic challenges that females face (menses, childbirth). Hemophilia is the most common severe bleeding disorder affecting about 1 in 5,000 males. Approximately 80% of cases are hemophilia A (factor VIII [FVIII] deficiency) and 20% are hemophilia B (factor IX [FIX] deficiency). Hemophilia is inherited in an X-linked fashion, but a third of newly diagnosed males have no previous family history and represent new mutations. Other inherited coagulation disorders and platelet disorders are rare and are listed in Table 84-1.

Acquired abnormalities of coagulation or platelets are much more common. These can occur in the setting of liver disease, vitamin K

deficiency, renal disease, disseminated intravascular coagulation (DIC), infection, medications, malignancy, massive transfusion, post-surgery, and autoimmunity or alloimmunity. Immune thrombocytopenic purpura (ITP) is a common acquired childhood bleeding disorder with an incidence of 4 to 8 per 100,000 children per year. Neonatal alloimmune thrombocytopenia occurs in approximately 1 in 1,800 live births. Common acquired bleeding disorders are also listed in Table 84-1.

Clinical Presentation

Bleeding disorders can present in various ways depending on the etiology. Inherited bleeding disorders will often present during infancy or early childhood; however, mild disorders may go undiagnosed until later in life. In general, disorders of primary hemostasis (ie, von Willebrand disease, platelet disorders, collagen vascular disorders) will present with superficial, immediate, mucocutaneous-type bleeding. Characteristic bleeding symptoms include easy bruising, epistaxis, gum bleeding, menorrhagia, postpartum bleeding, and bleeding with dental extractions or surgeries. Disorders of secondary hemostasis, such as hemophilia A or B, will often present with deep, delayed bleeding, such as hemarthroses or muscular hematomas.

Acquired bleeding disorders typically present with an acute onset and often involve abnormalities of both primary and secondary hemostasis. Acute onset of bleeding symptoms in a toxic or ill-appearing child suggests a systemic process such as sepsis, DIC, malignancy, or hepatic or renal dysfunction. A well-appearing child with acute bleeding symptoms suggests ITP, an acquired inhibitor, or a medication-related cause.

Pathophysiology

Following vascular injury, hemostasis is initiated by exposure of flowing blood to subendothelial collagen and tissue factor. The primary phase of hemostasis leads to the production of a platelet plug. Von Willebrand factor (vWF), a multimeric glycoprotein of varying size, attaches to exposed subendothelial collagen and binds platelets via the platelet glycoprotein IB/IX receptor. Von Willebrand factor also serves as a carrier protein for FVIII, thereby localizing FVIII to areas of endothelial disruption. Once platelets adhere to vWF, they become activated and release their granular contents, produce thromboxane A₂, and express the fibrinogen receptor glycoprotein IIb/IIIa (GPIIb/IIIa). The release of thromboxane A₂ and other granular contents leads to local vasoconstriction and activation of additional platelets and their respective GPIIb/IIIa receptors, allowing for platelet aggregation. Fibrinogen binds to all of the exposed activated GPIIb/

IIIa sites, clumping the platelets together to form a platelet plug. The platelet plug stops local bleeding and provides a phospholipid surface for the coagulation reactions of secondary hemostasis to occur to form a definitive fibrin plug.

Secondary hemostasis is also initiated at the time of endothelial disruption with exposure of tissue factor to circulating blood. Tissue factor binds to FVIIa, and this complex serves as the key initiator of in vivo hemostasis by activating other tissue factor: FVII (TF:FVII) complexes, as well as FIX, and factor X (FX). Once activated (either by FIXa or TF:FVIIa), FXa along with its cofactor, factor Va, activates prothrombin (FII) to thrombin (FIIa). Thrombin cleaves circulating fibrinogen to fibrin monomers that self-polymerize. Factor XIII then stabilizes the fibrin clot by forming cross-links within the clump of fibrin polymers. These coagulation reactions occur on the surface of the platelet plug and, with the generation of cross-linked

fibrin, the primary platelet plug is converted into a definitive fibrin plug that prevents further bleeding. An overview of hemostasis is depicted in Figures 84-1 and 84-2. Deficiencies or impairments in any of these elements can lead to inadequate hemostasis and excessive hemorrhage.

The delicate balance of hemostasis and thrombosis is maintained by inhibitors (protein C, protein S, antithrombin, tissue factor pathway inhibitor) at each step of the coagulation cascade. These natural anticoagulants serve to prevent excessive thrombus formation. Fibrinolysis is mediated by plasmin, which cleaves both fibrinogen and fibrin within a thrombus, allowing for restoration of vessel patency following hemostasis. Plasmin is activated by tissue plasminogen activator (tPA) and urokinase. Fibrinolysis is kept in check by plasminogen activator inhibitor (PAI-1), which inactivates tPA, and α_2 -antiplasmin, which inactivates plasmin. Any defects in the fibrinolytic system that leads to an increase in fibrinolysis can result in excessive bleeding.

Differential Diagnosis

In developing the differential diagnosis for a child with bleeding symptoms, it is important to obtain a thorough bleeding history and physical examination. The age, bleeding pattern, duration of symptoms, family history, and overall clinical status of the child will help to narrow the spectrum of possibilities.

Child With Chronic History of Mucocutaneous Bleeding

In a child who presents with a history of easy bruising, epistaxis, or menorrhagia, the primary differential diagnosis includes von Willebrand disease, platelet disorders, and collagen vascular disorders (disorders of primary hemostasis). **Von Willebrand disease** is caused by a quantitative or qualitative defect of vWF. Von Willebrand factor plays an important role in both primary hemostasis (mediates platelet adhesion at sites of vascular injury) and secondary hemostasis (stabilizes FVIII in plasma). Von Willebrand disease is autosomally inherited and classified into 3 different types. Type 1 refers to a partial quantitative deficiency of vWF. Type 2 refers to qualitative abnormalities of vWF with a number of subtypes that fall within this classification. Type 3, the most severe form, refers to a complete deficiency of vWF. Type 1 is the most common form, accounting for 70% to 80% of cases. Bleeding symptoms tend to be mild and are characterized by easy bruising, epistaxis, menorrhagia, and prolonged oozing after minor or major surgeries. Only the most severely affected patients (type 3), with very low FVIII levels, will have soft tissue bleeding and hemarthroses similar to an individual with moderate or severe hemophilia.

Qualitative platelet disorders also present with mucocutaneous bleeding, often during infancy. In **Bernard-Soulier syndrome**, the platelets lack a functional glycoprotein IB/IX receptor complex on

Figure 84-1. Intrinsic pathway reflected by aPTT.

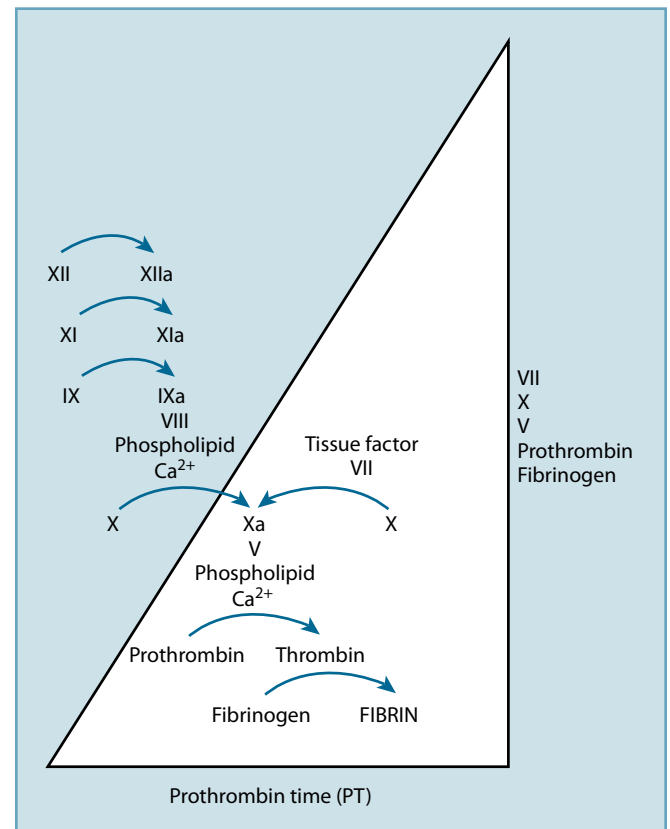

Figure 84-2. Coagulation pathway. Extrinsic pathway reflected by PT.

the platelet surface, resulting in defective platelet adhesion to vWF at sites of vascular injury. It is an autosomal-recessive disorder and is usually seen in consanguineous families. The platelets tend to be large on peripheral smear, and there may be a degree of thrombocytopenia. **Glanzmann thrombasthenia** is characterized by an absence or defect in the platelet membrane GPIIb/IIIa receptor, the main fibrinogen receptor on the platelet surface that allows for platelet aggregation. It is autosomal-recessively inherited and is more common in the presence of consanguinity. Other qualitative platelet disorders such as **storage pool disorders** and **platelet release defects** can also present in a similar manner.

Collagen-vascular disorders, such as Marfan syndrome and Ehlers-Danlos syndrome, can present with bruising and bleeding symptoms. This increased bleeding diathesis is due to an easy disruption of the integrity of the vascular endothelium.

Other rare coagulation disorders to consider in a child with recurrent bleeding symptoms include deficiencies of FXI, FXIII, PAI-1, and α_2 -antiplasmin. **Factor XI deficiency**, also known as *hemophilia C*, is a rare bleeding disorder with a high prevalence in the Ashkenazi Jewish population. It differs from the other hemophilias in that it is autosomally inherited and tends to have milder symptoms. Bleeding episodes are typically in response to trauma or surgery, and the deep tissue or intra-articular bleeds characteristic of FVIII or FIX deficiency are not seen. **Factor XIII deficiency** is characterized by delayed or prolonged bleeding because the clots formed are friable owing to the lack of cross-linkage of fibrin monomers by FXIII. It is inherited in an autosomal-dominant pattern, and in the homozygous state usually presents in infancy with umbilical cord bleeding or delayed separation, as well as intracranial hemorrhage. Heterozygotes may present later in life with delayed or prolonged bleeding following trauma or surgery and poor wound healing. **Disorders of fibrinolysis** (deficiency of PAI-1 or α_2 -antiplasmin) can also present with prolonged bleeding following trauma.

Child With History of Deep, Delayed Bleeding

Deep tissue and intra-articular bleeding is the hallmark bleeding pattern of **hemophilia**. The differential diagnosis for a child who presents with this type of bleeding is hemophilia A (FVIII deficiency) or B (FIX deficiency), FVII deficiency, and type 3 von Willebrand disease. Clinically, hemophilia is classified according to the factor level with less than 1% factor activity as severe, 1% to 5% as moderate, and greater than 5% as mild. The factor level correlates with the bleeding tendency. Males with severe hemophilia can have “spontaneous” bleeds or bleeding with minimal trauma. Males with moderate or mild hemophilia will bleed with more significant trauma. The bleeding pattern of hemophilia varies as the child grows. Infants may present with a cephalohematoma or intracranial hemorrhage, particularly if the delivery was complicated with the use of forceps or vacuum extraction. Bleeding with circumcision, heel sticks, or blood draws may also occur. As the infant starts crawling, bruises and soft tissue hematomas on the lower extremities become common. As the toddler becomes upright, the first hemarthroses can

occur, typically involving the ankle. The older child has hemarthroses primarily involving the knees and elbows.

Factor VII deficiency is very rare; however, it can present with a bleeding pattern similar to hemophilia A or B. Type 3 von Willebrand disease, which is characterized by an absence of vWF (the carrier protein for FVIII), can have FVIII levels as low as an individual with severe or moderate hemophilia A. In addition to the characteristic mucocutaneous bleeding seen with von Willebrand disease, these individuals can also have deep tissue and intra-articular bleeding.

Well-Appearing Child With Acute Onset of Bleeding Symptoms

An acute onset of bleeding symptoms is consistent with an acquired abnormality of hemostasis. Acute **ITP** is a common acquired bleeding disorder of childhood due to the development of autoantibodies directed against the patient’s platelets. These autoantibodies, which cross-react with platelet surface antigens, are thought to develop in response to an infection. Typically, a healthy child (usually between the ages of 2 to 4 years) presents with an abrupt onset of bleeding symptoms, diffuse petechiae and bruising and, occasionally, “wet” bleeding (epistaxis, gum bleeding, gastrointestinal [GI] bleeding). There is often a history of a viral illness or recent immunization. The complete blood cell count (CBC) reveals an isolated thrombocytopenia, and large platelets are seen on peripheral smear reflecting an active marrow with the production of young platelets. In approximately 80% of cases, ITP is an acute, self-limited process resolving within 6 months of diagnosis with or without therapy. Chronic ITP exists when the thrombocytopenia persists beyond 6 months. Although it is not possible to predict at diagnosis whether a patient will go on to have chronic ITP, there are certain presenting features that are associated with a higher risk for chronicity. These include older age at presentation (>10 years), female gender, existing autoimmune disease, and insidious onset of symptoms. In most cases of chronic ITP, the platelet count ranges between 40,000 to 80,000, and bleeding symptoms are minimal.

Acquired coagulation inhibitors are rare in children without an underlying coagulation disorder; however, they can occur in the setting of malignancy, infection, or post-surgery. Acquired FVIII deficiency due to FVIII inhibitor occurs primarily in the adult population, but has been previously reported in children. Acute onset of severe bleeding symptoms is the common presentation. Antiphospholipid antibodies can cause a prolongation of the partial thromboplastin time (PTT) or prothrombin time (PT); however, these antibodies are not associated with bleeding and are typically transient following a viral illness. The exception is if the antiphospholipid antibody is directed against prothrombin, resulting in low levels of prothrombin. In this situation, bleeding may be associated but is usually mild and intervention unnecessary.

Acquired abnormalities of coagulation or platelet function can also occur in association with **medications**. Aspirin and nonsteroidal anti-inflammatory drugs are common medications that affect the function of platelets. Warfarin, a vitamin K antagonist, is commonly

used as an anticoagulant. One percent to 3% of patients on therapeutic warfarin can experience bleeding complications. Chronic antibiotic use can result in vitamin K deficiency and a depletion of the vitamin K–dependent factors (II, VII, IX, X).

III-Appearing Child With Acute Onset of Bleeding Symptoms

Acute onset of bleeding in an ill-appearing child suggests an acquired systemic process. **Disseminated intravascular coagulation** is a consumptive coagulopathy that can occur secondary to a number of disorders, including sepsis, trauma, or malignancy. Disseminated intravascular coagulation occurs as a result of endothelial disruption and initiation of abnormal coagulation; fibrin deposition; and depletion of multiple clotting factors, inhibitor proteins, and platelets.

Because the liver is the primary site of synthesis for most of the coagulation factors, **liver dysfunction** due to any illness can result in an imbalance in the hemostatic system. In addition, thrombocytopenia may be present with chronic liver disease because of portal hypertension and associated splenomegaly with sequestration. Causes of the depletion of vitamin K–dependent factors, such as obstructive jaundice, malabsorptive states (cystic fibrosis), parenchymal liver disease, and chronic antibiotic use, can also predispose to bleeding.

Renal disease with uremia impairs platelet function and can present with bleeding symptoms as well. A **malignancy** infiltrating the bone marrow, such as leukemia, lymphoma, or neuroblastoma, can cause thrombocytopenia and resultant platelet bleeding. Acquired von Willebrand disease can occur with Wilms tumor and present with mucocutaneous bleeding. **Bone marrow failure syndromes** can also present with thrombocytopenia and associated bleeding.

Infant With Bleeding Symptoms

An infant who presents with bleeding symptoms may have a congenital bleeding disorder or an acquired condition. **Inherited coagulation deficiencies** (VII, VIII, IX, XI, XIII, type 3 von Willebrand disease) and qualitative platelet disorders may present in the newborn period with intracranial hemorrhage or cephalohematoma, bleeding with heel sticks or blood draws, umbilical cord bleeding, and bleeding with circumcision. **Congenital thrombocytopenias** usually present within the first year of life and are associated with other syndromic features. Thrombocytopenia–absent radius (TAR) syndrome is an autosomal-recessive condition, typically recognized in the newborn period, characterized by thrombocytopenia, skeletal anomalies (most commonly radial agenesis), and renal and cardiac abnormalities. Other congenital thrombocytopenias include amegakaryocytic thrombocytopenia, Fanconi anemia, and Wiskott-Aldrich syndrome.

Neonatal alloimmune thrombocytopenia (NAIT) is a rare condition in which an infant inherits platelet antigens from the father that are different from the mother. The mother becomes alloimmunized to the infant's platelet antigens during pregnancy, similar to erythrocyte alloimmunization from Rh incompatibility. The maternal

immunoglobulin G alloantibodies cross the placenta and destroy the infant's platelets, resulting in a transient but severe thrombocytopenia in the infant. Antibodies against the human platelet antigen-1a are responsible for 80% of NAIT cases in the Caucasian population. Thrombocytopenia in the infant can last several weeks until the maternal antibody is cleared. Unlike Rh alloimmunization, NAIT can occur in the first pregnancy. The risk of intracranial hemorrhage is significant, with a reported incidence of up to 20% in some series, and can occur in utero. Neonatal thrombocytopenia can also occur as a consequence of **maternal ITP** with maternal transfer of antibody. Bleeding tends to be mild in this setting and intracranial hemorrhage is rare. The thrombocytopenia resolves after several weeks. An acquired thrombocytopenia most often occurs in the setting of an ill infant with sepsis, congenital viral infection (*Toxoplasma*, rubella, cytomegalovirus, HIV), necrotizing enterocolitis, respiratory distress syndrome, asphyxia, or congenital heart disease. Drug-associated thrombocytopenia can also occur in the hospitalized infant.

Vitamin K deficiency in the neonate has 3 different presentations. **Classic hemorrhagic disease of the newborn** presents between days 2 to 7 of life and is due to the immature neonatal liver and impaired clotting factor synthesis, inadequate vitamin K intake, and a sterile neonatal gut. With the advent of vitamin K prophylaxis at birth, this form of vitamin K deficiency is rarely seen. **Early hemorrhagic disease of the newborn** presents in the first 24 hours of life and is due to maternal medications that affect vitamin K metabolism (anticonvulsants). **Late vitamin K deficiency** occurs after the first week of life and is associated with a number of conditions in which vitamin K stores may be low, such as inadequate intake in breastfed infants, impaired absorption in infants with chronic diarrhea, antibiotic use, cystic fibrosis, and other GI disorders. Bleeding symptoms associated with vitamin K deficiency can be quite severe with a significant incidence of GI, deep tissue, and intracranial hemorrhage.

Evaluation

History

A thorough bleeding history and physical examination should enable the pediatrician to determine the likelihood of an underlying bleeding disorder. The pattern of bleeding, the timing of the symptoms (acute vs chronic), the overall health of the child, and the family history are important in helping to determine the underlying etiology. Box 84-1 lists the pertinent questions to ask when obtaining a bleeding history.

Bruises are a common childhood complaint. Normal bruising that occurs in an active child must be differentiated from pathologic bruising owing to a possible bleeding disorder or non-accidental trauma. Bruises over exposed bony prominences such as the anterior tibial region or the knees are common. Bruises of a size inconsistent with the degree of reported trauma, and bruises in nonexposed or unusual areas (back, chest, shoulders, or upper arms) should alert the pediatrician to a possible bleeding disorder or

Box 84-1. Pertinent Questions for a Bleeding History

- Is the bleeding acute or chronic?
 - For acute onset bleeding
 - ~ What type of bleeding is the child experiencing?
 - ~ Is the child well-appearing or toxic?
 - ~ Is there a history of recent illness?
 - ~ Is the child taking any medications?
 - ~ Does the child have any medical problems?
 - For chronic history of bleeding
 - ~ What type of bleeding is the child experiencing?
 - ♦ Bruising (location, size, palpable hematoma)
 - ♦ Epistaxis (duration of bleeding, history of packing, cauterization, or transfusion)
 - ♦ Bleeding with vaccinations, injections, minor cuts
 - ♦ Bleeding with dental extractions/surgeries
 - ♦ Menses (total number of days of bleeding, leaking, alteration of activities during menses, diagnosis of iron deficiency, use of oral contraceptives, history of transfusion)
 - ~ Medications
 - ~ Family history (obstetric and gynecologic history of female relatives)

non-accidental trauma. Linear or geometric bruises are concerning for non-accidental trauma. Epistaxis, another common complaint, is most often due to digital trauma or allergic rhinitis. However, epistaxis unrelieved by 15 minutes of appropriately applied pressure or epistaxis requiring packing, cautery, or transfusions is highly suggestive of a bleeding disorder. Menorrhagia, defined as menstrual flow greater than 7 days, and a history of frequently stained clothes or iron deficiency anemia in an adolescent female are concerning. Persistent or recurrent bleeding with dental extractions (beyond the day of the procedure) or with surgeries also merits a closer evaluation. However, if a child has undergone previous dental extractions or surgeries without bleeding complications, an underlying bleeding disorder is unlikely.

Physical Examination

Depending on the underlying bleeding disorder and the time of presentation, the physical examination may be completely normal. If there is active bleeding, physical signs may include petechiae, ecchymoses, mucosal bleeding (nasal, oral, vaginal), hematuria, swollen joints (hemarthrosis), or limited range of motion. Children with bleeding associated with an acquired disorder such as infection, malignancy, autoimmunity, or liver or renal dysfunction may have physical signs specific to the underlying illness. Children with bleeding associated with a genetic disorder may have a normal examination or congenital anomalies associated with a particular syndrome.

Laboratory Tests

The extent of the laboratory evaluation is dependent on the bleeding history and clinical presentation. Initial laboratory studies for a potential bleeding disorder should include a CBC with a peripheral smear, a PT, and an activated PTT (aPTT).

The **CBC** is useful in providing a platelet count to identify suspected thrombocytopenia. In addition, abnormalities in the white blood cell count or red cell indices can provide clues to the underlying process. A microcytic anemia consistent with iron deficiency would suggest chronic blood loss and raise the suspicion for an underlying bleeding disorder. Pancytopenia would suggest an underlying bone marrow failure syndrome or a possible malignancy such as leukemia. Review of the **peripheral smear** can confirm the presence of true thrombocytopenia and allow for an assessment of platelet, white blood cell, and red blood cell morphology.

The **PT** reflects the extrinsic and common pathway and the **aPTT** reflects the intrinsic and common pathway. A prolonged PT or PTT should be followed up with a 1:1 mixing study to determine whether the prolongation is due to a factor deficiency or the presence of an inhibitor. The **bleeding time** is a reflection of primary hemostasis (platelets, vWF, vascular integrity), but is rarely performed in pediatrics because of the unreliability and difficulty of performing this test in children. The **platelet function assay** is a screening test of platelet function, measuring both platelet adhesion and aggregation (primary hemostasis).

A stepwise approach to more specific testing is dictated by the clinical presentation and screening test results and is best performed with the consultation of a pediatric hematologist. When an abnormality of primary hemostasis is suspected, the initial evaluation should focus on von Willebrand disease because it is the most common disorder. A **vWF panel**, which includes vWF antigen, ristocetin cofactor activity (functional measure of vWF), FVIII activity, and a vWF multimer analysis, should be performed. Many factors may transiently increase vWF levels (stress, inflammation, hormones, exercise, oral contraceptives), and normal results are frequently encountered in patients with type 1 von Willebrand disease. Repeat testing is often necessary to make the diagnosis and should be pursued if the suspicion is high. For hemophilia or any other suspected factor deficiency, a specific **coagulation factor assay** must be performed. For patients with suspected qualitative platelet disorder, **platelet aggregation studies** (measuring the degree and pattern of platelet aggregation to various agonists) or **flow cytometry** (measuring the platelet surface GP expression) can be performed. On a case-by-case basis, additional studies such as fibrinogen, d-dimer, fibrin split products, thrombin time, factor inhibitor assay, autoimmune studies, liver function tests, creatinine, or blood urea nitrogen may be indicated. Table 84-2 lists the major screening tests for hemostasis.

Table 84-2. Laboratory Evaluation for Hemostasis

Laboratory Test	Measured Hemostatic Function
CBC	Platelet count
Peripheral blood smear	Platelet morphology
aPTT	Factors I, II, V, VIII, IX, XI, XII (intrinsic and common pathway)
PT	Factors I, II, V, VII, X (extrinsic and common pathway)
aPTT and PT mixing studies	Performed when aPTT/PT is prolonged; patient plasma and normal plasma is mixed 1:1, and then aPTT/PT repeated; if the aPTT/PT corrects, there is a factor deficiency, if not, there is an inhibitor
Bleeding time (not recommended)	Primary hemostasis (platelets, vWF, endothelial integrity)
PFA-100 screen	Primary hemostasis (platelets, vWF)
Thrombin time	Fibrinogen
vWF panel	vWF antigen (amount of vWF) Ristocetin cofactor activity (function of vWF) Factor VIII activity vWF multimer analysis (distribution of multimers)
Coagulation factor assays	Specific factor activity
Platelet aggregation studies	Platelet function; patient platelets are exposed to agonists and the degree of aggregation and pattern of the response is unique for various qualitative platelet disorders

Abbreviations: aPTT, activated partial thromboplastin time; CBC, complete blood cell count; PFA, platelet function assay; PT, prothrombin time; vWF, von Willebrand factor.

Imaging Studies

In general, imaging studies are not indicated. Bone films may be taken of the upper extremities in patients with thrombocytopenia to rule out Fanconi anemia and TAR syndrome.

Management

The management of bleeding disorders is dependent on the underlying abnormality. However, general supportive measures, such as local pressure for bleeding, avoidance of blood draws, and avoidance of medications that affect the function of platelets or hemostasis, can be applied to most clinical scenarios of bleeding.

Treatment of **von Willebrand disease** is dependent on the subtype and the severity of bleeding symptoms. For mild bleeding symptoms, supportive measures alone may be all that is necessary—applying appropriate pressure for epistaxis, ice pack for bruises, and avoidance of antiplatelet medications. For type 1 von Willebrand disease, DDAVP (synthetic vasopressin) can be used and is available as a concentrated nasal spray or intravenously. DDAVP stimulates endothelial release of vWF and can increase levels 2- to 3-fold. For type 3 and most cases of type 2 von Willebrand disease,

replacement therapy with FVIII concentrates that contain vWF is necessary for significant bleeding episodes. Antifibrinolytic agents such as aminocaproic acid are very effective for mucosal bleeding and can be used either alone for mild cases or in conjunction with DDAVP or FVIII concentrates in more severe episodes of bleeding. For females with menorrhagia, a trial of oral contraceptives is reasonable because estrogen can increase vWF levels. This response is variable, however, and if not effective, aminocaproic acid and nasal DDAVP may be necessary.

The treatment for most **qualitative platelet disorders** is supportive. Mild bleeding episodes can be treated nonspecifically with antifibrinolytic agents or DDAVP. Platelet transfusions should be reserved for life-threatening bleeds and otherwise avoided because of the risk for developing antibodies.

The management for **acute ITP** consists of family education, supportive measures and, in selected cases, pharmacologic therapies. The use of pharmacologic therapies in acute ITP remains controversial. The natural course of acute ITP is for the platelet count to rise within 1 to 3 weeks of presentation. The impetus to treat is the theoretical prevention of intracranial hemorrhage; however, the incidence of this complication is less than 0.5%, and there are no data to confirm that any of the currently available therapies actually prevent this complication. Pharmacologic intervention will increase the platelet count more rapidly and may prevent a significant bleeding complication. In those at risk, the use of pharmacologic intervention will not reduce the likelihood of developing chronic ITP. The decision to treat must be individualized, taking into consideration the child's age, bleeding symptoms, child's activity level, and parental anxiety level. Treatment options include observation without medical therapy, corticosteroids, intravenous (IV) gammaglobulin, and anti-D immunoglobulin. Anti-D immunoglobulin can only be used in patients who are Rh positive. In all cases, parents should be instructed to avoid the use of aspirin, ibuprofen, and other antiplatelet medications; to avoid intramuscular injections; and to postpone immunizations and allergic desensitization injections that may exacerbate the degree of thrombocytopenia. Physical activity should be limited with specific instruction to avoid activities that may cause head injury. Parents should also be educated to the signs and symptoms of an intracranial hemorrhage and given instructions as to what to do in the event of an emergency. Therapeutic options for **chronic ITP** include observation without therapy, corticosteroids, regular infusions of IV immune globulin (IVIG) or anti-D immunoglobulin (for Rh+ patients), immunosuppressive agents, Rituximab, and laparoscopic splenectomy. Rituximab is a chimeric monoclonal antibody directed against CD20 (found primarily on the surface of B cells) and has been shown to be effective in chronic ITP and other autoimmune conditions. Treatment for acute bleeding in **neonatal alloimmune thrombocytopenia** includes transfusion of maternal platelets and IVIG.

Prevention and early treatment of bleeding episodes, family education, and good well-child care are important in providing comprehensive **hemophilia** care. The current standard of care for patients

with severe hemophilia is prophylaxis, the IV administration of factor on a regular schedule (every other day, 3 times a week, or twice a week depending on the type of hemophilia) to prevent bleeding episodes. Prophylaxis is usually initiated during the first few years of life. A subcutaneous central venous catheter is inserted for this purpose and, as the child grows, the parents, and eventually the child, are taught how to administer factor by peripheral infusion. For acute bleeds, prompt treatment is essential to prevent long-term complications. In 30% of patients with hemophilia A and 2% to 3% of patients with hemophilia B, an inhibitor to the respective factor can develop. In the presence of an inhibitor, acute bleeds must be treated with bypassing agents such as prothrombin concentrates or recombinant FVIIa. In the long term, immune tolerance is attempted by exposing the child to high doses of factor on a daily basis in an attempt to eradicate the inhibitor. A number of immune tolerance regimens have been in use with varying success.

Acquired causes of coagulation or platelet abnormalities can be treated supportively or by replacing the deficiency or removing the offending causative agent. Children with **DIC** may be given fresh frozen plasma, cryoprecipitate, and platelets as needed while the underlying etiology of the DIC is treated. In children in whom **vitamin K deficiency** is suspected as the cause of bleeding, one dose of vitamin K should correct the coagulopathy within 12 to 36 hours. Depending on the underlying cause of vitamin K deficiency, regular replacement may be required.

Prognosis

Most patients with inherited bleeding disorders will have an excellent prognosis if the diagnosis is made in a timely fashion and appropriate intervention is initiated.

Patients with **von Willebrand disease** usually have mild bleeding symptoms and, with appropriate education and intervention, the prognosis is excellent. Patients with **hemophilia** will also have an excellent prognosis assuming early diagnosis, family education, prophylaxis, and early treatment of bleeds. With the advent of prophylaxis, the severe hemophilic arthropathy that plagued older generations of males with hemophilia has been largely averted or minimized. In addition, the use of recombinant factor products and highly purified plasma-derived products in the pediatric population has minimized the risk for viral transmission. **Acute ITP** resolves

spontaneously by 6 months in 80% of cases, regardless of pharmacologic intervention, and the risk for significant hemorrhage is exceedingly low. For individuals with **chronic ITP**, most cases will also resolve with time, and individuals do not usually have significant bleeding complications.

CASE RESOLUTION

A vWF panel was performed and revealed a vWF antigen of 20%, ristocetin cofactor activity of 30%, FVIII activity of 40%, and a normal multimer analysis. The girl was diagnosed with type 1 von Willebrand disease. A DDAVP challenge was performed in clinic, and she was found to have an excellent response. She was prescribed nasal DDAVP (Stimate) and aminocaproic acid for significant bleeding episodes.

Lymphadenopathy

Wendy Y. Tcheng, MD

CASE STUDY

A 12-year-old girl is brought to the office with swelling of the anterior cervical nodes, which she has had for 2 weeks. Intermittent fever with temperatures as high as 101°F (38.3°C) and decreased appetite have been associated with the condition. On examination, her temperature is 100.4°F (38.0°C), and her other vital signs are normal. Three to 4 non-tender nodes 1 to 2 cm in diameter are present bilaterally. The remainder of the examination is normal.

Questions

1. When is lymphadenopathy of medical concern?
2. What are the clinical features of childhood diseases that present as cervical lymphadenopathy?
3. What are the diagnostic approaches to the evaluation of children with lymphadenopathy?
4. What is an appropriate therapeutic approach to cervical lymphadenopathy in children?

Lymphadenopathy is one of the most common clinical problems encountered in pediatrics. Palpable lymph nodes are a source of anxiety for parents, often prompting a pediatrician visit for evaluation. While most cases are due to a benign, self-limited infectious process, lymphadenopathy may also signal a serious underlying systemic illness. It is important for the pediatrician to make this distinction so that appropriate diagnostic and therapeutic measures can be initiated when necessary.

Epidemiology

Lymphadenopathy occurs frequently in childhood, and even healthy children may have palpable lymph nodes in the anterior cervical, inguinal, and axillary regions. Localized lymphadenopathy is largely due to an infectious etiology, whereas generalized lymphadenopathy occurs with systemic illnesses, such as systemic infections (viral, bacterial, protozoal, fungal), autoimmune disorders, storage disorders, and malignancies.

Clinical Presentation

Lymphadenopathy may be localized or generalized on presentation. **Localized** or **regional** lymphadenopathy refers to enlargement of lymph nodes within contiguous regions, whereas **generalized** lymphadenopathy involves more than 2 noncontiguous lymph node groups (Dx Box). Infection is the most frequent cause of localized lymphadenopathy in children. The anterior cervical lymph node region is the most commonly involved area reflecting the high frequency of upper respiratory infections (URIs). Bilateral cervical lymphadenopathy is often seen with viral and bacterial URIs, and the nodes tend to be soft, mobile, and non-tender. Viruses such as Epstein-Barr virus (EBV) or cytomegalovirus (CMV) can present with prominent posterior cervical lymphadenopathy as well as generalized adenopathy,

Dx Lymphadenopathy

- Enlarged lymph nodes
- Fever
- Tenderness or warmth over the lymph nodes (lymphadenitis)
- Antecedent infection (eg, pharyngitis, upper respiratory infection, otitis media)
- Pallor
- Weight loss
- Bone pain

and occasionally hepatosplenomegaly. Direct bacterial invasion of lymph nodes produces a lymphadenitis, which is typically unilateral, tender, erythematous, and fluctuant. Chronic lymphadenopathy may be due to atypical mycobacterial infections, tuberculosis, cat-scratch disease, EBV, CMV, toxoplasmosis, coccidiomycosis, or HIV. Generalized lymphadenopathy is concerning for an underlying systemic illness (infection, autoimmune process, storage disease, or malignancy). Lymphadenopathy due to malignancy is typically characterized by fixed, firm, non-tender lymph nodes in the setting of other signs and symptoms, such as fever, pallor, night sweats, and weight loss.

Pathophysiology

Lymph nodes are an integral part of the immune system where phagocytic cells filter microorganisms and particulate matter, and antigens are presented provoking a cellular or humorally mediated lymphocyte response. Lymph nodes are distributed in groups throughout the body and drain specific regions (head, neck, axilla, mediastinum, abdomen, extremities) (Table 85-1). Enlargement of a

Table 85-1. Lymph Node Drainage Patterns

Group	Drainage Pattern
Occipital	Posterior scalp
Preauricular	Superficial orbital and periorbital tissue, temporal scalp
Submental/ submandibular	Mouth
Cervical	Mouth, pharynx, ear, parotid gland, deep structures of neck (thyroid, larynx, trachea, upper esophagus)
Supraclavicular	Head, neck, arms, lungs, mediastinum, and abdomen
Mediastinal	Lungs, heart, thymus, esophagus
Axillary	Chest wall, breast, upper extremity
Abdominal	Abdominal organs, pelvis, lower extremities
Iliac and inguinal	Lower extremities, genitalia, buttocks, pelvis

lymph node may be due to proliferation of lymphocytes intrinsic to the lymph node (as a physiological immune response or a malignant transformation) or may be due to infiltration by extrinsic inflammatory or metastatic malignant cells.

Differential Diagnosis

The duration and extent of lymphadenopathy (localized vs generalized), the characteristics of the lymph nodes, and the presence of associated symptoms will help to focus the differential diagnosis. A list of the common causes of lymphadenopathy in children is provided in Table 85-2.

Localized lymphadenopathy is most often due to an infectious etiology. Acute bilateral cervical lymphadenopathy is most frequently due to viral URIs (respiratory syncytial virus, adenovirus, influenza virus) or EBV and CMV, which can also cause generalized adenopathy. Bacterial pharyngitis (most commonly *Streptococcus* species) and oral infections/dental abscesses can also present with cervical adenopathy. Unilateral lymphadenitis is most often due to *Staphylococcus aureus*, followed by *Streptococcus pyogenes*, anaerobes, and other species. When the condition appears subacute, cat-scratch disease; tuberculosis (scrofula); atypical mycobacteria; toxoplasmosis; tularemia; and, less commonly, histoplasmosis, brucellosis, and syphilis should be considered. Cervical lymphadenopathy can also occur with Kawasaki disease, along with high fever (5 days), redness/swelling/desquamation of extremities, conjunctivitis, rash, swollen lips/tongue.

Generalized lymphadenopathy may be due to systemic infections (eg, EBV, CMV, HIV, toxoplasmosis), autoimmune disorders (eg, juvenile idiopathic arthritis, systemic lupus erythematosus), storage disorders (eg, Niemann-Pick, Gaucher disease), histiocytic disorders (eg, Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis), drug reactions (eg, phenytoin), or malignancies. Malignancies include leukemia and lymphoma (Hodgkin and non-Hodgkin lymphoma) as well as solid tumors that can metastasize to lymph nodes (eg, neuroblastoma, rhabdomyosarcoma). With neoplastic infiltration, enlarged nodes are generally non-tender,

firm, rubbery, and immobile. In Hodgkin disease, the nodes enlarge sequentially, with involvement spreading from one chain to the next. Supraclavicular or epitrochlear adenopathy is highly suggestive of malignancy.

A number of head and neck lesions that occur in the pediatric population merit comment because they are often confused with cervical lymphadenopathy. These lesions include cystic hygromas, branchial cleft cysts, thyroglossal duct cysts, and epidermoid cysts. These are congenital malformations that often present as a neck mass in the young child and can easily be mistaken for a lymph node, particularly if infected (see Chapter 79).

Evaluation

History

A thorough history and review of symptoms is essential in determining the underlying etiology of lymphadenopathy in children. Inquiries should be made regarding the duration of the lymphadenopathy, the rate of nodal enlargement, and the occurrence of associated fever and other constitutional symptoms, such as bone pain, weight loss, fever, and night sweats. Recent illnesses or infections, insect or animal bites, and local trauma should be determined. A history of distant travel; recent emigration from countries with endemic tuberculosis (eg, Mexico, Central America, Southeast Asia); recent travel to areas with endemic histoplasmosis (southeastern United States) or coccidioidomycosis (San Joaquin Valley, CA); a detailed history of pet contact (cats/kittens, which can transmit toxoplasmosis and cat-scratch disease); and exposure to ill contacts, particularly individuals known to have tuberculosis, are also important (Questions Box).

Physical Examination

When evaluating a child with lymphadenopathy, the enlarged nodes should be measured and examined at their widest diameter and evaluated for evidence of erythema, tenderness, and warmth, all of which are suggestive of infection. The characteristics of the enlarged lymph node should be noted (eg, soft, firm, rubbery, mobile, matted, tender, discrete). The surrounding skin and soft tissue region that is drained by the involved lymph node should be examined for signs of inflammation or skin breakdown. The extent of the lymphadenopathy should be determined, as well as the presence or absence of hepatosplenomegaly.

Laboratory Tests

In most cases, a thorough history and physical examination can establish the likely diagnosis without any laboratory testing. If studies are deemed necessary, a complete blood cell count, peripheral blood smear, and tests of renal and hepatic function are useful to screen for an underlying systemic illness that may be associated with lymphadenopathy. Lymphocytosis with atypical lymphocytes on peripheral blood smear is consistent with a viral etiology such as EBV or CMV. Leukocytosis with a left shift suggests a bacterial etiology. Cytopenias

Table 85-2. Differential Diagnosis of Lymphadenopathy

<i>Diagnostic Category</i>	<i>Clinical Features</i>	<i>Epidemiological Features</i>	<i>Laboratory Features</i>
Infections			
Viral (EBV, CMV, rubella, HIV)	Usually generalized, not purulent or tender; may have hepatosplenomegaly		EBV/CMV with atypical lymphocytes on peripheral blood smear, viral titers
Mycobacterial (TB, atypical mycobacteria)	Usually localized; often tender, red, flocculent		PPD
Bacterial (staphylococcal and streptococcal infections, cat-scratch disease, tularemia, plague, diphtheria)	Usually localized; often tender, red, flocculent		Titers (cat scratch) Gram stain/culture
Protozoal (toxoplasmosis)	Generalized		Titers
Spirochete (syphilis)			Titers
Fungal (histoplasmosis, coccidioidomycosis)	May be generalized	Suspicion should be raised based on regional incidence	Titers
Neoplastic Conditions			
Hodgkin lymphoma	Often associated with "B" symptoms (eg, fever, weight loss, night sweats), pruritus	Common among higher socioeconomic groups, adolescents	ESR (can be >100), LDH, elevated eosinophils, anergy, elevated ferritin
Non-Hodgkin lymphoma	See Hodgkin lymphoma		
Leukemia	Generalized lymphadenopathy, hepatosplenomegaly, petechiae, purpura		Blasts on peripheral blood smear, hyperuricemia, hyperkalemia, hyperphosphatemia, elevated LDH
Solid tumors (eg, rhabdomyosarcoma, neuroblastoma)	Depends on underlying malignancy		
Langerhans cell histiocytosis	Eczema, failure to thrive, bony lesions, diabetes insipidus, proptosis, hepatosplenomegaly all possible		
Sinus histiocytosis with massive lymphadenopathy			
Autoimmune Disorders			
JIA	Generalized lymphadenopathy seen in systemic form (Still) (eg, fever, hepatosplenomegaly, evanescent rash, arthritis)	Equal incidence in males and females	ESR, anemia, negative ANA. and rheumatoid arthritis in Still JRA
Lupus	Arthritis, butterfly facial rash, effusions (lung, joint, cardiac), CNS, nephrotic syndrome	Increased incidence in girls	ESR, positive ANA, anti-ds DNA, $\bar{C}3$, C4, or CH50, anemia, platelets, proteinuria
Other			
Storage disorders (eg, Niemann-Pick, Gaucher disease)	Generalized lymphadenopathy, hepatosplenomegaly		
Drugs (eg, phenytoin)	Generalized lymphadenopathy		
Sarcoidosis	Bilateral hilar lymphadenopathy, non-caseating granulomas (lung, liver)	In African Americans and those of Irish heritage	Serum angiotensin-1 converting enzyme, serum lysozyme

Abbreviations: ANA, antinuclear antibody; CMV, cytomegalovirus; CNS, central nervous system; EBV, Epstein-Barr virus; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; JIA, juvenile idiopathic arthritis; LDH, lactate dehydrogenase; PPD, purified protein derivative; TB, tuberculosis.

Questions

Lymphadenopathy

- How long have the nodes been enlarged?
- Was the child sick before the swelling began?
- Does the child have any symptoms now, such as fever, weight loss, pallor, or anorexia?
- Does the child come in contact with any animals, particularly cats?
- Has the child traveled anywhere?
- Is the child taking any medications?
- Has the child been in contact with anyone who is ill?

or blasts on peripheral blood smear are concerning for leukemia. Uric acid, phosphorus, and lactate dehydrogenase are typically elevated in the setting of leukemia or lymphoma. An erythrocyte sedimentation rate is nonspecific but may be helpful. Depending on the clinical scenario, serum antibody studies for various infections may be warranted (ie, EBV, CMV, HIV, *Bartonella henselae* for cat-scratch disease). In addition, a purified protein derivative (PPD) skin test for tuberculosis or serological tests for fungal disease should be considered. In lupus and juvenile idiopathic arthritis, an antinuclear antibody may be positive and complement levels may be reduced.

If infectious lymphadenitis is suspected, an aspirate for a Gram stain and culture may be helpful, particularly if the infection has been unresponsive to empiric antibiotics. However, if there is **any** concern for malignancy, a fine needle aspiration is **not** the preferred method for diagnosis. An excisional biopsy should be performed so that the entire lymph node can be visualized and adequate samples for testing will be available.

Imaging Studies

A chest radiograph should be performed in any child with significant lymphadenopathy if there is a suspicion of an underlying systemic process. If leukemia or lymphoma is suspected, a chest radiograph is performed to evaluate for an anterior mediastinal mass. Other imaging studies are not routinely performed; however, if the nature of an enlarged lymph node requires further definition, an ultrasound can be done. In the setting of malignancy, additional radiographic studies are performed for staging purposes.

Management

Management is dictated by the underlying cause of lymphadenopathy. Cervical lymphadenopathy associated with URIs will typically resolve without intervention. Bacterial lymphadenitis can be treated with a trial of **antibiotics** with antistaphylococcal and antistreptococcal coverage. Underlying fungal and mycobacterial diseases should be treated with appropriate **antifungal or antibacterial agents**, with the exception of cervical adenopathy due to atypical mycobacteria, which requires **surgical removal**. Malignancies may require **multimodal therapy** with surgery, chemotherapy, and/or radiation, depending on the specific diagnosis and stage (see Chapter 141).

Prognosis

The outcome of lymphadenopathy depends entirely on the underlying etiology. In most cases, the cause is infectious, and the lymphadenopathy is self-limited or resolves with the use of appropriate antibiotics. Lymphadenopathy associated with an underlying systemic illness may have a more chronic or relapsing course depending on the disease.

CASE RESOLUTION

In the case history, the bilateral nature of the swelling and the lack of tenderness of the nodes are very worrisome and suggest a noninfectious etiology. The girl had a throat culture, an intermediate PPD, and a chest radiograph, all of which were negative. A complete blood cell count reveals leukocytosis with 28,000 white blood cells per deciliter (60% lymphocytes), with a normal hemoglobin and platelet count. A heterophil test for infectious mononucleosis is positive. Supportive measures are recommended, and the child makes a complete recovery in 3 weeks.

Heart Murmurs

Robin Winkler Doroshov, MD, MMS, MEd

CASE STUDY

A 6-year-old girl is brought to the office for a physical examination for school. Her medical history is unremarkable, and her growth and development have been normal. She is asymptomatic. Her physical examination is normal except for a grade II/VI low-pitched vibratory systolic ejection murmur that is loudest at the left lower sternal border, with radiation to the apex and upper sternal border. The murmur increases to III/VI in the supine position.

Questions

1. What is the significance of a heart murmur in asymptomatic children? How reassuring are a negative history and the absence of other physical findings?
2. What workup should be done by primary care physicians?
3. What are the costs of excessive tests and unnecessary consultation? What are the costs of an inadequate workup?
4. When should physicians refer children to specialists for consultation?

Asymptomatic children with heart murmurs are commonly encountered by physicians. A murmur is a finding rather than a medical sign or symptom because it is detected incidentally at an examination conducted for another purpose.

Correct assessment of the significance of a heart murmur is important to ensure appropriate management of children with heart disease. Complications of undiagnosed cardiac disease in children include progressive hemodynamic impairment, endocarditis, and even sudden death.

The misinterpretation of an innocent murmur as organic in nature can also take its toll, primarily as parental anxiety. Unnecessary restriction of activities may result, which can have a negative impact on children's school and social lives as well as self-image. As adults they may be denied health insurance, life insurance, and certain types of employment. In addition, misdiagnosis costs money and uses limited resources, with unnecessary tests and doctor visits, as this "non-disease" is evaluated and followed.

Epidemiology

An estimated 50% of healthy children have heart murmurs. The overall incidence of congenital heart disease (CHD), including symptomatic cases, is just under 1%, and some children with CHD have no murmur. Therefore, about 98 out of 100 murmurs noted during childhood are "innocent" (ie, have no organic basis).

Clinical Presentation

Heart murmurs are usually detected on routine examination for well-child care or on evaluation for an unrelated problem. Innocent murmurs are not associated with signs or symptoms because they are normal findings. Most of the symptoms sometimes associated with

organic murmurs (ie, murmurs of heart disease) are related to the presence of congestive heart failure (CHF) (see Chapter 88) and usually appear during infancy. Some children with murmurs come to medical attention with complaints of exercise intolerance or chest pain. It is necessary to determine whether these problems are actually referable to the heart.

Pathophysiology

A murmur is a sustained sound that can be detected with a stethoscope placed on the chest. This sound is produced by turbulence of blood flow in the heart or great vessels. This turbulence may be due to structural abnormalities (eg, aortic valve stenosis), benign or normal flow patterns (see below), or exaggeration of normal flow patterns (seen in high output states such as fever, exercise, anxiety, or anemia, and sometimes termed *functional*).

Not all significant heart disease in children is heralded by a murmur. Structural heart disease may be silent and be indicated by other findings. For example, transposition of the great arteries results in cyanosis, anomalous pulmonary venous return in pulmonary edema and hypoxia, and anomalous origin of the left coronary artery from the pulmonary artery in CHF. Acquired heart disease, such as Kawasaki disease, myocarditis, or cardiomyopathy, often produces no murmur.

The common innocent murmurs are better recognized than understood. Because they occur in normal, healthy individuals, there are few hemodynamic or anatomical data to correlate with the murmur, and pathophysiology is in some cases conjectural. **Still murmur**, which was once thought to be due to easily appreciated aortic valve flow, is now believed to result from vibration of normal fibrous bands ("false tendons") that cross the left ventricle. This

murmur may also be heard in children who have undergone spontaneous closure of a membranous ventricular septal defect, with a small residual aneurysm in the septum. The **pulmonary flow murmur** seems to be caused by normal flow across the pulmonary valve, perhaps made more apparent because of high cardiac output, close proximity to the chest wall, and (in adolescent females) mild anemia. The **venous hum** is attributed to turbulence at the confluence of the innominate veins, which is exacerbated in the upright position by gravity.

The **physiological peripheral pulmonic stenosis (PPPS) murmur** in newborns is produced by turbulence at the origins of the left and right pulmonary arteries. Because less than 10% of the combined ventricular output of the fetus goes to these branches, they are small and arise at a sharp angle from the main pulmonary artery. When postnatal circulation abruptly requires the entire cardiac output to enter these vessels, a relative stenosis is encountered. This physiological stenosis resolves gradually with remodeling of the pulmonary artery tree by 2 to 3 months of age.

Differential Diagnosis

In healthy children, the differential diagnosis of a heart murmur includes innocent murmurs and murmurs resulting from structural lesions, most of which are congenital. The specific features of a particular murmur usually provide most if not all necessary clues to the diagnosis. It is therefore important to develop and maintain auscultatory skills. A good quality stethoscope, with both diaphragm and bell correctly sized for the patient, is essential. Conditions should be optimized: The patient should be kept comfortable and, if necessary, distracted, and extraneous environmental noise should be minimized.

Some features may alert examiners to the organic nature of a murmur. Although very loud murmurs (grades IV–VI; ie, with associated precordial thrill) are usually not innocent, some innocent murmurs may be as loud as grade III, particularly with high cardiac output (eg, fever, anxiety, or anemia). Diastolic murmurs and continuous murmurs, other than the easily recognizable venous hum, are usually pathologic, as are high-pitched and harsh murmurs, which are better heard with the diaphragm of the stethoscope.

The common innocent murmurs of childhood are recognizable on auscultatory examination. **Still murmur**, or the **innocent vibratory murmur**, is a low-pitched, vibratory, or musical murmur that sounds like a groan. Because of its low frequency, the murmur is better heard with the bell. It is loudest at the left lower sternal border but is often distributed widely over the precordium. This murmur is often quite loud, particularly in the supine position, and is extremely common in school-aged children. The characteristics of the murmur are diagnostic, although the absence of other findings is supportive.

The **pulmonary flow murmur**, usually heard in older children, is a short, blowing systolic ejection (ie, crescendo-decrescendo) murmur localized to the left upper sternal border. It may be louder in the supine position.

The **venous hum** is a soft continuous murmur, similar to the sound heard in a seashell. Because of its constancy, it is often

overlooked. This murmur is very commonly heard in preschool and school-aged children. Loudest in the right infraclavicular area, it may also be heard on the left. This murmur is highly variable with head and neck position and compression of the neck veins, which may increase or diminish it. It usually disappears in the supine position.

The **PPPS** murmur is an innocent murmur found in newborns. Best heard at the upper left sternal border, this blowing systolic ejection murmur radiates strikingly over the lung fields into the back and both axillae.

Evaluation

History

The history may be helpful in assessment of the child with a murmur. If a thorough history shows that the child has no symptoms, this suggests the absence of severe heart disease and helps exclude many major or complex defects as well as CHF. The absence of symptoms does not, however, exclude several common defects that may require intervention (Table 86-1).

The most common cardiac symptom reported by children or parents is easy fatigability (Questions Box). This is difficult to quantify. Determining exercise intolerance on the basis of history is very subjective; it may be due, of course, to noncardiac causes and may be unrelated to the murmur. Easy fatigability during infancy may be reported as slow or poor feeding. Chest pain, a common symptom in adults with heart disease, is rarely cardiac in origin in children. A history of rapid breathing, excessive sweating, and other complaints referable to CHF suggests organic heart disease. Central cyanosis (ie, involving the oral mucosa rather than the perioral area or the fingers) may be reported occasionally by parents of children with cyanotic CHD but is often not recognized.

Physical Examination

The physical examination often gives strong clues to the cardiac diagnosis beyond the murmur itself. Even in children with known CHD, the non-auscultatory portions of the examination are critical in assessing the cardiac status (ie, how the patient is tolerating the defect). **Vital signs**, preferably obtained with the child at rest or sleeping, yield information regarding cardiac status more than

Table 86-1. Common Organic Murmurs in Asymptomatic Children

<i>Lesion</i>	<i>Other Clues</i>
Atrial septal defect	Fixed split S ₂
Ventricular septal defect (small to moderate)	Loud heart sounds
Patent ductus arteriosus (small to moderate)	Full or bounding pulses
Pulmonic stenosis	Systolic ejection click (SEC)
Aortic stenosis	SEC; suprasternal thrill
Coarctation of the aorta	Weak or absent femoral pulses

Heart Murmurs

Questions

- Is the child easily tired? Is his sleeping/napping pattern normal for age?
- Does the child keep up with others of his or her age?
- If the child is having a good time—for example, at a park or a party—how is the child's endurance?
- Does the child have a family history of congenital heart disease?
- Was the child exposed antenatally to possible teratogens such as maternal diabetes?
- Does the child ever complain of chest pain? At rest or with activity?
- Does the child ever appear blue?
- Does the child perspire excessively?

specific diagnosis. Tachypnea and tachycardia are present in CHF. A normal resting respiratory rate (ie, <60 breaths/min in infants) argues strongly against CHF. Blood pressure is normal in most patients with CHD. It may be useful to measure blood pressure in the legs, especially if coarctation of the aorta is suspected because of diminished pulses in the lower extremities.

The **growth pattern** may reflect the presence of any chronic illness, including hemodynamically significant CHD. Affected patients, particularly infants and children with large left-to-right shunts (with or without CHF) gain weight poorly. Height and head circumference are usually normal, although in more severe or prolonged situations height may also be affected.

A complete **cardiac examination** should be performed. Is the chest asymmetrical, a sign of long-standing cardiomegaly? Is the precordial impulse hyperdynamic? Are extra sounds (eg, clicks, rubs, gallops) heard? Is the second sound normal in intensity and in width and motion of splitting (ie, variation with respiration)?

Additional pertinent findings include lethargy, dysmorphic features suggestive of a genetic syndrome, central cyanosis, and clubbing. Hepatomegaly is found in children with CHF. The peripheral pulses should be normal in volume, neither diminished (eg, pedal pulses in coarctation) nor bounding (eg, in patent ductus arteriosus), and equal in all extremities. The temperature and capillary refill of the extremities in children who are not chilled reflect adequacy of the peripheral circulation.

Diagnostic Studies

Routine laboratory studies are not warranted in the evaluation of most murmurs. An **electrocardiogram (ECG)** is indicated when heart disease is known or strongly suspected, but a normal ECG may not rule out significant CHD. A **chest radiograph** may be helpful in this setting, but its potential benefits are usually outweighed by the risks of discomfort and radiation exposure. In the case of some tests, such as **echocardiography**, the manner in which the examination is carried out may vary depending on the suspected diagnosis; direct input from a cardiologist may be necessary to maximize the yield from these studies. Such tests are not suitable for screening purposes and should be obtained only after consultation with a pediatric cardiologist.

Management

If a heart murmur is suspected of being organic in origin because of its features or associated findings, referral to a pediatric cardiologist is indicated. For the young infant (particularly the newborn), prompt referral is essential because of the serious risks inherent in ductus-dependent defects (see Chapter 87), which may present with a simple murmur. In the case of a child who is asymptomatic there is no urgency, but parental and physician anxiety can best be allayed by proceeding to consultation promptly (ie, within weeks). In some cases, a repeat examination may be useful before deciding whether to consult a specialist, particularly if the murmur is initially heard under non-physiological conditions such as fever. Tests are usually best used if selected and ordered by specialists. Not all cardiologists perform all tests on all patients. Management of organic heart disease in infants or children is also best handled by specialists. Treatment may include **medications, interventional catheterization, or cardiac surgery**. Communication with the primary care provider, however, is essential to delivery of optimal patient care.

If the murmur is innocent, physicians must complete the following steps:

1. Children and their families must be informed about the presence of the murmur. Even if the murmur is benign, patients have a right to know that it was heard. In addition, they are likely to be examined by other practitioners who will report it, which may lead to the erroneous suspicion of either a new murmur or negligence on the part of the first examiner.
2. The diagnosis must be clearly explained to parents and children (depending on the age). It is essential that they understand that this is a normal finding rather than a minor abnormality. In some cases, notification of teachers or athletic coaches may be appropriate to prevent misunderstanding. Physicians must stress that no further evaluation is needed and no restrictions are indicated. Printed brochures that explain innocent murmurs are available from organizations such as the American Heart Association.
3. The description of the murmur and the diagnosis itself must be documented in the medical record. A murmur that is clearly and unequivocally innocent, with no evidence of heart disease, should not affect the child's access to insurance, participation in sports, etc. Medical documentation also helps protect patients from unnecessary reevaluations in the future.
4. Physicians should proceed no further. No laboratory studies or consultations need be performed. If the evaluation has been completed by a specialist because of suspicion of CHD by the referring physician, no follow-up with the specialist is indicated. The child is referred back to the primary practitioner.

Prognosis

The prognosis for children with heart murmurs depends on the cause of the murmur. Children with an innocent murmur, who by definition have normal hearts, have a normal prognosis—with one exception. If parents mistakenly believe their children to have heart

disease, parents may treat the children inappropriately (eg, unnecessary testing, restriction of activities). As a result, children may develop sedentary habits and inferior self-image.

With appropriate medical attention, the prognosis is normal or near normal in most cases of CHD. Children with minor defects not requiring intervention (eg, small ventricular septal defect, mild pulmonic stenosis) need only infrequent cardiology follow-up visits. With the development of refined cardiac surgery and interventional catheterization, even children with the most complex cardiac anomalies now have a good outlook with respect to both daily living and life expectancy.

CASE RESOLUTION

In the case presented, a healthy girl with no history of cardiovascular symptoms has a heart murmur and an otherwise unremarkable physical examination. The murmur is a typical Still (innocent vibratory) murmur, which is identifiable by its low-pitched, vibratory quality. No further evaluation is necessary. The diagnosis is explained, the girl and her parents are reassured, and the murmur and diagnosis are noted in the medical record.

Cyanosis in the Newborn

Robin Winkler Doroshow, MD, MMS, MEd

CASE STUDY

A 3,500-g term male infant born to a 29-year-old, gravida II para II, healthy mother by spontaneous vaginal delivery is well until 24 hours of age, when a nurse notes that he is cyanotic. On examination, he appears blue but in no distress. The vital signs are temperature (axillary) 37°C (98.6°F), pulse 130 beats/min, respirations 40 breaths/min, and blood pressure 80/60 mm Hg in the right arm. His general appearance is normal except for the cyanosis. His heart sounds are normal, and no murmur is heard. His liver is not palpable, and the peripheral pulses are normal and equal in all extremities. Capillary refill is normal. Oxygen saturation is 65% by pulse oximetry.

Questions

1. What are the causes of cyanosis in newborns?
2. What is the appropriate evaluation of cyanosis in newborns?
3. How urgent is the assessment? What are the risks and benefits of further evaluation?
4. Which aspects of management should be initiated by a primary physician at a community hospital?
5. Which types of treatment should be undertaken by the consulting pediatric cardiologist at the referral center?

Cyanosis is a bluish appearance of the skin due to the presence of reduced hemoglobin in the tissues. Central cyanosis, which is detected initially in the oral mucosa and nail beds but is generalized when severe, indicates at least 4 to 5 g of reduced hemoglobin per 100 mL blood. Hypoxemia is usually the cause. This condition is frequently present in neonates with pulmonary pathology but is also one of the most common presentations of severe congenital heart disease (CHD).

Because cyanotic CHD in newborns may be life-threatening, it must not go undiagnosed. Most diagnostic studies have minimal risk. Even the risk of cardiac catheterization in this setting is relatively low. Most of the lesions that cause cyanotic CHD can be palliated or corrected, and the prognosis is good.

Epidemiology

Cyanotic CHD occurs in about 2 to 3 of every 1,000 live-born infants. Approximately 80% to 90% of these cases, usually the most severe ones, are detected in the first 30 days of life. However, failure to diagnose major CHD *before newborn discharge* occurs in at least 10% of cases, leading to unnecessary morbidity and mortality. Infants with low pulmonary blood flow or lesions causing poor mixing most often present with obvious cyanosis, although initially they otherwise appear well and comfortable. Those with high pulmonary flow are less blue and often present first with congestive heart failure (CHF) or a murmur, but may be detected earlier using screening pulse oximetry.

Most cyanotic CHD is not diagnosed before birth. The antenatal history, gestational age, birth weight, and delivery room examination are unremarkable. Failure to identify CHD in the setting of a routine

obstetric ultrasound study does not rule it out; the sensitivity of such scans in the general population is very low. Congenital heart disease is more likely in some situations that can be anticipated prenatally (Box 87-1). In these settings, increased suspicion may lead to antenatal detection using specialized echocardiography.

Clinical Presentation

Children with cyanotic CHD often present within the first week of life with cyanosis of the oral mucosa. In more severe cases, generalized cyanosis occurs. The abnormal color may be more apparent with effort (eg, feeding, passing stool) or crying. Respiratory distress, heralded by grunting, nasal flaring, and retractions, is minor or absent in many newborn infants with cyanotic CHD. In cases of severe hypoxia, metabolic acidosis leads to poor perfusion and compensatory tachypnea with hyperpnea. Additional findings depend on the nature of the causal lesion (Dx Box). It is important to note that the absence of associated physical findings does not exclude cyanotic CHD.

Box 87-1. Settings With Increased Risk of Congenital Heart Disease

- Genetic syndromes (eg, trisomies, DiGeorge syndrome)
- Certain extracardiac anomalies (eg, omphalocele, forearm anomalies)
- High incidence of congenital heart disease in the family
- Maternal diabetes if poorly controlled during first trimester
- Fetal exposure to cardiac teratogen (eg, lithium, isotretinoin)
- Fetal or neonatal arrhythmia other than premature atrial beats

Dx Cyanosis in the Newborn: Possible Associated Findings

- Low oxygen saturation
- No improvement with oxygen
- Heart murmur
- Tachypnea
- Increased perspiration
- Abnormal cardiac silhouette on radiograph
- Abnormal electrocardiogram
- Abnormal echocardiogram

Pathophysiology

Cardiac cyanosis is due to **right-to-left shunting** so that systemic venous blood bypasses the pulmonary circulation and enters the systemic circulation. Two conditions are necessary to produce this type of shunting: a communication, such as a septal defect, for the blood to shunt across and a cause, such as pulmonic stenosis, for the blood to be shunted away from the lungs. The most notable exception is simple transposition of the great arteries (TGA), where the fundamental connections are abnormal, and all systemic venous blood is directed to the systemic arterial circulation. Lesions associated with cyanosis may be divided into 3 groups.

1. The **low pulmonary blood flow (LPBF) group** consists of tetralogy of Fallot, pulmonary atresia with intact ventricular septum, and virtually any combination of defects that includes pulmonary atresia or severe pulmonic stenosis. Pulmonary flow is diminished and may derive entirely from the ductus arteriosus while it remains patent. Aside from obvious cyanosis (and associated oxygen saturation below 80%), infants often appear well.
2. The **high pulmonary blood flow (HPBF) group** includes truncus arteriosus, single ventricle, and combinations of defects that involve mixing of oxygenated and unoxygenated blood and little or no obstruction to pulmonary flow. Although a right-to-left shunt is present, the left-to-right shunt is even greater. Pulmonary venous return is therefore voluminous and contributes disproportionately to systemic output. Cyanosis is less apparent; saturation is greater than 80% and may be as high as 95%. Pulmonary flow increases over the first days and weeks of life as the pulmonary vascular resistance falls, and CHF develops, as in patients with isolated shunt lesions (eg, ventricular septal defect). Some children with HPBF lesions also have obstruction to systemic blood flow (eg, coarctation of the aorta, hypoplastic left heart syndrome) and may depend on the ductus arteriosus to carry some or all of this flow.
3. The **poor mixing group** is limited to TGA and its variants. The right and left circuits are in parallel rather than in series, and survival depends on interchange of oxygenated and unoxygenated blood between them. Most newborns with poor mixing present with marked cyanosis (saturation <80%), like patients in the LPBF group.

Severe hypoxemia (oxygen partial pressure [pO_2] <35 mm Hg for the average newborn) is not compatible with prolonged survival. Infants experience tissue hypoxia, anaerobic glycolysis, and metabolic acidosis. Respiratory compensation may occur at first. Even with a normal pH, however, the presence of metabolic acidosis (large base deficit) indicates life-threatening hypoxia, necessitating immediate intervention, without which death ensues in a matter of hours.

Differential Diagnosis

The major causes of cyanosis are cardiac and respiratory (Box 87-2). Diagnoses in the latter group include problems of the lung, chest, airway, or respiratory drive.

The syndrome of **persistent fetal circulation** is perhaps most often confused with cyanotic CHD. It is also known as **persistent pulmonary hypertension of the newborn**. In this syndrome the heart and great vessels are structurally normal, but high pulmonary vascular resistance, which is often seen in post-term infants with perinatal distress or pulmonary disease, causes blood to shunt away from the lungs at the foramen ovale and ductus arteriosus. Profound cyanosis that is unresponsive to supplemental oxygen may be the only abnormal finding, and echocardiography is required to exclude CHD.

Pulmonary cyanosis may be due to **infection** (eg, group B streptococcal pneumonia); **aspiration** (eg, meconium, tracheoesophageal fistula); **pulmonary hypoplasia** (eg, Potter syndrome, diaphragmatic hernia); **respiratory distress syndrome** (eg, prematurity); or a host of other problems of the lung, chest, or airway. Neurologic depression may produce hypoventilation with resultant hypoxia.

Evaluation

Evaluation of the cyanotic newborn must be expeditious so that management is not delayed. In some cases, therapy may be initiated before the evaluation is complete. All available data, the statistical likelihood of CHD, and the risk-benefit ratio of the treatment must be taken into account.

History

Review of the history may be helpful, particularly in certain situations, such as in children with pulmonary disease (Questions Box). It is important to note that a negative response to any or all of the

Box 87-2. Noncardiac Causes of Neonatal Cyanosis

- Persistent fetal circulation
- Upper airway obstruction (eg, choanal atresia)
- Pulmonary infection (eg, group B streptococcal infection)
- Aspiration (eg, meconium aspiration syndrome, tracheoesophageal fistula)
- Pulmonary hypoplasia (eg, Potter syndrome, diaphragmatic hernia)
- Respiratory distress syndrome (eg, in prematurity)
- Thoracic hypoplasia (eg, thanatophoric dwarfism)
- Hypoventilation (eg, neurologic depression)

Cyanosis in the Newborn

Questions

- Has the infant been in any distress?
- Has the infant had difficulty feeding?
- Was the infant suspected of having a heart problem prior to birth (eg, fetal arrhythmia, abnormal heart on ultrasound)?
- Is the mother diabetic?
- Did the mother take any drugs (prescribed or not) during the pregnancy?
- Was the mother ill during the first trimester?
- Is there a positive family history of congenital heart disease or other birth defects?
- Did any perinatal problems (eg, passage of meconium in utero) occur?

questions does not render cyanotic CHD unlikely; in fact, negative responses are noted in most cases.

Physical Examination

Cyanosis may be the only abnormal physical finding in cardiac patients, but a careful, thorough examination often yields information about the underlying cardiac defect and the overall circulatory status. External anomalies or abnormal phenotypic appearance may indicate a genetic disorder with associated cardiac anomalies. Dyspnea (grunting, nasal flaring, intercostal retractions) is more often seen with lung disease, but tachypnea (rapid respiration) is common with both severe heart disease and pulmonary problems. Tachypnea results from CHF in HPBF lesions, and hyperpnea (deep breathing) from metabolic acidosis in severe hypoxia or impaired perfusion. Poor perfusion is also manifested by abnormal color (a gray or ashen appearance if combined with cyanosis), cool extremities, delayed capillary refill, and diminished pulses.

The peripheral pulses are palpated in all extremities. Abnormalities or discrepancies between extremities must be confirmed by measuring blood pressure. Weak pulses may be found in cardiogenic shock, and bounding pulses may be noted with diastolic runoff lesions such as patent ductus arteriosus or aortic insufficiency. Pulse quality and blood pressure may differ in different extremities if an aortic arch abnormality such as coarctation is present. The abdominal examination may reveal hepatomegaly (in CHF) or abnormal situs (as in asplenia syndrome, usually associated with complex cyanotic CHD).

The cardiac examination may disclose a loud murmur if an obstruction such as pulmonary stenosis is present. The physician should note, however, that atresia, being a total obstruction, produces no murmur. Heart sounds may be loud and the precordium hyperdynamic, particularly in children with HPBF. Splitting of the second sound confirms that 2 patent semilunar valves are present, but this finding is often difficult to appreciate even in normal newborns.

Laboratory Tests

A number of laboratory studies are available (see Chapter 88, Table 88-1). As in CHF, it is initially more important to determine whether patients have heart disease than to obtain a precise, complete diagnosis. In cyanotic CHD, sophisticated studies such as echocardiography, magnetic resonance imaging, and catheterization are usually needed to make a detailed diagnosis.

The suspicion of arterial hypoxemia should be confirmed by **pulse oximetry**, an indirect measurement. It is readily available and noninvasive but has shortcomings. Perfusion must be adequate to obtain a reading. Accuracy is diminished at saturations below 75%, although the presence of profound hypoxia can still be confirmed. Cyanotic CHD cannot be ruled out by pulse oximetry, however, because readings of 100% saturation may reflect pO_2 values that range anywhere between 75 and 250 mm Hg (Figure 87-1). **Arterial blood gases** are more accurate and give important additional information about ventilation and acid-base status. Arterialized capillary gases may suffice if perfusion is adequate.

Oxygenation may differ between the extremities in infants with certain lesions (eg, coarctation). The site of sampling should be noted. If possible, the saturation should be measured at sites both proximal and distal to the ductus arteriosus (ie, from the right arm and either leg).

A **shunt study**, also known as a hyperoxia challenge, may be performed to determine whether a right-to-left cardiac shunt is present, particularly if echocardiography is not readily available. Pure oxygen (fraction of inspired oxygen in gas [FIO_2] = 1.00) is given for 5 to 10 minutes by hood. In patients with LPBF or TGA, increasing the inspired oxygen does not affect the oxygenation of the blood

Figure 87-1. Comparison between oxygen partial pressure (pO_2) by arterial blood gas measurement and oxygen saturation by pulse oximetry. (Reproduced with permission from Niehoff J, DelGuercio C, LaMorte W, et al. Efficacy of pulse oximetry and capnometry in postoperative ventilatory weaning. *Crit Care Med.* 1988;16:701.)

because the blood is unable to enter the lungs; this is a positive result. In patients with pulmonary disease or hypoventilation, oxygenation increases strikingly, often to a pO_2 exceeding 200 mm Hg; this negative result rules out cyanotic CHD.

A blunted shunt study, characterized by a rise in pO_2 but rarely to levels above 150 mm Hg, is seen in patients with severe pulmonary disease and in those with HPBF lesions. With such lesions the pulmonary venous blood is high in volume, and the rise in its saturation causes a definite rise in arterial oxygenation. This effect is exaggerated by the further increase in pulmonary flow due to the vasodilating effect of oxygen.

A positive shunt study may be identified with pulse oximetry. It is difficult or impossible, however, to distinguish between a blunted study and a negative one with this tool. The oxyhemoglobin dissociation curve is flattened at the upper end, and the saturation changes very little over a wide range of pO_2 (Figure 87-2). Capillary gases may be equally inaccurate in this range, but directly measured arterial blood gases are highly reliable. In addition, they may reveal hypercapnia, with or without respiratory acidosis, suggesting a pulmonary cause for the hypoxia.

Electrocardiogram (ECG), a fairly inexpensive test, is readily available and noninvasive. However, it does not often help distinguish cyanotic CHD from other causes of cyanosis, particularly for those practitioners who lack experience with neonatal ECGs. The normal range is large in neonates, with much overlap between normal and CHD. Care must also be taken in placing the leads correctly and minimizing artifacts.

Imaging Studies

The **chest radiograph**, a relatively inexpensive and readily available test, is often extremely helpful in differentiating between cardiac and noncardiac disease. Pulmonary disease is often readily apparent on chest radiograph. The radiograph also helps define the cardiac

Figure 87-2. Oxyhemoglobin dissociation curve. Note that the position of the curve itself may vary with temperature, pH, oxygen partial pressure (pO_2), and 2,3-diphosphoglycerate.

diagnosis broadly but not precisely. Patients with LPBF lesions have small hearts and diminished pulmonary flow. In contrast, patients with HPBF lesions have large hearts and increased flow, such as is seen in infants with simple left-to-right shunts. With many cyanotic lesions, the cardiac silhouette is abnormal in configuration (eg, boot-shaped heart in tetralogy of Fallot) or position (eg, dextrocardia in patients with heterotaxia syndromes). Transposition of TGA may be more misleading: Pulmonary flow may be increased despite the severe cyanosis, and the heart size may be normal. An apparently normal radiograph does not exclude TGA.

Under optimal conditions, **echocardiography** enables the physician not only to recognize CHD but to identify details of anatomy and physiology. Conversely, a properly performed, complete, negative echocardiogram rules out CHD. The performance of a high-quality study requires the appropriate equipment (with high-resolution imaging), an experienced sonographer, and an experienced cardiologist for interpretation. In the absence of these elements, preliminary echocardiography may be used cautiously as a screening device as part of the initial assessment to confirm heart disease prior to referral to a specialist. Recently, availability of telemedicine for echocardiography has helped to fill this gap in some hospitals and avoid some unnecessary transports. When there is significant suspicion of cyanotic CHD, referral should not be delayed until echocardiography can be performed.

Management

Initial management prior to cardiac consultation (often with transfer to another institution) includes surveillance, assistance, direct medical management, and supportive care.

Close **surveillance**, including transfer to the highest level of neonatal care available, use of a cardiopulmonary monitor and continuous pulse oximetry, frequent monitoring of vital signs, and repeat physical examinations, is begun as soon as cyanotic CHD is identified. Even if the infant is feeding well, it is best to suspend feedings because of the likelihood of invasive procedures or spontaneous deterioration in the near future. An orogastric tube is placed to decompress the stomach, reducing the work of breathing as well as the risk of aspiration. At least one secure intravenous (IV) line should be placed for administration of fluids, glucose, and medications. If umbilical arterial catheterization can be expeditiously established, it will allow close monitoring of arterial blood gases and blood pressure. The latter may be difficult to measure by cuff in the compromised infant.

While undertaking these measures, the physician should make every effort to seek **assistance** from a pediatric cardiologist. A neonatologist may be consulted if a pediatric cardiologist is not immediately available. Much advice may be obtained over the telephone. In addition, plans for immediate consultation or transfer of patients may be discussed in this way.

The need for **supportive care** depends on the case. In the absence of metabolic acidosis or impaired perfusion, no special measures are indicated in this category. In some cases, IV fluid boluses, inotropic

agents, and other treatments may be needed as part of the early management. Mechanical ventilation should be used in patients with metabolic acidosis, whether compensated or uncompensated, because of the increased oxygen requirement produced by hyperventilation and the tendency for tiring, leading to superimposed respiratory acidosis.

The temptation to give supplemental oxygen for more than the few minutes necessary to perform a shunt study is great but must be resisted. Oxygen is rarely helpful and may be harmful in this setting. In infants with TGA or LPBF lesions, oxygenation is not affected. In infants with HPBF lesions, oxygenation is usually adequate in room air (saturation >80%), and an increase in FIO₂ may exacerbate the CHF. Patients at greatest risk for deterioration due to administration of oxygen are those with total anomalous pulmonary venous return with obstruction, in whom pulmonary arteriolar vasodilation precipitates severe pulmonary edema and secondary right heart failure. Oxygen may also directly constrict the ductus arteriosus on which the cyanotic newborn may depend.

The possibility of ductal dependency should prompt consideration of administering the ductus dilator, **prostaglandin E₁ (PGE₁)**. The definitive diagnosis of cyanotic CHD need not be made prior to institution of this lifesaving treatment. In infants who remain adequately oxygenated (no acidosis) and perfused, the drug can be prepared but administration deferred pending consultation. The benefits of giving PGE₁ to severely hypoxic infants or infants with compromised perfusion far outweigh the risks, which include apnea and fever. A dramatic improvement is often seen within seconds to minutes, confirming the diagnosis of a ductal-dependent lesion, and enabling the physician to stabilize the patient until more definitive evaluation and intervention can take place.

Prognosis

If untreated, LPBF lesions and TGA are usually fatal during infancy, most often during the neonatal period, because of severe hypoxia. Untreated HPBF lesions may lead to death in infancy from either CHF or complications such as pneumonia. If the systemic blood flow is ductus-dependent (eg, interruption of the aortic arch), death occurs shortly after ductal closure, usually during the first week of life. Delayed diagnosis, even when not fatal, may result in a suboptimal outcome including end-organ injury such as renal dysfunction or neurologic sequelae.

With early recognition and intervention, however, the prognosis for infants with cyanotic CHD is surprisingly good in the absence of a genetic syndrome (eg, trisomy 18) or a major complicating extracardiac malformation (eg, neural tube defect). If diagnosed before the onset of severe circulatory compromise, infants can be stabilized and evaluated promptly, and palliative or corrective procedures can be performed in the operating suite or catheterization laboratory. Most of these patients can survive well into adulthood with a good

quality of life. Infants with lesions in which all 4 chambers are adequate in size (eg, tetralogy of Fallot) have a better lifetime prognosis than those with a hypoplastic chamber (eg, tricuspid atresia). Even infants with abnormalities such as asplenia syndrome or hypoplastic left heart syndrome now have a reasonable outlook with complex reconstructive surgery or heart transplantation.

CASE RESOLUTION

In the case presented at the beginning of the chapter, marked hypoxia is present in the absence of other cardiac findings, such as a heart murmur. The oxygen saturation does not rise after the infant breathes 100% oxygen for 10 minutes. The chest radiograph shows a small, boot-shaped heart and diminished pulmonary blood flow, and the ECG is normal. Transport is arranged. Because of the marked cyanosis, infusion of PGE₁ is begun, and saturation increases to 80%, with the pO₂ rising from 33 to a safer 48 mm Hg. The infant is transferred to a tertiary care center, where consultation is obtained. An echocardiogram is also performed, which demonstrates tetralogy of Fallot with pulmonary atresia. A modified Blalock-Taussig shunt is placed in the newborn period, and complete repair using a pulmonary artery homograft is performed at 1 year of age.

Congestive Heart Failure

Robin Winkler Doroshow, MD, MMS, MEd

CASE STUDY

A 2-month-old infant is brought to the office by his mother, who complains that her son has been eating poorly and breathing oddly for the past few days. The perinatal history is unremarkable. A heart murmur was noted at the 1-month checkup.

The infant is scrawny and irritable. Physical examination shows that the baby's weight, which was at the 50th percentile at birth, is now at the fifth percentile; his height, which was at the 50th percentile, is now at the 25th percentile. He is afebrile, and his heart rate is 165 beats/min, with respirations 70 breaths/min and shallow but without respiratory distress. The skin is pale and diaphoretic, and the mucous membranes are pink. Examination of the head and neck is normal; no jugular distention is present. The lungs are clear. The precordium is hyperdynamic, and the heart sounds are loud; a prominent systolic murmur is audible at the left lower sternal border. The liver edge is palpable

4 cm below the right costal margin in the right midclavicular line, and the spleen is not palpable. The extremities are thin, with normal pulses and no edema. Capillary refill is slightly delayed.

Questions

1. What are acute and chronic signs of cardiac disease in children?
2. What are the signs of congestive heart failure (CHF) in children? How do these signs in children differ from those in adults?
3. What underlying disorders can cause CHF in young infants?
4. What is the appropriate emergent management for infants with CHF? What are the risks of treatment if the diagnosis is incorrect?

Congestive heart failure is the most common presentation of serious heart disease in infants. Although this condition also occurs in older children, an estimated 90% of cases of CHF in the pediatric population begin in the first year of life. In children CHF is most often caused by structural congenital heart disease (CHD). Compensatory mechanisms are fewer and less successful in small infants. Other causes of CHF are included in Box 88-1.

Epidemiology

The precise incidence of CHF in children is unknown; it is approximately 0.1%. Most cases result from CHD, which occurs in 0.8% of live births. The incidence of CHD varies little with geography, ethnic group, or gender. It is far more common in children with recognizable genetic syndromes (eg, trisomy 21 [Down syndrome], Turner syndrome).

Clinical Presentation

Most commonly, complaints about CHF take the form of concerns about an infant's feeding. Comments are often vague (eg, "my baby is not a good eater") but may be more precise (eg, "he is taking less formula with each feeding" "he is taking longer to nurse"). Parents may also describe rapid breathing, excessive sweating, or decreased activity, but usually only on specific questioning.

Box 88-1. Causes of Congestive Heart Failure in Children

Volume Overload

- Left-to-right shunts (eg, ventricular septal defect)
- Bidirectional shunts (eg, truncus arteriosus)
- Valvular insufficiency (eg, mitral regurgitation)
- Extracardiac conditions (eg, anemia, arteriovenous malformation)

Pressure Overload

- Outflow obstruction (eg, coarctation of the aorta)
- Inflow obstruction (eg, obstructed anomalous pulmonary veins)
- Vascular resistance (eg, hypertension, chronic pulmonary disease)

Myocardial Dysfunction

- Intrinsic conditions (eg, cardiomyopathy, anthracycline toxicity)
- Inflammatory conditions (eg, viral myocarditis, rheumatic fever)
- Coronary insufficiency (eg, anomalous left coronary artery)

Arrhythmias

- Tachyarrhythmia (eg, paroxysmal supraventricular tachycardia)
- Bradyarrhythmia (eg, third-degree atrioventricular block)

Congestive heart failure is also often detected on examination for routine infant checkups or for unrelated complaints. Careful assessment of the physical findings, including vital signs, reveals **tachypnea**, **tachycardia**, and **hepatomegaly** and frequently signs of underlying structural heart defects, such as a murmur (Dx Box).

Dx Congestive Heart Failure

- Tachycardia
- Tachypnea
- Hepatomegaly
- Sweating
- Decreased feeding
- Irritability
- Easy fatigability

Pathophysiology

High cardiac output may lead to CHF in infants with large left-to-right shunts. Myocardial contractility is relatively normal, and children remain on the “normal” line of the Frank-Starling curve, which relates cardiac output to diastolic volume (also called *preload*) or pressure (Figure 88-1). The shunt requires a very large volume of output, primarily to the pulmonary bed. Although the heart may be able to meet this demand, preload is high, leading to “congestive” signs and symptoms (eg, tachypnea, hepatomegaly). In more severe cases, systemic output may be compromised, resulting in hypotension, renal failure, and metabolic acidosis.

Left-sided failure caused by elevated pulmonary venous pressure produces increased lung water. Initially, this fluid is interstitial, and it does not interfere with gas exchange but does trigger reflex tachypnea. Minute volume is kept normal by decreasing tidal (breath-to-breath) volume, leading to shallow as well as rapid breathing (sometimes called “happy tachypnea” because of the absence of dyspnea). Only when the ability of the pulmonary lymphatics to drain this fluid is overcome by large volume does fluid accumulate in the alveoli; rales and respiratory distress, or dyspnea, then result and gas exchange may be compromised.

Right-sided failure caused by an elevated systemic venous load usually produces more volume than pressure load on this system, possibly as a result of the greater venous compliance in infants compared with adults. The liver becomes very distended and is easily palpated. As long as the liver can absorb the increased venous volume, the portal pressure does not rise, and splenomegaly does not occur. Because the venous pressure rises very little, jugular distention, which is difficult to detect in young infants in any case, is rarely seen, and edema is also rare.

The left and right (systemic and pulmonary) circulations are more interdependent in infants and younger children than they are in older children or adults. As a result, **bilateral heart failure** is much more common than right-sided or left-sided failure alone. Although this means that recognition of CHF may be easier, determination of the underlying condition may be more difficult because the clues are less specific. For example, in an adult with left-sided failure, the differential diagnosis includes mitral, but not tricuspid, valve disease.

Figure 88-1. Relationship of cardiac output to preload. The solid curve represents normal myocardial contractility, and the dotted curves represent impaired function (shifted downward) and the positive inotropic state (shifted upward). A. Normal range (no heart disease). B. Left-to-right shunt with congestive heart failure (CHF). Note that overall output is high but most of it is shunted. C. Same situation as B but after treatment for CHF. Cardiac output is the same or better, but preload is now out of the range that results in congestive symptoms.

Differential Diagnosis

When tachycardia, tachypnea without dyspnea, and hepatomegaly are present, the diagnosis of CHF is straightforward. Congestive heart failure is most commonly confused with major respiratory infections such as bronchiolitis or pneumonia. Pulmonary infections are frequently associated with dyspnea as well as tachypnea, impaired gas exchange, and other respiratory findings. Rhinorrhea, cough, fever, or wheezing may also be present. Rales may accompany pneumonia but are rare in CHF in infancy or early childhood. Hyperinflation due to lung disease may lead to a false impression of hepatomegaly. In some children, CHD, CHF, and respiratory infections coexist.

Clues to the presence of structural heart disease, such as a murmur or absent femoral pulses, may support the diagnosis of CHF. Severe CHF, with low cardiac output or even shock, has a broader differential diagnosis. In addition to cardiac causes, sepsis, hypovolemia, and disorders associated with inborn errors of metabolism should be considered.

Evaluation

History

The history should include specific questions about feeding and growth (Questions Box). Poor feeding, often a nonspecific complaint in chronically or subacutely ill infants, results from tachypnea and fatigability in infants with heart disease. Growth failure may result from poor feeding and increased cardiopulmonary work. The physician should specifically query parents about possible excessive sweating or rapid breathing in infants, because parents may not volunteer this information (see Chapter 61).

Physical Examination

The diagnosis of CHF is primarily based on clinical findings, and physical examination is essential. The resting respiratory rate must be precisely counted because infants in CHF most often have tachypnea without dyspnea. The liver edge is palpable more than 1 cm below the right costal margin in the midclavicular line, and the degree of enlargement mirrors the severity of the CHF.

In the older child or adolescent, the physical findings are more similar to those of the adult with CHF. Additional findings that may be present in this age group include jugular venous distension, basilar rales, and peripheral pitting edema.

Laboratory Tests

Many laboratory tests can be performed to assess infants' hearts (Table 88-1), including electrocardiogram and echocardiogram. However, some procedures are very costly, and some are invasive and therefore carry risk. The value of most of these tests depends on the expertise of the individuals who perform and interpret them. It is important to remember that although test results and consultation with a pediatric cardiologist may be invaluable in the identification of the underlying lesion, *these procedures are not usually required in order to make a diagnosis of CHF.*

Pressure or volume overload of the ventricles causes them to release a neurohumoral peptide, B-type natriuretic peptide (B-NP), which acts as a natural natriuretic, diuretic, and vasodilator. Studies in adults have demonstrated that blood levels of B-NP are elevated in CHF, and the degree of elevation closely reflects severity of CHF. This test, which may be performed at the bedside, may be used to distinguish between CHF and other similar disorders such as acute pulmonary disease. Because it closely parallels changes in severity of CHF, it may also be used to track response to treatment. Recent studies in children suggest that it may be similarly useful in the pediatric population; B-NP levels may be very effective in distinguishing between cardiac and noncardiac causes of CHF in children (Figure 88-2).

Imaging Studies

Because elucidation of the structure and function of the heart is central to assessment of the underlying cause of CHF in the pediatric population, imaging studies play a key role (see Table 88-1) in evaluation of these patients. Moreover, these tests (particularly

Questions

Congestive Heart Failure

- How has the infant been feeding? Does he or she get out of breath or appear exhausted?
- Has the infant's growth pattern changed recently?
- Does the infant tire easily? With eating? With playing?
- Does the infant perspire excessively, especially with efforts such as feeding?
- Does the infant breathe rapidly, even at rest?

Table 88-1. Laboratory Tests Used in the Evaluation of Heart Disease in Children

Test	Information
Chest radiograph	Presence and direction of shunt Hints concerning specific diagnosis (and possible pulmonary disease ruled out)
Serum B-type natriuretic peptide	Presence and severity of congestive heart failure
Electrocardiogram (ECG)	Cardiac rhythm and conduction Chamber overload Coronary insufficiency
Ambulatory ECG (24-hour ECG)	Subacute rhythm assessment Correlation of symptoms with rhythm
Oximetry	Presence and degree of hypoxemia
Arterial blood gases	Hypoxemia Acid-base status
Hematocrit	Anemia Polycythemia
Exercise test	Quantitation of exercise tolerance Provocation of symptoms or arrhythmia
Echocardiogram	Specific structural diagnosis and hemodynamics Chamber enlargement and function Presence of pericardial effusion
Cardiac magnetic resonance imaging or computed tomography	Specific structural diagnosis and hemodynamics Chamber enlargement and function
Cardiac catheterization	Specific structural diagnosis and hemodynamics Cardiac electrophysiology
Tilt table test	Autonomic function

echocardiography) may be used as a means of tracking response to treatment.

Chest radiograph, preferably in anteroposterior and lateral projections, may be very useful as a *supportive* study. It may show cardiomegaly, pulmonary venous congestion, and hyperinflation. Cardiomegaly is most commonly due not to myocardial dysfunction,

Figure 88-2. Utility of B-type natriuretic peptide (B-NP) in differentiating congestive heart failure (CHF) from lung disease in pediatric patients with respiratory distress. (From Koulouri S, Acherman RJ, Wong PC, Chan LS, Lewis AB. Utility of B-type natriuretic peptide in differentiating congestive heart failure from lung disease in pediatric patients with respiratory distress. *Pediatr Cardiol.* 2004;25:341–346, with permission from Springer Science + Business Media.)

but to volume overload from the shunt. In the absence of cardiac enlargement, the diagnosis of CHF must be seriously questioned. (However, CHF may occur in the absence of cardiomegaly in total anomalous pulmonary venous return with obstruction, which usually presents in the first week of life in association with hypoxia.) Pulmonary venous congestion occurs in left-sided heart failure, but increased pulmonary arterial flow from a left-to-right shunt often obscures the congestion. Hyperinflation resulting from peribronchial edema is also a common finding.

In children with severe CHF, further studies are indicated. **Arterial blood gases** show evidence of metabolic acidosis due to tissue anoxia, with respiratory compensation in early stages and superimposed respiratory acidosis in later stages. A **complete blood cell count** shows leukocytosis due to stress. It may not differentiate between heart disease and sepsis.

Management

All infants and children with CHF should be under the care of a pediatric cardiologist, often in concert with a pediatrician, intensivist, or neonatologist. Prompt referral to a cardiologist will aid not only in management of the CHF, but also in assessment and management of the underlying disorder.

The numerous pharmacologic treatments for pediatric CHF fall into a small number of categories based on mechanism of action (Table 88-2). Preload can be optimized by the administration of diuretics and venodilators, and afterload by the use of arteriolar dilators, some of which also have inotropic effects. Contractility is enhanced by inotropic agents, and antiarrhythmics control tachycardias and bradycardias to optimize heart rate. The most effective control of CHF is attained when more than one mechanism is used.

Inotropes and **diuretics** are used in the initial management of CHF in children. Inotropic support results in a shift to a higher Frank-Starling curve (see Figure 88-1), which allows affected patients to maintain the high volume output necessitated by the underlying CHD at lower diastolic pressures, thus alleviating congestive symptoms. **Digoxin**, a form of digitalis, is the drug of choice in such cases, where cardiac output is not severely impaired, and is therefore often used in outpatients. This agent is readily available, easily absorbed, safe in the therapeutic range, and easy to administer (elixir for oral administration). If digoxin is initially given at the maintenance dose (10 micrograms/kg/d, therapeutic levels are not attained for about a week; therefore, loading is preferable (Table 88-3) but may require hospitalization. Digoxin is well tolerated and rarely causes side effects. Because of the safety and reliability of absorption, blood levels need not be checked unless overdose is suspected (eg, history of over-administration, toxic ingestion, unexplained vomiting, or second- or third-degree heart block). In the neonate, blood levels may be difficult to interpret because of the presence of natural digoxin-like immunoreactive substance in the blood.

Table 88-2. Therapy for Pediatric Congestive Heart Failure

Category	Example
Chronic (Ambulatory)	
Cardiac glycosides	Digoxin
Diuretics	Furosemide, spironolactone
Angiotensin-converting enzyme inhibitors	Enalapril, captopril
Selective β -blockers	Carvedilol, metoprolol
Acute (Inpatient)	
Diuretics	Furosemide, bumetanide
β -agonists	Dobutamine, dopamine
Phosphodiesterase inhibitors	Milrinone, amrinone
Vasodilators	Nitroprusside, oxygen, inhaled nitric oxide
Severe, Refractory	
Mechanical support	Extracorporeal membrane oxygenation, ventricular assist
Cardiac or cardiopulmonary transplantation	
Exogenous B-type natriuretic peptide	Nesiritide

Table 88-3. Digoxin: Total Oral Loading Dose in Children^a

Age	Dose (micrograms/kg)
Preterm newborns	20–30
Term newborns and infants	25–35
1–5 y	30–40
5–10 y ^b	20–30
10 y to adult ^b	10–15

^a Intravenous loading dose = 75%–89% of oral dose. Usually given ½, followed 8 hours later by ¼, followed 8 hours later by ¼, followed 12 hours later by initiation of maintenance dose. Assumes normal renal function; the maintenance dose must be adjusted downward for renal failure.

^b In children older than 5 years, loading dose is more often based on surface area (0.5–1.0 mg/m²).

The elevated diastolic preload of CHF is the result of neurohormonally mediated sodium and water retention. **Diuretics** reverse this phenomenon. **Furosemide**, a potent loop diuretic that is available in an oral suspension and is fairly well absorbed, is the most frequent drug of choice for the outpatient. The starting dose is 1 mg/kg once or twice daily. Initially, furosemide may be given intravenously or intramuscularly rather than orally, which reduces the time to onset of action and is more effective. Such treatment also supports the patient while digoxin loading is in progress. **Spironolactone**, a less potent diuretic, may be used in combination with furosemide for its potassium-sparing effects, and may also reduce the deleterious histopathologic and structural changes known as *myocardial remodeling* that can accompany CHF.

Fluid and sodium restriction, often used in adults with CHF, is difficult to achieve with infants because their diet is predominantly or exclusively liquid. High-calorie diets using concentrated formulas, complex carbohydrate additives, or medium-chain triglyceride oils may reduce the intake of free water and the effort of feeding without compromising caloric intake. Breast milk and most proprietary formulas have a low sodium load. In older infants and children with CHF, salt intake is more easily modified and should be minimized.

Certain pediatric patients with chronic CHF may benefit from the addition of **angiotensin-converting enzyme inhibitors** to their regimen. These arteriolar dilators help control afterload and have been shown to be effective in children with dilated cardiomyopathy and those with large left-to-right shunts, such as ventricular septal defects (VSDs). Recent observations suggest that third-generation **β-blockers** such as carvedilol may be useful to control chronic CHF in children with dilated cardiomyopathy. Randomized, controlled clinical trials in adults with similar pathology have been very encouraging, despite poor understanding of the mechanism involved; similar trials in children have thus far been disappointing.

Children with acute, severe, or refractory cases of CHF may require additional medications or interventions, necessitating hospitalization, often in an intensive care unit. These therapies include **β-agonists** and **phosphodiesterase inhibitors** for inotropic support and **vasodilators** for afterload reduction, **correction of anemia** (eg, transfusion), **treatment of fever** (eg, antipyretics), and **reduction**

of metabolic demands (eg, ventilatory support, bed rest, sedation). **Diuretics**, usually given intravenously, provide effective control of congestive symptoms. Because of the importance of fluid balance and nutrition in the child hospitalized with CHF, close and accurate monitoring of fluid intake and output, measurement of daily weight, and measurements of serum electrolytes are essential data in the management of CHF.

In a minority of cases, CHF is refractory to all of the above measures. This may be seen in very severe acute myocarditis, longstanding cardiomyopathy of various causes, and during the postoperative period after complex CHD surgery. Additional options include short-term **mechanical support** such as extracorporeal membrane oxygenation and ventricular assist devices. **Exogenous recombinant B-NP** (nesiritide), which has shown some promise in the setting of adult CHF, may be helpful. In some cases, replacement of the ailing heart or heart-lung unit by **transplantation** may be the only remaining alternative.

Ultimately, the best management for CHF is **treatment of the underlying disorder**. In many cases, failure to treat the underlying disorder will result in limited or no success of other treatment modalities. The degree of urgency depends on the nature of the disorder and the severity of the CHF. For example, in neonates with ductus-dependent lesions such as hypoplastic left heart syndrome, maintenance of ductal patency with prostaglandin E₁ is crucial to initial management. In infants with CHF due to supraventricular tachycardia, prompt conversion to normal sinus rhythm is often the only treatment necessary. Congestive heart failure caused by severe anemia responds dramatically to correction of hemoglobin levels, often using exchange transfusion to avoid additional acute volume overload. Cor pulmonale, often seen in children with severe chronic lung disease, is most responsive to measures directed at improving the lung disease and/or decreasing pulmonary vascular resistance, such as supplemental oxygen or inhaled nitric oxide. When CHF is due to structural CHD (the most common situation), surgery or interventional catheterization to palliate the problem (eg, pulmonary artery banding in certain cases with large net left-to-right shunts) or correct the defect (eg, repair of VSD) usually reverses the CHF. Fortunately, it is rarely necessary to “tolerate” prolonged, uncontrolled CHF in children or to treat the condition aggressively at the expense of a major change in lifestyle.

Family counseling, which should begin when CHF is identified, is essential. Several important points should be included, in addition to a general description of both the cardiac defect and CHF. The term *heart failure*, which is commonly thought by laymen to refer to a sudden deterioration of heart function or even cardiac arrest, must be clarified. It is also important to stress that affected infants should be treated as normally as possible, with the exception of administration of medicines and keeping medical appointments. Contrary to popular belief, most infants with cardiac conditions are not fragile. Addressing quality-of-life issues such as parental concern, assuaging guilt, and normalizing existence are key responsibilities of the physician.

Prognosis

In most young infants and children with CHF, the prognosis is excellent. Congestive heart failure responds well to treatment, and the underlying defect can usually be corrected or at least palliated. Without cardiac surgery for CHD, CHF often remits spontaneously over months or years as a result of maturation of compensatory mechanisms, spontaneous improvement in the defect (eg, decrease in the size of a VSD), or increase in pulmonary vascular resistance because of long-standing high pulmonary artery pressure and flow (Eisenmenger syndrome). “Catch-up” growth occurs with remission of CHF, and children have the potential to reach their genetically determined height and weight.

CASE RESOLUTION

The case presented at the beginning of the chapter is typical of an otherwise normal infant with a large VSD who becomes symptomatic with the development of CHF. The baby's growth failure can be attributed to the chronicity of his illness.

The loud murmur and presentation in infancy strongly suggest the existence of underlying structural CHD as the cause of CHF. The time of onset of CHF also suggests a specific mechanism. When the onset is slightly delayed after birth, a lesion with changing postnatal hemodynamics, such as left-to-right shunt, which has increased as pulmonary resistance has fallen, is suggested. (Note that a ductus-dependent defect would have presented more acutely and severely in the first week of life.)

This infant responded fairly well to oral diuretics and digoxin, but continued to grow slowly and tire easily. He underwent surgical repair of this VSD at 5 months of age with an excellent result and no longer has symptoms or requires medication.

Chest Pain

Robin Winkler Doroshow, MD, MMS, MEd

CASE STUDY

A previously healthy 13-year-old boy comes to the office complaining of recurrent chest pain, occurring approximately once a week over the past 2 months. The pain is stabbing in nature, located over the mid-sternum, not associated with any other symptoms, and occurs randomly, both at rest and with exercise. It lasts for 2 to 3 minutes, is ranked as 4 on a severity scale of 10, and subsides spontaneously. He does not appear very concerned about the pain, but his mother is quite anxious to have it checked out. His teacher has sent him home from school twice because of the pain, and the soccer coach will not let him play until he is cleared by a doctor. His physical examination is unremarkable.

Questions

1. What is the significance of chest pain in an otherwise healthy child?
2. How likely is serious heart disease to be heralded by chest pain?
3. How much testing, and what type, is appropriate in working up chest pain?
4. Which chest pain patients should be referred to a cardiologist? To other specialists?

Chest pain in children is one of the most common reasons for referral to a pediatric cardiologist, second only to heart murmurs. It is, however, one of the least common presenting complaints of cardiac disease. In fact, from an etiologic standpoint, it would be more suitable for this chapter to be located in the section on gastrointestinal disorders, respiratory problems, psychological and psychogenic disorders, or hematology, rather than cardiology.

Why, then, approach it in the cardiology section, along with discussions of heart murmurs, cyanosis, and congestive heart failure? Perhaps the strongest reason is that it is the greatest fear of the patient, parent, and physician that chest pain could herald a serious—even lethal—heart problem in an otherwise healthy youngster. This fear is exacerbated by 2 social phenomena in our culture: the widespread press given to cases of sudden unexpected death in young, apparently healthy athletes (who had not, in fact, experienced chest pain in most cases), and the appropriately high level of concern over the underdiagnosis of ischemic heart disease in the adult population. Public information targeting the adult with chest pain may, unfortunately, be misinterpreted as applying also to the child. It is this apprehension, and the associated medicolegal defensive posture, that can so often drive the patient, and his referring primary care physician, to seek cardiology consultation and testing.

Epidemiology

The epidemiology of pediatric chest pain is not well studied. Published series have looked retrospectively at patients seen in an emergency department (ED), with a rate of about 0.25%; in an outpatient clinic at about 0.3%; or, as mentioned previously, at a high

rate in a pediatric cardiology clinic. In the primary care office setting, chest pain is the third most frequent pain complaint, after abdominal pain and headache. The most common age range is 8 to 18 years, peaking between 11 and 13 years of age. There is no gender or racial predilection, although the etiologic distribution may vary by gender.

Cardiac causes of chest pain are very uncommon for 2 reasons. Such pain is either a rare symptom in a common cardiac disorder (eg, aortic stenosis) or caused by a rare condition (eg, anomalous origin of coronary artery [AOCA]).

Clinical Presentation

There is substantial variability in the complaint of chest pain in children (Questions Box). Some youngsters experience a single, protracted, severe episode that brings them to the ED. In that setting, the patient may have other signs or symptoms of an acute medical problem, such as fever, shortness of breath, or hypotension, raising the level of suspicion for a serious organic cause.

More frequently, children report repeated episodes occurring sporadically over a period of months or even years. The pain may be induced or exacerbated by exercise, deep breathing, lying down, or eating. It can begin and end abruptly or gradually. It may be accompanied by other symptoms, which can give major clues to the diagnosis. In cases where the pain occurs on exercise, is this a consistent, predictable experience, or is it unpredictable?

Most (up to 97%) of children seen for chest pain have no serious medical history, and most have an unremarkable physical examination.

Questions

Chest Pain

- What is the pain like? Where is it located? Does it radiate? How severe is it?
- How long has the child been having pain? Did it begin after trauma? How often does the pain occur? How long does it last? Does it start and end suddenly?
- What brings the pain on? Is it related to exercise and, if so, is it consistent?
- Does the child have associated symptoms with the pain, such as syncope, shortness of breath, palpitations, fever, nausea, sour taste, wheezing, or cough?
- Does the child at other times have cardiac symptoms, such as easy fatigability, cyanosis, exertional dyspnea, edema, or syncope?
- Does the child's medical history include potentially pertinent disorders such as asthma, gastroesophageal reflux disease, psychiatric problems, heart disease, or sickle cell disease?
- How much impact is the pain having on the child's life? Is he or she missing school or sports?
- Is there a family history of sudden unexpected death, recurrent syncope, or known genetic syndrome?

Pathophysiology

The pathophysiology varies with the underlying cause of the pain, for which there is a broad differential diagnosis (Box 89-1). It is important for the patient, parent, and physician to understand that thoracic or abdominal pain, and particularly visceral pain, is poorly localized. This makes it difficult to distinguish between, for example, esophagitis and cardiac ischemia; hence, the term “heartburn” for the former. Thus precordial pain may originate from any intrathoracic organ or from the chest wall itself, and the patient cannot identify the source of his discomfort, which in itself is a cause of distress.

Cardiac causes are a heterogeneous category, which can best be viewed as ischemic and non-ischemic in origin (Box 89-2). Ischemic chest pain, or angina, is caused by a drop, often sudden, in the myocardial oxygen supply/demand ratio, causing pain or, in rare cases, sudden death. This may occur because of diseased coronary arteries as in adults, due to accelerated coronary atherosclerosis, which is very rare. It may be seen in progeria, mucopolysaccharidosis, post-transplantation coronary disease, and severe familial hypercholesterolemia. It may occur as a result of previous inflammation (as in Kawasaki disease with coronary aneurysms) leading to coronary artery stenosis. A congenital AOCA from the opposite sinus of Valsalva (Figure 89-1) or from the pulmonary artery may result in ischemia due to compression of the anomalous vessel between the great arteries, obstruction from a slit-like orifice at the origin or, in the case of the pulmonary artery, low pressure and low saturation in the perfusing blood.

The chest pain seen in patients with left ventricular outflow obstruction (aortic valve stenosis and hypertrophic obstructive cardiomyopathy) is likely also due to ischemia. The already diminished

supply/demand ratio due to hypertrophy and hypertension of the left ventricle falls further with strenuous exercise, causing pain and/or arrhythmia.

In abuse of drugs such as cocaine, chest pain may be attributable to arrhythmia, myocardial hypoperfusion, or a combination of the two; this may present as chest pain or overt collapse, in some cases with cardiac arrest.

Although many children with cardiac arrhythmias are asymptomatic or present with palpitations, dizzy spells, or syncope, some do complain of chest pain. In the case of the younger child, this may reflect an inability to express the discomfort of palpitations as other than “hurting.” In addition, ischemia does occur in some individuals with tachyarrhythmias, such as paroxysmal supraventricular tachycardia (SVT), due to high myocardial oxygen consumption and

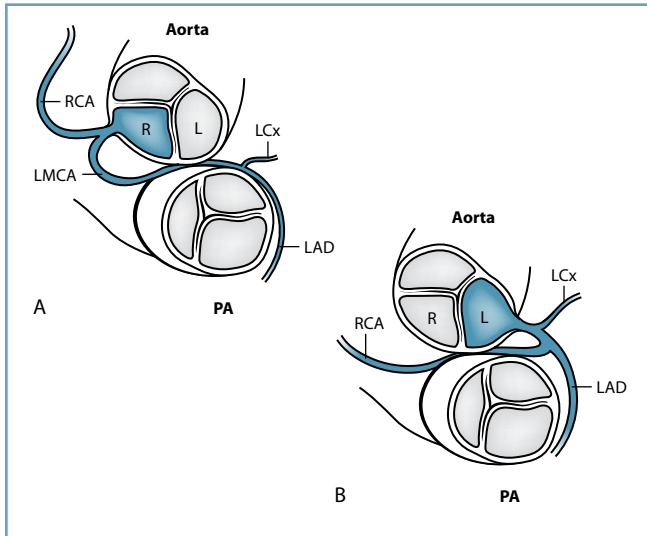

Figure 89-1. Schematic diagram of the 2 forms of anomalous origin of a coronary from the wrong sinus that are associated with myocardial ischemia. **A.** Anomalous origin of the left main coronary artery (LMA) from the right sinus of Valsalva. **B.** Anomalous origin of the right coronary artery (RCA) from the left sinus of Valsalva. In each case, the anomalous coronary artery can be seen coursing between the aorta and pulmonary artery (PA). L, left aortic sinus; LAD, left anterior descending; LCx, left circumflex; R, right aortic sinus.

shortened diastole, compromising perfusion. In these patients, ST segment depression may be seen on the electrocardiogram (ECG) during the arrhythmia and may persist for several minutes after the arrhythmia is terminated.

Non-ischemic cardiac causes of chest pain include pericarditis and less commonly myocarditis, aortic dissection, and mitral prolapse. The most common form of inflammatory heart disease is acute viral infection; acute bacterial pericarditis is more severe and associated with greater systemic toxicity. Connective tissue disease, such as lupus erythematosus or juvenile rheumatoid arthritis, is frequently

associated with immune-mediated pericarditis, as is the postpericardiotomy syndrome seen shortly after cardiac surgery. In these disorders the pain is due to inflammation of the pericardium and epicardium, directly stimulating the many sensory nerve endings in this area.

Aortic dissection also results in direct stimulation of pain fibers, in this case in the aortic wall. It is very rare in the normal pediatric population but may occur in the setting of Marfan syndrome. Chest pain is also seen in patients with mitral valve prolapse, but it is often difficult to establish a clear causal relationship in this setting. Interestingly, gastroesophageal reflux disease (GERD) can be demonstrated in a high percentage of these patients.

Differential Diagnosis

The differential diagnosis of pediatric chest pain is presented in the Box 89-1, and cardiac causes are listed in Box 89-2. The relative frequencies of these causes vary in reported series, but all report higher frequencies of respiratory, idiopathic, traumatic, and psychogenic etiologies and low frequencies of cardiac etiologies, usually in the range of 1% to 5% in patients with no previous cardiac history. These data must be viewed as approximations because the ultimate etiologic classification of cases in these series is not usually based on a definitive result but rather an attribution by the physician involved. Therefore, cultural factors and individual preferences may lead to higher reported rates of “idiopathic” chest pain in some centers, “chest wall pain” in others, and “anxiety disorder” in still others. Some studies report a higher incidence of cardiac etiologies because they so classify any chest pain patient with a cardiac finding (eg, premature beats, abnormal ECG), regardless of whether it may explain the pain.

Evaluation

The keystones to the evaluation of the child with chest pain are a thorough, methodical history and careful physical examination; indeed, in many cases these will suffice to arrive at a diagnosis and formulate a management plan.

History

The major questions to be addressed are outlined in the Questions Box. Because there are many pertinent details to be included in the **history of present illness**, and they are often provided in a variable sequence, some physicians find it helpful to use a printed format as a guide. Some offer a questionnaire for the patient or parent to complete. Witnesses to the episodes may provide additional helpful information, especially if the patient is not verbally expressive. The witness may estimate a pain score based on observation, which may differ substantially from the score assigned by the patient himself.

Pain that occurs repeatedly over time is less likely due to an organic cause of a serious nature, particularly if it is not reproducible. A severe, protracted episode (eg, lasting hours) is more likely to be organic in origin. The location of the pain has not been a strong predictor of diagnosis in reported series. Its timing and association

with other symptoms, however, may provide major clues. Reflux esophagitis may occur after eating, more often when supine or very active, and may be accompanied by a sour taste; it may be relieved by eating or use of an antacid. Associated symptoms that may raise a red flag for a cardiac cause include syncope, palpitations, sweating, and nausea; reproducible pain at a given level of exertion is also more likely anginal. Because pain and accompanying anxiety may cause sinus tachycardia, which can be interpreted by the patient as palpitations, it is important to get a sense of the heart rate experienced by patients with that complaint. The child can be asked to tap his chest or clap his hands as fast as his heart was racing during the palpitations; serious tachyarrhythmias such as supraventricular tachycardia and ventricular tachycardia are usually very rapid.

Recent fever and malaise are often present in pneumonia, pleurisy, or pericarditis. Exercise-induced asthma (EIA), in addition to being related to exertion, is sometimes accompanied by cough and/or wheezing. Shortness of breath is very frequently reported by patients in association with their pain; this may reflect anxiety or sensitivity to movement rather than pulmonary pathology.

In youngsters with psychogenic pain, other symptoms of anxiety or depression may be reported, although not necessarily simultaneously with the chest pain, and a history of recent stressors may be uncovered. These patients may also report other recurrent somatic complaints.

The nature, severity, and abruptness of the pain may also yield diagnostic clues. Exercise-induced asthma is often described as a chest “tightness,” is usually gradual in onset, and lasts beyond the exertion itself. The precordial catch syndrome, a poorly understood disorder also known as *Texidor twinge*, is a sudden, sharp, localized pain that is exacerbated by deep breathing, and lasts only seconds or minutes. In contrast, the slipping rib syndrome, in which the cartilaginous tips of the 8th, 9th, and 10th ribs become transiently subluxated, produces pain at the costal margin, is very sensitive to movement, and is often associated with a “popping” or “slipping” sensation in the affected area. Gastroesophageal reflux disease pain is usually described as “burning,” and may awaken the patient from sleep. In contrast, the pain of angina is reported as “crushing,” and may radiate to the left arm or the neck. The diffuse pain of pericarditis is often ameliorated by sitting forward. Aortic dissection results in an acute, tearing sensation.

A history of recent chest trauma will naturally suggest chest wall injury as the cause, but the fall or sports mishap may be forgotten if the onset of the pain is not temporally associated with the event. Chest wall pain may also result from overuse, as seen in weight lifters, or from inadequate breast support, as seen in female runners. Drug abuse, particularly with cocaine, may be disclosed if the patient is questioned in private. In some cases this may have occurred several days before the onset of pain.

The patient's **medical history**, if positive, may lead the clinician toward the underlying diagnosis. In children with sickle cell disease, acute chest syndrome must be considered early in the assessment. A history of respiratory disease may point to an acute respiratory infection or to EIA. Children with known heart disease, who may

experience benign chest pain, are more likely to have a cardiac etiology than their peers, depending on the cardiac diagnosis. Most congenital heart defects, for example, do not cause pain but may raise the level of anxiety in the family and lead to the perception or exaggeration of chest pain. Of greater concern is a history of heart disease that may affect myocardial perfusion, such as Kawasaki disease or cardiac surgery involving the coronary arteries (eg, arterial switch operation for transposition of the great arteries).

The **family history** must not be overlooked. Although most pediatric chest pain is not due to hereditary disorders, some of the more severe causes may be hereditary, such as hypertrophic cardiomyopathy, some arrhythmias, asthma, sickle cell disease, and aortic dissection in Marfan syndrome. It is also noted that in children with nonorganic chest pain, such as psychogenic pain, there is often a history of a close relative having had recent heart surgery or a heart attack, bringing attention to this area during a time of emotional stress.

A complete **review of systems** is essential in the assessment of children with chest pain, due to the wide range of differential diagnoses.

Physical Examination

A careful physical examination is imperative; in children with no history of serious illness, this should be focused on, but not be limited to, the chest. General inspection will immediately aid in distinguishing between the acutely ill child and the otherwise well child with chest pain. Abnormal vital signs, such as fever, tachycardia, or tachypnea, are associated with acute etiologies such as infection or inflammation. The child's pain level should be quantified with the aid of a pain scale. If the patient is dyspneic, pulse oximetry should be measured.

The chest wall should be examined for signs of trauma and for tenderness. Care must be taken with the latter because it is easy to obtain a false-positive examination for costochondritis, for example, because the costochondral junctions have some degree of normal tenderness, as do the female breasts. Asymmetry of tenderness, and a report that the pain produced is similar to that experienced, suggests chest wall injury. In patients with rib injury, the pain can be elicited not only on direct palpation but also indirectly by compression of the thoracic cage from another location. In girls with inadequate breast support, the breast ligaments may be symmetrically tender.

Auscultation of the lungs and heart will, of course, yield useful clues to diagnosis, especially in children with acute inflammatory processes (rales, rub) and in those with left ventricular outflow obstruction, such as aortic stenosis (murmur). It must be remembered, however, that many of the organic causes of chest pain, such as GERD, EIA, intermittent arrhythmias, and AOCA, will have a normal examination if the patient is not experiencing the pain at the time of the visit.

The other portions of the physical examination may also aid in the evaluation of the child with chest pain. Jugular distention, hepatomegaly, and peripheral edema suggest congestive heart failure or pericardial effusion with tamponade. The child's behavior pattern and interaction with his parents may suggest a psychological

disorder such as anxiety or depression. Poor dentition and halitosis in an adolescent with weight loss may be a sign of bulimia as a source of esophagitis. Excessive signs of trauma such as multiple ecchymoses may indicate a coagulopathy, and also raise the possibility of non-accidental trauma.

Laboratory Studies

A wide variety of diagnostic studies is available to help in arriving at a diagnosis; it is incumbent on the physician to select those appropriate to the individual patient, guided by the findings of the history and physical examination.

In the patient presenting with **acute chest pain**, often to the ED, there is a greater need for tests because the differential diagnosis more often includes serious, even life-threatening, disorders than in the child with chronic recurrent pain. Reported series show the chest radiograph to have a reasonably high yield of positive findings; a negative radiograph is reassuring in ruling out pathology such as pleural effusion, pneumonia, pneumothorax, pneumomediastinum, and thoracic tumor, but cannot be used to exclude most cardiac etiologies. More detailed imaging such as magnetic resonance imaging may be needed when major chest trauma is reported or aortic dissection suspected. Dyspnea or hypoxemia, particularly in the setting of recent immobilization or in an adolescent female taking oral contraceptives, should lead one to suspect pulmonary embolism, for which a spiral computed tomography or nuclear perfusion scan is indicated.

Although ECG is routinely performed as part of the evaluation for acute chest pain in children, it is rarely helpful in establishing a diagnosis other than arrhythmia, which may be suspected from the history or examination. ST segment changes may reflect pericardial irritation or myocardial ischemia if the ECG is done at the time of the pain. If ongoing myocardial ischemia is suspected, myocardial enzymes (creatinine phosphokinase-MB fraction, troponin-I) should be measured and a toxicology screen performed. If signs of acute infection such as fever are noted, a complete blood cell count, sedimentation rate or C-reactive protein, and appropriate cultures are indicated. Echocardiography is highly sensitive and specific for pericardial effusion and should be performed early in the evaluation of the patient with chest pain and jugular distention, a friction rub, fever, or ST segment elevation on ECG.

In patients presenting with **chronic recurrent chest pain**, the likelihood of serious pathology is very low. When the examination is normal and the history reassuring, the yield of “screening” tests such as chest radiograph and ECG is extremely poor, and the cost in dollars and anxiety not justifiable. In most cases the history and physical examination are adequate to lead to a focused selection of diagnostic tests, if any are needed. A description of pain suggestive of esophagitis, for example, may lead to endoscopy or upper gastrointestinal series. When EIA is suspected, pulmonary function testing is appropriate, in some cases with an exercise challenge. Strong suspicion of psychogenic causes should prompt further psychological evaluation at the initial encounter, including querying the patient about suicidality; further testing or consultation may be indicated.

The finding of a murmur of left ventricular outflow tract obstruction is an indication for echocardiography, which will confirm the diagnosis and yield further details that will guide management. A history of palpitations or syncope raises the possibility of arrhythmia; an ECG may give clues such as Wolff-Parkinson-White syndrome as a substrate for SVT, but a normal ECG does not rule out arrhythmia if the patient is asymptomatic at the time. Here an ambulatory ECG (Holter) monitor or transtelephonic event detector may enable the clinician to document the rhythm during an episode of pain. Consistent exertional pain merits evaluation for ischemia, using resting ECG and often exercise stress testing. These studies, unfortunately, can be negative between episodes in patients with AOCA. This diagnosis can, however, be identified by echocardiography, but only if the study is deliberately directed toward that diagnosis; therefore, the study should be done in a pediatric echocardiography laboratory, and the sonographer must be aware of the diagnosis in question.

Management

The management of pediatric chest pain depends on the underlying diagnosis or lack thereof. For management of GERD, acute chest syndrome, pneumonia, pericarditis, connective tissue disorders, thoracic tumors, anxiety disorder, pneumothorax, cocaine abuse, and chest wall trauma, as well as other serious disorders discussed under differential diagnosis, the reader is directed to other sources within and beyond this text.

When there is a strong suspicion of cardiac pathology, either on the basis of history and physical examination or on the basis of subsequent testing as described previously, prompt referral to a pediatric cardiologist is indicated. Management may include surgery (eg, for AOCA), antibiotics, anti-inflammatories, pericardiocentesis (eg, for pericarditis), antiarrhythmics, interventional catheterization (eg, balloon angioplasty, radiofrequency ablation), or a combination.

Short-term nonsteroidal anti-inflammatory medication is helpful for chest wall pain due to overuse, trauma, costochondritis, or slipping rib syndrome. In a minority of cases, local injection with anesthetic may be necessary.

Therapeutic trials may be considered in some cases to arrive at a diagnosis. A child with suspected esophagitis may be given an antacid at the time of the pain. If the pain is relieved, further workup and treatment can proceed accordingly. Similarly, a youngster with suspected EIA, particularly if there is a previous history of reactive airways disease, may benefit from a trial of an inhaled bronchodilator at the time of the pain.

In the exceedingly common setting of benign chest pain, such as with minor chest wall trauma, mild somatization, or occasional reflux esophagitis, the most important step in management is reassurance of the patient and family that this is not an indication of a serious disorder. It is essential to clarify how one has arrived at this conclusion, and why further testing is not appropriate.

A frequent observation in this setting is that most families do not require a definitive diagnosis of the cause of the pain. If a serious disorder is excluded—necessary because 50% of patients believe

that chest pain means heart disease—all participants are reassured. Follow-up studies have demonstrated that at least 80% of patients in this category do not seek further medical attention for their chest pain or return for follow-up.

Prognosis

The outcome depends on the underlying diagnosis. Most cases of benign chest pain spontaneously resolve, often within a short time of their evaluation. Even in serious and potentially life-threatening causes of chest pain, early diagnosis and intervention will usually lead to an excellent outcome.

CASE RESOLUTION

The patient and his parents are assured that he has no evidence of a serious medical problem. His heart is strong, his lungs clear, and his circulation good. They are told that chest pain in otherwise healthy children may be mysterious but is common, and very rarely a sign of illness. They are told in a gentle but definitive manner that he does not need any more evaluation at this time, but that if the problem does not resolve itself, the child should return for reevaluation.

The boy is delighted to hear that he may return to full sports participation, confirmed in writing to the coach. The parents are very relieved and grateful for the attention and reassurance of the physician.

Hypertension

Gangadarshni Chandramohan, MD, MS, and Sudhir K. Anand, MD

CASE STUDY

A 10-year-old girl is seen in the emergency department with a history of severe headache and generalized seizures lasting 2 minutes. Her medical history is remarkable for several episodes of unexplained fever as an infant and an episode of urinary tract infection at age 3 years; no radiologic studies were done. She also has a history of headaches for the past 2 years, which have been treated primarily with acetaminophen. There is no known history of drug ingestion or hypertension in the patient or family members.

The physical examination is remarkable for a pulse of 100 beats/min and a blood pressure of 210/130 mm Hg in the right arm in supine position. Equal pulses are palpable in all 4 extremities. Blood pressure (BP) is 216/134 mm Hg in the right lower extremity. The fundoscopic examination reveals evidence of petechial hemorrhages and mild papilledema. Chest examination finds normal breath sounds and an active precordium with the apical impulse shifted to the left; no murmurs are heard. The liver is palpable 1 cm below the right costal margin. The neurologic examination is remarkable for altered sensorium with lethargy;

no focal neurologic deficit is present. A routine urinalysis shows 2+ protein and normal urinary sediment. The hemoglobin is 11.2 g/dL and hematocrit is 33%. Sodium is 139 mEq/L, potassium 3.8 mEq/L, chloride 102 mEq/L, and bicarbonate 22 mEq/L. Blood urea nitrogen is 35 mg/dL and serum creatinine is 1.8 mg/dL. An electrocardiogram shows left ventricular enlargement. Computed tomography scan of the head is normal.

Questions

1. What is the definition of hypertension in children?
2. What are the causes of hypertension in children?
3. What is the appropriate evaluation of hypertension in children?
4. What are the comorbid conditions and long-term complications associated with primary hypertension?
5. What is the appropriate emergency treatment of symptomatic hypertension?
6. What is the long-term management of children with primary hypertension?

Hypertension has become a more common problem among children over the past few decades due to the increased prevalence of obesity, which is associated with primary hypertension. Although the increased prevalence of hypertension in children is predominantly due to increase in primary (essential) hypertension, there is a need with childhood hypertension to identify secondary causes. Secondary causes are proportionately more prevalent among children than adults and, if identified, may be curable, thereby eliminating the need for lifelong medical treatment. Conversely, primary hypertension typically persists into adulthood and is likely to become a major public health concern in the future. With early intervention, however, the long-term adverse consequences of hypertension are preventable. Children who are expected to be at increased risk for end-organ (heart, central nervous system [CNS], kidneys, and eyes) damage as they become adults are those with persistently elevated BP readings, high body mass index, excessive weight gain, and a family history of hypertension.

Normal Blood Pressure and Definition of Hypertension

Both systolic and diastolic BP gradually increase, from the newborn period through adolescence; therefore, age-appropriate norms

should be used to classify a given BP reading as normal or hypertensive. For example, a BP reading of 118/76 mm Hg would be regarded as normal for a 16-year-old adolescent, but it would signify stage 2 hypertension in a 2-year-old child, meaning that this child needs urgent medical attention. Blood pressure measurements should be part of routine physical examinations in all children older than 3 years and in all hospitalized children according to the American Academy of Pediatrics (AAP) guidelines. The guidelines also recommend that children who are younger than 3 years who have a history of prematurity, congenital heart disease, recurrent urinary tract infections (UTIs), or chronic systemic illnesses should have their BP measured as a routine part of their well-child care. An appropriately sized BP cuff should be used; the inner cuff width should be approximately 40% of the arm circumference midway between the olecranon and the acromion, and the length should be greater than 80% around the arm circumference at the same point to avoid inaccurately high readings (Dx Box). There are various other factors that should be taken into consideration while measuring BP to minimize errors, which include patient's posture (sitting versus lying down) and level of the arm in relation to level of the heart (elbow to be at the level of the heart) and, if it is the first visit, readings from all 4 extremities to rule out coarctation of the aorta should be performed

Dx Hypertension

- Blood pressure (BP) elevated >95th percentile for age, gender, and height on at least 3 consecutive occasions with the child in a quiet, non-apprehensive state and with BP cuff of appropriate size
- BP checked in both upper and at least one lower extremity
- Fundus examination: vascular changes, exudates, and papilledema
- Abnormal urinalysis

as well. It is also important that the child should remain calm and not be anxious or agitated while the measurement is taken.

Blood pressure values in children are a continuum, with no clear dividing line between normal and high (Tables 90-1 and 90-2). Therefore, the fourth report on high BP in children and adolescents (2004), by using the statistical percentile values, defines hypertension as systolic or diastolic BP of greater than 95th percentile for age, gender, and height on at least 3 occasions (Table 90-3). Furthermore, if the BP readings, either systolic or diastolic, are between the 90th and 95th percentile, it is considered as pre-hypertension. The report further classifies hypertension into 2 categories: (1) stage 1 hypertension, which is when systolic or diastolic BP is persistently between the 95th percentile to 5 mm above the 99th percentiles and (2) stage 2 hypertension, which is when systolic or diastolic BP is persistently more than 5 mm Hg above the 99th percentile. Because this is a statistical definition, 5% of all children (those with BP readings >95th percentile) would be expected to have hypertension. The BP values described in Tables 90-1 and 90-2 were determined from the normal distribution of BP values in healthy children from a study conducted in late 1980s; however, based on more recent data from National Health and Nutrition Survey 2004, the prevalence of hypertension using the BP values described in Tables 90-1 and 90-2 are in fact higher than 5%, suggesting that there is certainly a relative increase in the prevalence of hypertension over the last 2 decades.

Epidemiology

The prevalence of persistent hypertension in children based on the current definition is approximately 3% to 5%; however, it can vary depending on the age, ethnicity, geographic distribution, and type of hypertension. The consensus is that the overall prevalence of primary hypertension has been increasing over the past few decades secondary to increasing prevalence of obesity, cultural factors, and lifestyle changes, which includes increase in stress and sedentary lifestyle. Among those who are obese, the prevalence of hypertension has been reported to be up to 30% from some studies, compared to non-obese children. As in adults, hypertension is more common among African American and Hispanic children compared to Caucasian children. Furthermore, adolescent children and those from urban cities tend to have higher prevalence compared to younger children and to those from rural areas.

Secondary hypertension is more common among infants and young children, whereas primary hypertension is notably more

common among adolescents. Children who require hospital admission for their hypertension usually have secondary hypertension, which may have been triggered by an acute event, frequently volume overload. Occasionally the cause of the hypertension is uncertain. In many such children, the acutely increased BP resolves with appropriate medical intervention and most do not require long-term treatment. Data on prevalence of acute hypertension is sparse due to the transient nature of the condition, and there are no major long-term implications.

Clinical Presentation

Mild or stage 1 hypertension in most children is usually asymptomatic. However, children with moderate to severe hypertension can develop headaches, blurring of vision, and sometimes nose bleeds. Acute presentations of hypertension are divided into 3 categories: hypertensive urgencies, hypertensive emergencies, and hypertensive crisis. Occasionally, the terms hypertensive emergency and crisis are used interchangeably to describe the same situation when a patient has very elevated BP. Hypertensive urgency is defined by the sudden development of elevated BP without evidence of severe end-organ damage but can be symptomatic with headache and vomiting. A hypertensive emergency, in comparison, is defined by obvious signs of significant end-organ damage, such as encephalopathy, seizures, papilledema, retinal hemorrhages, or kidney injury, and must be dealt with immediately. Hypertensive crisis is merely a very severe form of hypertension marked by a more than 20% increase in the systolic and/or diastolic BP above the 95th percentile with clinical evidence of malignant hypertension.

Etiology and Pathophysiology

An increase in BP results from an increase in peripheral resistance or cardiac output, or a mixture of the two. The exact cause of hypertension in 90% to 95% of adults is still uncertain; hence, the term essential, primary, or idiopathic hypertension. In the past, hypertension was considered secondary to an underlying disorder in more than 80% of children and fewer than 20% of cases were idiopathic; however, this was true only in children with very severe hypertension. In most obese adolescent children with mild increases in BP, no etiology of hypertension is found and they are classified as having primary or essential hypertension.

Many factors play a role in the development of essential hypertension. Research reveals variable degrees of alteration in cardiac output, extracellular fluid volume, peripheral resistance, renin-angiotensin system, aldosterone, electrolyte balance, catecholamines, sympathetic nervous system, natriuretic hormones, prostaglandins, kinins, antidiuretic hormone, insulin response, endothelins, nitric oxide (endothelium-derived relaxation factors), and others. Whether these abnormalities are primary or secondary and what their exact role is in the pathogenesis of essential hypertension is still uncertain. Barker's hypothesis of epigenetic transmission, a recently promulgated theory, attributes certain disorders, including childhood

Abbreviation: BP, blood pressure.

*The 90th percentile is 1.28 SD, 95th percentile is 1.645 SD, and the 99th percentile is 2.326 SD over the mean.

hypertension, to altered gene expression from malnutrition or other adverse events during intrauterine life. This hypothesis has been further supported by data demonstrating association between fewer nephrons in children who were born small for gestational age and later development of hypertension.

Other important factors in the development of hypertension include race, heredity, stress response, sleep apnea, obesity, hyperlipidemia, and increased salt intake. Recently obesity has been strongly implicated in the increase in incidence of hypertension in the United States. Mirroring the increase in obesity, average BPs rose by 1.4 to 3.3 mm Hg between 1990 and 2000. Studies showing that weight reduction in obese patients lowers BP strengthen the argument that obesity contributes to hypertension. There also seems to be strong

associations between sleep-disordered breathing, sleep apnea, and hypertension.

Recent knowledge from ambulatory BP (ABP) monitoring has contributed significantly to the understanding of hypertension in children by revealing different BP responses under different clinical settings. Ambulatory BP involves using a continuous monitor such as is done when children have a Holter monitor to detect episodic cardiac arrhythmias. The device particularly assesses changes in BP during sleep and notes whether an individual has dips (“dipper”) or no dips (“non-dipper”). The apparatus is somewhat cumbersome, the study is costly, and sleep may be disturbed by the cuff inflation, thereby influencing the results. In adults, surges of BP in the morning are felt to be predictive of strokes.

Abbreviation: BP, blood pressure.

*The 90th percentile is 1.28 SD, 95th percentile is 1.645 SD, and the 99th percentile is 2.326 SD over the mean.

There are 2 different situations where casual BP measurements in the office setting can significantly differ from ABP or home BP readings: (1) when office BP readings are higher, which is known as white-coat hypertension, and (2) when they are lower, which is called masked hypertension. The prevalence and long-term significance of these 2 types of hypertension is still unclear. White-coat hypertension is usually considered a benign finding. Some studies, however, show significant association between white-coat hypertension and increased left ventricular mass index, but long-term cardiac outcome has not been studied in this population yet. Children with masked hypertension are twice as likely to have a family history

of hypertension. If they also have a high pulse rate and body mass index, their risk of developing cardiovascular disorders is increased. It is a significant challenge for pediatricians to diagnose these 2 conditions, particularly masked hypertension, in which BP is increased only when away from the usual office or clinic settings. These findings also raise a question regarding which children need home BP monitoring or ABP monitoring to detect these conditions. In the future, we may better understand white-coat and masked hypertension and whether there are long-term sequelae of these conditions.

Secondary hypertension is more likely in very young children with hypertension, those who meet the criteria for stage 2 hypertension,

Table 90-3. Definitions of Hypertension^a

Term	Definition
Normal blood pressure (BP)	Systolic and diastolic BPs <90th percentile for age, gender, and height
Pre-hypertension	Average systolic and/or average diastolic BP between 90th and 95th percentiles for age, gender, and height Any BP >120/80 mm Hg regardless of age
Stage 1 hypertension	Average systolic and/or average diastolic BPs ≥95th percentile to 5 mm above 99th percentile for age, gender, and height with measurements obtained on at least 3 occasions
Stage 2 hypertension	Average systolic and/or diastolic BP >5mm above the 99th percentile for age, gender, and height

^aFrom the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics*. 2004;114:555–576.

and those with systemic symptoms of hypertension. The etiology of secondary hypertension varies with the age of the patient and with the nature of the hypertension (ie, whether the condition is acute or chronic). Renal abnormalities account for 70% to 80% of secondary hypertension in children. The pathogenesis of the hypertension may be related to either an increase in extracellular fluid volume (eg, acute glomerulonephritis or chronic renal failure), an increase in renin-angiotensin II activity (eg, renal artery stenosis, renin-producing tumor, pheochromocytoma or reflux nephropathy), or a combination of both mechanisms (eg, a patient with chronic renal failure caused by reflux nephropathy).

Differential Diagnosis

A reasonable effort should be made to identify the cause of hypertension in all young children who are diagnosed with hypertension because only 30% of them are likely to have essential hypertension (see Boxes 90-1 and 90-2). In older children and adolescents with mildly elevated BPs, primary hypertension is the most likely diagnosis, but must remain a diagnosis of exclusion. The cause of hypertension is often obvious from a detailed history, complete examination, and simple laboratory tests. However, extensive evaluation is sometimes necessary to determine the etiology of hypertension, especially in cases of renovascular hypertension.

Evaluation

When a child is identified as having an elevated BP on any occasion, the finding should be verified with at least 2 additional measurements. The physician should also verify that an appropriately sized cuff is being used to take the measurements and that efforts have been made to put the child at ease. Many children develop mild increases of BP (which can extend into the hypertensive range) when they visit a doctor's office because of anxiety or apprehension ("white coat hypertension"). Sometimes 24-hour ABP readings are necessary

Box 90-1. Causes of Acute or Intermittent Increases in Blood Pressure in Children

Renal Causes

- Acute glomerulonephritis
- Hemolytic uremic syndrome
- Henoch-Schönlein purpura nephritis
- Renal trauma
- Renal artery or vein thrombosis
- After renal biopsy
- Acute obstructive uropathy
- Post-genitourinary surgery
- Blood transfusions in patients with renal failure
- After kidney transplant or with transplant rejection

Drug-Induced Causes

- Corticosteroids
- Amphetamine overdose
- Phencyclidine overdose
- Cocaine overdose
- Anabolic steroids
- Oral contraceptives
- Excessive erythropoietin use in patients with end-stage renal disease
- Cyclosporine A and tacrolimus

Central Nervous System Causes

- Increased intracranial pressure (eg, subdural hematoma, meningitis, tumors)
- Encephalitis
- Poliomyelitis
- Guillain-Barré syndrome
- Porphyria
- Familial dysautonomia

Miscellaneous Causes

- Wrong blood pressure cuff size
- Anxiety, apprehension (white coat hypertension)
- Pain
- Fractures
- Orthopedic procedures (especially leg lengthening and those requiring traction)
- Burns
- Leukemia
- Stevens-Johnson syndrome
- Bacterial endocarditis
- Hyponatremia
- Hypercalcemia
- Heavy metal poisoning

to confirm whether hypertension is present. An isolated finding of a mild increase in BP with normal subsequent readings does not indicate hypertension. Once hypertension is confirmed, a detailed history, complete physical examination, and appropriate laboratory evaluation should be performed.

Box 90-2. Causes of Chronic Hypertension in Children

Renal

- Scarred kidney: due to pyelonephritis and/or vesicoureteral reflux nephropathy
- Chronic glomerulonephritis
- Connective tissue disease: systemic lupus erythematosus, Henoch-Schönlein purpura
- Hydronephrosis
- Congenital dysplastic kidneys, multicystic kidney
- Polycystic kidney disease
- Solitary renal cyst
- Tumors: Wilms, pericytoma (renin-producing tumor)

Renal Vascular Lesions

- Renal artery stenosis (fibromuscular dysplasia)
- Renal artery thrombosis (especially in the newborn following umbilical artery catheterization)
- Renal vein thrombosis
- Renal artery lesions with neurofibromatosis, tuberous sclerosis

Other Vascular Lesions

- Coarctation of aorta: thoracic, abdominal
- Polyarteritis nodosa and other vasculitides

Endocrine

- Corticosteroid treatment
- Neuroblastoma or other neural crest tumors
- Pheochromocytoma
- Congenital adrenal hyperplasia with 11 β - or 17 α -hydroxylase deficiency
- 11 β -hydroxysteroid dehydrogenase deficiency
- Liddle syndrome
- Primary hyperaldosteronism
- Dexamethasone-suppressible hyperaldosteronism
- Hyperthyroidism
- Hyperparathyroidism
- Cushing syndrome

Central Nervous System

- Intracranial hemorrhage
- Intracranial mass
- Sleep apnea/disordered breathing

Essential (Primary) Hypertension

As stated earlier ABP monitoring may be indicated in the evaluation of hypertension in select children where BP readings are consistently increased in the physician's office but the history suggests severe anxiety associated with the visit. Ambulatory BP monitoring may also help in identifying masked hypertension or a pre-hypertensive state in children by detecting the usual nocturnal dips in the BP. Because ABP monitoring is expensive, home BP monitoring twice a day in adults has been shown to be as effective as ABP monitoring, and it is currently used by many practitioners. Therefore, home or school BP monitoring should be considered as an alternative by pediatricians who have no access to ABP devices.

History

Information should be obtained about the child's symptoms that may be associated with hypertension, such as headaches and visual difficulties (Questions Box). Inquiry should also be made about the child's history of renal disease, especially previous UTIs, unexplained fevers during infancy and early childhood, edema, hematuria, enuresis or nocturia, duration of gestation, birth weight, and the use of umbilical artery catheterization during the newborn period. Information regarding the child's physical growth; BP recordings during previous physical examinations; eating habits, especially salt intake; use of drugs, especially illicit drugs; and the family's history of hypertension and renal disease should be obtained.

Physical Examination

A thorough examination is essential for determining the etiology of hypertension and the extent of target organ damage caused by hypertension. Poor physical growth or short stature may indicate the presence of an underlying condition, such as Turner syndrome or chronic renal disease with or without renal failure; it may also be the consequence of long-standing severe hypertension alone. Fundus examination is essential to determine if hypertension has been severe and chronic leading to arterial changes, exudate, hemorrhages, and/or papilledema. Tachycardia may signify heart failure or thyrotoxicosis. The child's pulses should be felt in both the upper and lower extremities, and the BP should be measured in all 4 extremities to evaluate for coarctation of the aorta and other vascular lesions. A heart murmur may also be present in patients with coarctation of the aorta. Some patients may present in heart failure secondary to chronic severe hypertension or renal disease with fluid retention. The abdomen should be carefully examined for presence of masses caused by cystic kidneys, Wilms tumor, or neuroblastoma and for tenderness, especially in the costovertebral angle (CVA). Bruits sometimes may be heard over the CVA in patients with renal artery stenosis. Presence of café-au-lait spots or depigmented spots on the skin may signify hypertension secondary to neurofibromatosis or tuberous sclerosis, respectively.

Questions

Hypertension

- Does the child have any symptoms associated with hypertension (eg, headache, dizziness, nosebleed, visual difficulty, or shortness of breath)?
- Have blood pressure readings been taken during previous routine physical examinations?
- Has the child had any hematuria, generalized swelling of the body (edema), enuresis (nocturia), burning urination, previous urinary tract infection, or other kidney problems?
- How much salt does the child take? Does he or she love to put extra salt on most foods and frequently like to eat salty foods?
- How has the child been growing?
- Is there a history of use of illicit drugs or oral contraceptives?
- Is there a family history of hypertension or renal disease?

Laboratory Tests

The extent of laboratory evaluation depends on the clinical findings, the nature of the hypertension (eg, stage 1 or stage 2, acute or chronic), and whether an etiology is apparent or obscure. This can be done in 3 different phases in order to minimize unnecessary cost and discomfort to patient. Box 90-3 outlines suggested laboratory workups for patients with stage 1 or stage 2 hypertension.

Presence of hematuria, heavy proteinuria, pyuria, and/or elevated blood urea nitrogen or plasma creatinine would clearly imply a renal disorder as the cause of hypertension and require an appropriate renal evaluation. A kidney biopsy should be performed to diagnose glomerulonephritis, and radiographic investigations, such as ultrasound and nuclear medicine scans, can help identify scarred kidneys, hydronephrosis, cystic kidneys, or tumors.

The presence of electrolyte abnormalities, such as hypokalemia, hypochloremia, or metabolic alkalosis, would indicate the presence of an increased mineralocorticoid hormone either on a primary basis (primary hyperaldosteronism, adrenogenital syndrome with 11 β - or 17 α -hydroxylase deficiency, Liddle syndrome, 11 β -hydroxysteroid dehydrogenase deficiency, etc) or secondary basis to increased renin activity in renovascular hypertension, renin-producing tumor, or reflux nephropathy; these values would also indicate a need to measure plasma renin activity and urinary or plasma aldosterone levels. Endocrine-based causes of hypertension in children are uncommon, and tests like plasma or urinary fractionated metanephrines and

Box 90-3. Laboratory and Radiologic Evaluation of Hypertension

Phase I: Initial Evaluation (to identify common causes of hypertension and evaluate for cardiac end-organ damage)

1. Urinalysis (urine culture if indicated)
2. Complete blood cell count, serum electrolytes, blood urea nitrogen, and creatinine; lipid profile for obese patients
3. Urine toxicology screening in adolescent children
4. Echocardiography

Phase II: More Extensive Evaluation (to rule out rare causes of hypertension)

1. Liver profile, calcium, phosphorus, and PTH
2. Plasma renin activity and plasma aldosterone, cortisol, and TSH
3. Plasma fractionated catecholamines and metanephrines
4. 24-hour urine for creatinine, catecholamines, metanephrines, VMA, HVA, and aldosterone (if plasma aldosterone is high)
5. Renal Doppler ultrasonography
6. Enalapril- or captopril-enhanced iodine-131 MAG3 renal scan
7. Renal arteriography (selective if necessary)

Phase III: To Identify Specific Etiologies (studies done mostly by specialists)

1. Diuretic renal scan, DMSA scan, or voiding nuclear cystogram
2. Renal biopsy
3. Specific imaging studies, including nuclear scan to rule out pheochromocytoma or neuroblastoma
4. Other endocrine, neurology, or cardiology studies

Abbreviations: DMSA, 99mTc dimercaptosuccinic acid; MAG3, mercaptoacetyl triglycine; PTH, parathyroid hormone; TSH, thyroid stimulating hormone; VMA, vanillylmandelic acid.

catecholamines, plasma cortisol, thyroid-stimulating hormone, and triiodothyronine are measured on an individual basis depending on the clinical evaluation of the patient to rule out neuroendocrine tumors, Cushing syndrome/disease, or hyperthyroidism, respectively.

Imaging Studies

Although electrocardiograms and chest radiographs are often requested to evaluate the effects of hypertension on the heart, in most instances they are normal until the patient enters the late stages of severe hypertension. Echocardiography is now the recommended primary tool for assessing for the presence of target organ damage and, according to the AAP guidelines, is included as part of the initial evaluation of patients with hypertension. In several studies, left ventricular hypertrophy is present even in children with untreated mild, white-coat or masked hypertension, especially when they are overweight. Newer recommendations also include obtaining sleep studies in overweight patients to evaluate for obstructive sleep apnea, which can contribute to the development of hypertension and left ventricular hypertrophy. Evidence suggests that with appropriate treatment to improve sleep apnea, BP normalizes and end-organ damage is prevented.

If the history, physical examination, and initial investigation do not reveal the etiology of severe hypertension in a young child, renovascular disease should be investigated with a renal Doppler ultrasound, enalapril- or captopril-enhanced iodine-131 mercaptoacetyl triglycine renal scan, renal vein renin measurements, or selective renal arteriography (sometimes magnetic resonance imaging angiography may be used as a substitute) (Box 90-3). However, in a patient with suspected renal artery narrowing, interventional renal angiography is the gold standard that can be done not only for diagnostic evaluation but also for therapeutic purposes if these patients require angioplasty or stent placement during the study.

Management

As previously stated, an effort should be made to identify a remediable cause in all children diagnosed with hypertension so that an appropriate medical or surgical treatment can be offered.

Patients with stage 1 hypertension can be initially managed with non-pharmacologic measures unless the patient is symptomatic or has significant cardiovascular risk factors, such as diabetes or hyperlipidemia, and a strong family history of hypertension, or stroke, or myocardial infarction in young age. These strategies include supportive care, reduction in sodium intake to about 80 to 100 mEq/d, weight reduction if the child is obese, and biofeedback. The 2004 report also recommends treating obstructive sleep apnea if present. If after a 3- to 6-month observation period BP remains persistently elevated, drug treatment should be initiated and a decision should be made whether the child needs a more thorough laboratory evaluation. Drug therapy may begin with a β -blocker (eg, atenolol), a calcium channel blocker (eg, amlodipine or isradipine), an angiotensin converting enzyme (ACE) inhibitor (eg, enalapril), an angiotensin II blocker (eg, losartan), or a diuretic (eg, hydrochlorothiazide).

A child can have more than one risk factor that becomes important when instituting a treatment plan. For example, an obese child with a family history of hypertension may also have chronic kidney disease as well as other risk factors contributing to the development of hypertension and/or end-organ damage. Therefore, management should be targeted not only toward aggressive control of BP using medications appropriate for a patient with kidney disease, but also recommendations for weight reduction, dietary modifications, and increased physical activity. If a patient smokes cigarettes, cessation of smoking is essential as well.

Patients with stage 2 hypertension may require combination therapy or the use of additional drugs, such as α -blockers (eg, prazosin), combined α - β -blockers (eg, labetalol), peripheral vasodilators (eg, hydralazine, minoxidil), or centrally acting drugs (eg, clonidine). The use of one or more of these drugs controls the BP in most patients within a satisfactory range and has a limited number of side effects. Patients with renal artery stenosis can be successfully treated with balloon dilatation of the stenosis or placing a stent. If this procedure is unsuccessful or restenosis occurs, surgical correction of the stenosis is usually successful.

Hypertensive emergencies require immediate and rapid intervention with intravenous (IV) medications such as labetalol, nicardipine, or sodium nitroprusside. Hypertensive urgencies may be treated initially with either the above IV medications or oral labetalol or an ACE inhibitor. In both cases, the aim is to lower the BP by about 20% to 25% of the presenting values in the first 8 hours. Over the following days to weeks, BP can gradually be controlled to come within normal values for age.

Prognosis

The long-term outcome of hypertension in children depends on the underlying etiology. In children with severe hypertension, BP control improves growth and overall well-being. The very long-term (40–50 years) prognosis for children with persistent, mild essential hypertension is largely unknown; however, adequate BP control should prolong life and reduce cardiovascular, CNS, renal, and retinal morbidity. In untreated or poorly controlled hypertension the prognosis is poor, especially in combination with obesity and hyperlipidemia, where hypertension is linked with severe cardiovascular morbidity and mortality in adults.

Prevention

While there are no specific predictors for the development of hypertension later in life, it is likely that early childhood health plays a role. Children who are small at birth and undergo rapid

catch-up growth seem to have a higher incidence of both obesity and hypertension later in life, while breastfed infants have a slower catch-up rate and subsequently have lower rates of hypertension as adults. As a result, it has been postulated that encouraging breastfeeding may have a protective effect. In addition, limiting intake of sodium and caffeine may reduce rates of hypertension in adolescents. Of course, programs aimed at preventing childhood obesity will likely prevent hypertension as well.

CASE RESOLUTION

Because of the elevated BP and evidence of end-organ dysfunction, the case presented is a clear-cut hypertensive emergency. The history of previous UTI and the laboratory findings of proteinuria and elevated plasma creatinine suggest chronic pyelonephritis with scarred kidneys secondary to vesicoureteral reflux and chronic renal failure. The elevated creatinine also suggests that both kidneys are affected either by the primary process or as a consequence of severe hypertension. After controlling the initial severe increase in BP, a renal Doppler ultrasound is the appropriate test to determine the kidney size, the extent of kidney damage, and possibly the etiology.

Ambiguous Genitalia

Jennifer K. Yee, MD, and Catherine S. Mao, MD

CASE STUDY

A term infant is being evaluated in the newborn nursery. The mother received prenatal care from the 8th week of gestation, reportedly had no problems during the pregnancy, and took no medications except prenatal vitamins with iron. She specifically denies taking any progesterone-containing drugs. Her previous pregnancy was uneventful, and her 3-year-old son is healthy.

On physical examination, the infant is active and alert, with normal vital signs. Aside from a minimum amount of breast tissue bilaterally, the physical examination is unremarkable, except for the genitalia. The labioscrotal folds are swollen bilaterally with slight hyperpigmentation and mild rugae. No masses are palpable in the labioscrotal folds. The clitoris/phallus is 1.5 cm in length. Labioscrotal

fusion is present, with a very small opening at the anterior aspect. The urethra cannot be visualized.

Questions

1. What conditions should be considered in newborns with ambiguous genitalia?
2. What should families of such infants be told regarding the gender of the newborns?
3. What key historical information should be obtained from families of such newborns?
4. What laboratory studies must be obtained to aid in the diagnosis?
5. What psychosocial issues should be addressed with families while infants are in the newborn nursery?

Ambiguous genitalia result from disorders of sex development (DSD) in newborns and are classified according to the chromosomal status and gonads present. This standard classification, using newer nomenclature with previously used nomenclature in parentheses, includes 46XX DSD (female pseudohermaphroditism) and 46XY DSD (male pseudohermaphroditism), ovotesticular DSD (true hermaphroditism), and 46XX testicular DSD or 46XY gonadal dysgenesis (complete or mixed gonadal dysgenesis). Gonadal dysgenesis in 45XO and 46XX individuals do not present with ambiguous genitalia but are also classified as DSD.

A multidisciplinary health care team should be involved in the care of infants with ambiguous genitalia. In addition to the general pediatrician, the nurses, social workers, neonatologists, pediatric endocrinologists, geneticists, and surgeons are all significant members of the team. The role of primary care physicians, however, cannot be underestimated because they are always involved in the initial evaluations of the newborns and often have already established relationships with the families.

Epidemiology

The prevalence of ambiguous genitalia in newborns is approximately 1:3,000 to 1:4,000 live births. 46XX DSD is characterized by female chromosomes (46XX), normal ovaries and müllerian structures, and virilized external genitalia. The most common DSD, 46XX DSD, is most often caused by congenital adrenal hyperplasia (CAH). Neonatal screening studies suggest that the incidence of CAH is 1:5,000 to 1:15,000.

46XY DSD occurs in genetic males (46XY) who have testes but insufficient masculinization of the external genitalia. This disorder most commonly results from androgen insensitivity. Ovotesticular DSD is a rare condition in which both ovarian and testicular tissues are present. Seventy percent to 80% of affected individuals have the 46XX karyotype, and the morphology of the external genitalia varies widely.

The mixed variant of 46XY gonadal dysgenesis is characterized by one testis and an abnormal streak gonad. Reports indicate that this condition is the second most common form of ambiguous genitalia. Affected newborns often have chromosomal mosaicism (45X/46XY).

Clinical Presentation

Variability in the phenotypic as well as clinical presentation of these disorders is considerable (Dx Box). The newborn with ambiguous genitalia may have an enlarged clitoris or small phallus and varying degrees of labioscrotal fusion. Signs of virilization in the female infant might include hyperpigmented labia and the presence of labial rugae. Other findings suggestive of a 46XX DSD are perineal hypospadias or an inguinal hernia. More dramatic presentations, such as severe dehydration and shock in a neonate, are associated with CAH of the salt-wasting form. Females with gonadal dysgenesis often present in adolescence with primary amenorrhea (see Chapter 98). Turner syndrome (45XO) is a common cause of gonadal dysgenesis and may present with additional clinical features, but 46XX pure gonadal dysgenesis is a distinct entity.

Dx Ambiguous Genitalia

- Indeterminate or ambiguous genitalia
- Enlarged clitoris or small phallus
- Hyperpigmented, rugated labia majora that may be fused
- Blind-ending or completely absent vaginal pouch
- Phenotypic male neonate with hypospadias and/or bilateral cryptorchidism
- Phenotypic female neonate with an inguinal hernia or mass

Pathophysiology

In order to appropriately evaluate and interpret laboratory results of neonates with ambiguous genitalia, it is important to understand the physiology of sexual differentiation and how deviations from this process lead to DSD.

Normal Sexual Differentiation

Normally, before embryos are 6 weeks old, undifferentiated bilateral gonads into which germ cells migrate from the yolk sac have developed. Both wolffian and müllerian duct systems are present at this time, making the embryonic gonads of males and females indistinguishable.

If a Y chromosome is present, a testes-determining factor (known as the sex determining region of the Y chromosome, or SRY) induces differentiation of these gonads into testes, thus blocking female development. This process involves the formation of seminiferous tubules that surround the germ cells. Leydig cells begin to produce testosterone, which in turn acts on the wolffian duct to result in the male internal genitalia: vas deferens, epididymis, and seminal vesicles. Concurrently, regression of the müllerian ducts occurs secondary to Sertoli cell production of anti-müllerian hormone (AMH), also called müllerian-inhibiting substance. For normal male external genitalia to form, testosterone must be converted to dihydrotestosterone (DHT) via 5 α -reductase. Dihydrotestosterone then combines with a specific androgen receptor, which allows formation of the phallus and scrotum from the previously undifferentiated external genitalia. The process primarily involves growth and fusion. Later in gestation, the testes migrate into the scrotum.

For the undifferentiated gonads to develop into female organs, the Y chromosome must be absent and 2 intact and normal functioning X chromosomes must be present. Because androgens are not produced and there is no AMH, the wolffian duct degenerates, and the müllerian duct develops into the internal female structures: fallopian tubes, uterus, and upper vagina. Fusion of undifferentiated external genitalia does not occur in the absence of DHT, so folds and swellings become the labia, and the genital tubercle becomes the clitoris. Female differentiation was previously believed to be the default development in the absence of SRY, but recent studies support the existence of female determining factors as well.

Development of Ambiguous Genitalia

Congenital adrenal hyperplasia is the most common cause of virilization of the female and is an autosomal recessively inherited defect. Congenital adrenal hyperplasia is the result of an enzymatic deficiency in the pathway for synthesis of cortisol and aldosterone from cholesterol. The most common of these enzymatic defects is 21 α -hydroxylase deficiency. Other less common defects are 11 β -hydroxylase deficiency and 3 β -hydroxysteroid dehydrogenase deficiency. Lipoid adrenal hyperplasia results from a defect in the steroidogenic acute regulatory protein (StAR) enzyme that transports cholesterol across the mitochondrial membrane for steroid synthesis. A recently identified rare form of CAH is P450 oxidoreductase deficiency, which can be associated with Antley-Bixler syndrome. Prenatally, circulating levels of androgens are abnormally high from the overproduction of precursors in the steroid synthesis pathways. Hence, the external genitalia of the fetus, which are controlled by androgens, are virilized in the female. Internal female organs, however, are normal, because their development is not influenced by androgens. Males may exhibit hyperpigmentation and rugosity, but otherwise have normal external genitalia.

The salt-wasting form of 21 α -hydroxylase deficiency is found in approximately two-thirds of patients with classic CAH. As a result of low levels of aldosterone, sodium resorption in the renal tubules is reduced, leading to hyponatremia and hyperkalemia. If this salt-wasting condition goes undiagnosed and untreated, shock and death may result in the first few weeks of life. Newborn screening programs are currently in place in all 50 United States. These programs screen for elevated 17 α -hydroxyprogesterone, targeting identification of patients with 21 α -hydroxylase deficiency, and are less sensitive for detection of infants with 11 β -hydroxylase deficiency and 3 β -hydroxysteroid dehydrogenase deficiency.

46XY DSD is secondary to insufficient testosterone production or insensitivity at the cellular level. Androgen insensitivity, the most common cause of this disorder, is the result of either an abnormality or a reduction in the number of androgen receptors. Not all affected individuals present with ambiguous genitalia at birth because the spectrum of sensitivity is broad. If the androgen receptor is completely nonfunctional or absent, the external genitalia are those of a normal female (complete testicular feminization). When there is partial function of the androgen receptor, genital ambiguity does occur. This is an X-linked condition so that only 46XY individuals are affected.

Other causes of 46XY DSD are (1) inadequate testosterone production secondary to low levels of fetal gonadotropins; (2) defects in testosterone synthesis from enzyme deficiencies or disruption of electron transport; (3) failure to convert testosterone to DHT as a result of 5 α -reductase deficiency; (4) deficient müllerian duct-inhibiting substance, which can be autosomal recessive or X-linked recessive; and (5) intrauterine loss of both testes secondary to torsion or another prenatal event. The defect in testosterone synthesis resulting in 46XY DSD include congenital adrenal hyperplasia due

to deficiencies of StAR, P450scc, 3- β -hydroxysteroid dehydrogenase, 17 α -hydroxylase, and P450 oxidoreductase.

Although most causes of ambiguous genitalia are related to chromosomal abnormalities and inherited enzymatic defects, exogenous sources of hormones can affect the differentiation of sexual organs. In most cases, the effect is minimal, and no ambiguity develops. Masculinized female external genitalia can occur, however, depending on the timing and duration of prenatal exposure to androgens or other virilizing drugs. Currently the most commonly used androgens are probably anabolic steroids. An infant may even be exposed prenatally through transdermal passage to the mother from a family member using androgen creams. An adrenal tumor or poorly controlled CAH in the mother will also lead to virilization of the female fetus. Birth control pills do not contain sufficient androgens to cause a problem.

Differential Diagnosis

The differential diagnosis of ambiguous genitalia depends on the classification of the DSD (Table 91-1). Some causes of this condition can be life-threatening and therefore must be recognized immediately (eg, salt-wasting CAH).

Table 91-1. Classification and Causes of Ambiguous Genitalia in the Newborn

Disorder	Causes
46XX DSD	Congenital adrenal hyperplasia
	Maternal androgen ingestion
	Maternal virilizing hormones
	Idiopathic, associated with dysmorphic syndromes
46XY DSD	Biochemical defects in testosterone biosynthesis (enzyme deficiencies)
	Androgen insensitivity (complete or partial receptor defects)
	5 α -reductase deficiency
	Persistent müllerian duct syndrome
	Gonadotropic failure
	Dysgenetic testes
	Bilateral vanishing testes syndrome
	Idiopathic, associated with dysmorphic syndromes
Ovotesticular DSD	Chimerism
46XX testicular DSD or 46XY complete gonadal dysgenesis	Chromosomal mosaicism

Abbreviation: DSD, disorders of sex development.

Evaluation

History

The general obstetric history should be reviewed, although it may not be helpful in all cases. Probably the most important source of information on family history can be derived from family pedigrees (Questions Box). The mother of affected infants should be interviewed thoroughly for any clinical findings that might suggest the mother as the source of androgens. Undiagnosed chromosomal disorders, consanguinity, and recurrent medical conditions may be established or inferred from the family background.

Questions

Ambiguous Genitalia

- Did the mother take any medications containing estrogen, progestins, or androgens during the pregnancy? Did she use any other virilizing drugs, such as danazol, during pregnancy?
- Was the mother in contact with anyone using hormonal creams or gels?
- Does the mother have poorly controlled congenital adrenal hyperplasia or an adrenal tumor? Does the mother have any virilizing symptoms that suggest she should undergo an evaluation for the above conditions?
- What is the mother's prior obstetric history?
- Did she have any problems with any previous pregnancies?
- Is there a history of any unexplained neonatal deaths, particularly in male offspring?
- Are her other children growing and developing normally?
- Is there a family history of ambiguous genitalia, including microphallus, hypospadias, and cryptorchidism?
- Is there a family history of sterility, female hirsutism, or amenorrhea?
- Are the parents or other family members consanguineous?

Physical Examination

A complete physical examination of newborns must be performed in the nursery, in addition to a detailed assessment of the genitalia. In particular, the presence of dysmorphic features (eg, microcephaly, low-set ears, micrognathia), which suggests the presence of a chromosomal abnormality, should be appreciated. The areola should be examined for any evidence of hyperpigmentation, and the inguinal area should be palpated for any masses or hernias.

A thorough genital examination should then be performed. The appearance and size of the labioscrotal folds should be noted in terms of pigmentation, presence of rugae, and size. Physicians should keep in mind that normal female labia majora may not completely cover the labia minora, and that the labia may be extremely underdeveloped in premature infants. Practitioners should determine whether any masses are palpable in what appear to be the labia and whether the testes are palpable in what appears to be the scrotum. The size of

the phallus/clitoris should be measured; a normal stretched phallus is at least 2.5 cm long, whereas a normal clitoris should not exceed 1 cm in term infants. The labioscrotal folds should then be spread apart to look for a vaginal introitus. The presence of posterior labioscrotal fusion, which may preclude this, confirms the suspicion of indeterminate genitalia. The clitoral index (product of clitoral transverse and sagittal dimensions) and the anogenital distance can be determined by an experienced clinician. Limited data on these measurements in normal children is available in the literature. Finally, the location of a urethral meatus should be noted, because if hypospadias and cryptorchidism occur together, the chance of a DSD disorder is approximately 50%. A rectal examination may help detect the presence of a uterus or prostate but may be difficult.

Laboratory Tests

The most important study to obtain is a karyotype, which can be performed in 24 to 48 hours by many laboratories. Examination of Barr bodies in a buccal smear is not recommended because this test is unreliable. In addition, serum electrolytes should be ordered in the nursery and monitored closely if CAH is suspected. A serum 17 α -hydroxyprogesterone level is mandatory in evaluation for CAH. Other intermediate metabolites, such as 11-deoxycortisol, androstenedione, dehydroepiandrosterone sulfate, and sex steroids (eg, testosterone and dihydrotestosterone) can also be measured to evaluate for androgen excess or deficiency. Measurement of 17-ketosteroids and pregnanetriol in the urine may provide supportive data in newborns with ambiguous genitalia, especially in newborns whose gonads are not palpable.

A human chorionic gonadotropin stimulation test may be performed to measure response in testosterone production if ovotesticular DSD is suspected.

Imaging Studies

Pelvic ultrasonography is effective in determining if müllerian structures are present, but this technique is not as useful for locating the gonads. If the gonads are not palpable, magnetic resonance imaging of the pelvis may be considered. Genitography can aid in visualizing the duct structures under fluoroscopy.

Management

An interdisciplinary team consisting of a pediatrician, pediatric endocrinologist, medical geneticist, urologist, social worker, and psychologist or psychiatrist should be involved in the care of infants with ambiguous genitalia. All aspects of treatment can then be addressed in an efficient and comprehensive manner. A consensus statement regarding management of infants with DSD and proposed ethical guidelines for management are available (see Selected References).

Initial Phase: Delivery Room and Newborn Nursery

If the gender of the newborn is uncertain, it should not be assigned in the delivery room. Parents and nursing staff should be notified immediately of the ambiguity, and a unisex name should be assigned such as “Baby Smith” instead of “Baby Boy Smith” or “Baby Girl Smith.” Hospital name plates should also reflect a gender neutral status in wording and in color. Physicians should congratulate the parents on the birth of their child, then inform them of the genital ambiguity. Physicians should then reassure parents that they will determine the baby’s gender as soon as possible, but that additional tests would be necessary to find out. Parents should be encouraged not to speculate on the gender of the infant in the meantime.

During the initial hours after birth, parents may have difficulty comprehending the condition. An open line of communication must be maintained with the family, however, even while waiting for test results. Parents should be assured that gender assignment will be made as soon as possible and that more information will follow with test results. Gender assignment can potentially be made within 3 to 5 days or even earlier in some institutions because most preliminary laboratory results are reported in 24 to 48 hours. However, some cases may require more extensive workup, such as a trial of testosterone in partial androgen insensitivity, so gender assignment in these infants may take more time. The interval of time to gender assignment, therefore, must be individualized. Necessary radiographic studies should be ordered as soon as possible.

Intermediate Phase: Psychological Issues

Several psychological issues should be addressed at the time of diagnosis. Alleviation of parental anxiety regarding the cause of the condition should be the priority; general questions can also be answered. For example, parents may be unclear about what to tell others about the gender of the infant and find this process very awkward. In addition, parents should be educated about the normal sexual differentiation. Pediatricians must emphasize that during the first 6 to 8 weeks of gestation, sexual organs are undifferentiated. Ambiguous genitalia should be explained as overdevelopment or underdevelopment rather than as freaky or highly unusual. For parental perspective, genital ambiguity can be compared to another type of birth defect, such as a cardiac septal defect.

Primary care physicians must also assess parents’ level of sophistication and their cultural and religious beliefs about gender identity and sexuality. The gender preference for newborn infants should be addressed. Were the parents hoping for a boy or girl? Do they feel strongly about one gender? The medical team can also help families establish a plan for newborns regarding what they want to tell the extended family and in what detail they want to disclose the information. After the initial meeting and while awaiting laboratory data, other questions regarding sexual orientation, puberty, fertility, and self-esteem may arise.

Final Phase: Gender Assignment

After the karyotype is confirmed and the type of DSD has been considered, team members should meet with families to discuss gender assignment before discharge from the hospital. Traditionally, gender assignment was based on size of the phallus, potential response to androgen stimulation, and potential for fertility. More recently, additional factors have been recognized as important in gender assignment, including in utero brain exposure to androgens and likely adult gender identity, quality of sexual function with or without surgery, and psychosocial risk for patient and family in the event of gender dysphoria. Parents must be involved in this decision and must agree with the final outcome. Some investigators strongly believe that gender reassignment and genital surgery should be discussed with the patient at a later date rather than assigned during the neonatal period. Such an approach involves consistent counseling for the patient, open discussion among the family, and a primary care physician willing to work diligently with both the patient and the family. Support groups should also be offered regardless of the decision regarding gender reassignment.

Detailed information should be given once again regarding the origin of the condition. The timing and nature of any future hormonal treatment and surgical procedures should be addressed as well. Parents should be urged to move beyond the issue of ambiguous genitalia once a decision regarding gender has been made. They must then deal with activities such as birth announcements and inquiries regarding gender from extended family, siblings, and babysitters. The entire medical team should offer parents encouragement concerning their parenting ability.

Treatment

Hormone replacement therapy is indicated for some newborns with ambiguous genitalia. Cortisol replacement is mandatory in infants with CAH at daily physiological doses of 10 to 20 mg/m²/d. In infants with salt-wasting or classic 21 α -hydroxylase deficiency, mineralocorticoid replacement is indicated. Oral fludrocortisone should be administered at doses that suppress plasma renin activity to normal levels without causing hypertension.

Testosterone or estrogen replacement is needed at puberty in disorders in which the gonads failed to develop or were surgically removed. For disorders involving micropallus, injections of testosterone enanthate at regular intervals may be used to increase the length and width of the phallus. Recombinant human growth hormone replacement may also be considered for short stature in mixed gonadal dysgenesis.

Surgical procedures may be necessary in many cases, but can be done later in infancy. Although laparoscopy or laparotomy may be indicated for a gonadal biopsy, this is generally not needed in the neonatal period for gender assignment. A gonadectomy is indicated prophylactically in all phenotypic females with all or part of a Y chromosome because of the potential for malignant conversion of gonadoblastoma. Clitoral reduction and recession, vaginoplasty,

and labioscrotal reduction are usually performed if infants are to be raised as females. For children to be raised as males, orchiopexy, hypospadias repair, and chordee release are often indicated, but these surgical procedures may be difficult. In some specific cases, however, surgical procedures should be delayed until response to medical treatment is evaluated. For example, in CAH, clitoral size may decrease with glucocorticoid replacement.

Psychological support for the patient and family will be necessary during the child's growth and development into adulthood. Issues revolving around gender identity, gender role, and sexual orientation require ongoing discussion with the patient and the parents. Gender dissatisfaction may occur later in life.

Prognosis

The prognosis for most infants with ambiguous genitalia is excellent. Problems arise with undiagnosed CAH, which may lead to shock and death in the neonatal period if unrecognized and untreated. Otherwise, children should be able to live long, healthy lives once their families have come to grips with the diagnosis. Amenorrhea in females and sterility in males or females will need to be addressed during adolescence, at which time psychological services should be provided.

CASE RESOLUTION

In the case described at the beginning of the chapter, the infant has ambiguous genitalia. The parents should be informed immediately of this finding, and all references related to gender should be avoided. A karyotype and 17 α -hydroxyprogesterone analyses should be performed immediately. In addition, serial serum electrolytes should be performed starting at 12 to 24 hours of life. The physician should then meet with the family to further discuss DSD and explain the diagnostic workup. General psychological services and information regarding support groups should also be provided.

Inguinal Lumps and Bumps

Julie E. Noble, MD

CASE STUDY

A 2-month-old male infant presents to your office for evaluation of a lump in his right groin for 1-week duration. The lump has been coming and going, and his mother notices that it is larger when he cries. Today, the lump is prominent, and the infant seems fussy. He has been crying more often and vomited once today. His history is remarkable for having been born at 32 weeks' gestation by spontaneous vaginal delivery. Birth weight was 1,500 g, and he did well in the nursery with no respiratory complications. He was sent home at 4 weeks of age and has had no other medical problems. He breastfeeds well and has normal stools.

Physical examination reveals a well-nourished, irritable infant in no acute distress. His vital signs demonstrate mild tachycardia and temperature to 100°F (37.8°C). His

abdomen is soft, and the genitourinary examination is significant for a swelling in the right inguinal area that extends into his scrotum. The mass is mildly tender and cannot be reduced. The rest of the examination is normal.

Questions

1. What are the possible causes of inguinal masses?
2. How does age affect the diagnostic possibilities?
3. How do you differentiate between acute and non-acute conditions?
4. What diagnostic modalities can help with the diagnosis?
5. What are the treatment choices for inguinal masses?
6. Are there long-term consequences?

Inguinal masses occur either from disease in normal tissue in the inguinal area or from ectopic tissue, frequently of embryological origin. A child may present with the chief complaint of an inguinal mass, and the mass may vary in position from anywhere along the inguinal canal to the scrotum or labia (Figure 92-1). Along the inguinal canal, a mass might be an enlarged **lymph node**, a **retractile**

testis, an **ovary**, or a **synovial cyst**. At the inguinal ring, a mass might also be a testis or an ovary, or an inguinal hernia. In the scrotum, swelling could be due to a **hernia**, **hydrocele**, **varicocele**, **trauma**, or **testicular pathology**. Labial lesions could be secondary to trauma, an **ectopic ovary**, **mixed gonadal tissue**, an actual testis as in testicular feminization, or a **Bartholin gland cyst**. The differential diagnosis and the subsequent evaluation will vary not only according to the location of the mass and the patient's age but also with the acuity of presentation of the mass.

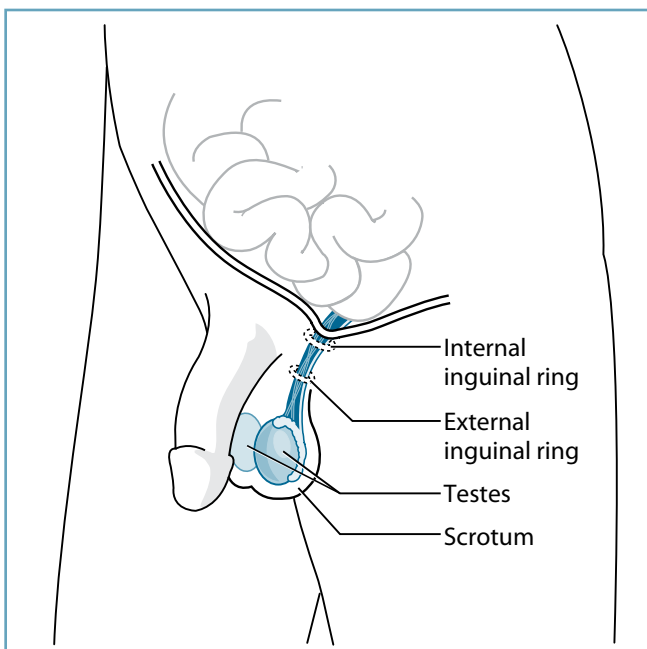

Figure 92-1. The inguinal area.

Epidemiology

Inguinal masses are a fairly frequent complaint in the office setting. The usual cause is an enlarged lymph node, but **hernias and hydroceles** are also common. Surgical repair of hernias and hydroceles are the most common surgical procedures performed in children. The incidence of inguinal hernias has been estimated at 1 to 4 per 100 live births. There is a 60% risk of incarceration in the first 6 months of life. For this reason surgical correction is recommended early. Hernias are present on the right side in 60% of cases, on the left in 30%, and bilateral in 10%. Of affected children, males outnumber females 4:1. Femoral and direct hernias are more common in girls. Certain conditions are associated with a higher incidence of hernias (Box 92-1). The most significant predisposing factor is prematurity, with hernias reported in 30% of infants weighing less than 1,000 g at birth.

The other common acute scrotal lesions—**testicular torsion** and **torsion of the appendix testis**—have an incidence of 1:160 in

Box 92-1. Conditions Associated With Hernias

|--|--|

males. The peak incidence of testicular torsion occurs in the perinatal period and again at puberty. Torsion of the appendix testis is most likely to occur between ages 7 and 10. **Varicoceles** occur in pubertal and postpubertal males, with a fairly high incidence of up to 15%. **Testicular tumors** are rare in childhood. They occur at an incidence of 0.5 to 2.0 per 100,000 children and account for only 1% of all pediatric solid tumors. But in adolescence, testicular cancer is the most common cause of cancer in young males and may affect as many as 1 in 10,000.

Clinical Presentation

The child with an inguinal mass presents either acutely or non-acutely. In the acute presentation, the swelling occurs rapidly and is associated with pain. There may be systemic symptoms of nausea and vomiting. Inguinal pathology should be suspected in any child with abdominal pain. The involved area may be extremely tender. Non-acute masses appear more slowly. Some may be present from birth. They may come and go, especially with crying or straining. Non-acute masses usually are not tender and are not associated with systemic symptoms (Dx Box).

Dx Inguinal Masses

Acute

- Rapid onset
- Painful
- Tender
- Nausea and vomiting
- Fever
- Overlying skin red
- Cremasteric reflex absent

Non-acute

- Slower onset
- Not painful
- May fluctuate in size
- Cremasteric reflex present

Pathophysiology

Pathophysiological developmental features of an inguinal mass vary depending on the cause of the mass. An enlarged lymph node may result from proliferation of intrinsic lymphocytes or inflammatory infiltrate from infection (lymphadenitis). The etiology of lymphadenopathy is extensive (see Chapter 85). Any of these processes can appear in the inguinal nodes. An enlarged node can also be secondary to metastatic infiltration from another cell line and represent tumor spread.

A hydrocele develops secondary to failure of obliteration of the patent processus vaginalis during embryologic development. During

the 27th to 28th weeks of gestation, the testicle, gubernaculum, and processus vaginalis descend from the peritoneum through the inguinal canal into the scrotum. The processus vaginalis begins closing prior to birth and attaches to the testis, forming the tunica vaginalis testis. The closure is complete by 1 to 2 years of age. Failure of closure results in a hydrocele (a peritoneal connection with fluid) or a hernia, with intra-abdominal contents. Either may bulge into the inguinal canal and scrotum. If the hernia cannot be reduced and abdominal contents are at risk for vascular compromise, the hernia is termed *incarcerated*. This condition is a surgical emergency.

Sometimes a parent may misinterpret a normal testicle in the process of descent as an abnormal mass. A delay in the normal descent process of the testis occurs occasionally, and the testicle may not be in the scrotum at the time of birth. Torsion of the testis after it has reached the scrotum can occur in the newborn if the testis twists on the spermatic cord. Similarly, the testicle can also twist in the pubertal period on its own vasculature within the tunica vaginalis. This is frequently secondary to a high attachment of the tunica vaginalis to the spermatic cord, allowing the testis to hang freely, like a bell clapper. Both types of torsion cause vasculature compromise and an ischemic testis.

Likewise, a vestigial remnant called the appendix testis can twist, resulting in vascular compromise of that localized part of the testis.

Pathologically, a traumatic scrotal mass is usually a hematoma, although testicular rupture may occur if the tunica albuginea is torn as a result of trauma. Testicular neoplasms in prepubertal children tend to be germ cell tumors. Yolk sac carcinoma, teratomas, and mixed germ cell tumors with infiltration of their respective cell lines are the usual diseases found.

A varicocele, another scrotal mass, is caused by increased pressure within the venous drainage of the testicle with subsequent dilatation of the veins, producing a mass. Because of the anatomy of the venous drainage, 90% of varicoceles occur on the left side.

Infections of the epididymis or testis can cause an inflammatory infiltrate and swelling. In the female, infection of Bartholin gland in the labia creates an abscess and leads to an acute, painful mass.

Differential Diagnosis

Location, acuity, and patient age aid in establishing the differential diagnosis.

Non-acute masses, which have a slow onset and are not painful, include lymphadenopathy, a retractile testis, hydrocele, hernia, varicocele, tumor, and ectopic ovary.

Acute masses that have a sudden onset and are associated with pain include epididymitis, orchitis, testicular torsion, traumatic hematoma, torsion of the appendix testis, lymphadenitis, and incarcerated hernia (Box 92-2).

Skin changes can mimic an acute scrotal mass. Henoch-Schönlein purpura, a vasculitis of unclear etiology, can develop in the scrotal area. Scrotal edema can also occur acutely.

Testicular torsion occurs most commonly in the newborn period and again at puberty. Incarcerated hernias are seen most often in the

Box 92-2. Differential Diagnosis of Inguinal Masses**Non-acute**

- Idiopathic scrotal swelling
- Incarcerated hernia
- Lymphadenitis
- Orchitis
- Testicular torsion
- Torsion of appendix testis
- Trauma

first 6 months of life. Varicoceles are noted almost always at adolescence and are located in the upper left area of the scrotum. Testicular tumors are also much more common in adolescence.

The gender of the patient will also influence the differential diagnosis of the lesion as well as the workup.

Evaluation**History**

A thorough, focused history will help define the differential diagnosis (Questions Box). Inquiring about systemic symptoms should always be included and, if positive, may suggest a more generalized process such as a tumor or systemic infection. Symptoms of dysuria would point to epididymitis or orchitis. A history of trauma or possible sexual abuse should always be sought. Hernias and testicular torsion may have a family history positive for the same condition.

Physical Examination

A complete physical examination should always be performed in assessing any pediatric complaint. Evidence of diffuse adenopathy may be present. With an inguinal mass, a concentrated, thorough examination of the inguinal area and lower extremity is needed. A lower extremity lesion may indicate a reactive adenopathy. If the mass is not apparent on inspection and it comes and goes, ask the

parent to point to its location. Observe the skin for evidence of erythema, swelling, or bruising. Gently palpate the inguinal canal to see if you can feel a mass, then assess the scrotal or labial area. If the mass is of acute onset, observe the scrotum and try to localize the tenderness. An incarcerated hernia, testicular torsion, torsion of the appendix testis, epididymitis, and orchitis are extremely tender. If there is torsion of the appendix testis, there may be a classic blue dot at the upper pole of the testis. Try to elicit a cremasteric reflex. If present, it virtually eliminates testicular torsion. If the testis has a horizontal lie, it may indicate a bell clapper type of abnormal fixation. The pain of epididymitis and orchitis is relieved partially when the testis is elevated (Prehn sign). Transilluminating the mass may be helpful. A fluid-filled mass, such as a hydrocele, will definitely transilluminate; incarcerated bowel may also transilluminate.

Any mass should be accurately measured. Evaluating the borders of an inguinal mass is important. A hydrocele does not extend into the inguinal canal; therefore, the top border can be felt below the pubis. A hernia will extend into the inguinal canal, so an upper border will not be apparent. Reduction of any hernia with gentle pressure should be attempted. To detect a hernia that is not readily apparent, causing the infant to cry increases intra-abdominal pressure and may demonstrate the hernia. An older child should be asked to stand and cough while the inguinal canal is palpated. A varicocele, which feels like a bag of worms, is a non-tender mass over the spermatic cord and is readily palpated if the teen is in a standing position.

Laboratory Tests

The laboratory tests should be directed toward the most likely diagnosis as determined by the history and physical examination.

If an infection is suspected, a complete blood cell count (CBC) should be obtained. If the infection is thought to be epididymitis or orchitis, a urinalysis and urine culture, along with gonorrhea and chlamydia cultures, should also be obtained. If lymphadenopathy is suspected, a CBC, mononucleosis test, cat-scratch disease test, and possible biopsy may be necessary. An inguinal mass in a female may be a normal testes, and chromosomal evaluation may be indicated to diagnose a disorder of sexual differentiation (see Chapter 91). If a tumor is suspected, the α -fetoprotein level, which is elevated in 90% of yolk sac tumors, and β -human chorionic gonadotropin should be assayed.

Imaging Studies

Ultrasound can be helpful in defining inguinal masses and is the best test to define scrotal contents. It can be useful in differentiating between a hydrocele or hernia and enlarged lymph nodes where a characteristic central echolucent area can be seen. It gives accurate information in evaluating tumors. Ultrasound can provide information in identifying a mass as ovarian or testicular because the ovary is smaller, more echogenic, and may have follicular cysts. Color Doppler ultrasonography is the test of choice in evaluating the scrotum when symptoms are acute to identify a testicular fracture and also assess blood flow in testicular torsion, but has a longer time

Questions**Inguinal Masses**

- How long has the mass been present?
- Is it painful?
- Does it come and go?
- Was there a history of trauma?
- Does the child have dysuria?
- Is there fever or vomiting?
- Are there any other masses?
- Has the child had any lower extremity infections?
- Is there a history of renal disease?
- Is there a history of preterm delivery?
- Is there a positive family history?

frame and may not be practical in the acute setting. Nuclear imaging may be possible, but also has a long time frame. If incarceration of a hernia is suspected, a flat plate radiograph of the abdomen is helpful to detect signs of intestinal obstruction. Computed tomography and magnetic resonance imaging are only moderately effective in evaluations.

Management

Many inguinal masses require surgical treatment. Acute symptoms involving the scrotum present a surgical emergency. There may not be time to perform diagnostic studies. If there is a high probability of a testicular torsion, the scrotum should be surgically explored immediately. Surgery within 6 hours of symptom onset has an excellent rate of a viable testis. If surgery is beyond 6 hours, the possibility of a viable testis is progressively worse. After 48 hours it is unlikely that the testis will be salvaged. If the testis is nonviable, it is removed. Torsion of the appendix testis does not need to be explored if the diagnosis is certain.

Surgical intervention may also be indicated with scrotal trauma, which can cause torsion or testicular rupture. A urological referral is indicated for assessment.

All hernias require surgical repair at some time. Immediate surgery is indicated for an incarcerated hernia that cannot be reduced. If it is reduced, then elective surgical repair can be scheduled. There is controversy regarding the indications for surgery on the contralateral side. An infant younger than 1 year has a 20% chance of developing a hernia on the other side, and most surgeons repair both sides at the same time. Other accepted indications for exploration of the unaffected side include preterm infant, twin gestation, left-sided hernia, increased abdominal pressure, and female gender. Currently some surgeons use laparoscopy at the time of the hernia repair to define a patent processus vaginalis on the opposite side and repair it if patency is found. Hydroceles do not have to be repaired surgically unless they persist beyond 1 year of age. This persistence implies a peritoneal connection and an impending hernia, so repair is indicated. A fracture of the testicle also dictates the need for surgical repair. Varicoceles are removed if there is significant pain, the testicle shows growth retardation, there is bilateral disease, or the teen has a solitary testis. Subinguinal microsurgical varicocelectomy can now be performed preserving lymphatic drainage. All testicular tumors are removed. Additional antitumor therapy is dependent on the stage and cell line of the tumor.

Infectious inguinal masses are treated according to the specific bacteriologic diagnosis.

Prognosis

After surgical treatment for either an inguinal hernia or testicular torsion, the child generally does well. The most significant long-term complication of hernia surgery is subsequent impaired testicular function, and decreased testicular size is noted in up to 27% of cases. Damage to the vas deferens and testicular vessels may impair spermatogenesis and result in a higher incidence of impaired fertility. Surgery for testicular torsion may also be associated with subsequent infertility, particularly if an affected testis is left in place. Two-thirds of affected testicles demonstrate atrophy. If there is loss of a testis, the physician should offer a prosthesis in the future since there can be significant psychological implications.

There may be recurrence of a hernia following repair. A hydrocele may develop following varicocele repair.

CASE RESOLUTION

In the case presented at the beginning of the chapter, the infant's history of prematurity associated with a mass that comes and goes most likely indicates an inguinal hernia. With the additional symptoms of pain, fever, and vomiting and the findings of an inflamed, non-reducible mass on examination, there is a high likelihood that the hernia is incarcerated. The infant is taken to the operating room where this diagnosis is confirmed. The hernia is reduced and repaired, and the intestine is noted to be viable. The contralateral side is explored and found to be normal. The infant makes an uneventful recovery.

Hematuria

Elaine S. Kamil, MD

CASE STUDY

A 5-year-old boy is brought to the office for a school entry examination. He was the full-term product of an uncomplicated pregnancy, labor, and delivery. Although he has had 4 or 5 episodes of otitis media, he has generally been in good health. He has never been hospitalized or experienced any significant trauma. He has no known allergies, has been fully immunized, and is developmentally normal.

In addition, the physical examination is completely normal. The boy's height and weight are at the 75th percentile, and his blood pressure is 100/64 mm Hg. Screening tests for hearing and vision are completely normal. The boy's hematocrit is 42. His urinalysis comes back

with a specific gravity of 1.025, pH 6, 2+ blood, and trace protein. Microscopic examination shows 18 to 20 red blood cells (RBCs) per high-power field; 0 to 1 white blood cells per high-power field; and a rare, fine, granular cast.

Questions

1. What disease entities cause hematuria?
2. How should hematuria be evaluated?
3. How does the approach to hematuria differ in children who complain of dark or red urine?
4. What is the appropriate follow-up of children with asymptomatic microscopic hematuria?

Hematuria is a common problem in pediatrics, and primary care physicians should have a clear understanding of its pathophysiology, etiology, evaluation, and therapy. Hematuria can be caused by a serious medical problem, or it may only be an incidental finding with no potential for impairment of patients' health. In general, hematuria is categorized as either gross or microscopic (microhematuria). The etiology and approach to hematuria vary with its severity. Gross hematuria is defined as red or brown urine caused by the presence of RBCs. Microhematuria is defined as 3 or more consecutive urine samples with a positive dipstick and 6 or more RBCs per high-power field in a fresh, spun urine sample.

Epidemiology

The incidence of **gross hematuria** is about 1.3 in 1,000 patient visits (Table 93-1). In one series, the causes in about half of the patients were readily apparent from the intake history or physical examination. The incidence of gross hematuria may increase in the community during an epidemic of a disease, such as acute glomerulonephritis, a condition often associated with gross hematuria. In another series, approximately 30% of children with gross hematuria had glomerular diseases, most commonly immunoglobulin (Ig) A nephropathy. The incidence of kidney stones is increasing in the pediatric population.

Microscopic hematuria is a more common pediatric problem. Prevalence rates for persistent, microscopic hematuria range from 0.5% to 2.0%, but 4% to 5% of school-aged children may have microhematuria on a single voided specimen. The incidence is artificially increased in late summer because at that time children tend to visit pediatricians for school physicals that typically include a screening urinalysis.

Table 93-1. Etiology of Gross Hematuria in an Unselected Pediatric Population^a

Clinical Presentation

Children with gross hematuria present with the sudden appearance of red or brown urine, which may be associated with flank or urethral pain or with a history of trauma.

Children with microscopic hematuria may have urinary complaints (eg, dysuria). In children who appear well, microhematuria is usually detected on screening dipstick examination.

Pathophysiology

Gross Hematuria

Gross hematuria occurs because of the presence of large numbers of RBCs in the urine. Blood may enter the urine because of rupture of blood vessels following trauma or inflammation in the glomeruli or interstitial regions of the kidney. It may also occur as a result of severe inflammation of the bladder wall.

Causes of gross hematuria are listed in Box 93-1. The presence of casts in the urine suggests the diagnosis of glomerulonephritis. The most common causes of glomerulonephritis in children include acute poststreptococcal glomerulonephritis, anaphylactoid purpura, IgA nephropathy, membranoproliferative glomerulonephritis (MPGN), and systemic lupus erythematosus (SLE).

Box 93-1. Common Causes of Gross Hematuria in Pediatric Patients

Glomerular Causes

- IgA nephropathy
- Acute poststreptococcal GN
- Lupus nephritis
- Membranoproliferative GN
- Anaphylactoid purpura GN
- Alport syndrome
- Thin basement membrane disease
- Rapidly progressive GN
- Vasculitis, ANCA positive
- Anti-glomerular basement membrane disease
- Hemolytic uremic syndrome

Hematologic Causes

- Sickle cell disease or trait or hemoglobin C
- Hemophilia
- Thrombocytopenia
- Thrombosis (renal arterial or venous)

Other

- Hypercalciuria
- Munchausen by proxy

Structural Causes

- Renal trauma
- Tumor
- Obstruction
- Renal stones
- Polycystic kidney disease

Vascular Abnormalities

- Hemangiomas
- Nutcracker syndrome
- Arteriovenous malformations

Infectious Causes

- Bacterial urinary tract infection
- Viral cystitis
- Schistosomiasis
- Tuberculosis

Interstitial Diseases

- Acute interstitial nephritis
- Tubulointerstitial nephritis with uveitis

Abbreviations: ANCA, antineutrophil cytoplasmic autoantibody; GN, glomerulonephritis; IgA, immunoglobulin A.

Common causes of gross hematuria in the absence of RBC casts include urinary tract infection (UTI), **either from bacteria or some viruses; renal trauma; bleeding diathesis** (eg, hemophilia or idiopathic thrombocytopenic purpura); **renal tumors; obstruction of the urinary tract; renal stones; hypercalciuria; or hemolytic uremic syndrome (HUS)**. A hemangioma in the urinary tract is an extremely rare cause of gross hematuria. In endemic areas gross hematuria may be caused by schistosomiasis. Another rare cause of gross hematuria is Nutcracker syndrome caused by left-sided renal vein congestion from compression of the renal vein by the superior mesenteric artery. The symptoms are distinctive, intermittent gross hematuria associated with left-sided flank pain that is relieved by lying down.

Microhematuria

Microhematuria occurs when small numbers of RBCs enter the urine via tiny ruptures in the glomerular capillary walls or in the capillaries of the tubular or bladder lining. One study showed that otherwise healthy children with microscopic hematuria had increased erythrocyte deformability, making it easier for the RBCs to slip through the glomerular capillaries. For purposes of discussion, the following causes of microscopic hematuria are considered: infectious, structural, traumatic, glomerular, and interstitial. Separate consideration of the causes of microscopic and gross hematuria is often helpful, although significant overlap exists. The presence of gross hematuria calls for a more rapid, and usually more extensive, evaluation.

Urinary tract infection is one of the most common **infectious causes** of hematuria. Bacterial infections of the bladder or kidney occur much more frequently than viral cystitis. Adenovirus is the most common viral cause of hemorrhagic cystitis and is usually associated with dysuria. Other viral causes include cytomegalovirus, parvovirus 19, and polyomavirus type BK. Vaginitis in girls and prostatitis in teenaged boys may also result in hematuria.

Any type of congenital obstructive uropathy may lead to massive dilatation of the urinary tract, which makes the urinary tract more susceptible to bleeding, even with trivial trauma. **Chronic urinary tract obstruction** in children (eg, posterior urethral valves or congenital ureteropelvic junction obstruction) is often asymptomatic. In the past these conditions were typically diagnosed when children presented with UTIs or with gross hematuria after relatively trivial trauma. Now they are commonly diagnosed after a prenatal ultrasound reveals hydronephrosis. Nevertheless, urinary tract obstruction may be detected during an evaluation for asymptomatic microhematuria.

Any **tumor** of the genitourinary tract may be associated with both gross and microscopic hematuria. Pelvic tumors rarely cause urinary obstruction in children, although such tumors frequently cause obstruction in adults. Children with Wilms tumor, the most common childhood renal tumor, usually present with an abdominal mass, but may experience hematuria.

Congenital renal malformations are quite common. Any of these may be associated with hematuria and include polycystic

kidney disease, renal dysplasia, medullary sponge kidney, and simple cysts. Patients with polycystic kidney disease may even have severe, painful hematuria.

Vascular problems may also lead to hematuria. Hemangiomas of the kidney, bladder, or ureter are very rare. Arteriovenous malformations also occur infrequently. Hematuria may be a sign of a renal artery or vein thrombosis, particularly in sick neonates.

Young children are more susceptible to **renal injury**, which may result in hematuria, than older children or adults because their kidneys are relatively less protected by the rib cage. In addition, children may insert foreign objects into the urethra and bladder that cause pain and hematuria. Microhematuria has also been described after extremely vigorous exercise, such as marathon running. Child abuse or Munchausen by proxy should be considered if any suspicions are raised on the basis of the history or physical examination.

Hypercalciuria is another cause of microscopic hematuria. Children with hypercalciuria often have a family history of urinary calculi. Calcium oxalate crystals may be present on the microscopic examination of the urine. A urinary calcium-creatinine ratio is best obtained on a first morning, fasting urine sample. Calcium excretion varies with age. Normal values are listed in Table 93-2.

Table 93-2. Normal Values for Urinary Calcium-Creatinine Ratios^a

Age	Urine Calcium-Creatinine	24-Hour Urine Calcium
Preterm	≤ 0.82	≤ 8.9 mg/kg/d ^b
<7 mo	≤ 0.86	
7–18 mo	≤ 0.60	
19 mo–6 y	≤ 0.42	
6 y–adult	≤ 0.22	< 4 mg/kg/d

^aSamples for calcium-creatinine ratio should be obtained on a fasting, first-voided morning specimen. The calcium and creatinine concentrations must be in the same units (eg, milligrams per deciliter) before the ratio is calculated.

^bFor healthy preterm infants taking no medications. Calcium excretion varies with diet and phosphorus intake and it is higher if patients are treated with furosemide, xanthines, or glucocorticoids.

There are 2 types of hypercalciuria: absorptive and renal leak. Children with absorptive hypercalciuria over-absorb calcium from the gastrointestinal tract, probably because of an exquisite sensitivity to vitamin D, and can be treated with a reduced calcium diet. Children with renal leak hypercalciuria have an inherently higher rate of urinary calcium excretion and may require thiazide diuretics to reduce urinary calcium excretion. **Interstitial nephritis**, usually from drug exposure, may also cause hematuria. Generally patients with interstitial nephritis may exhibit other signs of tubular disease such as glucosuria or proteinuria.

Glomerular disease may cause gross or microscopic hematuria. Etiologies include acute or chronic glomerulonephritis, such as acute post-streptococcal glomerulonephritis, MPGN, antineutrophil cytoplasmic antibody-associated vasculitis, IgA nephropathy, SLE, and

Alport syndrome. The red cells originating from the glomeruli are dysmorphic, and these patients often have RBC casts when the urine is carefully examined.

Sickle cell disease, sickle cell trait, and hemoglobin C trait have been associated with gross or microscopic hematuria.

Differential Diagnosis

When children complain of gross hematuria or “red” urine, practitioners must first determine if they have hematuria or pigmenturia by using a urine dipstick. If the dipstick is negative for blood, then the dark urine is due to dyes, drugs, or pigments (Table 93-3). If the dipstick is positive for blood, the red color is caused by intact RBCs, hemolyzed RBCs, hemoglobin, or myoglobin; the clarification is based on microscopic examination of fresh, spun urine.

Children whose dipsticks are positive for blood but show no RBCs may have hemoglobinuria or myoglobinuria. Hemoglobinuria may be seen with acute autoimmune hemolytic anemia, drug-induced hemolysis, paroxysmal nocturnal hemoglobinuria, a mismatched blood transfusion, cardiopulmonary bypass, freshwater drowning and, in some cases, HUS. Myoglobinuria is seen in individuals with rhabdomyolysis. Acute rhabdomyolysis can occur after a crush injury or a very prolonged seizure, and in certain susceptible individuals with an inborn error of muscle metabolism. Myoglobinuria may also be seen with the myositis associated with influenza infections. Both free hemoglobin and myoglobin are toxic to the renal epithelial cells, mandating a generous fluid intake and close monitoring.

Table 93-3. Distinguishing Hematuria From Pigmenturia

Problem	Urine Color	Hemastix	Microscopic Appearance
Hematuria	Red, brown, or red-brown	Positive	Red blood cells
Hemoglobinuria	Red, brown, or red-brown	Positive	Negative
Myoglobinuria	Red, brown, or red-brown	Positive	Negative
Porphyryns	Red	Negative	Negative
Exogenous pigments ^a	Red or orange	Negative	Negative

^aSome common exogenous pigments include phenytoin, beets, rifampin, nitrofurantoin, sulfas, amitriptyline, methyl dopa, phenothiazine, and chloroquine.

Evaluation

Gross Hematuria

History

The history is crucial to an accurate, efficient, and cost-effective evaluation of patients with hematuria (Questions Box). The family should be questioned carefully about trauma (to trunk, abdomen, or perineum), recent skin infection or pharyngitis, dysuria, and abdominal or flank pain. Parents should be asked whether their

Questions

Hematuria

- Has the child suffered any recent trauma?
- Has the child had fever or dysuria?
- Does the child have any flank or abdominal pain?
- Does the child have any rashes, joint pains, or edema?
- Does the child have a family history of hematuria, kidney disease, kidney stones, or gross hematuria?
- Is there a family history of bleeding disorders or inborn errors of muscle metabolism?

children appear “puffy.” A family history of kidney disease, bleeding diathesis, hemolytic anemia, or inborn error of muscle metabolism may be important.

Physical Examination

A complete physical examination is also essential. Blood pressure should be measured accurately. The skin should be examined thoroughly for rashes or petechiae; the abdomen should be checked carefully for renal masses or tenderness; the genitalia should be examined thoroughly for signs of trauma, masses, or rashes (see Chapter 128); and the joints should be checked carefully for signs of arthritis. Fundi should be examined for any hypertensive changes. Children should be assessed for the presence of edema.

A careful cardiac and chest examination is necessary to detect signs of congestive heart failure (CHF), a finding sometimes seen in acute glomerulonephritis.

Laboratory Tests

Recent studies have shown that careful microscopic examination of a urine sample can help determine whether bleeding originates from the upper urinary tract or the lower urinary tract. Red blood cells originating in the glomerulus have a dysmorphic appearance. The first morning urine sample is the most reliable but is not appropriate in some settings, such as after a motor vehicle crash. Sometimes the gross hematuria is so substantial that spinning the urine results in a large pellet of debris that is difficult to examine. In such instances, it is prudent to examine an unspun sample. The presence of RBC casts indicates glomerulonephritis, but the absence of such casts does not rule out this condition.

If the urine shows RBC casts, then the evaluation should include an antistreptolysin-O (ASO) titer, antinuclear antibody (ANA), C3, complete blood cell count (CBC) and differential with platelet count, blood urea nitrogen (BUN) and creatinine, serum albumin, and a random urine for a urinary total protein-creatinine ratio.

If the urine shows only large numbers of RBCs, no RBC casts, and no bacteriuria, a CBC with differential and platelet count, a urine culture, and a prothrombin time (PT) and partial thromboplastin time (PTT) should be obtained. A sickle cell test should be considered as well. Hypercalciuria can be evaluated by collecting a first morning sample for calcium/creatinine ratio, or a more extensive evaluation to assess risk factors for kidney stones should include a 24-hour

urine for a stone risk profile that includes urinary calcium, citrate, uric acid, and oxalate.

Imaging Studies

If the urine has large numbers of RBCs and no bacteriuria, a renal ultrasound should be obtained. With gross hematuria and a history of serious trauma, an abdominal computed tomography scan should be performed. Computed tomography scan is also an excellent modality to detect kidney stones. Children with RBC casts should also have a chest radiograph to evaluate for signs of CHF. Special renal Doppler ultrasound studies are indicated if Nutcracker syndrome is being considered in the differential.

Microhematuria

The evaluation of microscopic hematuria is similar to that of gross hematuria. Figure 93-1 outlines an approach to the evaluation of microscopic hematuria.

History and Physical Examination

Because many conditions may cause either gross or microscopic hematuria, the same historical questions apply to both conditions, and the same careful physical examination is indicated.

Laboratory Tests

Generally, the initial evaluation includes a urine culture and a careful microscopic examination of the urine. If the culture is negative, the hematuria is minimal with no associated proteinuria, and children are otherwise healthy, the urinalysis should be repeated once or twice over the following 2 weeks. Red blood cell casts always signify a glomerular origin. Casts are best preserved in acidic, concentrated urine. Thus the first morning urine is the best sample to examine for casts. Red blood cell morphology should be assessed. Red blood cells originating in the glomerulus are **dysmorphic** and of smaller caliber, whereas those that come from lower downstream appear like normal **biconcave** disks. Although RBC morphology is best appreciated with the use of a polarizing microscope, with experience, dysmorphic RBCs can be recognized using an ordinary microscope. Red blood cells of glomerular origin have a mean cell volume of 50 μL or less. In contrast, RBCs of non-glomerular origin have a mean cell volume of 80 to 90 μL . The presence of a newly described, special form of dysmorphic erythrocyte, the G1 cell, is even more specific for glomerular bleeding. These cells are doughnut shaped and contain one or more blebs on their surfaces. Clotting ability should be determined with a platelet count, PT, and PTT. A sickle cell test should be performed. Renal function should be screened with a BUN and creatinine, and a urine calcium-creatinine ratio should be determined. A C3, ANA, and ASO titer should also be checked. If a urine dipstick shows more than a trace of protein, a urinary protein-creatinine ratio should also be determined. If there is a family history of renal disease, a hearing screen should be ordered. All immediate family members should have their urine checked for blood.

If a bloody urine sample is analyzed with a Coulter counter, characteristic distribution curves are seen for glomerular and non-glomerular hematuria. This test is not readily available, however.

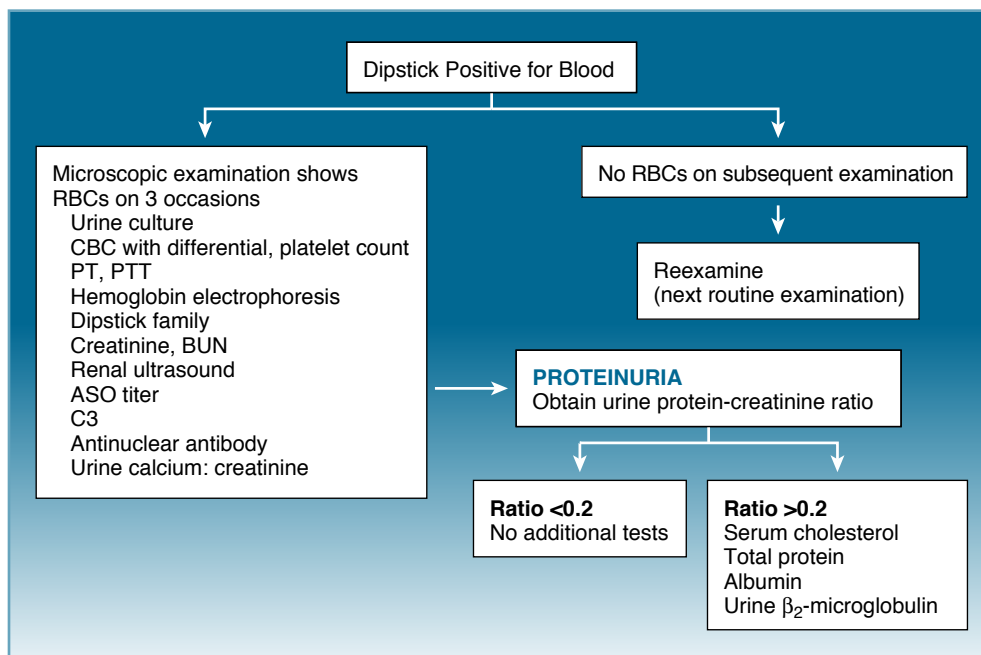

Figure 93-1. Evaluation of asymptomatic, microscopic hematuria. ASO, anti-streptolysin-O; BUN, blood urea nitrogen; CBC, complete blood cell count; PT, prothrombin time; PTT, partial thromboplastin time; RBCs, red blood cells.

Imaging Studies

A renal ultrasound should be performed to rule out structural abnormalities and tumors. Chest radiographs should be obtained if acute glomerulonephritis is suspected.

Renal Biopsy

The definitive diagnosis of the etiology of hematuria may require a kidney biopsy. Generally, pediatric nephrologists perform kidney biopsies only in selected instances after ruling out non-glomerular causes for the hematuria. Indications for renal biopsy in a child with hematuria would include an associated abnormal urinary protein excretion, decreased renal function, recurrent macroscopic hematuria, persistently depressed serum complement levels, serologic evidence for SLE, positive ANCA testing, hypertension, or a family history of renal insufficiency of unknown etiology.

Glomerular Diseases Associated With Hematuria

Glomerulonephritis

Both acute and chronic glomerulonephritis are associated with hematuria. The diagnosis of acute poststreptococcal glomerulonephritis requires a “nephritic” urine sediment (RBCs, RBC casts), a low serum complement, and an elevated streptococcal titer (ASO titer, anti-deoxyribonuclease B, or positive streptozyme). It is important to document that the serum complement returns to normal within 3 months because MPGN may present in a similar way. The serum complement is chronically depressed in MPGN.

The most common form of glomerulonephritis in children is **acute poststreptococcal glomerulonephritis**. Many cases are asymptomatic, however, and do not come to the attention of physicians. The resulting hematuria, which may be gross or microscopic, is rarely seen before the age of 2 years. The condition is most

commonly diagnosed in preschool-aged and school-aged children, who typically present with gross hematuria, often with some edema and hypertension. The hypertension may be severe, and occasionally children even have hypertensive seizures. The edema results from transient, acute renal failure with salt and fluid retention.

Most children with acute poststreptococcal glomerulonephritis recover completely and have an excellent long-term prognosis. Proteinuria is rarely severe enough to cause nephrotic syndrome, and renal failure is rarely serious enough to require dialysis. If hypertension occurs, the chest radiograph often shows some degree of pulmonary edema, even in the absence of overt clinical signs of CHF. Any hypertension requires treatment. Other infections cause postinfectious glomerulonephritis, but they are less common and less well characterized.

The most common form of chronic glomerulonephritis that affects children is **IgA nephropathy**. On kidney biopsy, patients have mesangial proliferation with mesangial deposits of IgA as the dominant Ig. In the later stages, glomerulosclerosis and interstitial fibrosis are apparent. More than one-third of adults with IgA nephropathy develop end-stage renal disease; the percentage of children who progress to this point is less well known. Gross hematuria in IgA nephropathy is occasionally so severe that patients may pass clots and have flank pain. The presence of persistent proteinuria is considered a poor prognostic sign.

Other forms of primary chronic glomerulonephritis include **MPGN**, **mesangial proliferative glomerulonephritis**, and **membranous nephropathy**, which is technically not a form of glomerulonephritis because it usually lacks a significant proliferative component. Children with these diseases present with hematuria almost always associated with heavy proteinuria.

Secondary forms of glomerulonephritis include the nephritis of SLE, anaphylactoid purpura, and the nephritis associated with various vasculitides such as Wegener granulomatosis and pauci-immune

crescentic glomerulonephritis (ANCA-positive glomerulonephritis). An ANCA panel is indicated in children with glomerulonephritis and decreased renal function. Children with lupus tend to present with multisystem disease but may have only renal manifestations of the disease. Antinuclear antibody is a good screening test for lupus. If the ANA is positive, C3, C4, antidouble-stranded DNA, and a Coombs test should be checked.

Anaphylactoid Purpura

This disease is almost always accompanied by the classical cutaneous vasculitis rash, which is prominent over the lower arms and lower extremities. Abdominal pain may be severe, and affected patients are at risk for the development of intussusception. Children with anaphylactoid purpura have microscopic hematuria, which usually clears, but is occasionally associated with heavy proteinuria and nephrotic syndrome. These children are at risk for developing progressive renal disease. All children with anaphylactoid purpura should have their urine monitored for cessation of hematuria or development of proteinuria. Children with heavy proteinuria and suspected anaphylactoid purpura should have a diagnostic renal biopsy.

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome is a disease characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. It typically follows a prodrome of bloody diarrhea from acute colitis caused by a verotoxin-producing strain of *Escherichia coli* (O157/H7). The verotoxin is believed to be toxic to human endothelial cells. The damaged endothelial cells incite the deposition of fibrin within the glomerular capillaries. These fibrin thrombi lead to the shearing of RBCs and consumption of platelets. Several other organisms, such as pneumococcus and *Shigella*, may precipitate HUS. In atypical cases of HUS, the precipitating event may be an upper respiratory infection. Some cases are familial. Children present with pallor and severe abdominal pain. Urine output may be diminished as a result of renal failure, and in many cases dialysis is required. Hypertension may be severe.

Other Glomerular Diseases

Alport syndrome, thin basement membrane disease (benign familial hematuria), focal segmental glomerulosclerosis (FSGS), and minimal change disease (MCD) are also associated with hematuria. Alport syndrome is a disease of the glomerular basement membrane, where thinning and duplication of the basement membrane occur. The renal involvement eventually leads to end-stage renal disease. Patients or their family members often have nerve deafness or keratoconus. The inheritance of Alport syndrome varies by kindred; it may be either autosomal-dominant, autosomal-recessive, or sex-linked. The sex-linked inheritance is by far the most common mode of inheritance, with female carriers being much less severely affected than the affected males. Thin basement membrane disease also is characterized by thinning of the glomerular basement membrane, but the glomeruli are otherwise normal, and the clinical course is

benign. Patients with MCD and FSGS present with nephrotic syndrome but may also have microscopic hematuria.

Management

Gross Hematuria

The management of gross hematuria depends on the underlying cause. Children with a history of trauma should be placed on bed rest pending surgical consultation (see Chapter 63). If the evaluation indicates acute glomerulonephritis and if children are not hypertensive, they can be followed carefully as outpatients with monitoring of blood pressure and renal function with consultation with a pediatric nephrologist. Children with coagulopathies require specific treatment of their bleeding disorders (eg, intravenous gamma globulin for idiopathic thrombocytopenic purpura). If kidney stones are found, after the acute episode has passed, the children should have an evaluation for stone risk factors.

If some degree of renal insufficiency is present, then children should promptly be referred to a pediatric nephrologist to rule out more unusual causes of glomerulonephritis, for consideration of renal biopsy, and for treatment.

Microhematuria

Laboratory tests other than urinalysis may be negative in otherwise healthy children with microscopic hematuria. Some of these children may be recovering from subclinical cases of poststreptococcal glomerulonephritis, which can cause microscopic hematuria for up to 1 year. Others may have early IgA nephropathy and not yet have significant proteinuria, and some may have thin basement membrane disease. As long as children have normal renal function, normal urinary calcium excretion, normal blood pressure, a negative renal ultrasound, no significant proteinuria, and all other tests are normal, it is safe to monitor them every 3 to 6 months until the problem resolves. Healthy children with an otherwise negative workup who show no change in their clinical state for a period of 1 year may subsequently be monitored annually. If hypercalciuria is detected, a low-calcium diet or treatment with thiazide diuretics may be tried. Increased urinary microalbuminuria has been shown to be predictive of glomerular lesions in children with isolated microscopic hematuria.

Prognosis

The prognosis for children with hematuria depends on the underlying cause. Gross hematuria is more often associated with serious renal disease, such as acute glomerulonephritis, HUS, or renal trauma. Even so, most children with gross hematuria have a good prognosis, provided the diagnosis is rapidly discovered and appropriate specific therapy is given. Children with persistent microscopic hematuria who have no family history of the condition, have a negative evaluation, and do not develop hypertension or proteinuria have an excellent long-term prognosis.

CASE RESOLUTION

The boy in the opening scenario shows no worrisome clinical signs, such as hypertension or significant proteinuria. His urine should be rechecked twice more, and if the hematuria persists, his evaluation should follow the algorithm in Figure 93-1.

Proteinuria

Elaine S. Kamil, MD

CASE STUDY

A 14-year-old boy is brought to the office for a preparticipation sports physical examination. He has been previously healthy but had one hospital admission at the age of 2 years for treatment of a fractured humerus. He has no acute complaints. The family history is positive for diabetes mellitus in the paternal grandfather and lung cancer in the maternal grandfather. It is negative for renal disease or hypertension. The boy's height and weight are at the 75th percentile for age, and his blood pressure is 110/70 mm Hg.

On physical examination he is a well-developed, well-nourished, athletic teenager. No abnormal findings are present. The complete blood cell count reveals a hemoglobin of 14.8 g/dL, a hematocrit of 48.3%, and a white blood

cell (WBC) count of 8,400/mm³ with a normal differential. The urine has a pH of 5, a specific gravity of 1.025, and 3+ protein on dipstick. The rest of the dipstick is negative. Microscopic examination shows 0 to 1 WBC count per high-power field and 0 to 2 hyaline casts per low-power field.

Questions

1. What conditions cause proteinuria?
2. When should children with proteinuria undergo further evaluation?
3. What type of evaluation should be carried out to assess proteinuria?
4. When should children with proteinuria be referred to a pediatric nephrologist?

A small amount of **protein** is normally present in the urine. Urine protein levels increase somewhat under certain conditions, such as vigorous exercise, febrile illnesses, accidental trauma, and congestive heart failure (CHF). Most of the protein in the **glomerular filtrate** is reabsorbed by the tubular cells. Pathologic amounts of protein are present in the urine when the **glomerular leak** of protein is increased, when the **tubules fail to reabsorb** the protein filtered by the glomerulus, or if **inflammation in the renal interstitium** leads to the addition of tubular proteins to the urine.

Urinary protein is initially detected by **urine dipstick**, but this method may be falsely positive in alkaline urine. Dipstick protein is also affected by urine concentration. A dipstick positive for protein of 1+ in concentrated urine may not correlate with an abnormal 24-hour urinary protein excretion, whereas a dipstick of 1+ in very dilute urine may be associated with an abnormal 24-hour urinary protein excretion. Proteinuria may be more accurately determined by performing a timed urine collection or a random sample for chemical determination of the total protein concentration divided by the urinary creatinine concentration (urine TP/Cr).

Epidemiology

The prevalence of **proteinuria** depends on how the condition is defined. In a Texas study, 10 mg/dL of proteinuria was found consistently in the urine of 2% to 3% of children in 3 consecutive urine samples. When 50 mg/dL was used as the cutoff for proteinuria, however, only 0.4% to 0.7% of boys and 0.4% to 2.5% of girls had proteinuria in 2 of 3 consecutive samples. The prevalence of proteinuria

increased with age. In Finland, about 11% of school-aged children had at least one episode of proteinuria of 25 mg/dL by dipstick when the urine was tested 4 times. Approximately 2.5% of the children had proteinuria on 2 of 4 occasions.

Clinical Presentation

Proteinuria is a laboratory finding that may present incidentally on a screening urinalysis or be detected during the evaluation of a complaint, such as edema, that may be caused by kidney disease. When proteinuria is detected as an incidental finding in otherwise normal children, the laboratory evaluation of the proteinuria should be delayed until its persistence is confirmed on repeat dipstick, preferably on a first morning urine sample (Dx Box). **Edematous children** with proteinuria most likely have renal lesions or more rarely congestive heart failure. Additional findings on examination could include the presence of hypertension, ascites, pleural effusions, or the rash of systemic lupus erythematosus or anaphylactoid purpura.

Dx Proteinuria

- Presence of dipstick proteinuria (>1+ confirmed on 3 occasions)
- Random urine total protein-creatinine ratio greater than 0.2 or 24-hour urine protein greater than 4 mg/m²/hour
- Orthostatic proteinuria (assessed through separate measurement of afternoon and first morning urine for total protein-creatinine ratios)

Pathophysiology

The glomerular capillaries are adapted to permit the filtration of minimal amounts of plasma proteins, particularly those with a small molecular radius. Approximately 320 mg of albumin and 360 mg of lower molecular weight proteins are filtered by the glomerular capillaries each day. Ninety-five percent of this is reabsorbed by the proximal tubular cells. Normally, children may excrete up to 100 mg/m²/day of protein. Urinary protein excretion is increased in newborns to about 240 mg/m²/day and in adolescents to about 300 mg/day. Adults may normally excrete up to 150 mg of protein per day. Only 10% to 15% of this is albumin; the rest of the proteins are other plasma proteins and urinary glycoproteins.

When increased proteinuria results from glomerular disease, higher levels of urinary proteins are primarily due to the enhanced filtration of albumin. Protein excretion may be increased transiently by any condition that raises intraglomerular capillary pressure, such as CHF, strenuous exercise, epinephrine use, fever, or surgery. Children and adults with very early diabetic nephropathy or early end-organ damage from hypertension will show elevated urinary microalbumin/creatinine ratios. Children with diabetes or hypertension should have regular determination of urinary microalbumin/creatinine ratios to detect early, reversible glomerular damage.

Orthostatic proteinuria, which affects some children, is a poorly understood, benign condition. Individuals excrete pathologic amounts of protein in their urine while they are upright, but their urinary protein excretion returns to normal when they are recumbent. This condition seems to be more common in athletic individuals. Orthostatic proteinuria may be due to increased pressure in the renal vasculature while patients are upright. Several investigators have shown partial obstruction of the left renal vein by entrapment between the aorta and the superior mesenteric artery in patients with orthostatic proteinuria while they are standing.

Differential Diagnosis

The proteinuria may be **physiological** (secondary to fever, CHF, **orthostatic**, **tubular** (as seen in allergic interstitial nephritis), or **glomerular**. Aminoaciduria as a form of tubular proteinuria may occur, as is seen in certain inborn errors of metabolism.

Evaluation

History

It is important to elicit a complete history (Questions Box) in children with proteinuria. When asking about a history of swelling, the practitioner should note that subtle periorbital edema may be present only in the early morning hours. If the proteinuria is detected at a routine screening examination, the conditions under which the urine was obtained should be determined. Children may have been sick with a high fever or have just participated in an athletic event such as a track meet.

Questions

Proteinuria

- Was the mother's pregnancy remarkable in any way? What was the child's birth like?
- Did the child have any neonatal problems that may indicate possible renal damage?
- Is any swelling apparent in areas such as the ankles, the abdomen, or the periorbital region?
- Has the child had any recent illnesses, particularly pharyngitis or impetigo?
- Does the child have a history of joint pains and skin rashes, especially the adolescent patient who may be at greater risk of having a collagen vascular disease?
- Has the child had any previous urinary tract infections, urinary abnormalities, or dark urine?
- Does the child have a history of hypertension or weight loss or gain?
- Is there a family history of renal disease?
- Does the child have diabetes mellitus?

Physical Examination

The physical examination should include a determination of blood pressure and measurement of height and weight. A careful assessment for edema should be made. The skin should be examined for signs of rashes such as that seen in Henoch-Schönlein purpura or healing impetigo. The joints should be inspected for any signs of swelling or joint inflammation. The abdominal examination should include a careful search for ascites or organomegaly.

Laboratory Tests

The extent of the laboratory evaluation depends on the child's general health (eg, the child is ill with another problem), the amount of proteinuria on dipstick, and whether the child has edema. The suggested evaluation is outlined in Figure 94-1. In non-edematous, otherwise healthy children, it is prudent to examine the urine sediment and, if negative, recheck the dipstick in a few days. If proteinuria of 1+ is consistently present and no hematuria is evident, a first-stage evaluation is indicated. If children are ill with a fever or are hospitalized with a serious illness, it is often appropriate to delay the evaluation of the proteinuria until the acute illness is under control, providing no associated hematuria, hypoproteinemia, hypertension, or azotemia is present.

In healthy ambulatory patients with persistent, isolated dipstick proteinuria on 3 occasions, it is important to quantitate the proteinuria (Box 94-1). This may be done simply by ordering a urine protein-creatinine ratio (urine TP/Cr). If the ratio is abnormal (>0.2), children need to be evaluated first for orthostatic proteinuria. Orthostatic proteinuria can be ruled out in several ways. The simplest evaluation involves checking a urine dipstick on a first-voided morning sample and again on an afternoon specimen. This procedure should be repeated on 2 different days. It is critical to be sure that children empty their bladders before going to bed, because urine produced when they are non-recumbent may contain protein

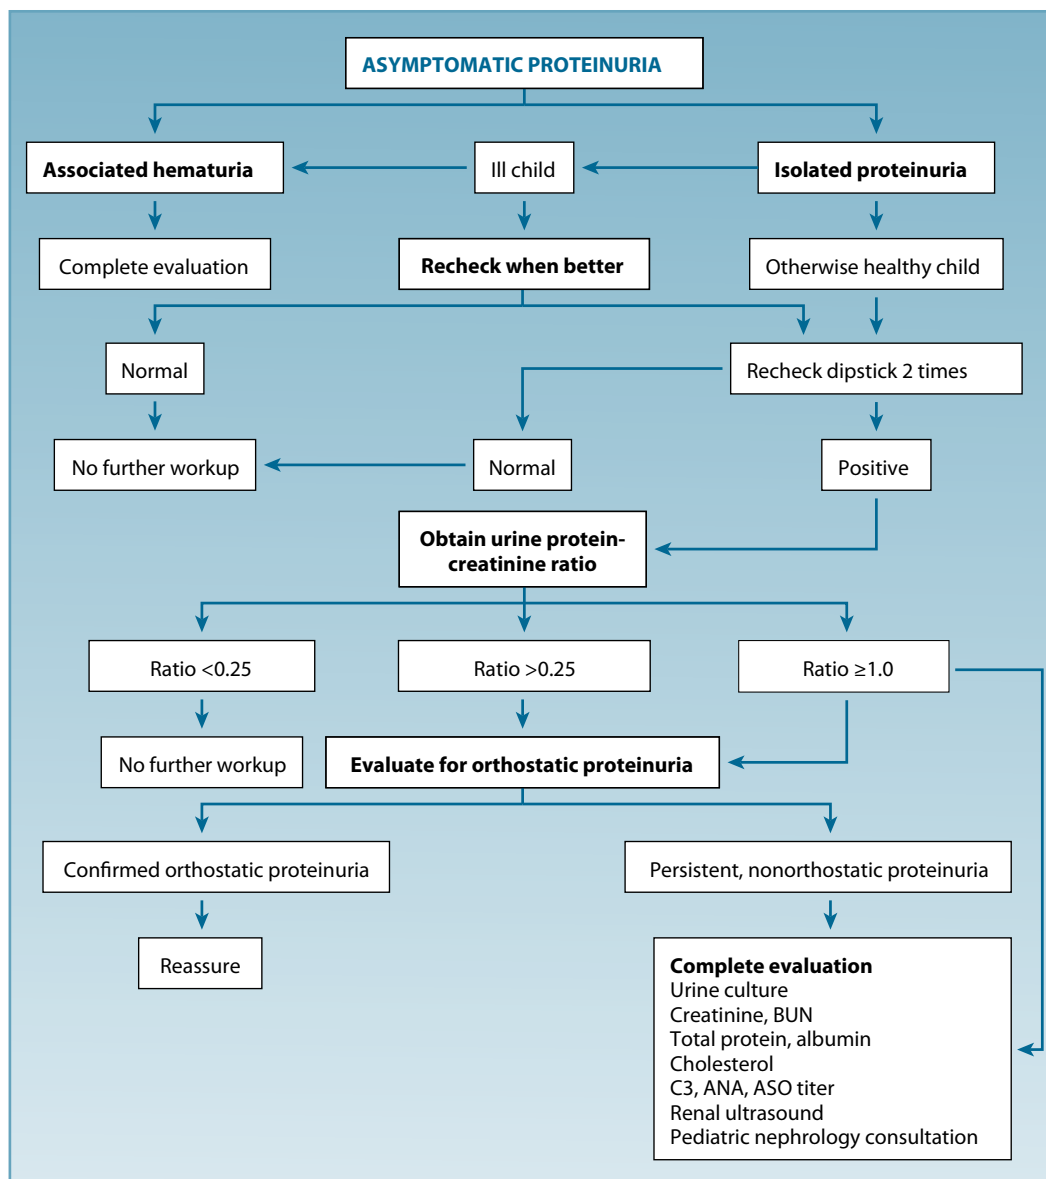

Figure 94-1. Suggested evaluation of children with asymptomatic proteinuria. ANA, antinuclear antibody; ASO, antistreptolysin-O; BUN, blood urea nitrogen.

and give an inaccurate result. If the dipstick from the morning urine is negative on a concentrated acid urine, and if the afternoon sample is positive on a concentrated acid urine, the child most likely has orthostatic proteinuria.

A more accurate way of checking for orthostatic proteinuria involves the determination of urine TP/Cr ratios on the first morning and afternoon urine samples. A diagnosis of orthostatic proteinuria can be made if the ratio is normal on the recumbent sample and elevated on the daytime sample. The most accurate way of diagnosing orthostatic proteinuria entails collecting 2 timed urine samples, one during the hours that children are up during the day and the other while they are in bed at night. In most instances of orthostatic proteinuria in children, the total urinary protein excretion is less than 1 g. The urine collected in the recumbent period should contain less than 50 mg/m² of protein. If these 2 timed samples meet the criteria

for orthostatic proteinuria, they do not need to be repeated. It is important to remember, however, that even in renal disease proteinuria improves somewhat when patients are recumbent.

If children do not have orthostatic proteinuria, a 24-hour urine protein excretion may be determined. If the collection of a 24-hour urine sample is impractical, the urine protein-creatinine ratio is a reliable alternative. Blood chemistries (eg, blood urea nitrogen [BUN], creatinine) should be obtained to determine renal function. Electrolyte status should be assessed with total carbon dioxide, total protein, albumin, and cholesterol. Serologies should be obtained for antinuclear antibodies, C3, antistreptolysin-O titer, and hepatitis B surface antigen if children come from a population at risk for hepatitis B.

Twenty-four-hour urine protein excretion should be less than 4 mg/m²/hour. Neonates may excrete as much as 150 mg/m²/12

Box 94-1. Methods for Assessment of Urinary Protein

Detection of proteinuria by dipstick is only semiquantitative. This examination is affected by urinary pH and concentration and, therefore, more definitive tests are warranted if a patient's urine consistently shows dipstick proteinuria. The sulfosalicylic acid (SSA) turbidity test is also semiquantitative. When SSA is added to an aliquot of urine, it precipitates urinary proteins. The amount of turbidity is graded on a scale of 0 to 4+.

Urinary protein is most accurately quantitated by a chemical determination on a timed urine collection (usually 24 hours). The concentration (measured in milligrams per deciliter) is multiplied by the total urine volume to determine the milligrams of protein excreted in 24 hours. Twenty-four-hour urine samples are difficult to collect in young children. However, several studies have shown that a random urine sample for a protein-creatinine ratio correlates well with the 24-hour urinary protein excretion. The ratio is determined by dividing the urine protein concentration (milligrams per deciliter) by the urine creatinine concentration (milligrams per deciliter). The units must be the same for each component. The urinary protein-creatinine ratio is normally less than 0.2. A ratio of 3.5 or greater in an adult or greater than 1.0 in children indicates nephrotic range proteinuria. A recent study has found that proteinuria in combination with leukocyturia (by dipstick) is likely to indicate more significant noninfectious renal inflammation.

Occasionally it is important to determine whether proteinuria has a tubular or glomerular basis. In these instances, a urinary β_2 -microglobulin is helpful. β_2 -microglobulin, a very small protein that is freely filtered at the glomerular level, is nearly completely reabsorbed by the proximal tubules. In instances of tubular injury, such as interstitial nephritis, acute tubular necrosis, or nephrotoxic renal injury, urinary β_2 -microglobulin is increased. With glomerular proteinuria, urine protein electrophoresis shows a heavy preponderance of albumin. The urine microalbumin-creatinine ratio is an excellent indicator of glomerular proteinuria. It is readily available in most laboratories and will detect minimal but pathologic amounts of glomerular proteinuria such as that seen in early diabetic nephropathy and with early hypertensive glomerular damage.

hours, however. Table 94-1 gives a summary of normal urinary protein excretion. If children have nephrotic range proteinuria or symptoms consistent with nephrotic syndrome (heavy proteinuria accompanied by hypoalbuminemia and hypercholesterolemia), they require further evaluation for nephrotic syndrome (see Chapter 145). If they do not have nephrotic range proteinuria, abnormal tubular proteinuria should be ruled out. A normal urinary β_2 -microglobulin rules out tubular proteinuria. In general, consultation with a pediatric nephrologist is recommended if children have an abnormal 24-hour urinary protein excretion (see Table 94-1). If the proteinuria exceeds 1 g/day or if any other minor signs of renal dysfunction or hematuria are present, a biopsy is warranted. Sometimes, otherwise healthy children with small amounts of isolated proteinuria of less than 750 to 1,000 mg/day are followed by the pediatric nephrologist without a kidney biopsy. However, if this degree of proteinuria persists for 1 year or more, a renal biopsy is warranted.

Table 94-1. Urinary Protein Excretion by Age

Age	24-hour Urine Protein (mg)	Urine Protein-Creatinine
Premature infant	14–60	—
Full-term infant	15–68	—
2–23 mo	17–85	≤0.50
2–4 y	20–121	≤0.2
4–10 y	26–194	≤0.2
10–16 y	29–238	≤0.2

Imaging Studies

A renal ultrasound should be obtained to rule out any structural abnormalities but may not be indicated in the child with simple orthostatic proteinuria.

Management

Most children with normal renal function and normal blood pressure whose evaluation reveals physiological or orthostatic proteinuria should have repeat urinalysis on an annual basis. If the proteinuria worsens or if hematuria develops, a repeat evaluation of renal function is indicated. Children whose initial evaluation reveals persistent, significant proteinuria require careful follow-up to detect and monitor signs of serious renal disease. This follow-up should include repeat blood pressure measurement and urinalysis every 3 months and repeat chemistries (BUN, creatinine, serum albumin) and urine protein-creatinine ratios every 6 months. These children should be managed in consultation with the pediatric nephrologist, whose experience is helpful in reassessing the need for kidney biopsy.

Children with physiological or orthostatic proteinuria who have minimal, persistent proteinuria should be able to follow a full school schedule and be allowed to participate in sports, provided there are no other contraindications. The usual immunization schedule should not be interrupted, and children should follow a regular diet. No increase in dietary protein is necessary to compensate for the minimal amounts of protein lost in the urine. Results of recent studies in nephrotic patients have found that a high-protein diet may actually increase urinary protein losses.

Prognosis

The outlook for children with proteinuria depends entirely on the underlying cause of the proteinuria. Children whose proteinuria is associated with edema or hematuria are more likely to have significant renal disease, such as glomerulonephritis, however, and the prognosis may be less favorable. If the proteinuria is due to a form of chronic glomerulonephritis, children may ultimately develop end-stage renal disease. In individuals with glomerular diseases, persistent proteinuria is a strong risk factor for progressive loss of renal function. If the proteinuria is physiological or orthostatic, however,

the long-term prognosis is excellent. The likelihood that these children will develop renal functional impairment is no greater than for the rest of the general population.

CASE RESOLUTION

In the case presented at the beginning of the chapter, odds are that the evaluation of the healthy teenaged boy with isolated proteinuria will reveal that he has orthostatic proteinuria, and his long-term prognosis is good.

Urinary Tract Infections

Gangadarshni Chandramohan, MD, MS, and Sudhir K. Anand, MD

CASE STUDY

A 7-month-old girl is brought to the office with a 1-day history of fever (temperature: 103°F [39.4°C]), vomiting, and mild diarrhea. The mother has not noticed any change in urination pattern or any unusual urine odor. The child has been somewhat irritable but fully alert.

Physical examination reveals an active infant. The temperature is 102.6°F (39.2°C), the heart rate is 122 beats/min, the respiratory rate is 30 breaths/min, and the blood pressure is 90/60 mm Hg. The neck is supple. The head, eye, ear, nose, throat, chest, heart, abdominal, and genital examination are all normal. Urinalysis shows specific gravity 1.025, pH 6.0, leukocyte esterase and nitrite both strongly positive, protein trace, and blood trace; the sediment has 15 to 20 white blood cells per high-power field and 2 to 4 red blood cells per high-power field. The Gram stain shows more than 100,000 gram-negative rods, and the urine culture is pending.

Questions

1. What should be the initial approach to children with suspected urinary tract infections (UTIs)?
2. What are the possible diagnoses of children with positive leukocyte esterase or nitrite on urinalysis?
3. What are the indications for hospital admission of children with UTIs?
4. What antibiotics are used in the treatment of UTIs?
5. What is the appropriate diagnostic workup for children with suspected UTIs? When are renal ultrasound, technetium 99m-DMSA renal scan, and voiding cystourethrogram included in the evaluation?
6. If workup reveals vesicoureteral reflux (VUR), how should children be managed over the long term?

Urinary tract infection is one of the most common serious bacterial infections that affect infants and children. Older children with UTI may present with lower urinary tract symptoms such as burning urination, frequency, and urgency with or without flank pain. Infants and newborn babies usually present with nonspecific symptoms, such as fever, vomiting, and diarrhea, or occasionally can develop signs of circulatory failure when complicated by sepsis. In most children UTIs resolve completely with appropriate antibiotic therapy. However, in children with underlying anatomical abnormalities (eg, VUR) or delayed or inadequate antibiotic treatment, UTIs may result in renal scarring that sometimes leads to hypertension or end-stage renal disease.

Urinary tract infection is a nonspecific, generic term implying significant bacteriuria, irrespective of the site of bacterial growth in the urinary tract. In many young children with bacteriuria, clinical findings overlap and precise classification of whether it's an upper or lower tract infection cannot be easily made. We clarify some of the commonly used terms below.

Asymptomatic, covert, and screening bacteriuria are synonymous terms usually used when bacteriuria is detected during surveys of healthy children. The term *screening bacteriuria* is more accurate because some affected children may actually have urinary symptoms on close questioning.

Urethritis implies infection of the urethra and is usually seen in the setting of sexually transmitted infections. The usual symptoms are dysuria and urethral discharge.

Cystitis implies infection of the bladder only. Its major feature is voiding symptoms (eg, dysuria, frequency, urgency, enuresis, and foul-smelling urine). Fever, if present, is usually low-grade.

Acute pyelonephritis is a symptomatic infection of renal parenchyma characterized by systemic symptoms such as high fever, chills, flank pain, and vomiting in addition to dysuria.

Recurrent UTI generally refers to reinfection with a new organism (often same species but different strain). According to studies, this condition is common, especially in the first year after initial UTI. If the recurrence occurs within a few months of the initial infection with a negative culture at the time of completing the course of antibiotic and grows the same organism as before, it is considered as persistence of bacteriuria. But, if there was a positive culture after completing the course of antibiotic, and the patient remains symptomatic it would be unresolved bacteriuria. In both of these instances, it could be a result of noncompliance and, therefore, it is essential that the parents become aware of the long-term consequences of an unresolved prolonged course of infection, particularly about the risk of renal scarring and hypertension.

Chronic pyelonephritis is a term that has been used in various ways. Ideally, it should be employed only after renal biopsy

specimens reveal renal scarring along with infiltration of plasma cells, monocytes, and macrophages on histology due to chronic repeated infections. Practically, the term often refers to scarred kidneys as demonstrated by nuclear medicine studies and/or reduced kidney function.

Complicated UTI refers to an infection that has an underlying risk factor, such as structural urinary tract defects, functional voiding problems, the presence of stones, or an immunocompromised state.

Epidemiology

Bacteriuria is detected in approximately 1% of girls and 2% of boys during routine screening of healthy newborns and young infants. Approximately 1% of girls continue to have asymptomatic bacteriuria throughout childhood. Bacteriuria in boys older than 1 year is very uncommon. In most affected infants and children, bacteriuria resolves spontaneously with time and does not lead to renal damage. Antibiotic treatment is not indicated unless the child develops a symptomatic infection. Routine screening for bacteriuria in infants and children, however, is not indicated. Symptomatic UTI occurs in approximately 2.5% of children annually and accounts for more than 1 million office visits per year and 14% of pediatric emergency department visits. Among vaccinated febrile infants, UTI is the source of fever in approximately 4% to 8% of patients, even in some of those who have upper respiratory infection symptoms. In early infancy, UTI is about twice as common in boys than in girls and about 5 to 10 times more common in uncircumcised boys than circumcised boys. After the first 6 months of life, the incidence of symptomatic UTI becomes considerably higher in females than males, and the difference between circumcised and uncircumcised males disappears.

Clinical Presentation

Signs and symptoms of UTI in neonates and young infants are usually nonspecific and include fever, irritability, poor weight gain, diarrhea, and vomiting, but many such infants on physical examination do not appear ill. On the other end of clinical spectrum, a few neonates and infants with UTI and bacteremia or sepsis appear quite ill and may also have temperature instability, apnea, bradycardia, cyanosis, anemia, jaundice, and disseminated intravascular coagulation. Older children with symptomatic UTI usually complain of suprapubic, abdominal, or flank pain; dysuria; frequency; urgency; secondary enuresis in a previously toilet trained child; foul-smelling or cloudy urine; and occasionally gross hematuria (Dx Box and Table 95-1).

Pathophysiology

The pathogenesis of UTI involves interaction between various bacterial factors, protective host factors, and environmental factors.

Bacterial Factors

Escherichia coli accounts for 80% to 90% of first-time UTIs. The remainder are caused by other gram-negative enteric bacilli

Dx Urinary Tract Infection

Infants

- Any unexplained fever
- Irritability
- Vomiting
- Nonspecific symptoms such as apnea, jaundice, or poor feeding
- Uncircumcised male infant
- History of congenital renal anomalies

Older Children

- Abdominal pain
- Burning or pain on urination
- Urgency
- Frequency
- Fever
- Leukocyturia
- Positive nitrite on urinalysis
- Positive urine culture

(*Proteus*, *Klebsiella*, *Enterobacter*) and gram-positive cocci (enterococci, *Staphylococcus saprophyticus*). Most organisms that cause UTI originate from the fecal flora. *Staphylococcus saprophyticus* (a coagulase-negative staphylococcus) infections are primarily seen in adolescents with UTI.

Microorganisms that cause UTI usually enter the urinary tract by an ascending route. To initiate colonization and infect the urinary tract, these organisms must first adhere to uroepithelium so they are not swept away during voiding. Bacterial adhesion in *E coli* is mediated by fimbriae, which are fine, hairlike proteins emanating from the bacterial cell wall. One important type of fimbriae, called P-fimbriae, adheres to receptors (Gal-Gal) on the uroepithelium, and some studies have shown that women and children with recurrent UTI have increased numbers of these receptors. P-fimbriae receptors have also been identified in high abundance on the epithelial surface of prepuce in male infants who have recurrent UTIs. In most young children with normal anatomy, acute pyelonephritis is caused by *E coli* with P-fimbriae. In most patients with VUR and scarred kidneys, however, the infection is caused by *E coli* lacking P-fimbriae. Hence, the role of P-fimbriae in the pathogenesis of renal scarring is uncertain. Additionally, many of these bacteria, which are typically extracellular organisms, are able to survive and flourish intracellularly by evading immune defenses and taking advantage of the host cell's nutrients. Other bacterial virulence factors include K and H antigens, colicin, hemolysin, and their ability to acquire iron, but their role in the pathogenesis of UTI is not clearly defined.

Host Factors

There are many unalterable host factors that contribute to the pathogenesis of UTI, including age, sex, genetics, anatomy, and immune response to infection. Preterm babies and neonates carry a higher risk than older children partly related to their immature immune

Table 95-1. Suggested Clinical Approach to Suspected UTI in Children of Different Age Groups

<i>Initial Approach</i>	<i>Follow-up Approach</i>
<p>Infant <2 months old (but >4 weeks) Fever (>39°C)/irritability/lethargy or any other signs and symptoms of infection or dehydration</p> <ol style="list-style-type: none"> Admit the child. Perform urine and blood culture (CSF culture is usually indicated). Check electrolytes, BUN, and creatinine. Start IV antibiotics (broad spectrum). Start appropriate IV fluids (even if the child tolerates oral feeds). Monitor trend in temperature and urine output closely. Obtain renal ultrasound. 	<p>If fever does not improve after 48–72 hours—reevaluate. Look for other sources of infection. Check the cultures and sensitivity results. Check the antibiotic dose. Re-culture blood and urine. Obtain renal ultrasound if not already done. Continue IV fluids.</p> <p>If urine and blood cultures are positive, monitor for fever and continue IV antibiotics for 7 days, complete 10–14 days course with PO as outpatient.</p> <p>If urine culture is positive, but blood culture is negative, fever is trending down and the patient is active and tolerating PO, discharge home with oral antibiotics to cover total of 10 days.</p> <p>If both cultures are negative, make a clinical judgment and if the possibility of clinical UTI is strong, treat infant with PO as described above.</p> <p>Renal ultrasound and VCUG (if not already done) to be done as an outpatient as soon as feasible. Repeat urine culture 2 weeks after completing antibiotics.</p>
<p>Children 2 months–2 years old High fever, septic appearing</p> <ol style="list-style-type: none"> Admit. Perform urine and blood culture (CSF culture if meningitis suspected). Start on broad-spectrum IV antibiotics. Start IV fluids. Check serum electrolytes, BUN, and creatinine. Monitor urine output. <p>Low-grade fever but patient has PO intolerance</p> <ol style="list-style-type: none"> Admit. Perform urine culture. IV fluids advance to PO as tolerated. <p>Fever, child appearing well</p> <ol style="list-style-type: none"> Treat patient with oral antibiotic for 10 days. Encourage fluid intake. 	<p>Check urine culture and sensitivity results. If patient continues to have fevers, check antibiotic dose, re-culture urine, request renal ultrasound. Monitor PO intake and determine the need for IV fluid. Renal ultrasound and VCUG to be done as an outpatient as soon as feasible. Repeat urine culture 2 weeks after completing antibiotics.</p>
<p>Children 2 years–12 years</p> <ol style="list-style-type: none"> If PO intolerance, admit. IV antibiotics and fluids. If tolerating PO well and not appearing septic, treat and do the workup on an outpatient basis. 	<p>Check BP. Check electrolytes, BUN, and creatinine. Perform renal ultrasound in all and VCUG in children between 2–5 years of age (particularly in those with hydronephrosis).</p>
<p>Adolescent children</p> <ol style="list-style-type: none"> If PO intolerance, admit, start IV antibiotics and fluids. If suspected cystitis or clinically stable pyelonephritis, treat as an out patient with oral antibiotics for 5–7 days. 	<p>Check BP. Check electrolytes, BUN and creatinine. Perform renal ultrasound in all cases of pyelonephritis.</p>

Abbreviations: BUN, blood urea nitrogen; CSF, cerebrospinal fluid; IV, Intravenous; PO, oral; UTI, urinary tract infection; VCUG, voiding cystourethrography.

mechanisms. Females seem to be at increased risk because the female urethra is shorter than the male urethra and closer to the anus. As previously stated, the receptors that have the higher affinity to bacterial fimbriae in the uroepithelium of older girls and uncircumcised boys contribute to the gender differences in the prevalence of UTI at different stages of life. In addition, individuals with certain P and Lewis blood groups develop more UTIs than others. Urinary obstruction or other anomalies may contribute to the development of UTIs in about 2% of girls and 5% of boys, especially infants.

Vesicoureteral reflux signifies retrograde passage of urine from the bladder to the ureter. After passage through the bladder wall, the normal ureter tunnels under the bladder mucosa before it opens into the bladder lumen. Under normal circumstances the submucosal segment is compressed when the bladder is filled and during voiding, preventing reflux of urine into the ureter. Most VUR is primary and caused by a congenital abnormality of the ureterovesical junction, with the ureter having a short submucosal segment and more laterally placed openings. Secondary reflux may occur in the presence of normal ureteral anatomy when bladder pressures exceed 40 cm of water, as seen in patients with posterior urethral valves or neurogenic bladders. Vesicoureteral reflux is graded on a scale of I through V, with grade V being the most severe (Figure 95-1).

There are insufficient data on the incidence of VUR in normal infants, but generally the incidence of VUR in normal infants is considered to be less than 2%. In infants with UTI, the incidence of VUR is about 25% to 50%; in school-aged children, about 25% to 30%; and in adolescents, about 10% to 15%. These figures suggest that, with increasing age and maturation of the bladder wall, VUR often spontaneously resolves. The risk of having VUR in those with one of the parents or siblings with VUR is much higher compared to those with no family history of VUR, with reported incidence in 10% to 30% of siblings of index cases. The incidence of UTI is increased in the presence of VUR probably because of incomplete emptying of

Figure 95-1. Grading of vesicoureteral reflux by vesicoureterogram based on international classification. I. Ureter only. II. Ureter, pelvis, and calyces, but without dilatation. III. Mild or moderate dilatation of ureter and mild or moderate dilatation of renal pelvis, but no or slight blunting of fornices. IV. Moderate dilatation or tortuosity of the ureter with moderate dilatation of renal pelvis and calyces and complete obliteration of the sharp angles of fornices, but maintenance of papillary impressions in most calyces. V. Gross dilatation and tortuosity of ureters, renal pelvis, and calyces; papillary impressions are no longer visible in most calyces.

the bladder; the urine refluxed into the ureters or kidneys returns to the bladder via the abnormally tunneled ureters at the end of voiding. This also provides infected urine direct access to the kidneys, which can lead to pyelonephritis and potential renal scarring.

Intuitively, it would seem that the greater the severity of VUR in children with UTI, the greater the likelihood of renal scarring. Recently, however, it has been clearly recognized that many neonates (especially boys) with antenatal VUR, even in the absence of UTI, have congenital dysplastic renal parenchymal defects, which had been misidentified as infective scars. This suggests that children with VUR can develop scarring even without infections; however, if they develop recurrent infections, it may augment further damage to the kidneys.

Genetic factors: Several gene mutations, candidate genes, and single nucleotide polymorphisms, such as CXCR1, CLR4, tyrosine-related protein 2 and 4, tumor necrosis factor- α and RANTES promoter polymorphisms, have been identified to be associated with high incidence of recurrent UTIs in children in the absence of genitourinary anomalies.

While there are many predisposing host factors that cannot be changed, there are several modifiable behavioral issues that are often associated with UTI in older children. School-aged children with frequent complaints of dysuria or recurrent UTIs who do not have a history of UTI as infants should be questioned for symptoms of dysfunctional voiding. The term *dysfunctional voiding* is often applied in the setting of children (especially girls) who have no neurologic or anatomical abnormalities, but who exhibit abnormal voiding behavior. These girls will often hold their urine for so long that they need to rush to the bathroom only to incompletely empty their bladder, leading to urinary stasis and the potential for infection. Additionally, severe constipation and abnormal stooling patterns are frequently associated with dysfunctional voiding and can also lead to the development of UTI.

Environmental factors: Poor genital hygiene, wiping from back to front, bubble bath use, and wearing of tight nylon panties have often been mentioned in the past as contributing risk factors for UTI; however, the evidence to support these potential risk factors is lacking. Nevertheless, common sense would dictate that fecal contamination of external genitalia and potential colonization be avoided or reduced as much as possible by simple measures such as wiping front to back, avoiding urethral irritation by bubble baths; and wearing loose-fitting cotton underwear in children with UTI.

In the adolescent female, use of spermicidal agents in diaphragms and/or condoms increases the risk of cystitis by altering the normal vaginal flora and enhancing adherence of uropathogenic strains.

Differential Diagnosis

In infants and young children, symptoms of UTI are often nonspecific. Thus a high degree of suspicion for UTI must be maintained. An acute abdomen may rarely be confused with UTI. Some children with dysuria may have chemical irritation from exposure to materials such as bubble baths. Overweight girls may retain urine in their labial folds, which can cause maceration, urethral irritation, or

vulvitis. Similarly, some young girls do not sit with their legs spread wide enough on the toilet, which can lead to reflux into the vagina and cause post-void dribbling with subsequent urethral irritation or vulvitis. In these cases, urinalysis and urine culture findings usually help differentiate UTI from vulvitis or urethral irritation. Patients with acute appendicitis may have nonspecific pyuria, which can lead to the misdiagnosis of UTI.

Evaluation

In all infants and young children with fever without an apparent source, urinalysis, urine Gram stain, and urine culture should be obtained to evaluate for UTI.

History

In older children, a history of fever, dysuria, frequency, abdominal pain, and nausea and vomiting is suggestive of UTI. History of previous UTIs, abnormal voiding pattern, and constipation should also be sought. (Also see Table 95-1 and Questions Box).

Physical Examination

The abdomen should be examined for masses and tenderness, the genitalia for local lesions, and the lumbosacral area for anomalies such as deep sacral dimples, lipomas, or tuft of hair that may be suggestive of occult spinal defects that could lead to urinary retention followed by recurrent UTIs. Tenderness is often present in the suprapubic and/or flank regions in children with UTIs. Blood pressure should be measured to evaluate for hypertension secondary to inflammation, scarring, or congenital anomalies of the kidneys. Alternatively, hypotension may be present if the patient is dehydrated or in septic shock.

Questions

Urinary Tract Infection

Neonates and Infants

- Does the urine have unusual odor or color?
- Is the child irritable or not feeding well?
- Is the child urinating like before?
- Is the child a premature or a full-term baby?
- Was the child diagnosed with any previous kidney diseases?
- Is there a family history of urinary tract infections or congenital kidney disorders?

Older Children and Adolescents

- Does it hurt when the child urinates? Does the child scream when urinating?
- Does the child have a good urinary stream? Or does the child dribble?
- Does the child void more frequently?
- Does the urine have an unusual odor?
- Has the child had previous urinary infections?
- If an adolescent, is the teenager sexually active?

Laboratory Tests

The diagnosis of UTI is established by documenting significant bacteria in a urine specimen sent for culture. In young infants the specimen should always be obtained by bladder puncture (suprapubic tap) or catheterization. In infants and children, because of the risk of contamination, a “bag urine” sample is not reliable. In older children with bladder control, a midstream urine collection is satisfactory. The diagnosis of UTI should never be based on the presence or absence of white blood cells alone. Although most older children with symptomatic UTI have pyuria, many neonates and young infants with UTI (25%–50%) may not manifest this finding. Furthermore, leukocyturia may occur in other renal disorders in the absence of UTI. A positive urinary nitrite test is very strongly suggestive of UTI (specificity 95%–100%), but the false-negative rate is nearly 50%.

Most patients with UTI (>85%) have urine bacterial counts greater than 100,000/mL on a voided specimen (ie, significant bacteriuria), although some adult women and teenaged girls with symptomatic recurrent UTI have catheterized or “clean catch” urine colony counts less than 1,000/mL. In general, this has not been observed in young children. Colony counts between 10,000 and 100,000/mL obtained via clean catch are generally unlikely to be significant unless children have symptoms of UTI, associated leukocyturia, and/or cultures that are pure growths of a single organism. Any growth of an organism from a suprapubic tap is considered significant. A colony count of at least 10,000/mL in samples obtained by catheterization is usually necessary to diagnose a UTI. However, in most children with UTIs, urine collected by either of these techniques grows more than 50,000 organisms/mL.

C-reactive protein is usually increased in infants and children with high fever and clinical findings suggestive of acute pyelonephritis. Several other laboratory studies, including erythrocyte sedimentation rate, urinary lactic acid dehydrogenase isoenzymes, urinary concentrating ability, and antibody-coated bacteria, have been used with varying success to differentiate upper (renal) from lower (bladder) UTI in older children and adults. Overall, the reliability of these studies in pediatric patients, especially infants and young children, is not adequate to recommend their routine use. More recently, some studies indicate that with pyelonephritis, increase in procalcitonin level occurs several hours prior to increase in C-reactive protein. This finding may have predictive value in early diagnosis of pyelonephritis and initiating appropriate antibiotic therapy.

Imaging Studies

The last position statement from the American Academy of Pediatrics (AAP) in 1999 states that all girls younger than 2 years and all boys (irrespective of age) should have renal ultrasonography and voiding cystourethrography (VCUG) performed following detection of the first UTI. These 2 studies detect structural renal anomalies and VUR in most patients. In girls, nuclear VCUG instead of contrast VCUG is an acceptable alternative. Renal ultrasound can be performed as soon as feasible after diagnosis. Voiding cystourethrogram may be done once there is clinical evidence that the UTI is

resolving, or it may be delayed 4 to 6 weeks depending on the clinical circumstances. Antibiotic prophylaxis, according to the AAP position statement, must be administered until completion of the studies. An excretory computed tomography urogram or intravenous pyelogram is no longer recommended other than under specific circumstances.

Several recent studies (summarized by Feld et al) have demonstrated no or minimal difference in the incidence of repeat UTIs, pyelonephritis, or renal scarring in children who were treated with prophylaxis or no prophylaxis and have questioned the need for routine VCUG in children with their first UTI who have normal renal ultrasound. This controversy is currently unresolved and the AAP has not updated its position statement.

Some authorities recommend a routine technetium 99m-dimer-captosuccinic acid (99mTc-DMSA) renal scan to differentiate upper from lower tract infection. Although the test is positive in 60% to 90% of children with a clinical diagnosis of acute pyelonephritis, the cost, exposure to radiation, and the fact that therapy is usually not altered preclude the routine use of this study. The scan is most helpful in a child where the diagnosis of acute pyelonephritis is in doubt or when used in follow-up to detect development of renal scars, especially in patients with VUR.

Management

All infants younger than 2 months with UTIs should be treated with parenteral **antibiotics**, starting with broad-spectrum antibiotic coverage, such as ceftriaxone, cefotaxime, or ampicillin and gentamicin, pending results of sensitivity studies. Children older than 2 months who appear well and are able to tolerate liquids may receive oral antibiotics on an outpatient basis. Most physicians recommend cephalixin for the first infection until the results of bacterial sensitivity tests are available and treatment is then continued for a total of 10 days. In older children with clear-cut lower tract infection, shorter courses of trimethoprim-sulfamethoxazole are also effective. One should be aware of the local *E coli* resistance patterns because some communities have a high incidence of *E coli* resistance to trimethoprim-sulfamethoxazole. Children who appear toxic and/or are vomiting should be admitted to the hospital and started on parenteral antibiotics until they show clinical improvement, at which time they can be sent home on oral therapy. In most cases there is clinical improvement within 48 hours of initiating treatment and the urine becomes sterile. In high-risk individuals with urinary abnormalities, immunocompromise state or disorders, or sickle cell disease or those who clinically fail to improve within 48 hours a urine culture should be repeated in a timely manner in order to determine whether there is a new infection or the patient has developed resistance to the previous organism. The culture should be repeated again in 2 to 4 weeks after completing the course of antibiotic to determine eradication of the infection. Although recent studies have suggested that prophylactic antibiotics do not necessarily prevent infections or renal scarring and may cause increased risk of resistant infections, most children

with VUR, especially those with grade III or higher, are still placed on low-dose antibiotics (trimethoprim-sulfamethoxazole, cephalixin, or nitrofurantoin) that are continued for 12 to 18 months following treatment for an acute infection. At the end of this period, a radionuclide VCUG is repeated to determine whether reflux has resolved. Development of new renal scars can be best detected by 99mTc-DMSA renal scanning.

Surgery is not necessary in most infants with VUR, including many with severe disease (grades IV and V) because most grade I through III and some grade IV and V reflux in infants disappears with increasing age. In children older than 5 years with grade IV or V reflux, the rate of disappearance with medical treatment is much lower (about 20%–25%). The results of the International Vesicoureteral Reflux Study Group show no difference in the rate of renal scarring between prophylactic medical treatment and surgery. Therefore, surgical reimplantation of the ureter is usually recommended only for those patients who have poor adherence with prophylaxis or breakthrough infections, especially if the upper tract is involved. This latter group seems to have benefited the most from surgery.

An alternate to surgical reimplantation, Deflux is a gel composed of dextranomers and hyaluronic acid that can be injected endoscopically into the ureters. It was approved by the US Food and Drug Administration in September 2001 after having been used extensively throughout Europe with great success. Most pediatric urologists agree that Deflux should be used for persistent grades II through IV, while grade I can be managed expectantly. Severe grade V reflux usually requires surgical reimplantation of the ureter to prevent recurrent infections and scarring of the kidneys.

Prognosis

In most children, UTI is a minor illness with very few long-term or serious consequences. However, UTI commonly reoccurs, especially during the first year following the initial UTI. Repeat urine cultures should be obtained during follow-up assessments in all children with VUR, first at 1- to 2-month intervals and later at 3- to 4-month intervals for at least 1 year or until disappearance of reflux.

The risk factors for the development of renal scars and eventual hypertension and/or renal failure include young age (<1 year), recurrent episodes of acute pyelonephritis, delay in starting effective antibiotic therapy, high-grade reflux, and anatomical or neurogenic obstruction. If repeat infection is prevented in these children, however, development of fresh scars is uncommon, and renal function and growth remain normal. As a group, infants and children younger than 3 years with UTI and high-grade VUR are more likely to develop calyceal clubbing and renal scarring, whereas progressive renal scarring as a result of UTI or reflux after 5 years of age is relatively less common.

CASE RESOLUTION

In the case history, the young girl is hospitalized because of the vomiting. She is started on intravenous ceftriaxone and she improves in 48 hours. Her inpatient renal ultrasound is normal, and she is discharged home with oral antibiotics. Because a radionuclide VCUG is planned in 4 weeks, she is also given a prescription for prophylactic antibiotics to take until the VCUG is completed.

Vaginitis

Monica Sifuentes, MD

CASE STUDY

An 11-year-old girl is brought to your office with vaginal itching for 1 week and a yellow discharge on her panties for the past 4 days. The girl reports no associated abdominal pain, vomiting, or diarrhea. She has no urinary problems and also denies any history of sexual abuse. Although she occasionally bathes with bubble bath, she most often takes showers. Except for the vaginal complaint, she is healthy, and she takes no medications.

The physical examination is notable for a soft, nontender abdomen with no organomegaly. Bowel sounds are audible in all quadrants. The genitalia are sexual maturity rating (SMR) (Tanner stage) 2. The labia majora and minora and the clitoris all appear normal, and the hymen is annular in shape with a smooth rim. A scant amount of yellow discharge, along with minimal perihymenal injection, is noted at the vaginal introitus. The anal examination is normal, with an intact anal wink.

Questions

1. What are the most common causes for vaginal discharge in prepubescent and adolescent females? How do they differ?
2. What basic historical information must be obtained from all females whose chief complaint is vaginal discharge?
3. What specific methods are used to perform a gynecologic examination in prepubescent and adolescent females?
4. What is the appropriate laboratory evaluation for prepubescent and adolescent females who complain of vaginal discharge? How does this evaluation differ for adolescent females who are sexually active?
5. What are the various treatment options for females with vaginitis?

Vaginal discharge is not an uncommon occurrence in prepubescent and adolescent females. Practitioners are largely responsible for differentiating between a physiological discharge, or leukorrhea, and a pathologic discharge, which occurs, for example, with a bacterial or yeast infection. In cases of an abnormal discharge, the possibility of abuse needs to be considered and investigated appropriately (see Chapter 128). Primary care physicians should become familiar with the various causes of vaginal discharge in both prepubescent and adolescent females. More importantly, they should be comfortable performing gynecologic examinations in these patients so that the appropriate treatment can be initiated.

Vulvovaginitis, which is often used interchangeably with vaginitis or vulvitis, signifies inflammation of the perineal area, often accompanied by vaginal discharge. The discharge may be bloody, malodorous, or purulent, depending on the etiology (Table 96-1).

Epidemiology

Vulvovaginitis is the most common gynecologic complaint in prepubescent girls. Most cases of vulvovaginitis in these girls result from **nonspecific inflammation**; vaginal cultures show normal flora in 33% to 85% of such cases. The incidence of more specific **bacterial causes**, such as group A beta-hemolytic streptococcus (GABHS), has been reported in approximately 14% of patients. However, its occurrence seems to be seasonal, and confirming the diagnosis depends on the use of proper culturing techniques using the appropriate

Table 96-1. Characteristics and Specific Causes of Vaginal Discharge

Color	Consistency	Amount	Cause
Clear/white	Thin	Variable	Physiological; bacterial vaginosis
White	Cottage cheese–like	Moderate	<i>Candida</i>
White/yellow	Variable	Variable	Chemical irritation, <i>Chlamydia trachomatis</i>
Yellow/green	Thick	Moderate–profuse	<i>Neisseria gonorrhoeae</i> , foreign body, <i>Trichomonas vaginalis</i>
Bloody	Variable	Variable	<i>Shigella</i> , group A streptococcus, foreign body

media. Other bacterial causes include respiratory pathogens such as *Haemophilus influenzae*, *Neisseria meningitidis*, *Streptococcus pneumoniae*, and enteric organisms such as *Shigella*. A positive culture for *Chlamydia trachomatis* or *Neisseria gonorrhoeae* can be found in approximately 5% of children who are evaluated for sexual abuse. Higher figures have been reported from selected centers and when data from adolescent victims are included. These organisms are not considered part of the normal flora in prepubescent girls. Vaginal and rectal infections with *C trachomatis* can be acquired perinatally,

but usually are not considered perinatally acquired after 2 to 3 years of age.

Parasitic infections may also lead to vaginal symptoms. Twenty percent of females with a rectal infestation of *Enterobius vermicularis*, the organism known as pinworm, have vulvovaginitis. Affected patients often complain of anal pruritus in addition to the vaginal discharge. **Mycotic infections** with organisms such as *Candida albicans* also can cause symptoms in prepubescent girls, although many of these girls have a previous history of oral antibiotic use.

Clinical Presentation

Prepubescent and adolescent females with vulvovaginitis most commonly present with a vaginal discharge, which may be white, purulent (ie, yellow or green), or serosanguineous. Its consistency can range from smooth and thin to thick and cottage cheese-like. The discharge may also be malodorous. In addition, females may complain of associated pruritus, erythema, urinary problems such as dysuria and increased frequency, and abdominal pain (Dx Box). Sexually active adolescent females with vaginitis from a sexually transmitted infection (STI) (eg, gonorrhea) generally have a more profuse, purulent discharge.

Dx Vaginitis

- Nonphysiological vaginal discharge
- Profuse or malodorous vaginal discharge
- Perineal erythema
- Vaginal pruritus or irritation
- Dysuria

Pathophysiology

Prepubescent girls are at risk for developing vulvovaginitis for both anatomical and physiological reasons. Unlike pubertal adolescents and young women, prepubescent girls have no pubic hair and a smaller labial fat pad to protect the vaginal introitus. The labia minora are small and tend to open when girls are in a squatting position, thereby exposing the vaginal introitus. The relative proximity of the anus to the vagina in young girls also contributes to vaginal contamination with enteric organisms. More importantly, poor hygienic practices (ie, wiping back to front after urination or defecation) can further compound the problem.

In addition, the normal physiology of the vaginal epithelium in prepubescent girls predisposes to vaginitis. The unestrogenized vaginal epithelium is relatively thin, immature, and easily traumatized. In addition, the pH of the vagina is neutral to alkaline, compared with the acidic environment of the vagina in adult females. Local antibody production also may be lacking in the vagina of prepubescent girls.

Differential Diagnosis

A vaginal discharge is normal at 2 distinct times in prepubescent girls: shortly after birth, secondary to the effects of maternal estrogen, and approximately 6 months to 1 year before the onset of menarche, which occurs, in most girls, by SMR (Tanner Stage) 4. Other causes of vaginal discharges in prepubescent and pubescent females are presented in Box 96-1.

Box 96-1. Causes of Vaginal Discharge in Prepubescent and Pubescent Females

Prepubescent Females

- Estrogen withdrawal (neonates)
- Chemical irritation secondary to soaps and detergents
- Mechanical irritation from nylon panties or tight-fitting clothes
- Foreign body in vagina
- Poor hygiene
- Pinworms
- Yeast infection (eg, *Candida*)
- Bacterial infection (eg, group A streptococcus, nonencapsulated *Haemophilus influenzae*, *Shigella* sp, *Salmonella* sp)
- Sexually transmitted infection (eg, gonococcal infection, chlamydial infection, trichomoniasis)
- Congenital abnormality (eg, ectopic ureter [local inflammation])
- Acquired abnormality (eg, labial fusion [pooling of urine in vagina])
- Urethral prolapse
- Systemic illness (eg, scarlet fever, Crohn disease)

Pubescent Females

- Physiological leukorrhea
- Foreign body in vagina (eg, retained tampon or condom)
- Yeast infection (eg, *Candida*)
- Bacterial infection (eg, group A streptococcus, *Staphylococcus aureus*)
- Sexually transmitted infection (eg, gonococcal infection, chlamydial infection, trichomoniasis, bacterial vaginosis)
- Chemical irritation (eg, douches, spermicides, latex [condoms])
- Local trauma (eg, penile studs)

Evaluation

Prepubescent Females

History

A complete history should be obtained in all females with a vaginal discharge (Questions Box). Practitioners should inquire about the appearance of the discharge, its duration, and the relative amount. A profuse, purulent discharge is probably more consistent with one specific etiology (eg, *N gonorrhoeae*) than is a scant, thin discharge that suggests a nonspecific etiology. The existence of urinary problems also should be determined. Pooling of urine in the vagina secondary to labial fusion can lead to vulvovaginitis in addition to a

Questions

Vaginitis

Prepubescent Females

- What is the color of the discharge?
- What is the consistency of the discharge?
- How profuse is the discharge?
- Is the discharge malodorous?
- How long has the discharge been present?
- How often does the discharge occur (ie, is it found on the panties daily)?
- Are there any associated problems (eg, dysuria, abdominal pain)?
- What types of laundry soaps or detergents are used?
- Does the child take bubble baths?
- Has the child had any recent illnesses or treatment with oral antibiotics?
- Does the child clean herself after using the toilet, or does she require help?
- In what direction does she tend to wipe after a bowel movement?
- Is there a concern for, or history of, child sexual abuse?

Adolescent Females (all of the above questions plus the following)

- What is the reproductive history (menstrual and sexual)?
- Does the adolescent douche or use scented panty liners?
- Is there a history of sexual assault/abuse?
- If appropriate, is the adolescent using any form of barrier or hormonal contraception? When was the last episode of unprotected intercourse?
- How many sexual partners has the patient had?
- Does the patient or partner have any history of a previous sexually transmitted infection, including hepatitis B or C?

urinary tract infection. Changes in bowel or bladder habits and sudden changes in behavior, such as nightmares or inappropriate stranger anxiety, also should be noted. Such changes in behavior warrant a further inquiry into the possibility of sexual abuse, regardless of the practitioner's index of suspicion. Depending on the information disclosed and the age of the patient, a decision might be made to interview the child and parents independently. Other points to discuss include the type of detergents or soaps used for laundry as well as for bathing, because these may be irritating. Any recent illnesses also should be documented as a possible source of autoinoculation or, if oral antibiotics were required, as a reason for the alteration of the normal vaginal flora. In addition, patients' hygienic practices should be reviewed. Adolescent patients should always be interviewed alone (see Chapter 6). In particular, a reproductive history must be obtained, keeping in mind that puberty and sexual activity both alter vaginal flora.

Physical Examination

Although the genital examination is the priority, a complete physical examination should be performed. This not only allows clinicians to identify other abnormal physical findings, but it also alleviates some of the anxiety often associated with a genital examination. Because

most vaginal discharges in prepubescent girls result from nonspecific vulvovaginitis, visualization of the cervix with a speculum is not indicated. Regardless of the gender of the examiner, a chaperone is recommended during the genital examination, particularly in postpubertal patients.

The overall demeanor of young girls at the onset of the genital examination should be noted. Overly compliant, apathetic behavior in children may be a cause for concern regarding abuse, especially in the context of a chronic or recurrent purulent vaginal discharge.

On physical examination, children's SMR must be noted and recorded. In addition, the external genitalia should be examined closely for the presence of any lesions or any evidence of erythema. Chronic changes in labial skin, such as those associated with constant scratching, also should be documented.

Girls should be placed in the modified lithotomy or "frog leg" position, and the labia majora should be gently spread apart to visualize the hymen. The knee-chest position also can be used, depending on the comfort of the practitioner as well as the patient. If the labia cannot be spread apart, the girl may have labial fusion. Perihymenal and periurethral erythema and injection should be noted, in addition to any evidence of edema, trauma, or abnormal masses such as urethral prolapse. Hymenal size and appearance should be carefully evaluated for any evidence of abuse (see Chapter 128). The appearance, consistency, and amount of the vaginal discharge, including the presence or absence of an odor, also should be documented. These findings may vary depending on the characteristics and cause of the discharge. Finally, the anus should be inspected for tone and any evidence of trauma or abnormal lesions such as genital warts. An anal wink is normally elicited. Although not usually indicated, a rectal examination should be performed in an attempt to palpate a foreign body or mass in those patients with a chronic or bloody vaginal discharge.

Laboratory Tests

Laboratory studies are often unnecessary in prepubescent girls with a nonspecific, non-bloody vaginal discharge, diffuse vulvar erythema, and no suspicion or history of sexual abuse. A vaginal culture for isolation of GABHS is indicated in girls with an abrupt onset of a serosanguineous discharge and a history of a systemic illness. The cellophane tape test may be helpful in diagnosing a pinworm infection in girls with associated anal pruritus. A KOH wet mount reveals pseudohyphae if a monilial infection is present, although this diagnosis is often made clinically.

If the discharge is purulent or malodorous or if abuse is suspected, vaginal cultures must be obtained for *N gonorrhoeae* and *C trachomatis*. For suspected cases of sexual abuse or assault, culture remains the gold standard because of the risk of a false-positive result with non-amplified probe tests (direct immunofluorescent smears, enzyme immunoassays) and nucleic acid amplification tests (NAATs). With genital and anal specimens, false-positive results can occur because of cross-reaction with fecal flora. In certain cases, a normal saline wet mount to check for mobile trichomonads may be indicated.

Pubescent Females

History

In adolescent or pubescent females with vaginal discharge, physicians should inquire about a history of sexual activity or assault in addition to other information that relates to their condition (see Questions Box). Questions concerning the possible acquisition of an STI also must be asked in a nonjudgmental confidential manner.

Physical Examination

Virginal adolescents with an uncomplicated history should be examined in a similar fashion as the prepubescent female. The external genitalia should be examined to evaluate the SMR of the patient and the presence of any lesions. Perihymenal or periurethral erythema and hymenal size and appearance should be noted. In the absence of a mucopurulent or bloody discharge, a speculum examination is generally not warranted.

In addition to an overall physical examination, a complete genital examination using a speculum is indicated in the sexually active female. The purpose of the speculum examination is to visualize the cervix, properly obtain vaginal and cervical specimens, and examine the vagina for lesions (eg, condylomata acuminata). A bimanual examination must also be performed to check for cervical motion tenderness as well as adnexal masses or uterine tenderness, which are associated with pelvic inflammatory disease (PID).

Laboratory Tests

Adolescent females who are not sexually active should have a laboratory evaluation similar to that described for prepubescent girls. Sexually active teens, however, warrant a more thorough evaluation to establish the etiology of their symptoms and investigate for cervicitis. In general, because a speculum examination is being performed in these adolescents, a single-swab endocervical sample should be obtained and sent for gonorrhea and chlamydia via NAATs (eg, ligase chain reaction, polymerase chain reaction). Urine also should be sent for *N gonorrhoeae* and *C trachomatis* in those adolescents who refuse a pelvic examination or for screening purposes. Recommendations have changed for teenagers regarding when cervical cancer screening (Pap smear) is indicated (see Chapter 40 for details). A culture or direct fluorescent antibody test for herpes simplex is indicated only if the history of exposure is positive and ulcerative or vesicular lesions are present.

Other causes of vaginal symptoms can be determined by the pH and microscopic analysis of a fresh sample of the vaginal discharge. A normal saline wet mount should be made using a sterile, saline-moistened swab, especially if a nonspecific discharge is present or bacterial vaginosis (BV) is a concern. In addition, motile or static trichomonads may be seen on a wet mount as well as white blood cells. A 10% KOH mount is appropriate in cases of suspected candidiasis. Mixing 10% KOH with the discharge may also produce a “fishy” odor (positive “whiff test”), which is consistent with BV and sometimes a trichomonal infection. In addition, a vaginal pH greater than 4.5 is commonly seen with BV or trichomoniasis, although it

is not specific. Commercial kits to evaluate for BV, trichomoniasis, and candida via nucleic acid probes also are available for the office setting where pH paper, KOH, and microscopic analysis of vaginal fluids is not possible. A Gram stain of any purulent material may lead to an early diagnosis of gonococcal cervicitis. Serologies for syphilis should also be obtained in adolescents with suspected (symptomatic) or proven STIs. In addition, these patients should be offered testing for HIV, with appropriate pretest and posttest counseling.

Management

Management of a **nonspecific vaginal discharge** is aimed at relieving the uncomfortable symptoms associated with this type of inflammation. Prepubescent females should be instructed to **discontinue use of all chemical irritants**, including bubble baths, in the genital area. Warm water **sitz baths** should be recommended twice daily for approximately 1 week, or until patients feel better. In addition, females should be instructed in **proper hygiene** (eg, wiping front to back after a bowel movement, appropriate hand washing). The use of cotton or cotton-crotch panties and loose-fitting skirts or pants should be encouraged.

Antifungal medications such as **clotrimazole** (Lotrimin) or **miconazole** (Monistat) cream may be prescribed if a monilial infection is present. Empiric treatment may be warranted in children or adolescents with a previous history of oral antibiotic usage, diabetes mellitus, or other chronic conditions that may alter the normal vaginal flora.

Pinworms are treated with a single oral dose of **mebendazole** (Vermox), 100 mg, or **pyrantel pamoate** (Antiminth), 11 mg/kg/dose (to a maximum of 1 g). Most authorities recommend repeat treatment after 2 weeks to kill worms that may have hatched after the first dose. Bedding and clothing should be laundered.

If a retained foreign body is suspected in prepubescent girls, an examination under general anesthesia may be necessary. Alternatively, practitioners can attempt vaginal irrigation in cooperative children by placing a small feeding tube at the hymenal opening and injecting warm saline. Toilet paper is the most commonly retrieved material in prepubescent girls.

Adolescent females who are not sexually active should be treated as outlined above. If the discharge is believed to be physiological leukorrhea, practitioners should reassure patients and educate them about other issues related to puberty (eg, menarche, body odor). Sexually active adolescents with positive vaginal cultures, NAATs, or highly suspicious vaginal discharges should receive treatment depending on the causal organism (see Chapter 97 for details concerning treatment). Table 96-2 briefly outlines current recommendations.

Any disclosure of molestation by prepubescent or adolescent females must be reported to the appropriate authorities. In addition, abnormal physical findings and positive cultures of STIs in prepubescent females and adolescent females who have never been sexually active must be reported to law enforcement and investigated.

Table 96-2. Treatment Recommendations for Adolescents With Infectious Vaginal Discharge

Organism	Treatment^a
<i>Neisseria gonorrhoeae</i>	Ceftriaxone, 250 mg intramuscularly, once, or cefixime, 400 mg orally, once
<i>Chlamydia trachomatis</i> ^b	Azithromycin, 1 g orally, once, or doxycycline orally 100 mg twice a day for 1 week
<i>Trichomonas vaginalis</i>	Metronidazole, 2 g orally, once, or tinidazole 2 g orally, once
Bacterial vaginosis	Metronidazole, 500 mg, orally twice a day for 7 days; or clindamycin cream 2%, one applicatorful intravaginally at bedtime for 7 days; or metronidazole gel 0.75%, one applicatorful intravaginally once a day for 5 days
<i>Candida albicans</i>	1% clotrimazole cream 5 g intravaginally for 7–14 days; 2% clotrimazole cream 5 g intravaginally for 3 days; 2% miconazole cream 5 g intravaginally for 7 days; 4% miconazole cream 5 g intravaginally for 3 days; 0.4% terconazole cream 5 g intravaginally for 7 days; 0.8% terconazole cream 5 g intravaginally for 3 days; fluconazole, 150 mg orally once

^aFor a complete list of treatment options, refer to Centers for Disease Control and Prevention, Workowski KA, Berman SM. Sexually transmitted disease treatment guidelines. *MMWR Recomm Rep.* 2010;59:1–110.

^bMay be associated with vaginal discharge because it causes cervicitis.

Prognosis

In most prepubescent females, vaginitis resolves spontaneously or after appropriate treatment with no permanent sequelae. In contrast, adolescent females treated for vulvovaginitis or uncomplicated cervicitis from an STI continue to be at risk for the development of PID, HIV, and pregnancy given their high-risk behavior and inconsistent use of barrier contraception (eg, condoms).

CASE RESOLUTION

In the case presented at the beginning of the chapter, the girl and her parents should be assured that the discharge is consistent with a nonspecific process. She should be instructed to take sitz baths for 1 week, discontinue bubble baths and the use of soap in the genital area, and wear loose-fitting clothes with cotton underwear. The girl should be reexamined in 1 to 2 weeks. No laboratory studies are warranted at this time.

Sexually Transmitted Infections

Monica Sifuentes, MD

CASE STUDY

A 17-year-old male presents with a small red lesion on the tip of his penis. He noticed an area of erythema a few weeks before, but it resolved spontaneously. He reports no fever, myalgias, headache, dysuria, or urethral discharge. He is sexually active and occasionally uses condoms. He did not use a condom during his last sexual encounter 2 weeks ago, however, because his partner uses oral contraception. The adolescent has never been treated for any sexually transmitted infections (STIs) and is otherwise healthy. His partners are exclusively female.

On examination, he is a sexual maturity rating (SMR) (Tanner stage) 4 circumcised male with a 2- to 3-mm vesicle on the glans penis. Minimal erythema is present at the base of the lesion, and there is no urethral discharge. The testicles are descended bilaterally, and no masses are

palpable. Bilateral shotty, non-tender, inguinal adenopathy is evident.

Questions

1. What conditions are associated with vesicles in the genital area?
2. What risk factors are associated with the acquisition of STIs during adolescence?
3. What screening tests should be performed in patients with suspected STIs?
4. What recommendations regarding partners of patients with STIs should be given?
5. What issues of confidentiality are important to address with adolescents who desire treatment for STIs?

Most teenagers in the United States have their first sexual experience before they graduate from high school. In the 2009 national Youth Risk Behavior Survey conducted by the Centers for Disease Control and Prevention (CDC), nearly half of all students in high school reported having had sexual intercourse during their lifetime, with 6% of students nationwide reporting sexual intercourse for the first time before age 13 years. More importantly, nearly 16% of boys and 11% of girls in grades 9 to 12 reported having had 4 or more sexual partners during their life. The consequences of sexual activity in adolescents include increased rates of bacterial and viral STIs, unintended pregnancy, and the possible acquisition of long-term infections such as HIV in the 15- to 24-year age group. Without adequate antiretroviral therapy, the average time from acquisition of HIV infection to the development of AIDS is approximately 10 years. Given the complex nature of these consequences, the physician must be skilled in obtaining a complete sexual history in teenaged patients and in diagnosing and treating STIs.

Increasing levels of sexual activity directly affect STI trends in adolescents. Other influential factors include multiple (sequential or concurrent) sexual partners; inconsistent and incorrect use of condoms and other barrier methods; experimentation with drugs, including alcohol, which results in poor judgment concerning sexual activity; poor compliance with antibiotic regimens; and biological factors, such as an earlier age of menarche and the presence of cervical ectopy in adolescent females. The feeling of invulnerability and the associated risk-taking behavior that occurs during adolescence make sexual activity spontaneous rather than premeditated.

As a result, preventive measures are hindered, ignored, or simply unheard of, allowing adolescents to deny the possible consequences of their actions. Other factors influencing STI trends are related to societal norms. Traditionally, educational materials and STI services have not been readily available to adolescents in some areas of the United States, unlike other industrialized countries. Many teens also have difficulty accessing health care in their communities and are concerned about confidentiality when obtaining medical services for sensitive issues. In addition, the depiction of casual sexual relationships in television sitcoms, music videos, and motion pictures may play a major role in glamorizing sex. Advances in technology via Internet access also gives teenagers the opportunity to communicate with peers that were previously unreachable.

Epidemiology

The overall prevalence of STIs in adolescents is difficult to estimate because not all STIs are reportable, and collected data are often influenced by the particular population studied. It has been estimated, however, that nearly 50% of all new STIs diagnosed annually in the United States occur among teenagers and young adults aged 15 to 24 years. *Chlamydia* remains the most common cause of cervicitis and urethritis in adolescents, with age-specific rates highest among girls and young women 15 to 24 years of age and young men 20 to 24 years of age. Additionally, studies have shown that certain adolescent subpopulations are at greater risk for chlamydial infection, such as homeless and incarcerated youth, socioeconomically disadvantaged youth, teenagers attending family planning clinics, and

pregnant adolescents. Complications of untreated chlamydial cervicitis occur in 10% to 30% of cases and include pelvic inflammatory disease (PID), ectopic pregnancy, chronic pelvic pain, and infertility. Epididymitis, a result of urethral infection, occurs in 1% to 3% of infected males. Other conditions that are uncommon but may occur in males as a result of an infection with chlamydia include proctitis, prostatitis, and Reiter syndrome.

Teenagers have the highest incidence of **gonorrhea** of any other age group, although the prevalence rates have decreased since 2001. The highest rates of gonorrhea reportedly occur in adolescent females, young men in their early 20s, young adult inner-city minorities, incarcerated youth, men who have sex with men, and prostitutes. A large number of sexual partners, injection drug use, exposure to prostitutes, and casual sexual contacts also contribute to the risk of infection. In 2009 the CDC reported gonorrhea rates to be highest among adolescents and young adults. The incidence of gonorrhea in 15- to 19-year-old women was 568.8 per 100,000. Men aged 15 to 19 years had the second highest rates of gonorrhea (250 per 100,000) compared with men aged 20 to 24 years who had the highest rates of gonorrhea (407.5 per 100,000). Of the more than 1 million cases of PID reported annually in the United States, 20% to 30% are in sexually active adolescents. The risk of developing PID is increased 10-fold in this age group compared with adults for several reasons. Failure to use condoms consistently, new partners within the previous 2 to 3 months, and a history of STIs have been cited as risk factors. Complications of PID, such as tubo-ovarian (TOA) abscess formation, are more likely in adolescents as a result of late presentation, delayed diagnosis, difficulty accessing health care, and non-compliance with prescribed treatment regimens.

Although the rate of primary and secondary **syphilis** declined from 1990 to 2000, the number of cases is now increasing, primarily among men. During 2005 the incidence of syphilis was highest among women in the 20- to 24-year-old age group and among men in their mid-30s. In 2009, however, young men aged 20 to 24 years had the highest rates of syphilis. Studies have shown that people with syphilis, as well as other STIs causing genital ulcers, also are at increased risk for HIV acquisition.

Human papillomavirus (HPV) is the most common STI in the United States, with the highest infection rates among adolescents and young adults. Recent studies report the prevalence in sexually active adolescents to range from 30% to 60% and to decline with age. The prevalence of HPV in adolescents varies widely for 2 reasons: (1) infection with HPV is often latent and generally regresses spontaneously and (2) HPV is not a reportable condition. Behavioral and biological risk factors for HPV infection have been identified and include early age of sexual initiation, multiple sexual partners, partner's number of sexual partners, a lack of consistent condom use, and a history of another STI such as genital herpes, which may facilitate HPV acquisition by compromising mucosal integrity. Cigarette use also increases the risk of infection and HPV-related disease, as does an altered immune system.

Infection with **HSV type 2 (HSV-2)** is underestimated and is the most common cause of genital ulcerative disease in the United States. Reportedly, HSV-2 occurs in approximately 4% of whites and 17% of African Americans by the end of their teenage years.

By 2005 the number of **HIV/AIDS** cases reported in the United States in adolescents aged 13 to 19 years was 6,324; the number of cases in young adults between 20 and 24 years of age was 34,987. As of 2008 there are more than 25,000 adolescents and young adults living with a diagnosis of HIV. Because the time from acute HIV infection to immunosuppression is approximately 10 years for untreated adolescents, estimates of asymptomatic or early HIV infection are often based on reported cases of AIDS in young adults in their 20s. AIDs in adolescents occurs primarily in males and ethnic minorities. Most of these individuals are infected through sexual contact or injection drug use. Teen subpopulations who are at particularly high risk for acquiring HIV are youth who have male-to-male sexual contact; are bisexual, transgendered, and/or homeless or a runaway; injection drug users; incarcerated; mentally ill; in the foster care system; or have been sexually or physically abused.

Clinical Presentation

Adolescents with an STI may go to their physicians with specific complaints related to the genitourinary system, such as painful urination or vaginal discharge. They also may report more generalized complaints, like fever and malaise, especially in cases of primary HSV or HIV (Dx Box: Sexually Transmitted Infections). In addition, some teenagers will use a vague complaint to see their primary care practitioner with the hope that the physician inquires about sexual

Dx Sexually Transmitted Infections (STIs)

Males

- Dysuria
- Urethral discharge or pain
- Testicular pain
- Presence of any lesions in the genital area such as ulcers, vesicles, or warts
- Sexual partner who has an STI

Females

- Dysuria
- Abnormal vaginal discharge
- Intermenstrual or irregular bleeding
- Dysmenorrhea
- Dyspareunia
- Postcoital bleeding
- Lower abdominal pain
- Systemic symptoms such as fever, nausea, vomiting, malaise
- Presence of any lesions in the genital area such as ulcers, vesicles, or warts
- Sexual partner who has an STI

activity. It may be only then that they will disclose their true concern if the provider is thorough and appears nonjudgmental.

Pathophysiology

A number of biological factors contribute to the increased prevalence rates of STIs in adolescents, particularly in females. At the onset of puberty, the columnar epithelial cells in the vagina transform to squamous epithelium while columnar cells at the cervix persist (Figure 97-1). With increasing age, the squamocolumnar junction recedes into the endocervix. In adolescent females, however, this junction, referred to as ectopy, is often located at the ectocervix and is relatively exposed, which places these females at particular risk for gonococcal and chlamydial infections. The infectious organisms preferentially attach to cervical columnar cells and infect them. Of note is that the use of oral contraceptives also prolongs this immature histologic state.

The cytologic changes seen in cervical cells of adolescents with HPV infection are also believed to be age-related. The immature cervical metaplastic or columnar cells seem to be more highly vulnerable to infection and neoplastic changes. In addition, exposure to other cofactors (eg, tobacco use, multiple episodes of new HPV infections) is likely to promote the development of squamous intraepithelial neoplasia (SIN) and cervical carcinoma. Not all young women exposed to HPV develop lesions or progress to SIN, however, and most will not remain positive for HPV throughout their lifetime.

The presence of genital ulcers has been shown to facilitate both the transmission and the acquisition of HIV. Such ulcers provide a point of entry past denuded epithelium. In addition, it is hypothesized that many activated lymphocytes and macrophages are located at the base of the ulcer and are therefore susceptible to infection by HIV.

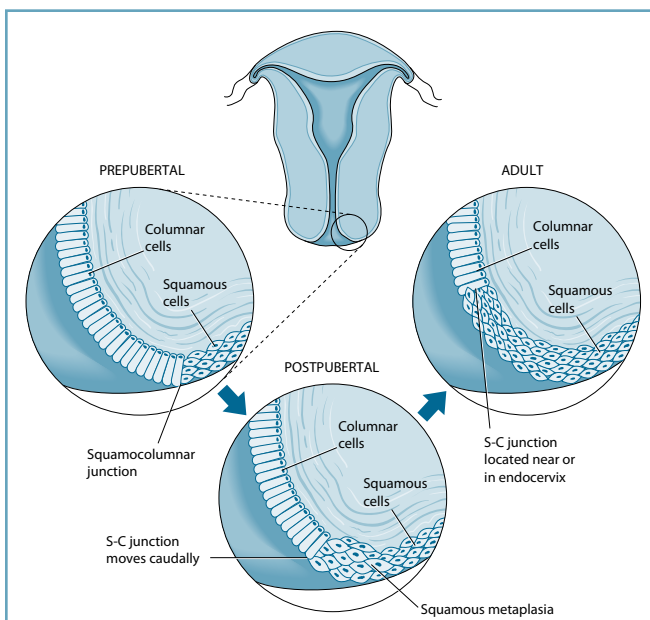

Figure 97-1. Development of the cervical squamocolumnar (S-C) junction, from puberty to adulthood.

Pelvic inflammatory disease usually develops from an ascending mixed polymicrobial infection, often related to an untreated STI of the cervix and vagina. The infection spreads contiguously upward to the upper genital tract, resulting in inflammation, scarring, and crypt formation in the fallopian tubes. The most common causal organisms, which account for more than half of the cases of PID in most studies, are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Other agents include *Escherichia coli*; other enteric flora; and microbes implicated in bacterial vaginosis, such as *Mycoplasma hominis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, *Bacteroides* species, and anaerobic cocci. Viruses such as HIV and herpes simplex can facilitate the process of this ascending infection by disrupting normal immunologic barriers to infection, such as altering the vaginal pH and flora and the cervical mucous barrier.

Differential Diagnosis

Most patients with STIs present with 1 of 5 clinical syndromes—urethritis/cervicitis, epididymitis, PID, genital ulcer disease, or genital warts, all of which can be easily diagnosed (Box 97-1). Other conditions that mimic STIs, however, must be considered in certain cases where the adolescent denies sexual activity or where

Box 97-1. Differential Diagnosis of Sexually Transmitted Infection by Clinical Syndrome

Urethritis

- *Neisseria gonorrhoeae*
- Non-gonococcal disease
 - *Chlamydia trachomatis*
 - *Ureaplasma urealyticum*
 - *Trichomonas vaginalis*
 - Herpes simplex virus
 - Yeasts

Cervicitis

- *C trachomatis*
- *N gonorrhoeae*
- *T vaginalis*
- Herpes simplex virus (especially primary type 2)

Pelvic Inflammatory Disease

- *N gonorrhoeae*
- *C trachomatis*
- Anaerobes
- Gram-negative rods
- Streptococci
- *Mycoplasma hominis*
- *U urealyticum*

Vaginitis

- *T vaginalis*
- *Candida albicans* and other yeast
- *Gardnerella vaginalis*

Genital Ulcers

- *Treponema pallidum* (syphilis)
- Herpes simplex virus, types 1 and 2
- *Haemophilus ducreyi* (chancroid)
- *C trachomatis* (lymphogranuloma venereum)

Genital Warts

- *T pallidum* (condyloma latum)
- Human papillomavirus (condyloma acuminatum)

Proctitis

- *N gonorrhoeae*
- *C trachomatis*
- *T pallidum*
- Herpes simplex virus
- Particular to homosexual youth (in addition to the above)
 - Hepatitis A and B virus
 - *Shigella*
 - *Campylobacter*
 - *Giardia lamblia*
 - *Entamoeba histolytica*

Pharyngitis

- *N gonorrhoeae*
- Herpes simplex virus, types 1 and 2

the disorder does not respond to routine treatment. These disorders include **muco-cutaneous ulcers** associated with systemic lupus erythematosus and Behçet disease. Often, systemic disorders such as these can be ruled out historically. **Benign oral lesions** such as aphthous ulcers also can be confused with herpetic ulcers. When evaluating an adolescent female with acute lower abdominal pain, surgical conditions such as **appendicitis, ovarian torsion, and ectopic pregnancy** must be ruled out. In the sexually active male with testicular pain, **testicular torsion** must be considered and thoroughly evaluated before a diagnosis of acute epididymitis is made.

Evaluation

In all sexually active adolescents, a complete history, including a sexual history, should be obtained (Questions Box). Because sexual identity and sexual behavior may differ, risk assessment for an STI, particularly HIV, should be based on a review of actual sexual behavior (eg, anal intercourse) rather than on an adolescent's stated sexual orientation. A detailed gynecologic history also should be reviewed with females. The rest of the history should then focus on the particular complaint and any associated symptoms. Sexually active adolescents should have a complete physical examination, including a thorough genital examination. Although diagnostic tests should be determined by the adolescent's risk for a specific STI based on historical and physical findings, one must keep in mind that many adolescent patients are asymptomatic, and screening for common STIs such as chlamydia and gonorrhea should be performed annually on all sexually active teenagers.

Questions

Sexually Transmitted Infections— Questions to Ask the Patient

- Are you currently sexually active?
- At what age did you begin to have sex?
- Do you have sex with men, women, or both?
- How many partners have you had? When was your last contact?
- Have you ever been forced to have sex, or have you ever exchanged sex for food, shelter, money, or drugs?
- Do you or your partner(s) use contraception? What type?
- Do you or your partner(s) use drugs or alcohol?
- Have any of your sexual contacts ever been diagnosed with a sexually transmitted infection?
- Do you have abdominal pain, dysuria, increased urinary frequency, or hesitancy?
- Have you noticed any ulcers, blisters, warts, or other bumps in the genital area? Are the lesions painful?
- For females: Do you have a vaginal discharge or itching? Is sex uncomfortable or painful? Do you have bleeding between periods or after intercourse?
- For males: Do you have a discharge from your penis? Any testicular pain or swelling? Any associated burning or itching?

Urethritis and Epididymitis

History

Because infectious urethritis is more common in young men, all sexually active adolescent males should be asked about the presence of dysuria, urethral discharge, and urethral erythema or pruritis. In females, symptoms such as dysuria may appear more gradually, and dysuria is reported more frequently than other symptoms like meatal edema, erythema, or urethral discharge, which are rarely noticed. General urinary symptoms such as acute urinary frequency or urgency are uncommon with urethritis, especially in males, but all patients should be asked about these symptoms. More often, urethritis is asymptomatic, and the diagnosis is made by routine screening in sexually active adolescents or through known contact with a partner with an STI (eg, *C trachomatis* or *N gonorrhoeae*).

To diagnose acute epididymitis, sexually active males should be asked about testicular pain and swelling. Symptoms associated with urethritis may be present or may have preceded the scrotal symptoms.

Physical Examination

In males, the urethra should be the focus of the genital examination. The presence of a urethral discharge and its consistency (ie, mucoid or purulent) should be noted. Any other urethral or genital lesions also should be assessed. The epididymis, spermatic cord, and testes should be palpated carefully for tenderness and swelling.

In females, a full pelvic examination should be performed after careful examination of the external genitalia for any ulcerative or wart-like lesions. Urethritis is most often caused by *C trachomatis*, but HSV and trichomoniasis can be other causes. The urethra should be inspected for edema, erythema, or any evidence of a discharge prior to speculum insertion. The presence or absence of a vaginal or endocervical discharge also should be noted during the pelvic examination.

Laboratory Tests

A Gram stain of the urethral discharge may confirm the diagnosis of urethritis in males. The specimen should be obtained using a Dacron or cotton swab because calcium alginate inhibits the growth of *Chlamydia*. The presence of gram-negative, intracellular diplococci with the typical “kidney bean” morphology is indicative of an infection with *N gonorrhoeae* (gonococcal urethritis). Five or more polymorphonuclear (PMN) leukocytes per oil immersion field but no organisms indicates the more common type of infection, nongonococcal urethritis (NGU), usually found in males. In 15% to 40% of cases, NGU is caused by *C trachomatis*. If no PMN leukocytes are seen on Gram stain or if the patient is asymptomatic, assessment for leukocyte esterase with a urine dipstick should be made using the first 10 to 15 mL of a first-voided urine specimen. The sediment also should be examined under the microscope to determine if more than 10 white blood cells per high-power field are present. A routine urine culture is generally not recommended in males and may be of little help in females.

Newer screening tests using urine samples are now available and considered standard of care for detecting gonorrhea and *C trachomatis*, especially in asymptomatic sexually active adolescents. These non-culture tests rely on amplification of DNA (ie, polymerase chain reaction [PCR] and ligase chain reaction) and are highly sensitive and convenient for screening teenagers because the test can be performed on a routine urine specimen. A disadvantage is that these tests are costly and may have a greater potential for false-positive results, making a definitive diagnosis questionable in a judicial setting. In the adolescent population, however, these urine nucleic acid amplification tests (NAATs) are definitely more acceptable than tests requiring a direct urethral swab specimen and can be used to confirm chlamydial or gonococcal urethritis.

Color duplex Doppler ultrasound may be necessary to make an accurate diagnosis of epididymitis, especially if there is any consideration for testicular torsion. If the diagnosis is questionable, a urologic consult should be obtained immediately.

Cervicitis

History

Cervicitis in females is parallel to urethritis in males. Because cervicitis is a local infection, systemic symptoms may not occur, which makes asymptomatic infections, especially with *C trachomatis*, very common. However, a variety of important historical points and associated complaints should be addressed in all sexually active teenagers. Is a vaginal discharge present? If so, does it have an odor? Is the patient experiencing any urinary frequency, urgency, or dysuria? Has she had any non-menstrual vaginal bleeding, including postcoital bleeding? A known exposure to other STIs also must be ascertained. Is the current partner symptomatic or receiving antibiotic treatment? Does the patient or her current or past partners have a history of an STI?

More generalized symptoms, such as moderate lower abdominal pain (either acute or chronic) associated with nausea, vomiting, and fever, may indicate a complication of untreated or undetected cervicitis, such as PID.

Physical Examination

After completing the full physical examination, the physician should focus on the genitourinary examination. The SMR should first be noted, then the presence of any lesions on the external genitalia or inflammation of the perineum. Any urethral erythema or discharge also should be noted. The presence of a vaginal discharge can be assessed more completely when performing the speculum examination, which should be performed in all sexually active adolescent females with vaginal or persistent lower urinary tract complaints.

During the speculum examination, the vaginal mucosa should be inspected, the presence of a vaginal discharge identified, and the appearance of the cervical os should be noted. The physician

should determine whether a purulent or mucopurulent exudate is visible in the endocervical canal and should look for any evidence of cervical friability or sustained endocervical bleeding as a swab is gently passed through the cervical os to perform the NAAT and wet mount. Cervical inflammation must be differentiated from normal adolescent ectopy. A presumptive diagnosis of mucopurulent cervicitis is made when there is a discharge from the cervical os, cervical erosion, or friability. A bimanual examination also must be performed to evaluate for cervical motion tenderness (CMT), adnexal masses or fullness, and uterine tenderness.

Laboratory Tests

According to the CDC, NAATs for *N gonorrhoeae* and *C trachomatis* are preferred for the diagnostic evaluation of cervicitis and can be performed on either vaginal, urine, or endocervical specimens. If a pelvic examination is being performed, an endocervical or vaginal swab specimen for NAATs can be collected by direct visualization. A Gram stain of the discharge also can be performed to detect the presence of gram-negative diplococci or PMN leukocytes. The presence of 30 or more PMN leukocytes per oil immersion field is presumptively positive for cervicitis. A wet mount to diagnose associated STIs, such as trichomoniasis, is recommended, especially if the discharge is foul smelling or frothy. Adolescents who are diagnosed with a new STI or engaged in other high-risk behaviors such as unprotected sex, inconsistent condom use, or young men having sex with men also should receive testing for other STIs such as HIV, syphilis, and viral hepatitis.

Pelvic Inflammatory Disease

History

When considering a diagnosis of PID, the history should include a discussion of known risk factors, such as unprotected sexual activity, including the number of sexual partners, especially new partners in the previous 2 months; a previous history of an STI or recent exposure to an STI; the type and consistency of contraceptive use; and the timing of the last menstrual cycle because most women present with PID during the first half of their menstrual cycle. The physician also should ask patients about the presence of symptoms that are often associated with PID: the onset, duration, quality, and location of abdominal pain; urinary symptoms that may indicate concomitant urethritis; intermenstrual bleeding; dysmenorrhea or dyspareunia; abnormal vaginal discharge; right upper quadrant pain; and systemic symptoms such as nausea, vomiting, fever, and malaise. The classic symptoms of PID, which include pelvic or lower abdominal pain, vaginal discharge, fever, and irregular vaginal bleeding, may not be present. More often symptoms are nonspecific or vague, and the practitioner must maintain a high index of suspicion in any sexually active female with pelvic or lower abdominal pain.

Physical Examination

Classic signs of acute PID include fever with lower abdomen pain and tenderness of the cervix, uterus, or adnexa. However, the clinical presentation can vary from vague discomfort to severe disease. A thorough physical examination should be completed before performing the pelvic examination to exclude other common causes of lower abdominal pain. This should include a review of the vital signs, looking for fever or tachycardia. The blood pressure also must be reviewed carefully because hypotension can be seen with a ruptured ectopic pregnancy, which may present with similar symptoms including abdominal pain and vaginal bleeding. The abdomen should be assessed for tenderness and guarding. The location of the pain is particularly relevant because certain acute surgical conditions, such as appendicitis, ovarian torsion, and ectopic pregnancy, are important considerations in the differential diagnosis of PID. In addition, right upper quadrant pain is consistent with perihepatitis, or Fitz-Hugh–Curtis syndrome, which can be seen with a gonorrheal or chlamydial infection. The speculum examination should then be performed, looking for a mucopurulent endocervical exudate or any evidence of cervicitis (cervical friability or erosion). The bimanual examination is the most important part of the physical examination. The cervix should be carefully palpated for any evidence of CMT and the uterus for tenderness or adnexal masses.

Laboratory Tests

The diagnosis of PID is based on clinical findings and a high index of suspicion, after other causes for pelvic or lower abdominal pain have been excluded. Previous CDC criteria for the diagnosis of PID included 3 major components: lower abdominal pain, cervical motion tenderness, and adnexal tenderness. Current recommendations now outline 2 minimal clinical criteria and 5 additional criteria to support the diagnosis (Dx Box: Pelvic Inflammatory Disease). Particularly when evaluating an adolescent for PID, early conservative treatment and maximum sensitivity for clinical findings are paramount to avoid a delayed or missed diagnosis. A NAAT for *N gonorrhoeae* and *C trachomatis* should be sent on the endocervical or vaginal swab specimen obtained during the pelvic examination. If readily available, a Gram stain of any cervical discharge should be performed. The specimen should be examined microscopically for PMN leukocytes as well as gram-negative, intracellular diplococci. The presence of numerous PMN leukocytes per oil immersion field is one of the clinical criteria for making a diagnosis of PID. (See Laboratory Tests section for urethritis and epididymitis.)

Other laboratory studies to obtain include a complete blood cell count with differential and a sedimentation rate or C-reactive protein, although in many cases the laboratory tests are normal. A urine pregnancy test should be performed to exclude the possibility of a concomitant intrauterine or ectopic pregnancy. Additionally, a urinalysis and urine culture should be obtained, as well as a serologic test for syphilis. HIV testing also should be offered to the adolescent female with appropriate verbal pretest counseling. Testing for viral hepatitis is recommended in the patient who has not been immunized against hepatitis B or who has exposure to injection drug use.

Dx Pelvic Inflammatory Disease^a

Pelvic or lower abdominal pain, and one or more of the following minimum criteria on pelvic examination:

- Cervical motion tenderness
- Uterine tenderness
- Adnexal tenderness

Additional Findings

- Oral temperature >38.3°C (101°F)
- Abnormal vaginal or cervical mucopurulent discharge
- Presence of abundant numbers of white blood cells on saline microscopy of vaginal secretions
- Elevated erythrocyte sedimentation rate or C-reactive protein
- Laboratory documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*

Specific Criteria for the Diagnosis

- Inflammatory tubal mass or tubo-ovarian complex seen on magnetic resonance imaging or transvaginal ultrasound, or evidence of pelvic infection (tubal hyperemia) via Doppler
- Histologic evidence of endometritis on endometrial biopsy
- Laparoscopic abnormalities consistent with PID

^aCenters for Disease Control and Prevention, Workowski A, Berman SM. Sexually transmitted diseases treatment guidelines, 2010. *MMWR Recomm Rep*. 2010;59:64.

Laparoscopy can be performed to make a definitive diagnosis of PID or to obtain direct cultures in cases where the diagnosis is equivocal or the patient is not improving on standard antimicrobial therapy. A gynecologist should be consulted for these challenging cases.

Imaging Studies

A transvaginal ultrasound may help exclude diagnoses such as ectopic pregnancy or ovarian torsion and also can aid in the detection of associated complications of PID, such as TOA. Fluid in the cul-de-sac may be seen on ultrasound; however, it is not specific for the diagnosis of PID.

Genital Ulcers

History

Probably the most important information to obtain from the adolescent with genital ulcers is whether they are painful. A painless chancre on the penis, around the mouth, in the oropharynx, or on the external genitalia in females is consistent with syphilis. If the lesions are painful or are associated with a grouped vesicular eruption, HSV is the likely cause. The presence of systemic symptoms such as fever, chills, headache, or malaise also is important to discern because these symptoms can be seen with a primary infection with HSV or secondary syphilis. Generalized complaints, however, are associated with secondary syphilis only 50% of the time. A history of adenopathy, either localized or generalized, also must be noted, along with dysuria, which may be present in females with HSV. In addition, a history of a viral-like illness accompanied by a rash should be explored

further. A diffuse maculopapular rash, especially on the palms and soles, is a classic sign of secondary syphilis. Since a nonspecific rash also can be seen with primary HIV infection, all possible exposures to other STIs should be reviewed with the teenager.

Physical Examination

All adolescents who present with chancres, or ulcers, should receive a complete physical examination. The skin, including the palms and soles, should be examined closely for any dull red to reddish-brown macular or papular lesions. The oropharynx should be carefully checked for chancres or blisters. All lymph nodes should be palpated for pain, enlargement, or induration. Suppurative or fluctuant nodes are often associated with chancroid caused by *Haemophilus ducreyi*. The genital examination should focus on the appearance of the lesions. The following questions should be asked of the patient: Are the lesions ulcerative, clustered, and painful (HSV or chancroid)? Are they associated with grouped vesicles on an erythematous base (HSV)? Is tender inguinal adenopathy present (HSV or chancroid)? Or is there a single, painless, indurated chancre with a clean base and a sharply defined, slightly elevated border (syphilis)? The lymph nodes associated with this syphilitic type chancre are often non-tender but enlarged. Other less common STIs produce genital ulcers that are often painful and deep and may be accompanied by some purulence. Adenopathy can be quite impressive with chancroid and lymphogranuloma venereum (*C trachomatis*).

Laboratory Tests

The necessary diagnostic tests depend on the patient's clinical picture. However, all adolescents who present with an ulcerative lesion should have dark-field microscopy performed for syphilis. Direct fluorescent antibody testing of the lesions is also available and very specific. Non-treponemal serologic tests for syphilis, such as the Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) tests, should be done if direct examination is not available or the clinical appearance of the ulcer is nonspecific. In cases of early primary syphilis where the VDRL or RPR may not be reactive initially, the test should be repeated in 1 week. Treponemal tests, such as the fluorescent treponemal antibody absorption test (FTA-ABS), should be used only as confirmatory tests and not for screening purposes.

Viral cell culture and PCR are the preferred HSV tests for persons who seek treatment for genital ulcers or other mucocutaneous lesions. Samples should be obtained from the base of an unroofed vesicle. Herpes simplex virus monoclonal antibody can be performed in older lesions that may be culture-negative and can differentiate between types 1 and 2. Herpes simplex virus serology is generally not helpful. Given the well-described correlation between genital ulcers and HIV, it is recommended that all patients with a diagnosis of syphilis be tested for HIV as well. Conversely, annual syphilis screening is recommended for an adolescent with multiple sexual partners; a history of injection drug use; a history of sex with men, women, or both; or a diagnosed STI.

Genital Warts

History

Risk factors for HPV infection should be assessed in all sexually active adolescents. These include a history of multiple sexual partners, age younger than 25 years, a previous history of STIs, lack of consistent condom use, pregnancy, altered immune response, and tobacco use. Symptoms may include pruritis, pain, or dyspareunia, but often the condition is asymptomatic. Adolescents may inadvertently palpate a lesion on the external genitalia or may note bleeding from larger, traumatized lesions, depending on their location.

Physical Examination

A complete pelvic examination should be performed on all sexually active female adolescents who complain of lower abdominal pain, vaginal discharge or intramenstrual or postcoital vaginal bleeding, or who express concern with "something they felt" in the genital area. Before the speculum is inserted, the external genitalia should be carefully inspected for lesions. Genital warts, or condylomata acuminata, most commonly appear on squamous epithelium as irregular polypoid masses with an irregular, cauliflower-like surface that may coalesce into larger lesions. They are usually located at the posterior introitus, labia minora, and the vestibule in females, and may be found on the cervix and vagina as well. In males, warts are found more commonly on the circumcised penile shaft, glans, or corona, as well as under the foreskin of the uncircumcised penis. They also may appear as flat, flesh-colored papules on the scrotum and anus. Because this is a common location for lesions, the anus should be inspected carefully in both males and females. Intra-anal warts are seen in persons who have receptive anal intercourse, but they can also occur in both men and women who do not have a history of anal sexual contact. Condylomata plana are subclinical lesions that are not grossly visible but are apparent on colposcopy and histology. Condylomata lata are flat, flesh-colored warts that occur in moist areas (anus, scrotum, vulva) and may be associated with other signs of secondary syphilis.

Laboratory Tests

The diagnosis of genital warts is often made by visual inspection and generally does not require confirmation by biopsy. A biopsy may be required in specific instances, such as an uncertain diagnosis; the lesions are not improving or worsen with standard therapy; the lesion is atypical; the patient is immunocompromised; or the warts appear pigmented, indurated, bleeding, or ulcerated. A definitive diagnosis of HPV infection is based on detection of viral nucleic acid or capsid protein. Tests that detect specific types of HPV DNA are available but are not routinely recommended because this information would not alter the clinical management of the condition, except in extraordinary circumstances.

Subclinical HPV infection can be detected using 3% to 5% acetic acid, Schiller iodine, and colposcopy. In the past, suspicious areas of white epithelium or a specific vascular pattern consistent with HPV

infection were biopsied. However, this procedure is no longer recommended because prospective studies have shown that many cervical and anogenital lesions, if left untreated in adolescents, resolve spontaneously. For this reason, in 2009 the American College of Obstetrics and Gynecology modified their recommendations regarding screening for cervical cancer in young women to begin at 21 years of age. Of note, the American Cancer Society continues to recommend that young women start cervical screening with Pap tests 3 years after the onset of vaginal intercourse, and no later than age 21 years (see Chapter 40 for details).

NAATs for the detection of gonorrhea or chlamydia can be performed on a urine, endocervical, or vaginal specimen. Additionally, a non-treponemal antibody test for syphilis (RPR or VDRL) is indicated. An HIV antibody test should be offered to all adolescents who are deemed appropriately at risk.

A urinalysis for asymptomatic hematuria is indicated in males with visible condyloma. Its presence would indicate a urethral or meatal lesion.

Management

Although many states differ with regard to the details of health care delivery for adolescents, all 50 states including the District of Columbia allow health care providers to evaluate and treat adolescents for an STI without parental consent, except for unusual circumstances. Routine laboratory screening for common STIs is recommended at least annually in all sexually active adolescents, and as indicated for those who are symptomatic. Positive laboratory results for gonorrhea, chlamydia, syphilis, chancroid, and HIV/AIDS are reportable diseases in every state. Notification of all partners within 60 days of the onset of symptoms or diagnosis of infection or, if greater than 60 days, the last sexual partner is usually anonymous and carried out by local public health officials. Contacts are informed that a partner has been diagnosed with an STI and are instructed to be evaluated and receive treatment.

The complete treatment of the sexual partners of patients diagnosed with an STI is extremely important to prevent reinfection. However, because partners are often asymptomatic and do not seek treatment, and persistent and recurrent infection rates are reported to be particularly high among adolescents, expedited partner therapy (EPT) is now advocated in many states. Expedited partner therapy is the practice of treating the sex partners of persons with STIs without an intervening formal medical evaluation or professional prevention counseling. An extension of EPT, patient-delivered partner therapy, is another practical means for providing patients with medications or prescriptions for their partners. Care must be taken when treating the female partners of men with gonorrhea or chlamydia because of the potential for undiagnosed PID in the female partner. Therefore, as per the CDC guidelines, EPT for female partners should include a review of the symptoms of PID and advice regarding when to seek medical attention in addition to accepting the prescribed medications. Antibiotic recommendations and dosing schedules for the treatment of PID are noted in Box 97-2, as well as in Chapters 96

Box 97-2. Parenteral Regimens for the Treatment of Pelvic Inflammatory Disease

Parenteral Regimen A

Cefotetan, 2 g IV every 12 h

or

Cefoxitin, 2 g IV every 6 h

plus

Doxycycline^a, 100 mg PO
or IV every 12 h

Parenteral Regimen B

Clindamycin 900 mg IV every 8 h

plus

Gentamicin loading dose IV or IM

(2 mg/kg body weight), followed by a maintenance dose of 1.5 mg/kg every 8 h (Single daily dosing 3–5 mg/kg may be substituted.)

The above regimens are continued for 24–48 hours after the patient improves clinically. Upon discharge from the hospital, doxycycline is continued orally for a total of 14 days. Clindamycin, 450 mg PO 4 times a day, can be used as an alternative to complete 14 days of treatment.

When tubo-ovarian abscess is present, clindamycin or metronidazole with doxycycline is recommended rather than doxycycline alone.

Abbreviations: IM, intramuscularly; IV, intravenously; PO, orally.

^aDoxycycline should be administered orally when possible because of the pain associated with intravenous infusion.

(Table 96-2) and 128 (Table 128-1) for other infections. For further details regarding specific conditions and therapies, consult Selected References at the end of the chapter, specifically the CDC 2010 treatment guidelines.

In addition to antimicrobial therapy, management of an adolescent with an STI should include preventive services and counseling regarding risk reduction in a nonjudgmental and developmentally appropriate manner. In addition, the patient's primary language, culture, sexual orientation, and age should be taken into account. Adolescents with a first-time STI as well as those with recurrent STIs should be educated about disease transmission, consequences of delayed treatment, and methods for the prevention of acquiring new and recurrent infections (eg, abstinence, condom use, limiting the number of sexual partners, modifying sexual behaviors, and pre-exposure immunization [Gardasil and Cervarix]). The risk for acquiring other specific STIs, such as HIV, also should be addressed. The physician should spend time with adolescents with recurrent STIs and explore the reasons why preventive methods have failed in the past. Several factors are extremely important to consider, including an untreated partner, poor sexual judgment secondary to substance use or abuse, and noncompliance with previously prescribed treatment regimens.

Except in pregnant women, test-of-cure (repeat testing 3 to 4 weeks after completion of therapy) is not indicated in most routine cases of gonorrhea and chlamydia where the patient has been treated with an appropriate antibiotic regimen. Most post-treatment

infections are the result of reinfection rather than treatment failure and occur either because the sex partner did not receive treatment or the initiation of sexual activity with a new infected partner. Because repeat infections can increase the risk of complications such as PID and the rate of reinfection in adolescents is so high, the CDC recommends that patients with gonorrhea and chlamydia be retested 3 months after treatment.

Prognosis

If diagnosed and treated in a timely manner, the prognosis for most STIs is good, especially since the advent of observed single-dose, oral therapies for the most common STIs in adolescents. Sequelae of PID, however, regardless of treatment, include TOA and Fitz-Hugh–Curtis syndrome (perihepatitis). Long-term consequences of PID are chronic abdominal pain, ectopic pregnancy, and infertility. Currently there is no pharmacologic agent to eradicate HSV, HIV, or HPV, although acyclovir, famciclovir, and valacyclovir are useful in treating the signs of primary herpes and reducing the incidence of recurrences. Long-term safety of using valacyclovir or famciclovir for longer than 1 year currently is unknown. The prognosis for HIV is variable, depending on the individual's disease progression at the time of diagnosis and their adherence to antiretroviral therapy. Recurrence of HPV lesions is common since the virus cannot be eradicated completely despite treatment.

CASE RESOLUTION

In the case presented at the beginning of the chapter, a diagnosis of HSV can be made clinically. The adolescent should be counseled with regard to the mode of transmission, the natural history of primary versus recurrent infection, and the role of antiviral agents. A first-void urine sample should be checked for leukocyte esterase or PMN leukocytes and sent for NAATs for the detection of gonorrhea and chlamydia. A serum RPR or VDRL test should be performed as well as a thorough assessment for HIV risk. HIV testing should be offered, allowing the patient time to ask questions or decline testing. The adolescent should be given a return appointment in 1 to 2 weeks to review laboratory results, discuss possible treatment options for recurrent HSV, and explore risk-reduction behavior.

Menstrual Disorders

Monica Sifuentes, MD

CASE STUDY

A 16-year-old female presents with a 9-day history of vaginal bleeding. She has no history of abdominal pain, nausea, vomiting, fever, dysuria, or anorexia, and she reports no dizziness or syncope. Her menses usually last 4 to 5 days and, in general, occur monthly. Her last menstrual period was 3 weeks ago and was normal in duration and flow. Menarche occurred at 14 years of age. She is sexually active, has had 2 partners, and reportedly uses condoms “most of the time.” Neither she nor her current partner has ever been diagnosed with or treated for a sexually transmitted infection (STI). She has no family history of blood dyscrasias or cancer, no history of chronic illness, and takes no medications.

On physical examination, she is in no acute distress. Her temperature is 98.4°F (36.9°C). Her heart rate is 100 beats/min, and her blood pressure is 110/60 mm Hg. The physical examination, including a pelvic examination,

is unremarkable except for minimal blood noted at the vaginal introitus.

Questions

1. What menstrual disorders commonly affect adolescent females?
2. What factors contribute to the development of menstrual disorders, particularly during adolescence?
3. What relevant history should be obtained in adolescents with menstrual or pelvic complaints?
4. What treatment options are currently available for primary dysmenorrhea?
5. What conditions must be considered in adolescents with abnormal uterine bleeding?
6. How is dysfunctional uterine bleeding managed in adolescent patients?

Gynecologic concerns and complaints are common reasons for adolescent females to visit their primary care physicians. The challenge for practitioners is to differentiate between an organic etiology, functional condition, and psychogenic complaints. When this cannot be readily done or if the physical examination is equivocal, multiple diagnostic procedures may be performed, often with variable results. In addition, many pediatricians are uncomfortable evaluating gynecologic problems in adolescents and performing pelvic examinations, which contributes to this diagnostic dilemma. The purpose of this chapter is to review some of the more common gynecologic conditions affecting the adolescent female and to highlight the significant historical and physical findings associated with each problem. For a discussion of the infectious conditions that cause pelvic pain, see Chapter 97.

Epidemiology

The overall prevalence of menstrual disorders during adolescence is estimated to be 50%, with the most common gynecologic complaint being dysmenorrhea, or painful menstruation. At least 70% to 90% of women have some pain associated with menses regardless of the degree of discomfort. Although most menstruating women report mild to moderate discomfort, severe dysmenorrhea occurs in 10% to 15% of women and has been reported to be responsible for significantly limiting daily activity in these females. Uterine

anomalies or pelvic abnormalities such as endometriosis can be found in approximately 10% of adolescents and young women with severe dysmenorrhea.

Prevalence estimates regarding premenstrual syndrome (PMS) are difficult to assess because most studies in adolescents are retrospective and self-reports can be unreliable and misleading. In these studies, between 30% and 75% of older adolescents report significant PMS-type complaints. An estimated 20% to 40% of adult women experience PMS symptoms bothersome enough to impair daily functions, and 5% to 10% have debilitating symptoms. Other menstrual problems in adolescents include abnormal uterine bleeding, vaginal discharge, and amenorrhea.

Several factors contribute to the occurrence of gynecologic problems during adolescence. The average age of menarche in the United States is 12.5 years (range: 9–16 years). Bleeding may be irregular or prolonged initially because 50% to 80% of menstrual cycles are anovulatory and irregular during the first 2 years after menarche. Once ovulatory cycles are established, bleeding problems may resolve, but menstrual symptoms such as pain, headache, and vomiting may predominate. Early sexual activity among adolescents and associated STIs also may contribute to the presence of certain gynecologic conditions in this age group, particularly vaginitis and abnormal uterine bleeding.

Clinical Presentation

Adolescents with menstrual disorders may present in a variety of ways. They may have specific symptoms, such as heavy bleeding, irregular periods, or painful menses, or more general complaints, such as fatigue, dizziness, and syncope (Dx Box). In addition, adolescents or their parents may have questions or concerns about delayed pubertal development and amenorrhea.

Dx

Menstrual Disorders

Primary Dysmenorrhea

- Painful menstruation
- Lower abdominal pain associated with menstruation, usually worse on the first few days of bleeding
- Associated back pain
- Pain sometimes accompanied by nausea, vomiting, fatigue, headache, bloating, and diarrhea
- Symptoms began 6 to 12 months after menarche

Dysfunctional Uterine Bleeding

- Prolonged bleeding (>8 days) *or*
- Excessive bleeding (>6 tampons/pads per day) *or*
- Frequent uterine bleeding (≤ 21 days)
- No demonstrable organic etiology
- Normal laboratory studies, except may have anemia

Primary Amenorrhea

- No spontaneous menstruation in a female of reproductive age
- Absence of menarche by age 16 in a female with normal pubertal development *or*
- Absence of menarche by age 14 in a female with no secondary sexual development *or*
- Absence of menarche within 1 to 2 years of reaching full sexual maturation (sexual maturity rating 5)

Pathophysiology

Puberty and the Normal Menstrual Cycle

Figure 98-1 depicts the menstrual cycle, which typically lasts for 21 to 35 days, with a mean length of approximately 28 days. Normal duration of menses is 4 to 7 days. Blood loss is usually 30 to 40 mL per cycle, and most women do not lose more than 60 mL per cycle. Regular ovulatory cycles usually do not occur until 2 to 3 years after menarche, although 10% to 20% of cycles can remain anovulatory as long as 5 years after menarche.

One-quarter of females begin menstruating when they reach sexual maturity rating (SMR) (Tanner stage) 3 of sexual maturation, but approximately two-thirds do not menstruate until they reach SMR 4 breast and genital development. It is important to note that several other processes occur before the onset of menstruation. Thelarche, or the beginning of breast development, takes place approximately 2 to 3 years before menarche, and growth acceleration usually begins about 1 year before thelarche.

Dysmenorrhea

This condition is often accompanied by other symptoms such as nausea, vomiting, diarrhea, bloating, low back pain, and headaches. It can be classified as either primary or secondary. Primary dysmenorrhea occurs in the absence of any pelvic pathology and is most commonly seen in adolescents once ovulatory cycles are established. Secondary dysmenorrhea refers to painful menses associated with some underlying pelvic pathology, such as pelvic inflammatory disease, endometriosis, ovarian cysts or tumors, or cervical stenosis. A complete list of causes of secondary amenorrhea can be found in Box 98-1. In adolescents, endometriosis is the most common cause of secondary dysmenorrhea.

Numerous studies have shown that cell membrane phospholipids, endometrial prostaglandins, and leukotrienes play a role in the pathogenesis of primary dysmenorrhea. After ovulation, fatty acids build up in the phospholipids of the cell membrane in response to the production of progesterone. Arachidonic acid as well as other omega-7 fatty acids are then released after the onset of progesterone withdrawal before menstruation. A cascade of prostaglandins and leukotrienes is initiated in the uterus during menses, which leads to an inflammatory response. Prostaglandin $F_{2\alpha}$, produced locally by the endometrium from arachidonic acid, is a potent vasoconstrictor and myometrial stimulant that causes uterine contractions, leading to tissue ischemia and pain. Another prostaglandin, $E_{2\alpha}$, causes hypersensitivity of the pain nerve terminals in the uterine myometrium. The cumulative effect of these prostaglandins may cause the pain of primary dysmenorrhea. Hormonal and endocrine factors also may play a role in the etiology of primary dysmenorrhea because ovulatory cycles with estrogen and progesterone are necessary for development of the condition.

Most cases of primary dysmenorrhea begin 6 to 12 months after menarche, and symptoms gradually increase until patients reach their mid-20s. Parity and advancing age are associated with a decrease in symptomatology.

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding (DUB) is defined as abnormal or excessive endometrial bleeding in the absence of any pelvic pathology. Menstruation is considered excessive if the cycles are short (<21 days) and the bleeding is prolonged (≥ 8 days). Although DUB is the most common cause of abnormal or excessive vaginal bleeding in adolescents, it should be considered a diagnosis of exclusion. Other causes of abnormal bleeding should first be investigated by obtaining a thorough history, performing a complete physical examination, and obtaining laboratory studies as indicated.

Dysfunctional uterine bleeding is usually the result of anovulatory, immature menstrual cycles. In adolescents, 50% of menstrual cycles are anovulatory within the first 2 years of menarche. If menarche occurs later in adolescence (ie, at SMR 5), this period of anovulation reportedly lasts even longer. Most cases of DUB in adolescence are thought to result from the delayed maturation of the hypothalamic-pituitary-ovarian axis. Normally, a positive feedback

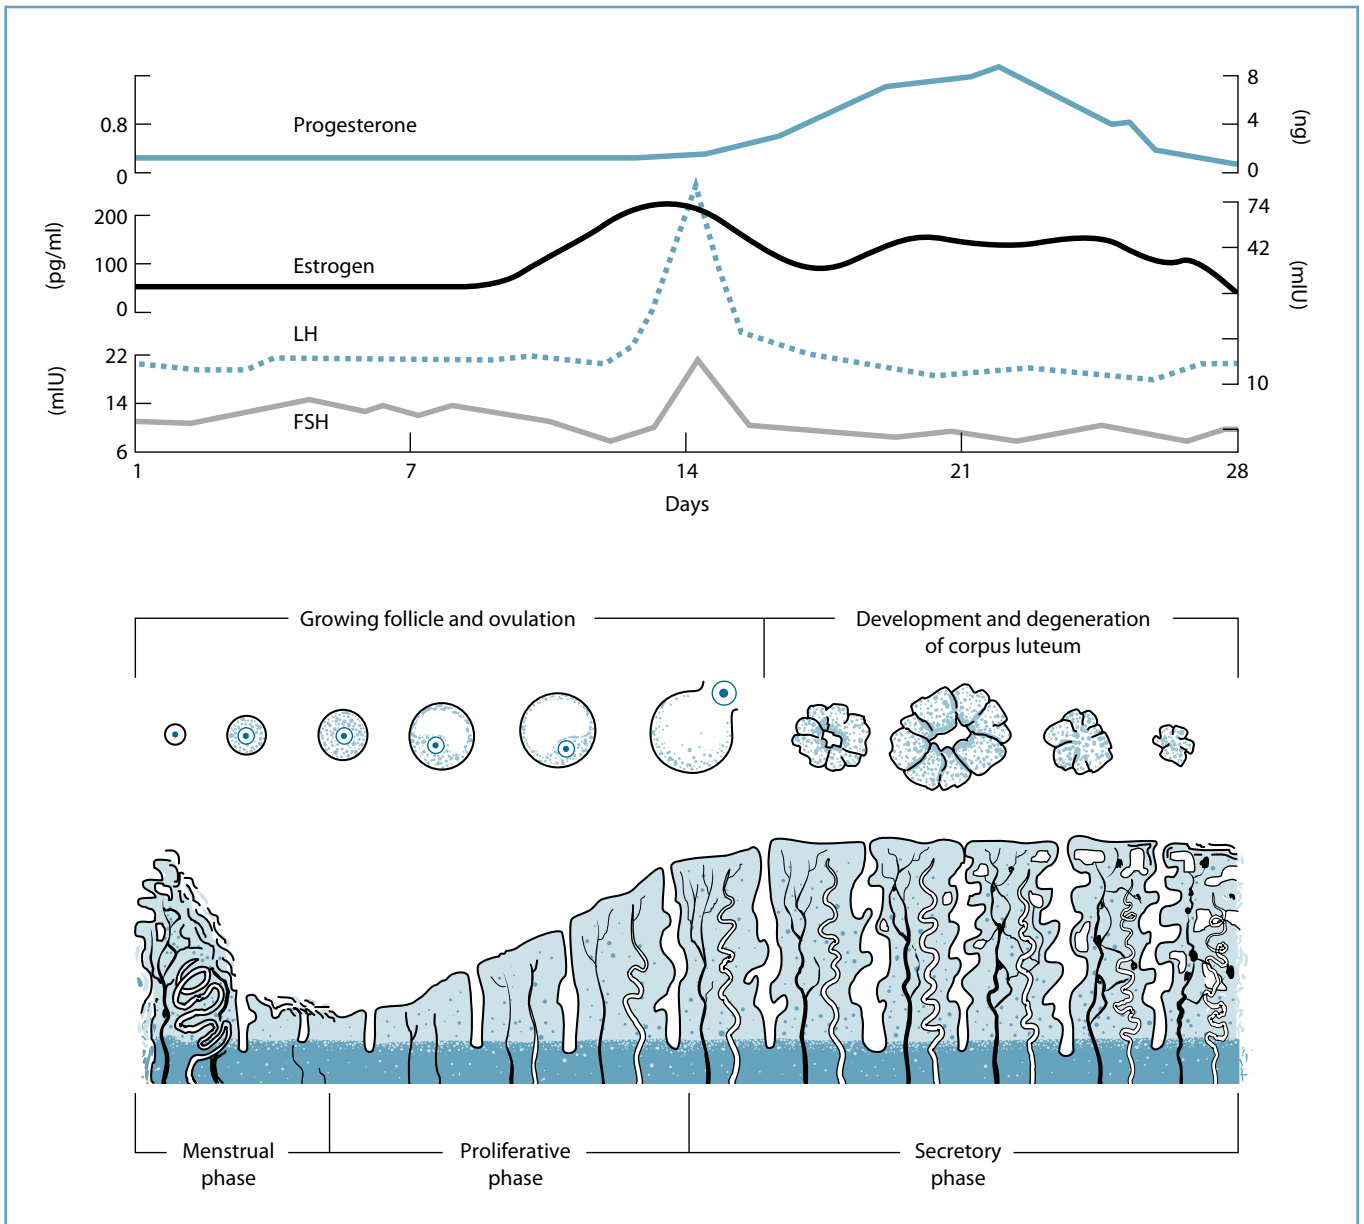

Figure 98-1. The normal ovulatory menstrual cycle. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

mechanism develops with rising estrogen levels, resulting in a surge in luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which triggers ovulation. The progesterone-producing corpus luteum then stimulates development of the secretory endometrium, with subsequent shedding after approximately 14 days if no fertilization occurs (menses). With anovulation, there is no progesterone-producing corpus luteum and, therefore, no development of a secretory endometrium. Thus estrogen remains unopposed, and proliferative endometrium continues to accumulate. Finally, when the tissue can no longer maintain its integrity, it sloughs. In addition, without progesterone, the normal vasospasm that helps limit endometrial bleeding does not occur. Hence, bleeding is prolonged, frequent, and heavy.

Premenstrual Syndrome

Premenstrual syndrome refers to a group of physical, cognitive, affective, and behavioral symptoms that occur prior to menses (during the luteal phase of the menstrual cycle) and resolve within a few days following the onset of menstruation. A variety of mechanisms have been proposed, including an increased sensitivity to the normal cyclic fluctuations in steroid hormones and releasing factors and alterations in neurotransmitters such as endorphins, γ -aminobutyric acid, and serotonin. The exact etiology remains unknown, however, despite multiple studies aimed at pinpointing the cause of this complex condition. Various other hormonal factors have been implicated as possibly having a relationship with PMS, including prolactin,

Box 98-1. Differential Diagnosis of Common Menstrual Disorders

Dysmenorrhea

- Primary
- Secondary
- Endometriosis
- PID
- Uterine myomas, polyps, or adhesions
- Adenomyosis
- Ovarian cysts or tumors
- Presence of an intrauterine device
- Cervical stenosis or strictures
- Congenital malformations (ie, septate uterus, imperforate hymen)

Abnormal Vaginal Bleeding

- Dysfunctional uterine bleeding: anovulation
- Complications of pregnancy: spontaneous/threatened/incomplete abortion, ectopic pregnancy, hydatidiform mole
- Infections of the lower and upper genital tract: PID, cervicitis/vaginitis
- Blood dyscrasias and thrombocytopenia: vWD, ITP, leukemia, platelet defects, leukemia, aplastic anemia
- Endocrine disorders: hypothyroidism and hyperthyroidism, hyperprolactinemia, late-onset 21-hydroxylase deficiency, Cushing or Addison disease, PCOS
- Vaginal anomalies: carcinoma
- Cervical/uterine abnormalities: endometriosis, polyp, hemangioma, sarcoma
- Ovarian abnormalities: ovarian failure, tumors, cysts
- Systemic illness: IBD, malignancy, SLE, diabetes mellitus
- Foreign body: retained condom or tampon, IUD
- Medications: aspirin, anticoagulants, hormonal contraception, androgens
- Trauma or sexual assault

Amenorrhea

- Pregnancy
- Systemic abnormalities: endocrinopathies (hypothyroidism, Cushing syndrome), chronic diseases (IBD, sickle cell disease), poor nutrition (anorexia nervosa), obesity, intense exercise, stress, drugs (opiates, valproate)
- Hypothalamic lesions: tumors, infiltrative lesions (TB, CNS leukemia)
- Pituitary lesions: prolactinoma, drugs causing elevated prolactins (marijuana, cocaine), cranial irradiation
- Ovarian failure: gonadal dysgenesis, autoimmune failure, galactosemia
- Congenital abnormalities of the reproductive tract: imperforate hymen, transverse vaginal septum, absence or abnormality of the uterus, complete androgen insensitivity (46, XY-testicular feminization)
- Androgen excess: PCOS, benign ovarian androgen excess

Abbreviations: CNS, central nervous system; IBD, inflammatory bowel disease; ITP, idiopathic thrombocytopenic purpura; IUD, intrauterine device; PCOS, polycystic ovary syndrome; PID, pelvic inflammatory disease; SLE, systemic lupus erythematosus; TB, tuberculosis; vWD, von Willebrand disease.

growth hormone, thyroid hormone, FSH, antidiuretic hormone, insulin, and cortisol. Vitamin deficiencies also have been considered, but have not been documented consistently in the medical literature.

Amenorrhea

Amenorrhea is defined as the lack of spontaneous menstruation in women of reproductive age. Like dysmenorrhea, it can be considered primary or secondary. Traditionally **primary amenorrhea** can be further defined by the following criteria: (1) an absence of menarche by age 16 years in females with otherwise normal pubertal development, (2) an absence of menarche by the age of 14 years in females with no secondary sexual development, and (3) an absence of menarche within 1 to 2 years of reaching SMR 5 pubic hair. Causes of primary amenorrhea range from congenital anatomical anomalies to genetic and endocrine conditions. However, since many of these disorders can be diagnosed and treated earlier than 16 years of age, guidelines have been modified regarding when menstrual conditions should be evaluated (Box 98-2). A detailed discussion of each of these etiologies that cause primary amenorrhea is beyond the scope of this chapter. See Selected References for more information.

Secondary amenorrhea occurs in females who have already established menstruation but have had no periods for 6 months or the equivalent of 3 cycles. The most common cause of secondary amenorrhea is pregnancy, which must be ruled out in all adolescents presenting with this complaint, regardless of their acknowledgment of sexual activity. Other causes include infections, systemic illnesses, significant weight loss, stress, exercise, eating disorders (eg, anorexia nervosa), and certain medications.

Box 98-2. Menstrual Conditions That May Require Evaluation*

Menses that

- Have not started within 3 years of thelarche
- Have not started by 13 years of age with no signs of pubertal development
- Have not started by 14 years of age with
 - Signs of hirsutism *or*
 - A history or physical examination suggestive of excessive exercise or eating disorder *or*
 - Concerns about an outflow tract obstruction or anomaly
- Have not started by 15 years of age
- Are regular, occurring monthly, then become markedly irregular
- Occur more frequently than every 21 days or less frequently than every 45 days
- Occur 90 days apart even for one cycle
- Last >7 days
- Require frequent pad/tampon changes (soaking more than 1 every 1–2 hours)

*Modified from: American Academy of Pediatrics Committee on Adolescence. Menstruation in girls and adolescents: using the menstrual cycle as a vital sign. *Pediatrics*. 2006;118:2248.

Vaginal Discharge

Vaginal discharge can be normal (physiological). A thin, white discharge, known as leukorrhea, occurs approximately 6 months to 1 year prior to the onset of menarche. A purulent, malodorous, or bloody discharge is considered abnormal, however. Etiologies are varied and may be infectious, inflammatory, or traumatic (see Chapters 96 and 97).

Differential Diagnosis

The differential diagnosis of common menstrual disorders is extensive and can be found in Box 98-1. Other etiologies of pelvic pain include midcycle menstrual disorders (eg, mittelschmerz), urinary tract infections, complications of untreated/inadequately treated PID, and abdominal conditions such as inflammatory bowel disease and irritable bowel syndrome. Psychogenic pain also should be considered as a cause of recurrent pelvic pain and may be secondary to depression, anxiety, previous sexual abuse, or another psychological condition.

Evaluation

History

A thorough history should be obtained in adolescent females with suspected menstrual disorders because many non-gynecologic conditions can affect menses as well. A complete psychosocial assessment also should be performed. The acronym **HEADSSS** (*home environment, employment and education, activities, diet, drugs, sexual activity/sexuality, suicide/depression, safety*) serves as a useful tool when interviewing adolescents (see Chapter 6).

Most of the interview should then focus on the gynecologic history (Box 98-3), including pattern of menstrual bleeding, and any associated problems (Questions Box). With primary dysmenorrhea,

Box 98-3. Gynecologic History

- Age at menarche
- Date of last menstrual period
- Regularity of menses
- Duration and pattern of bleeding
- Amount of flow (number of pads/tampons used per day and amount of saturation)
- Associated menstrual symptoms such as bloating, headache, lower abdominal pain, and cramping
- Maternal and sibling gynecologic history
- Treatment of menstrual symptoms
- Sexual activity (consensual and nonconsensual)
- Age at debut
- Number of partners and ages
- Date of last sexual encounter
- Protected versus unprotected vaginal intercourse
- Current method of contraception

Questions

Menstrual Disorders

Dysmenorrhea

- What is the pain like?
- Does it always occur with menses?
- When did the pain first begin?
- How frequently does the pain occur?
- How long does the pain last?
- Are any symptoms associated with the pain (eg, nausea, vomiting, diarrhea, headache)?
- Does the adolescent miss a lot of school or work as a result of painful menses?
- Do the painful menses interfere with other activities?
- What does the adolescent do for the pain? Has she tried any medications or complementary or alternative remedies?
- Is there a maternal or sibling history of painful menses?

Abnormal Uterine Bleeding

- Does the adolescent have any symptoms of anemia?
- Is she fatigued, easily tired, dizzy, or short of breath?
- Has she experienced any syncopal episodes?
- Does the adolescent have any history of blood loss in the urine or stool?
- Is there any evidence or a family history of a bleeding disorder (eg, easy bruisability, bleeding from the gums or nares)?
- Does the adolescent have any symptoms of pregnancy (eg, breast tenderness, nausea, fatigue)?
- Is there any known exposure to sexually transmitted infections?
- Is there a marked change in the adolescent's weight? Has the adolescent been on any diets recently?
- Is the adolescent using any medications such as aspirin, oral contraceptives, long-acting progestins, psychotropic medications, or anticoagulants?
- Does the adolescent have a history of a systemic illness such as systemic lupus erythematosus, diabetes mellitus, or renal disease? Does the adolescent have a history of trauma?
- Is the bleeding cyclic in nature?
- Is there breakthrough bleeding throughout the cycle?
- Is there a family history of bleeding disorders, type 2 diabetes mellitus, polycystic ovary syndrome, or thyroid disease?

Amenorrhea

- Has the adolescent ever had a period?
- Has she noticed any other changes associated with puberty (eg, breast development, pubic hair, growth spurt)?
- Does she have any other symptoms such as galactorrhea, weight loss, or hirsutism?
- Has the adolescent experienced significant changes/stressors in her life (eg, parental divorce, new school)?
- How often does the adolescent exercise?
- What is the adolescent's typical diet or are there any dietary restrictions (eg, vegetarian)?

pain that radiates to the anterior thighs or the lower back is not uncommon. The color of the blood may be helpful when assessing abnormal uterine bleeding. Brown or dark blood may be associated with a cervical obstruction or endometriosis, whereas red or pink blood is found with most other conditions. More importantly, the timing of the bleeding is extremely significant. Cyclical bleeding beginning at menarche is more consistent with the presence of a blood dyscrasia. In contrast, breakthrough bleeding throughout the cycle may indicate an infection, endometriosis, or perhaps a polyp. The passing of blood clots on rising in the morning is not uncommon secondary to the vaginal pooling of blood while the patient is supine. Clots throughout the day, however, are not normal and require further investigation.

Physical Examination

A complete physical examination, including an evaluation for stigmata of a systemic illness, must be performed in adolescent females with suspected menstrual disorders. Patients' height and weight should be plotted on the growth chart and compared with previous measurements. Depending on the SMR, physicians can then determine if they have experienced their expected growth spurt. Body mass index (body mass index = weight, kg/[height, m]²) also should be calculated and compared with previous values, especially in females with amenorrhea. Vital signs, including orthostatic measurements, are a screen for significant blood loss with resultant anemia and are especially important in patients with excessive uterine bleeding. The skin should be inspected for any evidence of androgen excess (eg, hirsutism, acne, acanthosis nigricans), bruising, or petechiae. The thyroid gland should be palpated for masses or any evidence of hypertrophy, and the abdomen and suprapubic area also should be palpated for masses.

In addition, the SMR of the breasts should be noted and compared with pubic hair development, particularly in adolescents with primary amenorrhea. The presence or absence of galactorrhea also should be noted. The external genitalia should then be carefully inspected for clitoral size (normal clitoral glans width 2–4 mm) and patency of the hymen. A bimanual or rectoabdominal examination should be performed in adolescents who are not sexually active to ensure the presence of a normal vagina, uterus, and adnexa. A speculum examination is generally not necessary for the virginal adolescent with suspected DUB or simple primary dysmenorrhea. If the sexually active teen is asymptomatic, screening for STIs, particularly chlamydia and gonorrhea, can be performed noninvasively using a voided urine sample, and the pelvic examination can be deferred. However, in adolescents who are sexually active and have an abnormal vaginal discharge, intercycle menstrual bleeding, history of dyspareunia, or lower abdominal pain, a complete pelvic and bimanual examination is indicated.

Laboratory Tests

The performance of laboratory studies depends on the particular menstrual complaint. No laboratory studies initially are necessary for primary dysmenorrhea because the diagnosis is usually based on

the clinical history and physical examination. The same is true for PMS. For a discussion of the diagnostic evaluation of amenorrhea, refer to Selected References.

In the case of abnormal uterine bleeding, baseline studies must include a hemoglobin or hematocrit. Other initial laboratory studies should include a complete blood cell count to evaluate the red cell indices and platelets, a reticulocyte count, and a urine pregnancy test. Further diagnostic studies depend on the severity of the anemia and findings on history and physical examination. These may include coagulation studies (prothrombin time/partial thromboplastin time), erythrocyte sedimentation rate, and thyroid function tests. Other tests for the evaluation of a blood dyscrasia, such as a von Willebrand panel, should be performed in the patient presenting with severe anemia, especially at menarche. The studies should be performed in consultation with a pediatric hematologist and obtained prior to the administration of any estrogen-containing medications, which may affect the results of certain assays. If the patient is sexually active and a pelvic examination is performed, an endocervical specimen can be obtained for nucleic acid amplification tests (NAATs) for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. NAATs of the urine to screen for gonorrhea and chlamydia are also available (eg, ligase chain reaction, polymerase chain reaction); however, a speculum examination is still generally indicated for abnormal vaginal bleeding. Follicle-stimulating hormone, LH, prolactin, testosterone, free testosterone, and dehydroepiandrosterone sulfate studies should be performed in patients with a history of chronic anovulation or in whom androgen excess is suspected.

Imaging Studies

A transabdominal or transvaginal pelvic ultrasound or computed tomography scan of the pelvis can be helpful in patients with abnormal uterine bleeding or amenorrhea if a mass is suspected or palpated on physical examination. Complex congenital anomalies, such as a longitudinal vaginal septum with hemi-obstruction, cervical agenesis or stenosis, or a partially obstructing uterine septum, may require magnetic resonance imaging if pelvic ultrasonography is inconclusive. Plain radiographs are not indicated.

Management

With each of these adolescent gynecologic conditions, effective treatment is multifaceted and includes patient and parent education, reassurance regarding the ease with which the condition can be treated, and appropriate medications for those conditions requiring therapy. In general, a **menstrual calendar** or diary initially can be very helpful with most gynecologic conditions to confirm the severity of the bleeding and to assess the pattern of the menstrual cycle.

Dysmenorrhea

General measures in the treatment of dysmenorrhea include education about menstruation, proper nutrition, application of heat (hot water bottle or heating pad), simple exercise, and psychological support. In addition, transcutaneous electrical nerve stimulation has been shown to have some efficacy as a nonpharmacologic therapy

for primary dysmenorrhea. It has been reported to work by blocking efferent pain stimuli.

For mild to moderate symptoms of dysmenorrhea, over-the-counter **nonsteroidal anti-inflammatory drugs (NSAIDs)**, such as ibuprofen and naproxen sodium, are appropriate for pain management and can also reduce blood loss. Physicians most often suggest that patients use ibuprofen initially because it is safe as well as efficacious when taken in appropriate doses and frequency. The dose is 200 to 400 mg every 4 to 6 hours. Ibuprofen should be taken at the onset of the menstrual cycle and continued for 24 to 72 hours.

For moderate to severe dysmenorrhea in patients who are not sexually active and do not desire birth control, a stronger NSAID, such as naproxen, is the treatment of choice (Table 98-1). The major mechanism of action of NSAIDs is the inhibition of prostaglandin synthesis. Side effects of these drugs, which most commonly relate to the gastrointestinal tract, are nausea, vomiting, and dyspepsia. These reactions can be minimized by taking the medication with food or an antacid. Other adverse reactions include renal effects; skin reactions, such as erythema multiforme and urticaria; and central nervous system effects, including headache and dizziness. Contraindications to NSAID use include peptic ulcer disease, clotting disorders, and renal disease. All NSAIDs should be administered with food and taken for 3 to 4 menstrual cycles before their efficacy is judged.

Table 98-1. Nonsteroidal Anti-inflammatory Drugs in the Treatment of Primary Dysmenorrhea

Generic	Trade Name(s)	Dosage
Ibuprofen	Motrin, Advil	200–400 mg every 4–6 h for 24–72 h
Naproxen	Aleve, Naprosyn	440 mg at onset, then 220 mg every 8–12 h 500 mg at onset, then 250 mg every 4–6 h
Naproxen sodium	Anaprox	500 mg at onset, then 275 mg every 6–8 h
Mefenamic acid	Ponstel	500 mg at onset, then 250 mg every 6–8 h

Low-dose combination oral contraceptives are indicated in adolescents with moderate or severe dysmenorrhea who are sexually active or in patients whose symptoms are not sufficiently relieved by NSAIDs alone and whose own medical or family history does not preclude their use. Oral contraceptives decrease the production of prostaglandins by inhibiting ovulation as well as endometrial growth. Because the symptoms of dysmenorrhea are prevented only after several cycles of oral contraceptive pill (OCP) usage, patients should be told not to expect complete resolution of symptoms during the first month of treatment. Most adolescents who fit the classic clinical presentation of primary dysmenorrhea do not warrant a pelvic examination prior to initiating oral contraceptives. If an adolescent is sexually active, routine STI screening can be performed using urine-based NAATs.

Thirty or 35 µg of ethinyl estradiol-containing oral contraceptives should be used for a minimum of 3 to 4 months. If symptoms do not improve, then an NSAID can be added to the treatment regimen. Oral contraceptives are more than 90% effective in cases of severe dysmenorrhea, and physicians should emphasize this hormonal benefit to both patients and their parents. Although 20 µg of ethinyl estradiol-containing OCP formulations are now available, the literature remains inconclusive regarding their first-line use for primary dysmenorrhea.

If the patient continues to have dysmenorrhea despite the judicious use of NSAIDs and oral contraceptives, a search for other pelvic pathology is warranted and the patient should be referred for possible laparoscopy.

Dysfunctional Uterine Bleeding (Table 98-2)

The management of DUB depends on the severity and frequency of the bleeding and the degree of anemia. The goal of treatment is 4-fold: (1) to control the bleeding, (2) to correct the anemia, (3) to replenish iron stores, and (4) to prevent further episodes of bleeding. Patients with mild or moderate anemia can be treated as outpatients with weekly to monthly follow-up depending on how quickly the bleeding stops. Although monophasic **combination oral contraceptives** are appropriate in the treatment of DUB if the condition is moderate or if birth control is desired, **other hormone regimens**, such

Table 98-2. General Guidelines for the Management of Dysfunctional Uterine Bleeding in Adolescents

	Mild Anemia	Moderate Anemia	Severe Anemia
Hemoglobin (g/dL)	>11	9–11	<9
Management	Reassurance, menstrual calendar, supplemental iron twice daily, COCP 1 pill daily (if sexually active) *Consider NSAID to help reduce blood loss	Initially, 2–3 monophasic COCPs (30–35 µg ethinyl estradiol and potent progestin ^a) every day to control the bleeding with antiemetic, then cycle for minimum of 3 mo; oral iron supplementation *Consider NSAID to help reduce blood loss	Hospitalization if signs of hypovolemia; consider intravenous estrogen until bleeding stops; begin 2–4 monophasic COCPs (50 µg ethinyl estradiol and potent progestin ^a) every day with antiemetic and taper over 21 days, then cycle with monophasic COCPs (30–35 µg ethinyl estradiol) for 3–6 mo; oral iron supplementation
Follow-up	2–3 mo	2–3 wk, then every 2–3 mo	1–2 wk, then every month

Abbreviation: COCP, combination oral contraceptive pill; NSAID, nonsteroidal anti-inflammatory drug.

^aPotent progestin: norgestrel or levonorgestrel.

as estrogen (alone) or synthetic progestin (alone), also can be used. This is especially important in adolescents who have a medical contraindication or disinterest in combined OCP therapy. **Supplemental oral iron therapy** is also required in all teens who are anemic.

Most adolescent females with severe bleeding and anemia require a more extensive evaluation, and such patients usually are hospitalized for appropriate parenteral therapy and possible blood transfusion. Occasionally, intravenous conjugated estrogens may be required every 4 to 6 hours for the first 24 hours to stop severe acute hemorrhage. Otherwise, in cases of severe anemia, a combination oral contraceptive containing 50 µg or 30 µg of ethinyl estradiol is initiated 3 to 4 times a day; the progesterone component is necessary to stabilize the endometrium. In addition, an antiemetic is often required 1 to 2 hours prior to the OCP during the first few days of therapy. Once bleeding is controlled, the frequency of OCP administration can be tapered, and adolescents can continue a monophasic combined oral contraceptive for a total of 21 days and then switch to a lower-dose combination oral contraceptive for at least 3 cycles. Studies have demonstrated that 20% to 25% of adolescents who require hospitalization for severe anemia within the first year following menarche have an underlying coagulopathy. In cases of DUB where oral contraceptives are used but patients do not desire birth control, oral contraceptives should not be stopped until at least 3 months after the anemia has resolved to ensure restoration of iron stores.

Surgical treatment, such as dilatation and curettage, is rarely indicated in the adolescent patient and is reserved for patients refractory to aggressive medical treatment.

Premenstrual Syndrome

Although various sources have advocated many different treatment regimens for the management of PMS, no definitive studies have been reported, and no single effective treatment has been found. Therapies for mild to moderate symptoms include diet modification for patients who complain predominantly of bloating, promotion of regular aerobic exercise, education regarding menstrual physiology and the relationship of changing hormones to symptoms, stress management, and cognitive-behavior therapy or group therapy. Calcium supplements also can be recommended initially. Although positive outcomes have been reported with vitamin and mineral supplementation as well as with certain herbal preparations, more research is needed to definitively recommend their usage. Of note, some therapies that had been used extensively in the past also have been associated with undesirable outcomes, such as the development of peripheral neuropathy with pyridoxine (B₆) at high doses. Combined OCPs, NSAIDs, and spironolactone may be helpful if physical symptoms predominate. Other medications that may be used when mood symptoms predominate and are significantly impairing function are the selective serotonin reuptake inhibitors such as fluoxetine and/or an anxiolytic, specifically alprazolam.

Vaginitis

See Chapters 96 and 97 for a discussion of the management of vaginal discharge in adolescents.

Prognosis

Most adolescents with common menstrual complaints who receive aggressive, appropriate care are symptom-free after 3 to 4 months of continuous therapy. Complications associated with oral contraceptive use and NSAIDs are rare in this otherwise healthy patient population. Symptoms associated with an immature hypothalamic-pituitary-ovarian axis, such as anovulatory bleeding and DUB, often resolve spontaneously. The prognosis for adolescents with amenorrhea depends in part on the underlying etiology.

CASE RESOLUTION

In the case presented at the beginning of the chapter, more information should be obtained to exclude the numerous other causes of abnormal uterine bleeding in the adolescent before a diagnosis of dysfunctional uterine bleeding can be made. Questions about breast tenderness, galactorrhea, weight loss, fatigue, visual changes, prolonged bleeding, and easy bruisability can be particularly important. If the adolescent has no other complaints, a hemoglobin or hematocrit as well as a complete blood cell count and a pregnancy test should be performed. An endocervical or urine specimen should be sent for NAATs for gonorrhea and chlamydia. Depending on the degree of anemia and the desire for contraception, the adolescent should be placed on twice-daily iron supplementation and oral combined hormonal therapy for at least 3 months.

Disorders of the Breast

Monica Sifuentes, MD

CASE STUDY

A 2-year-old girl is brought to the office for bilateral breast swelling first noticed 3 weeks ago by her mother. The swelling is non-tender and does not appear to be increasing in size. There is no history of galactorrhea. The child is otherwise healthy, takes no medications, and is not using any estrogen-containing creams or other products.

On physical examination, the vital signs are normal, and the child is at the 50th percentile for height and weight. A 1.5-cm firm, non-tender mass is palpated below her left nipple. Below the right nipple, a 1-cm non-tender mass of similar consistency is present. There is no discharge from either nipple and no areolar widening. The abdomen is soft with no masses palpated. The genitalia are those of a normal prepubescent female with no pubic hair and vaginal mucosa that appears red and not estrogenized.

Questions

1. What is premature thelarche, and how can it be differentiated from true precocious puberty?
2. What are the most common causes of breast hypertrophy in the infant?
3. When does pubertal breast development normally occur in females?
4. What are the most common causes of breast masses in adolescent females and how should they be managed?
5. How can transient pubertal gynecomastia be differentiated from pathologic causes of gynecomastia in young males?

Breast disorders can occur in all pediatric age groups. The neonate may present to the pediatrician with bilateral breast hypertrophy and galactorrhea or mastitis. A bewildered parent might bring in a young prepubertal daughter because of early breast development. An anxious adolescent female may notice for the first time that her breasts are asymmetrical, or she may feel a lump beneath the skin. An adolescent male can present with unilateral or bilateral gynecomastia that causes him severe psychological distress. Whatever the underlying cause, breast problems can be disconcerting at any age. Primary care providers should be equipped to differentiate between normal variants of growth and pathologic conditions in infants, children, and adolescents. Although rare, significant disorders can then be diagnosed and treated appropriately.

Epidemiology

Breast problems range from congenital anomalies and benign disorders related to hormonal stimulation to breast masses and tumors. Serious disorders such as breast cancer are practically unheard of in children and adolescents, although inappropriate breast enlargement or gynecomastia as a sign of another neoplastic process is not uncommon.

Benign breast hypertrophy can occur in 60% to 90% of neonates and is seen in both male and female term infants. It may occur unilaterally or bilaterally. Occasionally there is a nipple discharge, particularly in the case of well-intentioned family members who try to “extract the milk,” inadvertently promoting the central secretion of prolactin and oxytocin via breast stimulation.

Congenital anomalies of the breast include polythelia, athelia, polymastia, and amastia. Breast deformities such as a tuberous breast anomaly also can be thought of as a congenital anomaly, although it is not manifested until puberty when breast growth normally occurs. Polythelia, or extra nipples, can be found anywhere along the embryonic “milk line” from the axilla to the groin and is seen in 2% of the general population (Figure 99-1). Reportedly, abnormalities of the urologic and cardiovascular systems have been associated with polythelia. Polymastia refers to supernumerary breasts along the milk line and is seen less frequently than polythelia. The usual locations for supernumerary breasts are below the breast on the chest or the upper abdomen. Both polythelia and polymastia may be familial and can occur bilaterally as well as unilaterally.

Amastia (absence of a breast) and athelia (absence of a nipple) are rare occurrences, but their presence often is associated with other anomalies of the chest wall such as pectus excavatum. Amastia also is seen in Poland syndrome (Figure 99-2), which includes absence of the ipsilateral pectoral muscles, various rib deformities and upper limb defects such as syndactyly (webbed fingers), and radial nerve aplasia.

Premature thelarche is isolated unilateral or bilateral breast development in girls between 1 and 4 years of age without other signs of sexual maturation (eg, pubic hair, estrogenized vaginal mucosa, acceleration of linear growth). It has been estimated that 60% of cases occur between 6 months and 2 years of age and that a diagnosis after 4 years of age is uncommon. In contrast, precocious puberty is the appearance of any sign of secondary sexual maturation before age 7

Figure 99-1. Polythelia. Supernumerary nipples along the embryonic mammary ridge (milk line).

Figure 99-2. Amastia. Unilateral (left) complete absence of breast tissue.

in Caucasian girls or age 9 in boys. In young females, this involves either breast or pubic hair development, and in males, pubic hair or testicular enlargement.

Gynecomastia commonly occurs in males progressing through puberty and is often called transient or physiological pubertal gynecomastia (Figure 99-3). An estimated 70% of adolescent males are said to be affected, with a peak incidence between ages 13 and 14. This generally corresponds to sexual maturity rating (SMR) (Tanner stage) 2 to 3 genital and pubic hair development in the young male. Like breast development in the pubertal female, transient pubertal

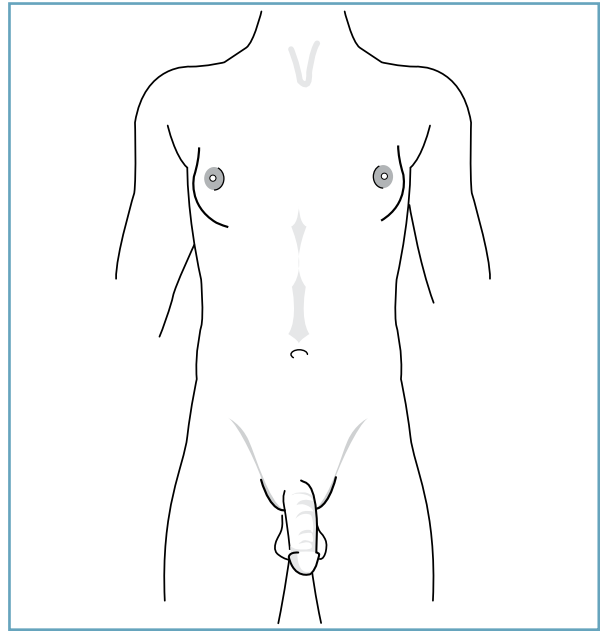

Figure 99-3. Gynecomastia. Breast tissue development in a male.

gynecomastia may be asymmetrical, although concurrent or sequential involvement of both breasts can occur.

In the adolescent female, breast masses are not uncommon; however, clinically significant lesions are rare. Breast cancer per se has an estimated annual incidence of 0.1:100,000 adolescents. In most patient series through age 20, the most common breast tumor is the fibroadenoma, which has been reported in 60% to 95% of biopsied lesions. Two-thirds of these lesions are located in the lateral quadrants of the breast, with most in the upper outer quadrant. Their peak incidence is in late adolescence (17–21 years of age), and they tend to occur more commonly in African American females. In addition, 25% of cases involve multiple fibroadenomas.

Fibrocystic changes are the second most common histologic diagnosis after fibroadenomas. Other breast masses include solitary cysts; abscesses; lipomas; and cystosarcoma phyllodes, a rare, slow-growing, painless breast tumor that is nearly always benign.

Malignancy is reported in less than 1% of excised lesions. There are fewer than 50 cases of primary breast cancer in children and adolescents reported in the literature to date. Rhabdomyosarcoma and fibrosarcomas are among the other rarely reported primary tumors of the breast in adolescents. Metastatic cancer of the breast has been reported in children with primary hepatocellular carcinoma, Hodgkin and non-Hodgkin lymphoma, neuroblastoma, and rhabdomyosarcoma. Of note is the increased lifetime risk for breast cancer in pubertal girls who receive chest wall irradiation, generally administered during treatment for Hodgkin lymphoma.

Normal Breast Development

In the adolescent female, the first sign of puberty is breast development. This begins with the appearance of a breast bud beneath the areola. Under the influence of estrogen, there is an increase in the adipose tissue along with the beginning of ductal and stromal

growth. Progesterone initiates alveolar budding and lobular growth and contributes to the development of secretory lobules and alveoli. The alveoli are later lined by milk-secreting cells under the influence of prolactin when full maturation occurs during the first pregnancy.

The normal progression of breast growth is divided into 5 stages or SMRs. These descriptions are used to follow normal breast development, which occurs parallel with and generally precedes pubic hair development. It usually takes 2 to 4 years for the completion of breast development although, as in all aspects of puberty, variations do occur. The practitioner should keep in mind that many females will remain in SMR 3 or 4 breast development until pregnancy. Additionally, especially between SMR 2 and 4, significant breast asymmetry can be quite common in the adolescent without indicating a pathologic process. Once both breasts are fully mature and reach SMR 5, adequate catch-up growth usually has occurred.

Clinical Presentation

Infants with breast disorders usually present in the first few weeks of life with bilateral breast enlargement that may be asymmetrical (Dx Box). There may be an associated clear or cloudy nipple discharge. If an infection is present, the overlying skin may be warm and erythematous. Fever or other nonspecific symptoms such as poor feeding and irritability also may be present because mastitis involves the entire breast bud and, although rare, septicemia can occur.

In prepubertal females, benign premature thelarche will present as unilateral or bilateral non-tender subareolar swelling without the appearance of other secondary sexual characteristics. In contrast, girls with precocious puberty may have axillary hair, nipple and areola enlargement and thinning, and pubic hair in addition to early breast development. Adolescent females with a breast problem often will complain of a unilateral breast lump noted incidentally by the teenager. It may be tender, fluctuant, firm, rubbery, or nodular. The adolescent also may complain of painful breasts (mastalgia) that can be cyclic in nature. For most breast masses, the overlying skin is normal, but occasionally skin changes do occur. Rarely, an associated nipple discharge may be present.

Because most breast masses occur in females, gynecomastia is particularly anxiety provoking in young adolescent males. It usually

appears as a unilateral or bilateral 2- to 3-cm firm mass beneath the areola, which may or may not be tender. There may be irritation of the skin of the nipple from rubbing against the clothing. Galactorrhea rarely accompanies pubertal gynecomastia and may indicate self-stimulation or illicit drug use, including marijuana, heroin, and amphetamines.

Pathophysiology

Neonatal breast hypertrophy seems to be a response to maternal estrogen exposure in utero. Constant stimulation can lead to persistent swelling, galactorrhea, and overt infection (mastitis). Of note, if galactorrhea is present, it should not persist beyond the first few months of life. In general, preterm infants are less responsive to maternal hormones and, therefore, breast hypertrophy occurs less often in this age group. It also may be delayed for weeks.

Central precocious puberty is due to early activation of the hypothalamic-pituitary-gonadal axis and the secretion of gonadotropin-releasing hormone (GnRH)-dependent pituitary gonadotropins in a pulsatile pattern. Although a search for an underlying central nervous system (CNS) or gonadal abnormality may be undertaken, most cases in females are idiopathic. In contrast, less than 10% of males with precocious puberty do not have an identifiable cause, and it has been reported that approximately half of boys with precocious puberty have an identifiable intracranial process. Central nervous system tumors cause precocious puberty by impinging on the neuronal pathways that inhibit the GnRH pulse generator in childhood. Cranial irradiation, received as a part of tumor therapy, also can lead to sexual precocity. Pseudoprecocious puberty is GnRH-independent and is caused by the extrapituitary secretion of gonadotropins or the secretion of gonadal steroids independent of pulsatile GnRH stimulation. (See Muir in Selected References for a complete discussion of precocious puberty.)

Benign premature thelarche is a variation of normal pubertal development with transient elevations in estrogen levels from either functional ovarian cysts or fluctuations in pituitary gonadotropin secretion. Often the breast enlargement occurs without other estrogen effects, such as an increase in uterine size or changes in the appearance of the external genitalia. In general, no linear growth or bone age advancement is associated with this condition.

The cause of fibroadenomas in adolescent females is postulated to be an abnormal sensitivity to estrogen. Observations supporting this hypothesis include the presence of estrogen receptors in the tumor and an increased incidence of this type of tumor during late adolescence. Thus prolonged exposure to estrogen may play a role in its development. Enlargement can occur during pregnancy or toward the end of the menstrual cycle.

The definition of gynecomastia is an increase in the glandular and stromal tissue of the male breast. Transient or physiological gynecomastia is thought to occur from a temporary imbalance of estrogen and androgens during puberty. Alterations in the ratio of these hormones leads to an increase in estrogen relative to testosterone. Certain medications can cause elevations in serum prolactin and lead

Dx Breast Disorder

Infants, Prepubescent Children, and Adolescent Males

- Unilateral or bilateral subareolar mass
- Possible associated nipple discharge
- Skin changes such as erythema in infants

Adolescent Females

- Firm, rubbery, freely movable mass
- Possible tenderness
- Breast asymmetry
- Skin changes such as shininess, venous distention, or dimpling (rare)
- Possible associated nipple discharge

Box 99-1. Causes of Galactorrhea

- Mechanical stimulation of the nipple

 - Tricyclic antidepressants
- Illicit drugs
 - Marijuana
 - Heroin
- Hypothalamic-pituitary disorders

to gynecomastia and/or galactorrhea (Box 99-1). Some illicit drugs, such as marijuana, contain phytoestrogens that can mimic estrogen or stimulate estrogen receptor sites. Others (eg, spironolactone, cimetidine) interfere with androgen receptors or induce inhibition of enzymes needed in steroid synthesis.

Differential Diagnosis

The differential diagnosis of breast disorders in children and adolescents depends on gender and age at onset. In addition, the presence or absence of other secondary sexual characteristics is helpful to differentiate between a variation of normal pubertal development and a pathologic process.

Infants and Children Younger Than 9 Years

In prepubertal children, the differential diagnosis of isolated early breast development includes exposure to exogenous sources of estrogen such as skin creams, makeup, and medications (oral contraceptives).

For patients with suspected precocious puberty, other etiologies must be considered in addition to exogenous hormones (Box 99-2). Central nervous system tumors, lesions, and insults are among the most common causes. Congenital tumors such as hypothalamic hamartomas are especially important to rule out because they often present before age 3 years. Other CNS tumors to consider are neurofibromas, optic gliomas, astrocytomas, and ependymomas. Specific CNS lesions include cysts in the area of the third ventricle and congenital brain defects. Hydrocephalus, postinfectious encephalitis or meningitis, head trauma, and static cerebral encephalopathy also can lead to sexual precocity. Endocrine disorders include primary

Box 99-2. Differential Diagnosis of Precocious Puberty

- Central (true)—gonadotropin-releasing hormone (GnRH)—dependent
- Idiopathic
- Central nervous system
 - Tumor
 - ♦ Optic and hypothalamic gliomas (often associated with neurofibromatosis), hypothalamic hamartoma, astrocytoma, ependymoma, craniopharyngioma
 - Lesion
 - ♦ Congenital defects, hydrocephalus, cyst in the third ventricle
 - Insult
 - ♦ Postinfectious encephalitis or meningitis, static encephalopathy
 - Infection
 - ♦ Abscess, tuberculous granulomas of the hypothalamus
 - Head trauma
 - Sequela of cranial radiation
 - Sarcoid granuloma
- Endocrine
 - Hypothyroidism (mechanism unknown)
 - Secondary to GnRH-independent precocious puberty (21-hydroxylase deficiency, McCune-Albright syndrome)
 - Peripheral (pseudo-)—GnRH-independent
 - Adrenal
 - ♦ Tumor
 - ♦ 21- or 11-hydroxylase deficiency
- Gonadal
 - Tumor
 - ♦ McCune-Albright syndrome
 - ♦ Familial testotoxicosis
 - Ectopic human chorionic gonadotropin-secreting tumor
 - Exogenous steroids

hypothyroidism, estrogen-producing tumors of the ovary or adrenal gland, and ovarian cysts.

Adolescents

The differential diagnosis of breast masses in adolescent females is extensive (Box 99-3). Conditions can be distinguished from one another based on the location of the lesion; its texture, mobility, and size; and how rapidly it is enlarging.

According to some authors, gynecomastia can be classified as type I, II, and III, which is determined by findings on physical examination. Type I is consistent with benign pubertal hypertrophy. The differential diagnosis for types II and III includes physiological gynecomastia (no evidence of an underlying disease process); organic disorders such as hyperthyroidism, liver disease, and testicular neoplasms; and side effects of medications or drug use (Box 99-4).

Persistent galactorrhea can be caused by several conditions in addition to excessive stimulation of the nipple from sexual activity

Box 99-3. Causes of Breast Masses in the Adolescent Female

- **Fibroadenoma**
- **Breast abscess**
- **Breast cyst**
- Juvenile (giant) fibroadenoma
- Cystosarcoma phyllodes (benign)
- Fat necrosis (secondary to trauma)
- Lipoma
- Hematoma
- Intraductal papilloma
- Adenocarcinoma
- Rhabdomyosarcoma
- Angiosarcoma
- Lymphoma
- Cystosarcoma phyllodes (malignant)

Box 99-4. Causes of Type II Gynecomastia in the Adolescent Male

- Idiopathic
- Tumors
 - Seminomas (40% of germ-cell tumors), Leydig cell tumor, teratoma, feminizing adrenal tumor, hepatoma, bronchogenic sarcoma (ectopic human chorionic gonadotropin production)
- Thyroid dysfunction (hyperthyroidism and hypothyroidism)
- Renal failure and dialysis
- Cirrhosis of the liver
- Klinefelter syndrome (XXY)
- Testicular feminization syndrome (partial androgen insensitivity syndrome)
- Drugs
 - Marijuana, amphetamines, heroin, methadone
 - Alcohol
 - Anabolic steroids
 - Estrogens, testosterone
 - Growth hormone
 - Cimetidine, ranitidine
 - Omeprazole
 - Digitalis
 - Spironolactone
 - Phenytoin
 - Tricyclic antidepressants
 - Risperidone
 - Selective serotonin reuptake inhibitors
 - Isoniazid
 - Ketoconazole
 - HARRT (highly active retroviral treatment)
- Pseudogynecomastia (adipose tissue in obese male)

or jogging without a support bra. Other etiologies include neurologic, hypothalamic, pituitary, and endocrine disorders. Common causes in the adolescent female are prolactin-secreting tumors and hypothyroidism. Drugs that induce galactorrhea in females are the same ones that can cause gynecomastia in males (see Boxes 99-1 and 99-4).

Evaluation**History**

In the infant or child, the history should focus on endogenous as well as exogenous sources of estrogen (Questions Box). In addition it is important to ascertain from the parents whether a growth spurt has occurred as well as if other physical features of puberty have appeared. With teenagers, it is important to inquire about drug use as well as systemic illness. All adolescent patients should be interviewed

Questions**Breast Disorder****Prepubertal Children**

- At what age was the breast mass first noted?
- Does it seem to be increasing in size?
- Is it tender or erythematous?
- Is there associated discharge from the nipple?
- Has the child been exposed to any estrogen-containing skin creams, medications, or other products?
- In the male patient, is he taking any medications known to cause gynecomastia, such as digoxin, omeprazole, or isoniazid?
- Is the child experiencing any neurologic symptoms such as headaches, ataxia, or visual disturbances?
- Is there a history of head trauma, central nervous system infection, or insult?
- Has the parent noted any other signs of early pubertal development (eg, pubic hair, acne, sudden increase in height)?

Adolescent

- When was the breast mass first noticed, and where is it located?
- Does it seem to be increasing in size?
- Is the lesion tender?
- Is there a history of trauma to the breast?
- Is there any discharge from either nipple?
- In the female, when was the last menstrual period?
- Is there a history of headache or visual disturbances?
- Are there any signs or symptoms of systemic illness, such as weight loss?
- Is there a family history of breast cancer in a first-degree relative, particularly the mother? What was her age at diagnosis?
- Is there a history of chest wall radiation or treatment with chemotherapeutic agents?
- In the male, is he taking any medications that can cause gynecomastia, such as cimetidine?
- Is the adolescent male using anabolic steroids?
- Is the adolescent using any other illicit substances such as marijuana or heroin?
- Is there a family history of gynecomastia or abnormal sexual development?

alone, especially when being asked about illicit substance use (see Chapter 132). The adolescent male may feel particularly embarrassed given the nature of his visit; thus the clinician should be especially patient and supportive during the interview.

Physical Examination

The physical examination includes an assessment of the patient's linear growth, especially in cases of suspected precocious puberty. The height and weight should be plotted on the growth curve and compared with previous measurements. Accelerations in height occur in sexual precocity. Excessive weight gain also should be noted because obesity can stimulate breast enlargement in young females and gynecomastia in males since fatty tissue can be mistaken for breast development if the tissue is not palpated correctly.

The extent of the breast examination depends on the age of the patient. In infants and young children, the breast tissue should be measured and the size recorded so that growth can be monitored over time. Consistency of the tissue and mobility also should be evaluated. Breast growth as a result of neonatal breast hypertrophy and benign premature thelarche is non-tender, firm, and freely mobile. The nipple should be examined for a clear or cloudy discharge by gently compressing each one separately.

In the adolescent female, the breast examination should include visual inspection of the breasts as well as palpation of any lesion and axillary nodes. Ideally this would be performed in the sitting and supine positions, as is done in adult women. Most adolescent females, however, may be uncomfortable with so extensive an examination. The physician must take the time to explain the reasons for the examination to help the patient feel less self-conscious. Male providers always should have a female staff member present to chaperone during the breast examination. In contrast, it is often left to the discretion of the individual female provider as to whether or not to have a chaperone present.

Visual inspection should assess for SMR, appearance of the skin, breast symmetry, and evidence of trauma. Shiny skin or superficial venous distention on one breast would indicate the presence of a large mass. A peau d'orange (orange peel) appearance of the skin or erythema and warmth should be noted as a sign of an infiltrative lesion or infection, respectively.

Palpation of the breast mass can be accomplished with the patient in the supine position using 1 of 3 methods. Using the second, third, and fourth fingers of one hand, the examiner should gently palpate each breast in a pattern of concentric circles, spokes of a wheel, or vertical and horizontal lines. The location of the mass should be noted; a mass beneath the areola might indicate an intraductal lesion, whereas the upper outer quadrant is the classic location for a fibroadenoma. The consistency of the lesion is important. Is it firm, rubbery, and fluctuant, or irregular and lumpy? Is it freely movable or attached to the chest wall? Fibroadenomas tend to be non-tender, firm, discrete, freely movable, and rubbery. A tender, poorly defined mass is consistent with a contusion; a hematoma is more sharply defined with associated skin ecchymoses. Fat necrosis can develop after trauma and is painless, firm, well circumscribed, and

mobile. The size of the mass should be measured and recorded. One must keep in mind that tumor size does not correlate with malignant potential. Finally, each nipple should be gently squeezed to check for a discharge. If present, note whether it is clear, milky, or bloody. A serosanguineous or sanguineous discharge would indicate the presence of an intraductal mass. In addition, a retracted nipple indicates involvement of the areolar area.

In the adolescent male, the breast tissue should be gently palpated in the supine position to distinguish between fatty tissue in the overweight patient and true gynecomastia. Type I gynecomastia presents as a unilateral or bilateral freely mobile subareolar nodule, which is generally up to 3 cm in size. Enlargement beyond the areolar perimeter is consistent with type II; type III resembles SMR 3 breast development in girls. The breast tissue associated with type I and II also is firm and rubbery and may be tender to palpation, whereas type III has a consistency similar to female breast tissue.

The examiner should palpate for axillary lymphadenopathy. Although most clinicians think of its association with breast cancer, it also may be found with infection or necrosis of a benign tumor. In the adolescent male, in addition to palpation of the breast tissue, it is important to evaluate liver size and texture as well as determine the SMR of the genitalia to determine whether pubertal development is consistent with the gynecomastia. The testicles should be palpated carefully for masses and evidence of atrophy (decrease in testicular size). In addition, findings suggestive of hypo- or hyperthyroidism, liver disease, or other stigmata suggestive of a syndrome must be noted.

A detailed neurologic examination should be performed, especially in children with sexual precocity to confirm or detect a CNS disorder.

Laboratory Tests

The laboratory workup for breast disorders is dictated by the findings on history and physical examination. Isolated neonatal breast hyperplasia and premature thelarche require no laboratory studies. Although serum gonadotropin concentrations (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]) and estradiol levels can be obtained in girls with precocious puberty, definitive demonstration of an activated hypothalamic-pituitary axis generally requires the administration of a GnRH stimulation test by the subspecialist. In addition, a morning testosterone level should be ordered in boys. Based on these results, further studies may be indicated, such as a serum human chorionic gonadotropin (hCG) level.

For most breast lesions in adolescent females, no laboratory studies are needed. A fine-needle aspiration (FNA) of the lesion may be performed for those cases that seem to be cystic or if the diagnosis is uncertain. The aspirated fluid should be sent for cytologic analysis if the mass does not completely disappear with this procedure. Sometimes it is necessary to perform another procedure, such as a core needle biopsy, to relieve patient and parental anxiety or to better identify the etiology of the mass. An excision biopsy of the mass allows for more accurate histologic information but is rarely indicated for most lesions.

In the healthy adolescent male with no evidence of systemic illness, no history of medication use or illicit substance abuse, and a normal physical examination including the testicular examination, no further laboratory studies are necessary. If pubertal gynecomastia and other systemic illnesses are ruled out, an endocrine workup is appropriate to elucidate the cause of nonpubertal gynecomastia. This should begin with fasting morning serum levels of hCG, LH, FSH, and serum testosterone and estradiol. DHEAS and liver enzymes also should be obtained. If these laboratory studies are normal, the diagnosis is idiopathic gynecomastia. If they are abnormal, consultation with a pediatric endocrinologist or adolescent medicine specialist should occur.

A pregnancy test and serum prolactin level should be ordered in the adolescent female with galactorrhea, regardless of the menstrual history.

Imaging Studies

Hand and wrist radiographs to determine the child's bone age should be obtained in children with a diagnosis of precocious puberty. In addition, boys should have magnetic resonance imaging (MRI) of the brain to evaluate for a CNS lesion or structural abnormality in the hypothalamus or pituitary gland. Depending on the history, an MRI may be indicated in some girls. Pelvic ultrasound, although rarely necessary, can be performed to rule out the presence of an ovarian tumor or cyst in girls.

Mammograms are not helpful in the pediatric age group, especially in adolescents, and are never indicated in the evaluation of a breast mass. They can be very difficult to interpret because of the dense breast tissue of adolescents. In addition, the risk of breast malignancy is very low. An ultrasound may help distinguish between a cystic lesion and a solid tumor and is noninvasive and not painful. It can also provide more accurate measurement of the size of the lesion and its location prior to the FNA or core needle biopsy.

A testicular ultrasound to search for a tumor is indicated in the adolescent male if the level of hCG or estradiol is elevated, or if a testicular mass is noted on physical examination. Other imaging studies for the evaluation of gynecomastia generally are not useful.

Management

In neonates, mastitis most often is caused by *Staphylococcus aureus* and group B streptococcus. Gram-negative bacilli also have been reported. Parenteral antibiotics should be initiated when the diagnosis is made. Incision and drainage of a breast abscess is rarely indicated and should only be undertaken by an experienced surgeon familiar with the anatomy of the breast to minimize the likelihood of injury to the affected breast bud.

Congenital anomalies such as polythelia and polymastia do not require any treatment. If, however, the patient or parent wants the tissue removed for aesthetic or psychological reasons, it is recommended to do so before puberty. Reconstructive surgery for amastia, as in Poland syndrome, is typically delayed until late adolescence to allow full development of the unaffected breast.

Although no treatment is required for benign premature thelarche, parents need to be reassured that the condition is self-limited. The patient should be reexamined periodically to check for any further progression of puberty, such as persistent breast growth, the appearance of pubic hair, or a growth spurt.

The treatment for central precocious puberty is directed at controlling the secondary sexual development with GnRH agonists. When GnRH is administered continuously, gonadotropin secretion decreases. Currently leuprolide acetate is the only GnRH agonist available for use in the United States. Children should be followed every 1 to 3 months in conjunction with a pediatric endocrinologist to monitor their progression and response to therapy.

Unless otherwise indicated by the type of tumor, children with a CNS lesion as a cause of precocious puberty usually do not require neurosurgical intervention. Therapy should focus on minimizing the degree of growth acceleration and the development of secondary sexual characteristics.

Most breast masses in adolescent females are small, well demarcated, firm or rubbery, and non-tender and can be managed with the "wait and watch" approach. The patient can be followed every 3 to 4 months, preferably allowing a few menstrual cycles to pass between each visit. If there is no change in the lesion or just a small increase in its size, no studies or procedures are indicated because it is most likely a fibroadenoma. As previously noted, an FNA or core needle biopsy may be requested to relieve the anxiety that accompanies the presence of a breast lesion and to confirm the diagnosis. Total excision of the tumor mass and a careful histologic evaluation may be warranted in some cases, but is generally unnecessary in most instances. According to the literature, if findings on physical examination, imaging, and biopsy are consistent with a benign lesion, the diagnosis of a benign mass can be made with 99% accuracy. If this is the case, no further procedures are indicated and the patient can be followed up every 6 months to 1 year. Surgical removal of rapidly enlarging tumors, such as a giant fibroadenoma is important. When the lesion becomes very large, an acceptable cosmetic result is more difficult. Accordingly, the lesion should be removed shortly after the time of diagnosis rather than "waiting and watching."

The primary treatment for transient pubertal gynecomastia, or type I, is reassurance for the adolescent male and his family that the condition is self-limited and should resolve in 1 to 2 years, although some sources state 6 months to 1 year. The teenager should be told explicitly that he is not "becoming a girl." In most cases, he should be reexamined periodically until resolution occurs. Type II gynecomastia may need surgical reduction of the mammary gland, although some studies have shown success with medical therapy. The use of 10 to 20 mg of Tamoxifen orally twice a daily for 3 months has been shown to decrease breast tenderness and pain, followed by a decrease in breast tissue. Plastic surgery intervention may be warranted for cases of persistent breast growth or moderate to severe gynecomastia (SMR 3–4 breasts) in the older adolescent with psychological difficulties related to the condition. Surgical intervention currently involves a combination of ultrasonic liposuction and direct excision

of the breast tissue beneath the nipple and areola. The young man may benefit from concurrent psychological counseling as well.

Other underlying causes for gynecomastia should be treated accordingly, and any drugs or medications contributing to the condition should be discontinued, if possible.

Prognosis

The prognosis of a breast disorder in the child or adolescent depends on the particular lesion. In general, most lesions, such as neonatal breast hyperplasia and premature thelarche, are self-limited and resolve on their own. Breast development persists for 3 to 5 years in 50% of cases of premature thelarche, but in one retrospective study, most cases regressed within 6 months to 6 years after the diagnosis. Aside from the short stature that may accompany idiopathic central precocious puberty, these females also tend to have a good prognosis. Fibroadenomas in the adolescent female can recur but typically are benign and have no proven link to the development of breast cancer. Most cases of transient pubertal gynecomastia resolve within 1 to 2 years.

CASE RESOLUTION

The child in the case history has a diagnosis of premature thelarche. She has no known exposure to exogenous sources of estrogen and has isolated breast tissue development with no other signs of pubertal maturation. Her parents should be informed of this diagnosis and reassured that the condition is self-limited and does not indicate that the child is starting puberty. The child should be scheduled for a follow-up visit in 3 to 4 months to remeasure the breast buds and reexamine the genitalia for the appearance of pubic hair as well as to monitor the patient's linear growth.

Developmental Dysplasia of the Hip

David P. Zamorano, MD, and Andrew K. Battenberg, BS

CASE STUDY

A 4-month-old girl is seen for her routine health maintenance visit. She is doing well and has no complaints. The results of the entire examination are within normal limits except for limited external rotation and abduction of the left hip, which is approximately 45 degrees, in comparison to that of the right hip, which is almost 90 degrees.

Questions

1. What factors are responsible for normal growth and development of the hip joint?
2. What specific physical maneuvers help in the evaluation of infants with decreased range of motion of the hip?
3. What are the clinical findings of hip dislocation during and after the neonatal period?
4. What are some of the conditions often seen in conjunction with hip dysplasia that may be noted on physical examination?
5. What is the appropriate diagnostic workup of infants with suspected hip dysplasia?

Developmental dysplasia of the hip (DDH) is a common pediatric orthopedic concern that requires a thorough understanding of normal development, pathoanatomy, natural history, and treatment. Developmental dysplasia of the hip defines a range of hip pathology from congenital dysplasia of the hip, partial dislocation of the femoral head, acetabular dysplasia, and complete dislocation of the femoral head from the true acetabulum. Developmental dysplasia of the hip may exist at birth or develop during infancy. In a newborn with true congenital dislocation of the hip, the femoral head dislocates into and out of the acetabulum. In an older child, the femoral head remains dislocated, leading to secondary changes in the head and acetabulum. When DDH is recognized and treated appropriately, children potentially develop completely normally. If the diagnosis is missed or delayed, however, children may suffer significant morbidity, including severe degenerative hip disease.

Epidemiology

Historically, the incidence of DDH is 1 in 1,000 live births. The literature has observed that pediatricians diagnose DDH in 8.6 in 1,000 live births and orthopedic surgeons in 1.5 in 1,000 live births, while the use of ultrasound has resulted in the diagnosis of 25 in 1,000 live births. Hip instability in the neonate is estimated to range from 11.5 to 17 per 1,000 live births. Approximately 50% of these cases resolve by 1 week of age, and 90% resolve by 2 months of age. Approximately 60% of infants affected by DDH are firstborn.

Girls are affected 5 times more frequently than boys. Ethnic variations exist, with incidence highest among the Native American

Navajo, followed by whites and African Americans. Approximately 20% of all DDH occurs in infants born in the breech position. A positive family history of DDH increases the risk by 10%. A female born in the breech position has a 1 in 35 chance of having DDH.

The left hip is involved in 60% of children with DDH, the right hip in 20% of cases, and 20% of cases are bilateral. Developmental dysplasia of the hip has an increased association with lesions of mechanical molding, such as congenital torticollis (approximately 8% of affected children may have DDH), metatarsus adductus (approximately 2%–10% of these children may have DDH), and talipes calcaneovalgus.

Clinical Presentation

The clinical presentation and signs of DDH in children vary with age. In neonates, diagnosis is made primarily by the physical examination (eg, Ortolani and Barlow maneuvers). In older infants, asymmetrical skin folds, limitation of hip abduction, and a positive Galeazzi sign are classic signs of DDH. Physical signs, which become more obvious once children are walking, include waddling gait, limping, and toe-walking (Dx Box).

Pathophysiology

Developmental dysplasia of the hip encompasses a wide variety of conditions ranging from hip instability to dislocation. For normal growth and development of the hip joint to occur, there must be a genetically determined balance of growth of the acetabular and tri-radiate cartilages and a well-located and centered femoral head. In

Dx Developmental Hip Dysplasia

- Breech presentation
- Oligohydramnios
- Female gender
- Positive family history or ethnic background
- Persistent hip asymmetry (asymmetrical skin folds, abduction of one hip and adduction of the other)
- Lower-limb deformity (limp, toe-walking)
- Torticollis

a normal hip at birth, there is a tight articulation between the femoral head and acetabulum; however, in DDH or dislocation, this tight articulation is lost. Dysplasia refers to (1) a hip that is dislocated but can be relocated, or (2) a hip with a positive Ortolani sign, meaning it can be provoked to dislocate. The term *dislocation* refers to any hip with a negative Ortolani sign, meaning that the hip is not reducible and is associated with secondary adaptive changes such as shortening, decreased abduction, and asymmetrical skin folds.

Dysplasia of the acetabulum is also associated with hip instability. The dysplastic acetabular cavity is shallower with a more vertical inclination angle (Figure 100-1). Although most dislocations occur at or near the time of delivery, this abnormal development of the acetabular cavity helps explain why dislocations can also occur later in infancy. Late hip dislocations are reported in 3% to 8% of affected infants.

Figure 100-1. In developmental dysplasia of the hip, inclination angle is increased. Because the acetabulum is more vertical-orientated, the hip articulation is less stable.

The etiology of DDH is multifactorial, involving genetic and intrauterine environmental factors. The primary **intrauterine environmental factors** are tight maternal abdominal and uterine musculature, breech presentation (causes abnormal hip flexion leading to dislocation of the femoral head), and positioning of the fetal hip against the mother's sacrum. In utero mechanical factors relate to molding and restriction of fetal movement. It is believed that the tight, unstretched maternal abdomen and uterine musculature of primigravidas may restrict fetal movement, thus predisposing firstborn infants to DDH. The increased occurrence of other conditions thought to be secondary to molding (eg, congenital muscular torticollis) with DDH supports this theory of space restriction.

Physiological factors relate to ligamentous laxity. Female infants may be more sensitive to maternal hormones such as estrogen and relaxin, which are present around the time of delivery, resulting in generalized ligamentous laxity, including laxity of the hip capsule.

Environmental factors that may predispose infants to DDH include swaddling with the legs in extension and adduction, which is still practiced in some societies (eg, Navajos in North America who use cradle boards). Other factors include muscle contractures due to neuromuscular disease, such as cerebral palsy.

Differential Diagnosis

The differential diagnosis of hip dysplasia depends on the age of the child and the presenting complaint. Infants may have a “click” on abduction of the hip that represents the snapping of a ligament rather than the reduction of the dislocated hip into the joint. Infants who have limited abduction may have a neuromuscular disorder such as spastic diplegia, a form of cerebral palsy affecting the lower extremities. Older children who present with gait disturbances such as limp, waddling gait, or toe-walking may have neuromuscular conditions, fractures, or infection (eg, osteomyelitis, septic arthritis).

Evaluation

History

Family history of DDH should be reviewed, and a careful neonatal history should be taken, including presentation (eg, breech versus vertex), type of delivery, history of prenatal problems (eg, oligohydramnios), and presence of congenital torticollis or metatarsus adductus (Questions Box).

Questions

Developmental Hip Dysplasia

- Was the infant a breech presentation?
- Does the child have any muscular problems, such as torticollis?
- When did the gait disturbance begin?
- Does anything make the child's gait better or worse?
- Is the child in any pain?
- Did any member of the family have hip dysplasia?

Physical Examination

It is important to evaluate the hip joint for instability or dislocation throughout the first year of life or until the child begins to walk. The **Ortolani and Barlow maneuvers** may be used in the neonatal period to evaluate for DDH (Figure 100-2). Both tests are performed with infants in a supine position and the hips and knees flexed to 90 degrees. Infants should be quiet and relaxed because both tests require a cooperative child for adequate results.

The Ortolani Test, also referred to as the *click of entry*, is a diagnostic test used to detect reduction of a dislocated femoral head. To

perform, the examiner gently abducts the hip and lifts the femoral head anteriorly. A positive sign is a palpable “clunk,” felt when a dislocated femoral head is reduced. This “clunk” differs from the audible hip click, which is due to non-pathologic processes, such as ligamentous snapping. Each leg should be examined separately, not simultaneously.

The Barlow maneuver, also referred to as the *click of exit*, is another diagnostic test; it identifies a dislocatable femoral head in an unstable or dysplastic acetabulum. To perform the maneuver, the hips are adducted and a posterior force is placed along the longitudinal axis of the femur. Subluxations or dislocations are readily palpable. The Ortolani and Barlow tests are rarely used after 6 to 8 weeks of age because the surrounding soft tissues and muscles adapt to the dislocated hip, making it more difficult to reduce.

If the diagnosis of DDH or dislocation is not made shortly after birth, there is a different set of physical findings. There is asymmetry of hip abduction that is secondary to adductor muscle shortening and contracture on the affected side. Limited hip abduction is the most reliable late diagnostic sign.

As the femoral head dislocates posteriorly, the thigh is shortened on the affected side, producing relative limb shortening and asymmetry of the gluteal, thigh, and labial folds. Asymmetrical gluteal folds result from bunching of skin and subcutaneous tissue on the affected side; however, asymmetrical skin folds have not been shown to be reliable signs and assessment for DDH requires further evaluation. **Galeazzi sign** is noted when the femoral head displaces laterally and proximally, causing apparent shortening of the femur on the affected side. On examination, a positive Galeazzi sign may be observed with discrepancy in knee heights noted when infants are supine, the sacrum flat on the examination table, and hips and knees bent (Figure 100-3).

In children of walking age, the physician may notice a limp because of the relative leg length discrepancy. Children may try to disguise the limp by toe-walking. A Trendelenburg test may be positive. Normally, when a child stands on one leg, the hip abductors straighten the pelvis and keep the center of gravity over the femoral head. If the abductors are weak, the weight shifts to the opposite side, causing it to droop. A child with bilateral involvement may display hyperlordosis and a waddling gait.

Figure 100-3. Late signs in the diagnosis of developmental dysplasia of the hip. A. Asymmetry of thigh folds. B. Asymmetry of hip abduction. C. Discrepancy of knee heights.

Imaging Studies

Radiologic and ultrasound evaluations may aid in the diagnosis. Hip sonography helps to confirm the diagnosis and to identify more subtle forms of the disorder. Ultrasonography is the only diagnostic test that allows real-time evaluation and a 3-dimensional view of the neonate's hip. Reliable radiograph changes begin to become evident by 4 to 6 months of age, when the ossific nucleus of the femoral head appears in most infants (Figure 100-4). A flat, shallow acetabulum and delayed ossification of the femoral head are the simplest and most easily recognizable findings.

Management

The need for repeat examinations of the hips during the first year of life cannot be overemphasized. Children suspected of any hip instability or any child with less than 60 degrees of hip abduction should be evaluated with appropriate imaging studies and referred to an orthopedic surgeon for further evaluation. An orthopedic surgeon

Figure 100-4. Radiographic findings associated with developmental dysplasia of the hip. The left hip is dislocated. The femur is lateral and proximal, the acetabulum is shallow and flat, and there is delayed ossification of the femoral head, as evidenced by the absence of the ossific nucleus on the left.

can aid the primary care physician in the diagnosis and management of DDH.

The goal of treatment is to return the femoral head to its normal position within the acetabulum and restore normal hip functioning. The common practice of triple diapering should be discouraged because it is unreliable, often delays definitive therapy, and may produce complications, such as avascular necrosis of the femoral head.

The management of DDH is divided into 5 different treatment groups:

1. Newborn to 6 months
2. Infant (6–18 months)
3. Toddler (18–36 months)
4. Child and juvenile (3–8 years)
5. Adolescent to young adult (beyond 8 years)

The **Pavlik harness** is the primary method of treating DDH during infancy. This device has evolved as the clear method of choice for treatment of infants with DDH and has become accepted as the standard of treatment worldwide. The Pavlik harness consists of a chest strap, shoulder straps, and anterior and posterior stirrup straps that maintain the hips in flexion and abduction while restricting extension and adduction (Figure 100-5). When properly used, the harness holds the hips in a flexed and abducted position while allowing infants to move their legs within safe limits of abduction and adduction until stability is achieved. In the newborn with DDH, the harness should be worn for 23 hours daily until the clinical and radiographic examinations are normal. The harness must be worn for a minimum of 3 months by children 3 months and younger, whereas children 4 months or older usually wear the harness for a period of double

Figure 100-5. Pavlik harness.

their age. A newborn with a diagnosis of true dislocation must wear the harness full time until the dislocatable hip has stabilized in the acetabulum.

The harness should be applied and monitored by an orthopedic surgeon because inappropriate application may lead to adverse outcomes, such as inferior dislocation and, the most serious, avascular necrosis of the femoral head. Parents play a key role in the successful use of the harness and must be educated on the disease process and the proper use of the harness. Overall, the Pavlik harness has an 85% to 95% success rate; however, it loses efficacy as the child ages because of soft tissue contractures that develop in previously untreated individuals.

If this treatment method is ineffective or if the diagnosis is not made until after 6 months of age, **traction** followed by either open or closed **reduction and spica cast immobilization** may be used. Good results are more difficult to obtain with increasing age, especially after children are walking. Operative treatment is required in children older than 18 months to safely reduce the dislocated hip and to surgically re-create normal anatomy. These procedures include (1) **femoral shortening**, (2) **acetabuloplasty** to correct acetabular dysplasia, and (3) **capsulorrhaphy** (suturing the joint capsule).

Prognosis

The prognosis of DDH depends on age at the time of diagnosis and severity of the deformity. The long-term prognosis for satisfactory hip function is good for children when DDH is recognized early and treated appropriately. Generally children with DDH that is diagnosed after the first year of life have a poorer prognosis for satisfactory hip function than those with DDH that is diagnosed during infancy. Left untreated, DDH may result in significant disability, ranging from limp, to pain and stiffness in the hip, to early-onset degenerative joint disease in adult life.

CASE RESOLUTION

The infant presented in the case history has less than 60 degrees of abduction of the left hip, a sign of DDH. An anteroposterior view of the pelvis may be ordered to confirm the diagnosis. Regardless of the radiographic findings, the infant should be referred to an orthopedic surgeon for further evaluation and management. If hip dislocation is confirmed, the initial treatment will involve bracing with the Pavlik harness.

In-toeing and Out-toeing: Rotational Problems of the Lower Extremity

David P. Zamorano, MD, and Andrew K. Battenberg, BS

CASE STUDY

A 3-year-old girl is brought to the office. Her mother is concerned because beginning a few months ago her daughter's feet appeared to "turn in" when she walked. The girl has never walked like this before, and she has no history of trauma, fever, pain, or swelling in the joints. The physical examination is within normal limits except for the in-toeing gait.

Questions

1. How can observation of children's gait help determine the etiology of their in-toeing and out-toeing (rotational problems)?
2. What are the common causes of in-toeing and out-toeing?
3. Does evaluation of in-toeing and out-toeing require any laboratory or radiologic studies?
4. What is the natural history of most rotational problems?

Benign rotational variations of the lower extremities such as in-toeing and out-toeing are seen in many healthy children. Although rotational problems that produce in-toeing and out-toeing may initially be physically alarming, spontaneous resolution occurs in most cases. They are a common cause of parental concern during infancy and childhood; however, they rarely lead to physical limitation. Most of these children can be managed adequately by primary care physicians and do not need orthopedic referral. A thorough understanding of the normal rotational variations that occur in children younger than 10 years of age is essential to proper treatment and patient and parent education. More importantly, a general understanding is imperative to identify more serious underlying structural problems.

Specific terminology used to describe limb positioning is as follows. **Version** is normal variation in limb rotation, whereas **torsion** refers to abnormal conditions (ie, >2 SDs above or below the mean). **Adduction** is movement toward the midline, in contrast to **abduction**, which is movement away from the midline. **Varus angulation** is deviation toward the midline, whereas **valgus angulation** is deviation away from the midline. An **inverted** foot is one turned toward the midline on its long axis. An **everted** foot is one turned away from the midline on its long axis.

Epidemiology

In neonates or young infants, in-toeing is most likely the result of clubfoot (talipes equinovarus), isolated metatarsus adductus, or metatarsus varus. The incidence of clubfoot is 1 in 1,000 live births, with a male to female ratio of 2:1. The condition is bilateral in approximately 50% of cases. The incidence of metatarsus adductus, a much more common problem, is about 1 in 500 live births. It is often bilateral. Internal tibial torsion is the primary cause of in-toeing in the second year of life, and femoral torsion accounts for most cases of this condition during early childhood.

Physiological out-toeing is classically evident in infants who have not yet begun to walk, and is the most common cause of bilateral out-toeing. In older infants and children, however, lateral tibial torsion is believed to be the most common cause of out-toeing.

Clinical Presentation

Children with congenital clubfoot, metatarsus adductus, and metatarsus varus present with in-toeing during infancy. Congenital clubfoot is usually evident at birth. A severe medial, midline, plantar crease is present, and the foot appears C-shaped, with both the heel and forefront turned inward (Figure 101-1). The affected foot is

Figure 101-1. Congenital clubfoot.

small, wide, and stiff, and the lower leg appears small due to hypoplasia of the calf muscles. In contrast to clubfoot, only the forefoot turns inward in metatarsus adductus and varus.

Tibial torsion is apparent during the second year of life. In affected children, the feet turn inward during ambulation, but the knees are straight because the deformity is distal to the knee. Medial femoral torsion is evident at 3 to 4 years of age and usually affects girls. Affected children can sit in the “W” position with both legs behind them. As the child walks, both the knees and the feet appear to turn inward because the deformity is proximal to the knee.

Physiological out-toeing is seen in infancy. Classically, parents note that when they hold their child in a standing position, both feet turn outward. Approximately 5 degrees of out-toeing is normal after age 3. Further degrees of out-toeing may be due to lateral tibial torsion.

Pathophysiology

Several factors are involved in the etiology of rotational conditions. Most of these deformations are caused by intrauterine positioning. Genetics are also believed to play a role in the development of rotational problems, as parents may often have the same rotational deformity as their children. Other contributing factors include **bony and neuromuscular abnormalities** in clubfoot and certain sleeping and sitting positions in metatarsus adductus and medial tibial torsion. For example, sleeping in the prone position with the legs internally rotated may worsen internal tibial torsion or metatarsus adductus.

During the early intrauterine period, internal rotation of the lower extremity brings the big toe to the midline. However, during

the later intrauterine period, infancy, and childhood, external rotation predominates. Alterations in this normal lateral process are caused by genetic and environmental factors, including intrauterine molding and sleep positions. Conditions influenced by intrauterine position, such as metatarsus adductus and developmental hip dysplasia, are sometimes found in the same children.

Congenital clubfoot is most commonly an isolated birth defect and is considered idiopathic. Two major etiologies have been proposed: (1) a germline defect in the talus results in abnormal bony development leading to plantar flexion, inversion, soft tissue contractures, and hypoplasia of the calf muscles and the bones of the foot and (2) clubfoot represents the final common pathway of disruption anywhere along the neuromuscular unit, including the central nervous system, peripheral nerves, and muscles. Additionally, genetics are believed to play a major role given that 25% of all cases are familial and there is 33% concordance of identical twins. Environmental factors, including intrauterine position and molding, are also thought to contribute.

In-toeing is usually caused by benign conditions such as metatarsus adductus, excessive internal tibial torsion, and excessive femoral torsion. Less frequently, patients have pathologic conditions such as clubfoot, skewfoot, hip disorders, and neuromuscular diseases. Out-toeing is typically caused by external rotation contracture of the hip, external tibial torsion, or external femoral torsion. We will now review the conditions associated with rotational variations in children.

In-toeing

Metatarsus Adductus and Metatarsus Primus Varus

Metatarsus adductus, with or without internal tibial torsion, is the most common cause of in-toeing from birth to 1 year of age. It is a functional deformity in which the forefoot is adducted with respect to the hindfoot with a neutral or slightly valgus heel. It is the most common pediatric foot problem referred to orthopedic surgeons and occurs in 1 in 500 live births and in 1 in 20 siblings of patients with metatarsus adductus. The rate is higher in males, twin births, and preterm babies. Numerous theories exist as to the cause of metatarsus adductus, including in utero positioning, sleeping position of the baby, muscle imbalance, and medial cuneiform abnormality.

Presenting complaints include cosmesis, in-toeing gait, or excessive shoe wear. On physical examination, the foot appears C-shaped with a concave medial border and convex lateral border. The forefoot can be brought into the neutral position either by stroking the lateral border of the foot or by gently straightening it. Metatarsus adductus can be classified into flexible or inflexible based on physical examination. Most cases of flexible metatarsus adductus resolve spontaneously and do not require splinting, bracing, or special shoes. However, patients with rigid metatarsus adductus should undergo early casting; uncommonly, resistant cases may require surgery.

Congenital **metatarsus primus** varus is a bony abnormality characterized by an isolated adducted first metatarsal. Unlike flexible metatarsus adductus, metatarsus varus is a fixed deformity. The foot cannot be brought into the neutral position, and there is a deep vertical skin crease along the medial border of the tarsometatarsal joints. Because it is a more rigid deformity, early casting is recommended and persistent deformity requires surgery.

Skewfoot or Congenital Metatarsus Varus

Skewfoot, also known as *serpentine metatarsus adductus*, is characterized by adducted metatarsals combined with a valgus deformity of the heel and plantar flexion of the talus. It is theorized that improper casting of metatarsus adductus or clubfoot may result in a skewfoot; however, most cases are idiopathic. Patients present with pain or callus formation under the head of the talus and base of the fifth metatarsal. Some feet undergo spontaneous correction, while surgery is indicated for a persistently symptomatic foot.

Dynamic Hallucis Abductus/Searching Toe

Dynamic hallucis abductus/searching toe, also known as *wandering* or *atavistic* toe, can cause in-toeing. Children with a so-called searching toe have a big toe that points medially when they walk. Unlike the other causes of in-toeing, which are structural and present at rest, this condition is a dynamic deformity. Searching toe results from the contraction of the abductors of the big toe during the stance phase of gait, which pulls the toe toward the midline. It usually resolves with age and subsequent development of fine motor coordination.

Clubfoot

Congenital **clubfoot**, a pathologic deformity of the foot, may be identified at birth (Figure 101-1). Clubfoot may be either an isolated deformity or seen in association with other neuromuscular anomalies such as arthrogryposis, myelomeningocele, amniotic band syndrome, cerebral palsy, or poliomyelitis.

The diagnosis of congenital clubfoot is made at birth on the basis of 3 conditions: forefoot varus, heel varus, and ankle equinus. Clubfoot can range in severity from a rigid deformity, in which the forefoot cannot be passively abducted into a neutral position, to nonrigid deformities, in which the forefoot can be gently brought toward the midline. Normal dorsiflexion of the ankle helps distinguish severe forms of metatarsus varus from clubfoot.

Internal Tibial Torsion

Internal tibial torsion is the most common cause of in-toeing from ages 1 to 3 years, is thought to be caused by intrauterine positioning, and is usually first noticed by parents when their child begins to walk. Parents often complain that the child is clumsy and trips frequently. The condition is bilateral in two-thirds of affected children; when unilateral, it more commonly affects the left leg. Observation of gait reveals that the knees point forward but the feet turn inward. Because the knees are straight, the site of the rotational deformity is below this joint. If the feet are normal and no metatarsus adductus

or varus is present, the rotational deformity can be isolated to the lower leg. It is important to measure the thigh-foot and transmalleolar axes in the physical examination. Expectant observation is recommended because the natural history of internal tibial torsion strongly favors spontaneous resolution by 4 years of age.

Internal Femoral Torsion

Internal femoral torsion is the most common cause of in-toeing in children presenting at 3 to 6 years of age and is usually bilateral. Children generally present when parents notice worsening in-toeing in a child who has no previous history of in-toeing. Although excessive medial femoral torsion may be present at birth, it is often masked by the external rotatory forces present during infancy. Children with excessive internal femoral torsion characteristically sit with their legs in the “W” position and run with an eggbeater-type motion. No treatment is necessary for most cases of femoral torsion, which usually resolves by 8 years of age.

Out-toeing

Physiological Out-toeing

Out-toeing of infancy, which is most commonly seen in children who are just learning to walk, is caused by intrauterine positioning that leads to external rotatory contractures of the soft tissues surrounding the hip. This condition may be perpetuated in children who sleep in the prone, frog-leg position, which holds the hips in external rotation and prevents normal stretching of the external rotators. Although both feet turn outward when infants stand, the lateral rotation of both hips is normal on examination (Figure 101-2). More serious conditions, such as slipped capital femoral epiphysis, hip dysplasia, or coxa vara, are less common but should be considered.

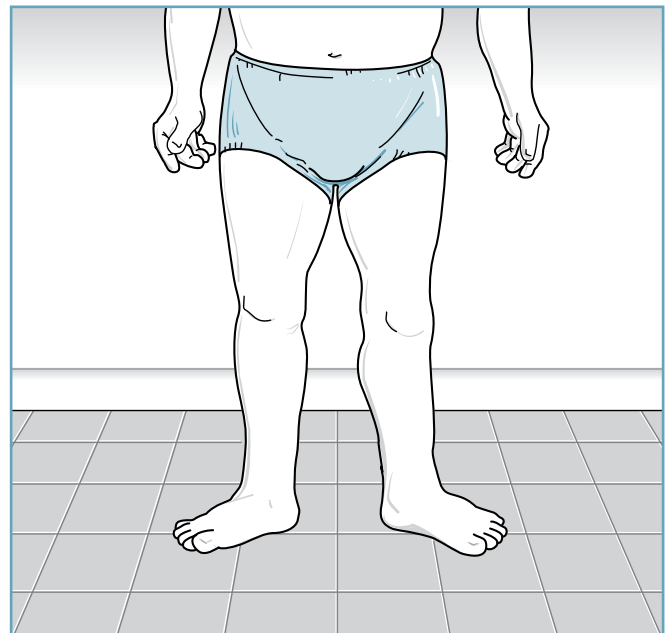

Figure 101-2. Physiological out-toeing of infancy.

External Tibial Torsion

This condition may be suspected in children who are 3 to 5 years of age and present with out-toeing that worsens with time. Increased external tibial torsion is often associated with neuromuscular conditions, such as myelodysplasia and poliomyelitis. Because the tibia normally rotates laterally with development, the condition may become more severe with age. Malalignment between the knee and the direction of gait may produce knee pain.

In-toeing and out-toeing comprise a long list of differential diagnoses; thus, a methodical and meticulous history and physical examination are necessary.

Differential Diagnosis

In-toeing and out-toeing may be classified according to anatomical level and usual age at presentation (Table 101-1). These conditions may be localized to one of 4 areas: toe, foot, tibia, and femur. If intoeing problems are placed in chronological order by age of presentation, the affected area follows a toe-to-femur sequence.

Table 101-1. Site and Age of Onset of Rotational Problems of the Lower Extremity in Children

<i>Problem</i>	<i>Site of Problem</i>	<i>Age of Onset</i>
<i>In-toeing</i>		
Searching toe	Toe	Infancy
Clubfoot	Foot	Birth
Metatarsus adductus/varus	Foot	Birth/infancy
Medial tibial torsion	Tibia	Toddler stage (12–24 mo)
Medial femoral torsion	Femur	Early childhood (3–5 y)
<i>Out-toeing</i>		
Physiological out-toeing	Hips	Infancy
Lateral tibial torsion	Tibia	Childhood

Evaluation

History

The clinical history must delineate the onset, duration, and progression of any structural problems. The typical natural history of benign rotational conditions shows improvement over time, whereas a more serious condition would have a more progressive deformity. Relevant family and birth history, including gestational age, length of labor, complications, Apgar scores, birth weight, and length of hospital stay, should be noted. These details may heighten suspicion for cerebral palsy or the presence of hereditary disorders, such as vitamin D-resistant rickets, mucopolysaccharidoses, achondroplasia, epiphyseal dysplasia, or metaphyseal dysplasia, that may affect rotational profiles. A thorough developmental history is important because developmental delays may be a sign of underlying neuromuscular or neurologic disorders (Questions Box).

Questions

In-toeing and Out-toeing

- Is there any family history of in-toeing or out-toeing?
- What is the birth history? Was the child a breech presentation?
- At what age did the child begin walking?
- When did the rotational deformity appear? Is it getting better or worse?
- Does the rotational problem produce any disability (eg, tripping or falling a great deal when walking or running)?
- Has any previous treatment been tried?
- In what position does the child sleep? In what position does the child sit?

Physical Examination

Normal variability in the lower extremities of young children must be differentiated from more serious structural problems. A detailed physical examination, including assessment of gait and neurologic and musculoskeletal function, is essential for making the correct diagnosis. The evaluation should determine whether the rotational problem has caused a functional impairment, such as tripping, pain, or footwear difficulties. This evaluation should include examination of the hips for signs of hip dysplasia, which may be associated with metatarsus adductus (see Chapter 100).

Evaluation of postural conditions requires both static and dynamic physical examination. Static examination includes an overall evaluation of the patient and a rotational profile. The child's rotational profile, as described by Staheli, consists of 5 components (Figure 101-3). The 5 components of this profile are internal and external hip rotation, thigh-foot axis, transmalleolar axis, heel-bisector angle, and foot progression angle during gait (Figure 101-4).

Hip rotation in infants averages 40 degrees of internal rotation and 70 degrees of external rotation. By 10 years of age, internal hip rotation averages 50 degrees and external rotation 45 degrees. Internal rotation measuring between 70 and 90 degrees is evidence of femoral torsion.

The **thigh-foot axis** consists of the rotation of the tibia and hind-foot in relation to the longitudinal axis of the thigh and indicates the amount of tibial torsion. In infants, the thigh-foot angle averages 5 degrees internal (range: -30 to +20 degrees). Excessive internal tibial torsion spontaneously resolves by 3 to 4 years of age, and by 8 years of age the thigh-foot axis averages 10 degrees external.

The **transmalleolar axis** also aids in determining the amount of tibial torsion. It is formed by the angle at the intersection of an imaginary line from the lateral to medial malleolus and a second line from the lateral to medial femoral condyles. At gestational age 5 months, the fetus has an average of 20 degrees of internal tibial torsion. During development, the tibia externally rotates to an average final adult position of 23 degrees of external rotation.

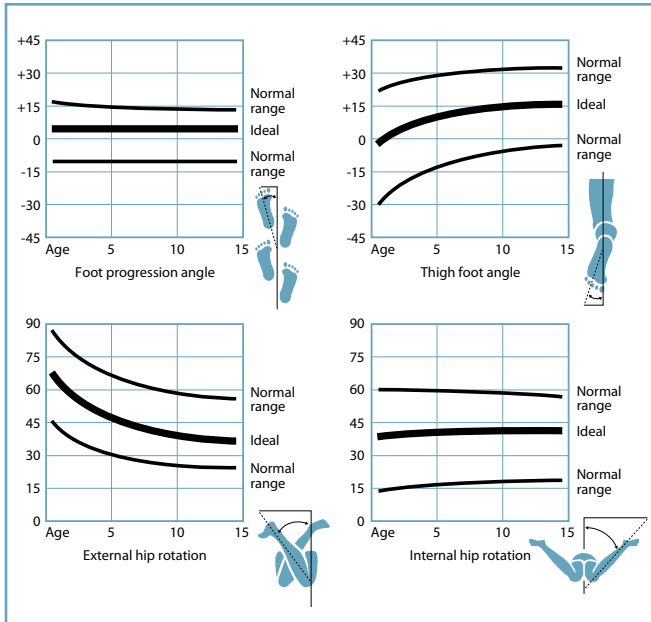

Figure 101-3. Rotational profile. (Reproduced with permission from Wenger DR, Rang M. *The Art and Practice of Children's Orthopedics*. New York, NY: Raven Press; 1993.)

Figure 101-4. Evaluation of foot progression angle.

The **heel-bisector** line examines the foot, and is a line drawn through the midline axis of the hindfoot and forefoot. In a neutral foot, the heel-bisector line passes through the second web space.

Finally, the **foot progression angle during gait** is the angle of the foot relative to an imaginary straight line in the patient's path (see Figure 101-4). Patients who in-toe are assigned a negative value and patients who out-toe are assigned a positive value. This value represents the sum total effect of the child's structural alignment and dynamic torsion forces resulting from muscle forces.

The examination of infants with clubfoot should include a careful examination of the back for signs of possible spinal dysraphism (eg, skin dimples and hairy patches) and a thorough neurologic examination.

Internal tibial torsion may be diagnosed by having children sit at the end of the examination table with both knees flexed to 90 degrees and palpating the medial and lateral malleoli with the thumb and index finger. Normally, the medial malleolus lies anterior to the lateral malleolus (approximately one fingerbreadth). If the lateral malleolus is on the same plane or anterior to the medial malleolus, internal tibial torsion is indicated.

The diagnosis of tibial torsion can also be made by measuring the thigh-foot angle (Figure 101-5). Measurement of the thigh-foot angle involves having children lie prone on the examination table and observing the relationship of the long axis of the foot compared with the axis of the thigh as viewed from above. The shape of the foot itself can also be assessed with children in this position. Slight internal rotation is normal as children first learn to walk.

Diagnosis of medial femoral torsion can be made by observing children's gaits and measuring hip rotation. For example, when a child with medial femoral torsion ambulates, the knees and feet appear to turn inward. Internal and external hip rotation are evaluated with the child in a prone position, the pelvis flat, and the knees flexed 90 degrees (Figure 101-6). The degrees of normal rotation vary with age (see Figure 101-3). During childhood, internal hip rotation greater than 70 degrees implies medial femoral torsion.

Imaging Studies

Routine imaging studies are not necessary for rotational deformities. Imaging studies may be considered by the orthopedic surgeon in severe deformities when operative correction is being considered. In patients with clubfoot, radiographs are used to assess the relationship and development of the bones and to monitor cast correction.

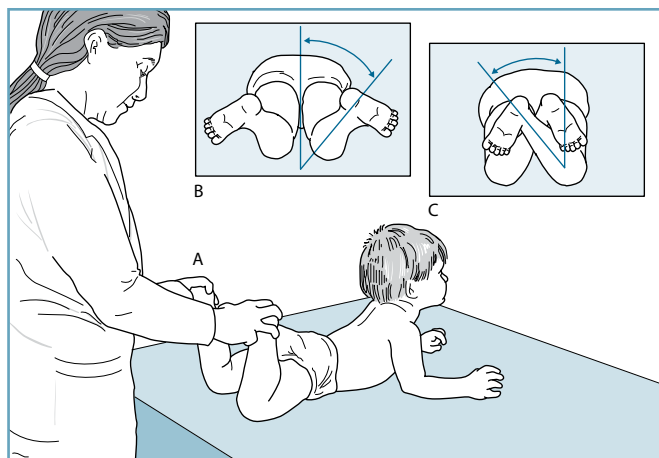

Figure 101-6. Evaluation of hip rotation. A. The child is prone and knees are flexed to 90 degrees. B. Medial rotation is measured. C. Lateral rotation is measured.

Management

In-toeing

Metatarsus adductus generally resolves spontaneously, but stretching exercises for the foot may be advisable, particularly if parents are anxious to “do something.” Parents are instructed to manipulate the foot with each diaper change. Because most cases resolve within the first 3 months of life, referral to an orthopedic surgeon should be made if the deformity is still present at 3 to 4 months of age. Cast correction may be required for rigid deformities or deformities that persist beyond 3 to 4 months. Shoe modifications (eg, putting shoes on the wrong foot) should be avoided because they have not been shown to have any long-term benefits.

Because metatarsus varus may progress when children begin walking, referral to an orthopedic surgeon should be made as soon as the condition is detected. Serial casting followed by corrective shoes or inserts is the first line of treatment, and surgery is rarely required. Treatment for medial tibial torsion is rarely required because this problem generally corrects with time when children learn to walk. Night splinting, although still occasionally instituted, has not been shown to affect the natural history of this condition. If the deformity is severe, persists without improvement beyond the age of 18 months, or persists after the child has been walking for 1 year, referral to an orthopedic surgeon should be made. Surgical correction (eg, tibial rotational osteotomy) may be required if the deformity is severe or persists beyond 8 to 10 years of age.

Like other conditions that produce in-toeing, medial femoral torsion generally does not require treatment. Even if it persists into adulthood, it usually produces no disability nor does it increase the risk for degenerative arthritis in the involved joint. Nonoperative treatment is ineffective. Surgical correction may be required if there is a history of repeated falls or severe gait problems. A derotational femoral osteotomy is the only effective method of treatment. It should not be performed until children are at least 8 to 10 years of age.

Clubfoot, unlike other problems, is a pathologic deformity that requires treatment. Treatment, which should begin during the first week of life, consists of serial manipulations of the foot and casting. Several months of casting may be required to attain full correction. Surgery is often required for resistant or recurrent cases. As many as 50% to 75% of patients with clubfoot may eventually require surgery. Surgery is usually delayed until infants are 6 to 12 months of age.

Out-toeing

Physiological out-toeing of infancy is a rotational problem that spontaneously resolves when children learn to walk. Most cases resolve by 18 months of age. Severe lateral tibial torsion may require surgical correction with a tibial rotational osteotomy.

Prognosis

Because the lower extremity rotates laterally with growth, the natural history of internal rotational problems, such as internal tibial torsion and medial femoral torsion, is resolution over time. In contrast, lateral tibial torsion may become worse with time.

The prognosis for most rotational problems is excellent. Parental reassurance and education regarding the natural history of these deformities may decrease anxiety and prevent unnecessary visits to specialists. Functional disability or degenerative arthritis is not associated with these conditions.

Left untreated, clubfoot often leads to considerable pain and disability. The affected foot can be difficult to fit with shoes. Additionally, clubfoot can be unsightly and cause children significant emotional distress.

Selected References

CASE RESOLUTION

The girl described in the case history seems to have medial femoral torsion because she has no history of rotational problems. Her entire leg turns in when she walks. Internal hip rotation greater than 70 degrees confirms the diagnosis. The mother can be reassured that this is a normal, age-related phenomenon that will most likely resolve over time. The child can be reevaluated in 4 to 6 months. Orthopedic referral is not required at this time.

Angular Deformities of the Lower Extremity: Bowlegs and Knock-Knees

Carol D. Berkowitz, MD, and Andrew K. Battenberg, BS

CASE STUDY

During the routine health maintenance examination of a 2-year-old child, you observe moderate to severe bilateral bowing of both legs. The child's mother reports that her son began walking at 10 months. She has not noticed problems with his gait and says he does not trip or fall excessively. On examination, the boy's weight is greater than the 95th percentile for age, but otherwise he appears to be a healthy African American child.

Questions

1. What types of angular deformities affect children's lower extremities?
2. How does children's age help determine whether they have physiological or pathologic angular deformities?
3. What clinical measurements can help distinguish physiological from pathologic angular deformities?
4. To what extent are radiographs used in the routine assessment of angular deformities?

With normal growth and development, the angular alignment of children's legs progresses through a series of developmental stages—from relative bowlegs to knock-knees and eventually straight legs. Rotational problems such as in-toeing and out-toeing are deformities in the transverse plane that occur when a bone rotates either internally or externally along its long axis (Figure 102-1). Angular deformities such as bowlegs and knock-knees are deformities in the frontal plane. In bowleg deformity, the legs distal to the knees are angled or tilted toward the midline (tibial varus), whereas they are tilted away from the midline of the body in knock-knee deformity (tibial valgus) (Figure 102-2). Variations in the knee angle that fall outside the normal range (eg, more than ± 2 standard deviations of the mean) are referred to as genu varum for bowlegs and genu valgum for knock-knees (Dx Box). Appreciation of the normal developmental sequence in conjunction with a careful history and physical examination can help pediatricians identify pathologic cases of bowlegs and knock-knees and initiate prompt treatment.

Epidemiology

Bowlegs and knock-knees are common in infants and children. While babies are all born bowlegged, parents usually don't appreciate this finding until infants begin to walk. Knock-knees occur less frequently than bowlegs, are seen more often in females, and are

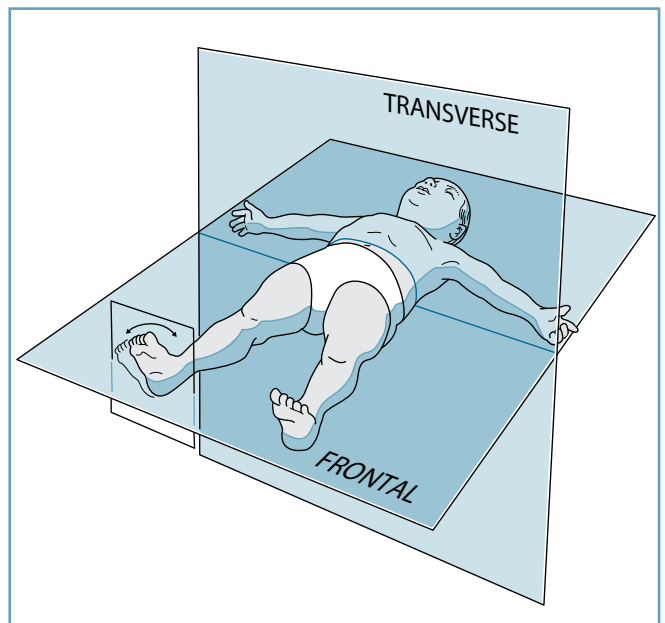

Figure 102-1. Select body reference and rotational planes. Rotational problems are deformities in the transverse plane. Angular deformities are in the frontal plane.

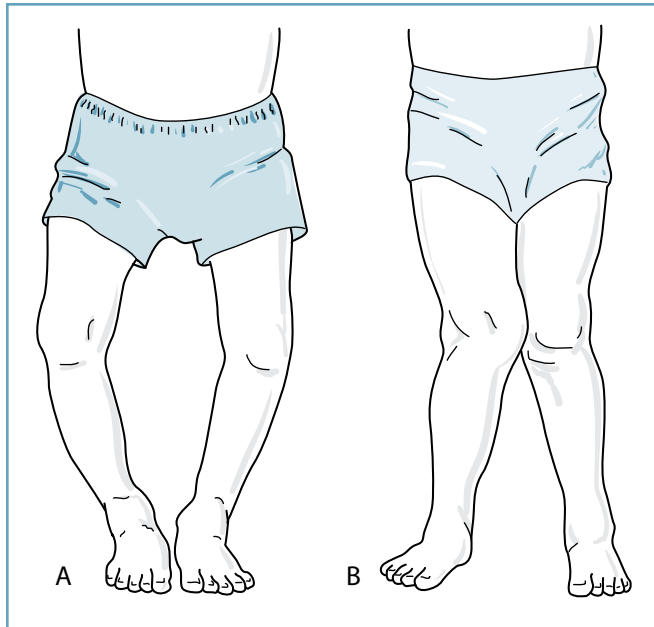

Figure 102-2. Varus and valgus deformities of the lower extremities. **A.** Bowleg deformity. **B.** Knock-knee deformity.

Dx

Pathologic Bowlegs and Knock-Knees

- Asymmetrical deformity
- Inconsistency with the normal sequence of angular development
- Stature less than the fifth percentile for age
- Severe deformity (>10 cm intermalleolar or intercondylar distance)
- History of rapid progression
- Presence of other musculoskeletal abnormalities

commonly associated with generalized ligamentous laxity. Pathologic cases of bowlegs and knock-knees are uncommon and are defined by the degree of the angulation.

Clinical Presentation

Children with **bowlegs** have a characteristic wide-based stance with increased distance between the knees. They may walk with a waddling gait. In-toeing may be noted as a result of associated internal tibial torsion. Evaluation is required for pathologic bowlegs when the intercondylar distance (distance between the knees) is more than 10 cm with the child lying supine with the medial malleoli touching.

Severe **knock-knees** may produce an awkward gait with the knees rubbing. Children may walk with both feet apart in an effort to avoid knee-to-knee contact. They may need to place one knee behind the other to stand with both feet together. Evaluation for pathologic knock-knees is warranted when the intermalleolar distance (distance between the ankles) is more than 10 cm with the child lying supine with the knees touching.

Pathophysiology

The normal variation in the angular alignment of the lower extremities changes with age. During the first 2 years of life, relative bowing of the legs is common. Although physiological bowing of the lower leg may be appreciated at birth, it is most prominent during the second year of life, when it most commonly involves both the tibia and the femur. When associated with internal tibial torsion, the deformity may appear more striking. Physiological knock-knees develop between 3 and 4 years of age. The knock-knee stage resolves somewhere between 5 and 7 years of age, when normal adult alignment develops. A slight knock-knee appearance remains in normal adults. Bowlegs or knock-knees that develop outside of this sequence require further evaluation for pathologic causes.

The **tibiofemoral angle**, the angle between the long axis of the femur and the long axis of the tibia, is used to assess the angular alignment of the leg. At birth the tibiofemoral angle is approximately 15 degrees varus, and it decreases to 0 between the ages of 18 and 24 months. By 3 to 4 years, the angle peaks at about 10 degrees of valgus angulation. Then between 5 and 7 years it decreases to the normal range of about 7 to 9 degrees in girls and 4 to 6 degrees in boys (Figure 102-3).

Figure 102-3. Development of the tibiofemoral angle. (Reproduced with permission from Salenius P, Vankka E. The development of the tibiofemoral angle in children. *J Bone Joint Surg.* 1975;57A:259–261.)

Differential Diagnosis

The most common causes of genu varum and genu valgum are presented in Box 102-1. Physiological bowlegs and knock-knees are usually bilateral, and they occur in a sequence that follows the normal developmental pattern. Lateral bowing of the tibia is commonly noted during the first year of life. Bowlegs (involving both the femur and the tibia) are pronounced during the second year, and knock-knees become prominent between 3 and 4 years of age. This is the normal sequence of angular development. Most cases of bowlegs are the result of normal physiological processes, Blount disease (tibia

Box 102-1. Common Causes of Genu Varum and Genu Valgum

Genu Varum

- Physiological bowlegs
- Rickets (vitamin D deficiency [nutritional] or vitamin D resistance [hereditary])
- Blount disease (tibia vara)
- Achondroplasia
- Metaphyseal dysplasia
- Trauma, infection, or tumor of the proximal tibia (resulting in malunion or partial physal arrest)
- Excessive prenatal fluoride ingestion

Genu Valgum

- Physiological knock-knees
- Rickets (renal osteodystrophy)
- Trauma, infection, or tumor of the distal femur or proximal tibia (resulting in malunion or partial physal arrest)
- Paralytic conditions (eg, myelodysplasia, polio, cerebral palsy) leading to contracture of the iliotibial band
- Osteogenesis imperfecta
- Rheumatoid arthritis of the knee

vara), and rickets. Common causes of pathologic knock-knees are severe renal rickets and previous fractures of the proximal tibia.

Blount disease, a growth disturbance involving the posterior-medial aspect of the proximal tibia (physis, epiphysis, and metaphysis), is the most common cause of pathologic bowlegs and is due to idiopathic undergrowth of the medial side of the tibia. There are 2 forms of the disease: early-onset (or infantile) and late-onset, which are defined by disease development before or after 4 years of age. The late-onset form is further subdivided into juvenile (4–10 years of age) and adolescent (>10 years of age). At all ages, Blount disease is more common in African Americans.

The infantile form, initially classified by Langenskiöld, is bilateral 80% of the time and is associated with internal tibial torsion. The etiology is believed to involve mechanical stress on the growth plate, thus converting physiological bowlegs to pathologic varus. Affected children are often obese, in the upper growth percentiles, and early walkers, which puts early stress on the growth plate. Blount disease produces a sharp angulation at the proximal tibia, whereas physiological bowlegs lead to a gradual curvature of the legs involving both the femur and the tibia. Six stages of radiograph progression based on the degree of epiphyseal depression and metaphyseal fragmentation at the proximal tibia have been identified (Langenskiöld staging). It may be difficult to distinguish between early stages of Blount disease and physiological bowlegs, though criteria have been established to help predict infantile Blount disease in children presenting with idiopathic bowed legs: (1) a body mass index greater than or equal to 22 and (2) a tibial metaphyseal-diaphyseal angle greater than or equal to 10 degrees. These criteria have been shown to have a sensitivity of 95%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 98%.

The late-onset form of Blount disease is less common than the juvenile form and is usually unilateral. Knee pain, rather than deformity, is the most common presenting sign. It is more common in males than females, and affected children are generally obese but have a normal height. Although the etiology is unclear, it is believed that in predisposed obese adolescents, repetitive trauma due to excess weight leads to decreased growth of the medial tibial physis.

Rickets, a disease of the growing skeleton, is a disorder caused by abnormal calcium and phosphorus metabolism that produces inadequate bone mineralization. Rickets takes several forms, including vitamin D–deficient (nutritional) rickets, vitamin D–resistant (hereditary) rickets (the most common form), and severe renal osteodystrophy. Signs of rickets include short stature, poor muscle tone, joint pain, and angular deformities of the lower extremities. Nutritional rickets may occur in infants who are exclusively breastfed and not supplemented with Vitamin D. The alignment at the time of onset of disease determines the direction of angulation. For example, vitamin D–deficient or vitamin D–resistant rickets generally has an early onset and is more often associated with bowlegs. Children with rickets and bowlegs, unlike those with Blount disease, are late walkers and often have evidence of growth impairment. Renal osteodystrophy, which usually has a later onset, results in a valgus deformity (knock-knees).

Pathologic processes, including trauma (fractures), infections, and tumors, involving the proximal tibia, are additional potential causes of both bowlegs and knock-knees. Overgrowth or malunion following fractures of the proximal tibial metaphysis most commonly results in genu valgum rather than genu varum.

Evaluation

History

A family history; an assessment of the child's growth and nutritional history; and a description of the deformity, its progression over time, impact on function, and prior treatment (Questions Box) should be obtained from the parents or caregivers. A dietary history is also important, particularly whether the infant has been exclusively breastfed because of the risk for vitamin-D deficiency.

Physical Examination

Physical examination begins with a general screening of children's nutritional growth and developmental status. Children's growth parameters (height, weight, head circumference) should be measured and plotted on standard growth curves. The rotational status of the lower limb should be assessed because internal tibial torsion is often associated with bowleg deformity (see Chapter 101). Children should be observed both standing and ambulating to determine the alignment of the legs. The intercondylar and intermalleolar distances can be measured with the child supine to determine the presence of excessive bowlegs or knock-knees (see Clinical Presentation). The intercondylar and intermalleolar distances should be followed every 6 months to monitor the progression of the deformity.

Questions

Pathologic Bowlegs and Knock-Knees

- When was the deformity first noticed?
- Has it changed? If so, how fast?
- Has the problem been treated in any way?
- Does the problem seem to affect how the child walks?
- Has the child had any recent illness or trauma in the affected leg?
- Does anyone else in the family have a similar problem?
- Aside from this condition, is the child growing and developing normally?
- Has the infant been exclusively breastfed?
- Does the child eat a well-balanced diet?
- Does the child have any chronic medical problems such as kidney disease?

Laboratory Tests

Most children with physiological angulation do not require any laboratory studies. A general metabolic screening, including hemoglobin, calcium, phosphorus, vitamin D level, creatinine, and alkaline phosphatase, may be ordered if a systemic or metabolic abnormality is suspected.

Imaging Studies

Radiographs are usually performed in the evaluation of bowlegs or knock-knees if pathology is suspected. True pathology is more likely if the deformity is unilateral, painful, very asymmetrical, or progressing at an accelerated rate. If obtained, radiographs should include the entire lower extremity so that the alignment of the femur and tibia may be assessed. Children should be standing, and a single radiograph of both legs should be taken. Pathologic conditions such as rickets (osteoporosis, metaphyseal fraying, cortical thinning, widening of the growth plates), Blount disease (beaking of the medial metaphysis of the proximal tibia), various bone dysplasias, and forms of dwarfism can usually be ruled out by radiographs. An increased uptake of the proximal medial aspect of the tibia on bone scan may help differentiate early infantile Blount disease from extreme physiological bowlegs.

Management

Angular deformities within normal developmental limits should be managed with continual observation and reassessment. The severity of the deformity should be documented, and children should

be followed at 3- to 6-month intervals until the condition resolves. Physicians should **reassure parents** that bowlegs and knock-knees are normal developmental variations that resolve spontaneously with time. Special diets, braces or shoe wedges, arch supports, and bars are generally best avoided; they have not been shown to affect the normal developmental sequence.

Children with physiological varus may be followed clinically until 18 months to 2 years of age. Pathology should be suspected if correction has not begun by this time or if the angulation is progressive. Children with more than 10 degrees of valgus or with an intermalleolar distance greater than 10 cm after 8 to 9 years of age may require further evaluation. Children with suspected cases of pathologic bowlegs and knock-knees require **referral to an orthopedist** for evaluation.

Although treatment of Blount disease in children younger than 3 to 4 years may consist of **bracing** if the deformity is mild and identified early, **surgery** is often necessary. Surgery involves an osteotomy to realign the tibia. Failure to do so may result in damage to the medial aspect of the knee over time. Medical management, such as administration of vitamin D for nutritional rickets, is of primary importance in the treatment of the various forms of rickets. Surgical correction, such as osteotomies to correct varus or valgus deformities, should be reserved until medical management has been maximized because even severe deformities may resolve with conservative management.

Prognosis

Physiological bowlegs and knock-knees spontaneously resolve without further sequelae. Although knock-knees are primarily a cosmetic problem, degenerative arthritis may rarely be a late complication. Surgical correction may be required for adolescents with severe deformity to prevent such late complications.

CASE RESOLUTION

The boy described in the case history should be evaluated for pathologic causes of genu varum, especially Blount disease, for the following reasons: (1) his age is at the upper limit of normal for bowlegs and his deformity is severe, (2) he is African American, (3) he has a history of early walking, and (4) he is obese. A standing radiograph of the lower extremities should be obtained, and the boy should be referred to an orthopedist for further evaluation and management.

Orthopedic Injuries and Growing Pains

Sara T. Stewart, MD

CASE STUDY

A 6-year-old boy has a 1-week history of leg pains. He wakes up at night and cries because his legs hurt; yet during the day he is fine, with no pain or movement limitations. He has no history of trauma, fever, or joint swelling. The family history is negative for rheumatic or collagen-vascular disease. The boy's height and weight are at the 50th percentile for age, he is afebrile, and the physical examination is unremarkable.

Questions

1. What is the differential diagnosis of leg pains in school-aged children?
2. What laboratory or radiographic studies are appropriate for children with leg pains?
3. How do musculoskeletal injuries in children differ from those in adults (eg, the type of injury sustained, the location of the injury, etc)?
4. How does one decide the extent of the diagnostic workup in a child with extremity pain?
5. What physiological factors cause musculoskeletal injury patterns to change with age?

Children by nature are active and explorative. They experience cuts, scrapes, minor injuries, and pain routinely. Because primary care physicians are often the first to examine children with injuries, they play an important role in making the preliminary diagnosis and assessment regarding the need for further evaluation and treatment. The more common complaints and injuries seen in the pediatrician's office are discussed in this chapter: growing pains; nursemaids' elbow; and fractures, including growth plate injuries. The evaluation of children with limp is discussed in Chapter 105.

Epidemiology

The term **growing pains** is somewhat misleading because there is no evidence that these pains are associated with growth. The period of middle childhood, when growing pains are diagnosed, is not the period of most rapid growth in the child. *Leg aches* or *idiopathic leg pain* may be better terms, but growing pains is the most widely used term.

The prevalence of growing pains is not well defined, but seems to be between 15% and 30% of all children. They are seen most commonly in children between the ages of 4 and 14 years; the reported age range is infancy to 19 years. Girls are affected more frequently than boys.

Nursemaids' elbow, pulled elbow, or radial head subluxation is the most common joint injury in childhood. It occurs most commonly in children 1 to 4 years of age, with a peak incidence between

2 and 3 years of age. Other ligament and tendon injuries are relatively uncommon in prepubertal children due to the relative strength of these structures in comparison to the growth plate of the adjacent developing bone. Most commonly, fractures involving the growth plate occur before ligamentous injury. When joint dislocations and ligamentous injury occur in children (with the exception of nursemaids' elbow), they are usually due to significant trauma.

Trauma and injury are significant causes of morbidity and mortality in childhood. Injuries are the most common reason for hospitalization in children and adolescents younger than 18 years and are the leading cause of death beyond the first year of life. Musculoskeletal problems account for 15% of all injuries and most commonly occur in the upper extremity. Fractures are perhaps the most common significant form of musculoskeletal injury in children who present to physicians for evaluation and treatment.

Clinical Presentation (Dx Box)

Children with growing pains typically present with a history of intermittent, poorly localized pain in the bilateral lower extremities that occurs at night over a long period. The pain most commonly involves the calves and anterior thighs, never the joints. Symptoms usually resolve over several minutes, and in the morning the child has normal activity.

Nursemaids' elbow is characterized by a sudden onset of elbow pain associated with the traumatic event and subsequent decreased

Dx Growing Pains and Orthopedic Injuries

Growing Pains

- Age between 4 and 14 years
- Normal growth and development
- Intermittent pain or aches in the legs
- Occurrence of symptoms at night
- Pain poorly localized to the anterior thighs, calves, and behind the knees; absence of joint involvement
- Absence of limp, disability, or inflammation
- Response to supportive measures such as heat and massage

Nursemaids' Elbow

- Age between 1 and 4 years
- Elbow pain of acute onset
- History of sudden longitudinal traction on an extended and pronated arm
- Forearm held in a position of flexion and pronation
- Lack of spontaneous movement of the elbow

Fractures

- Obvious deformity
- Swelling or tenderness over the fracture site
- Limited range of movement or absence of movement of the affected extremity

use of the arm. At the time of presentation for medical care, a child with nursemaids' elbow typically appears well, aside from a refusal to use the affected arm. The child typically holds the arm close to the body with the elbow in slight flexion and the forearm pronated. There is usually no gross deformity, swelling, or overlying skin trauma, and the child typically refuses to supinate the forearm during examination. There may also be point tenderness laterally over the radial head.

An underlying **fracture** is strongly indicated by obvious deformity or lack of spontaneous movement in the extremity in question. Localized swelling, tenderness, and limited range of movement may all be signs of a fracture.

Pathophysiology

Growing pains are recurrent aches or pains localized most commonly to the muscles of the legs and occasionally to the muscles of the arms of children. The pain is located deep within the extremity and not in the joints. The etiology is unclear. Emotional and psychological stress, a low pain threshold, bone fatigue, and myalgias secondary to exercise or physical activity have all been implicated as possible contributory factors.

Nursemaids' elbow is a subluxation of the radial head caused by a rapid and forceful extension and pronation of the forearm. This mechanism most commonly occurs when a caretaker pulls a child toward himself or herself and the child resists, wanting to go in the other direction. As illustrated in Figure 103-1, the subluxation occurs due to tearing of the annular ligament, with trapping of the ligament

Figure 103-1. Nursemaids' elbow. The sudden traction on the outstretched arm pulls the radius distally, causing a tear in the annular ligament at its attachment to the radius. A portion of the ligament becomes trapped within the joint as the traction is released and the arm recoils. **A. Mechanism of injury. B. Pathology. C. Method of reduction (hyperpronation).**

between the radius and the capitulum. This injury is seen primarily in young children because the attachment of the ligament to the bone becomes thicker with age and growth.

Because of anatomical and physiological differences (eg, presence of cartilaginous growth plate as well as thicker periosteum and greater plasticity of the skeleton), fracture patterns seen in children often differ from those in adults. Additionally, fractures may influence long-term growth and development of the affected limb in a growing child.

Fractures are classified based on anatomical location, type of fracture, and degree of angulation or displacement. Fracture location may be described as diaphyseal, metaphyseal, or epiphyseal/growth plate depending on the portion of the bone involved (Figures 103-2 and 103-3). Fractures may be either open or closed. In closed fractures, the skin over the fracture site is intact, whereas in open fractures, the skin is broken. When 2 bone fragments are displaced relative to each other, the direction and degree of displacement are based on the distal fragment.

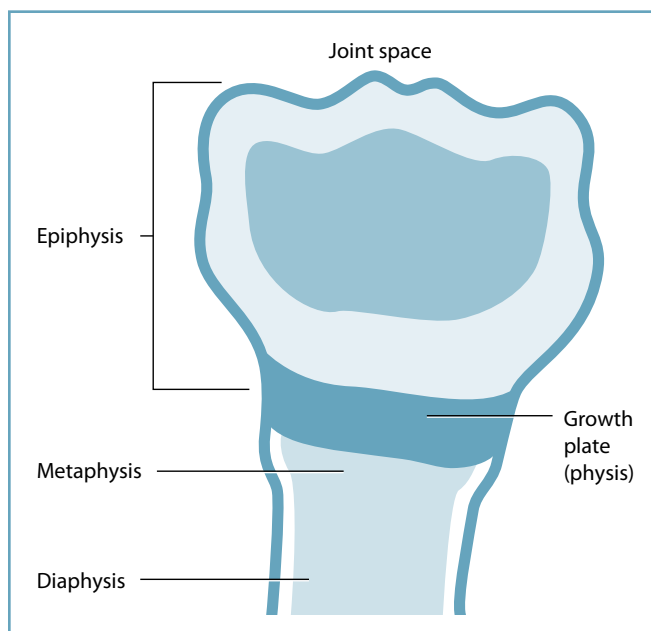

Figure 103-2. Anatomy of a long bone.

Figure 103-3. Non-epiphyseal plate fractures.

The Salter-Harris classification is used most commonly to classify growth plate injury (Table 103-1, Figure 103-4). Approximately 15% of all fractures in children involve the growth plate. Type I and II fractures are the most common fractures involving the growth plate. Type III and IV fractures involve the epiphysis and are considered to be intra-articular. Type V fractures are uncommon and are due to a crush injury to the growth plate. Initial radiographs in type I and V fractures may appear normal, because bone fragments are not displaced. Due to involvement of the growth plate, there is a risk of growth arrest with any physis injury. The risk is variable, however, depending on the type of injury.

Table 103-1. Long Bone Fracture Patterns Seen in Children

Type	Description
Non-Epiphyseal Plate Fractures	
Complete	Both sides of the bone fractured; type depends on direction of fracture line
Transverse	Perpendicular to long axis of the bone
Oblique	At an angle to long axis of the bone
Spiral	Zig-zag course around the bone
Comminuted	Fractures with 3 or more fragments (rare in children)
Buckle or torus	Bone compression causes it to bend or buckle rather than break; occurs at junction of metaphysis and diaphysis
Greenstick	Cortex broken on tension side but intact on compression side
Bowing	Deformation of bone due to bending without fracturing
Classic metaphyseal lesion	Fracture of distal, poorly mineralized metaphysis, perpendicular to long axis of bone; previously termed bucket-handle or chip fracture
Epiphyseal Plate Fractures (Salter-Harris Classification)	
Type I	Horizontal fracture through the physis
Type II	Fracture through the physis, extending into the metaphysis
Type III	Fracture through the epiphysis, extending into the physis
Type IV	Fracture through the epiphysis, physis, and metaphysis
Type V	Crush injury of the physis

Figure 103-4. Salter-Harris classification of epiphyseal plate fractures.

Differential Diagnosis

The diagnosis of **growing pains** is one of exclusion. Leg pain in children has many causes (Box 103-1). If they are limited to vague pains in the legs at night with no associated limp or signs of inflammation, the differential diagnosis may be limited to growing pains, general systemic diseases such as leukemia, benign bone tumors such as osteoid osteoma, and perhaps fibromyalgia. Leukemic infiltration of the bones may cause leg pain before systemic signs such as fever, weight loss, and adenopathy are present. Osteoid osteoma, a benign bone tumor that most commonly occurs in adolescent boys, characteristically causes pain that is worse at night and is usually relieved by anti-inflammatory medications. The pain may be localized in one place, however, unlike with growing pains. Fibromyalgia, which is

Box 103-1. Common Causes of Leg Pain in Children

Growing Pains (Leg Aches, Idiopathic Leg Pains)

Trauma

- Fracture
- Compartment syndromes
- Soft tissue injury
- Muscle strain/sprain

Infection

- Cellulitis
- Soft tissue abscess
- Myositis
- Osteomyelitis
- Septic arthritis

Neoplasia

- Malignant bone tumors (eg, osteogenic sarcoma, Ewing sarcoma)
- Leukemia
- Metastatic disease (eg, lymphoma, neuroblastoma)

Benign Bone Lesions

- Osteoid osteoma
- Bone cysts
- Histiocytosis X

Collagen-Vascular Disease

- Juvenile rheumatoid arthritis
- Dermatomyositis
- Fibromyalgia
- Rheumatic fever

Other Musculoskeletal Causes

- Legg-Calvé-Perthes disease
- Slipped capital femoral epiphysis
- Osgood-Schlatter disease
- Transient synovitis of the hip
- Osteochondritis dissecans
- Patellofemoral stress/chondromalacia patellae
- Generalized ligamentous laxity and joint hypermobility

Miscellaneous Causes

- Sickle cell disease pain crisis
- Psychosomatic conditions

probably underdiagnosed in the pediatric population, is a well-recognized cause in adults of chronic, generalized limb pain without a clear, organic source. It is seen more commonly in adolescents than in younger children. This benign, intermittent musculoskeletal pain syndrome is associated with multiple tender “trigger points,” stiffness, fatigue, and a non-restorative sleep pattern.

When evaluating for **nursemaids’ elbow**, an elbow fracture should be ruled out. Certain fractures and specific features of fractures deserve mention (see Figure 103-3). Fractures that often occur during childhood include clavicular fractures (the most common childhood fracture and most commonly fractured bone from birth trauma) and spiral fractures of the distal tibia—the “toddler’s fracture.” The toddler’s fracture typically occurs in children who have not been walking long, those between 9 months and 3 years of age. It is thought to be due to a rotational force on the lower leg, which could occur as an ambulatory child falls in a twisting motion. Often, when the child presents for medical care the parents are unaware of a history of trauma and the chief complaint is that the child refuses to bear weight on the affected leg. Elbow fractures, including supracondylar humerus, as well as lateral and medial condyle fractures, occur commonly due to a fall directly on the elbow or due to a fall on an outstretched hand. These fractures require careful attention to neurovascular status because of the risk of associated injury to the median or radial nerve, or brachial artery, leading to Volkmann ischemic contracture. A Monteggia fracture is a dislocation of the radial head in association with an ulnar shaft fracture. Long bone fractures in pre-ambulatory children, rib fractures, classic metaphyseal lesions, and the presence of multiple fractures in one child are all concerning for non-accidental trauma and should prompt a more thorough evaluation of possible physical abuse (see Chapter 127).

Because of the relative weakness of the physis compared with the surrounding ligaments, trauma sustained near joints may be more likely to cause a type I Salter-Harris growth plate fracture rather than ligamentous injury (eg, sprain or strain). Therefore, it is important to include this type of fracture in the differential diagnosis of children with point tenderness near the end of a long bone because this injury does require cast immobilization.

Evaluation

Accurate diagnosis of pediatric orthopedic injuries is often challenging because children may be not only poor “historians” but also uncooperative with examinations, especially if they are experiencing pain.

History

A thorough history is essential for the accurate diagnosis of growing pains and orthopedic injuries (Questions Box: Growing Pains and Questions Box: Orthopedic Injuries). A complete history of the events related to the injury, including what happened after the injury was sustained, should be obtained.

Questions

Growing Pains

- When (ie, what time of day) does the pain typically occur?
- How long has the pain been occurring?
- Does the pain resolve and then recur in any predictable manner?
- Where is the pain? Does it change location?
- Does anything make the pain better or worse?
- Is the child sick in any other way?
- Does the pain interfere with the child’s activities?
- Does the parent notice any changes such as swelling or redness in the child’s legs?

Questions

Orthopedic Injuries

- How did the injury occur?
- How long ago was the injury sustained? When did the symptoms begin?
- Was the incident witnessed by an adult?
- How strong was the injuring force? What direction did it come from?
- What was the position of the affected extremity at the time of the injury?
- Did the child experience any head trauma or loss of consciousness?
- What, if any, first aid was administered at the scene?
- Has the child been able to move the affected extremity since the injury occurred?

Physical Examination

The physical examination of children with suspected **growing pains** should include evaluation for signs of systemic disease such as fever, lymphadenopathy, hepatosplenomegaly, abnormal growth, and generalized weakness or fatigue. Leg length and circumference should be measured. The legs should be palpated and range of motion assessed in the hip, knee, and ankle.

Children with suspected **nursemaids’ elbow** should be observed for how they hold the affected arm compared with the unaffected arm. They should be evaluated for limited active motion at the elbow and resistance to attempts at passive movement, especially supination. No swelling should be present, but there may be tenderness over the radial head. The shoulder and wrist should also be well examined.

It is important to undress children with suspected **fractures** and perform a complete physical examination. Simply examining the involved extremity is insufficient. The presence of a deformity, point tenderness, or limitation of motion supports the diagnosis of a fracture. All long bones should be palpated, and the presence of bruises and scars should be noted because these may indicate child abuse. The examination of the involved extremity includes inspection of the overlying skin for swelling, lacerations, or punctures. The degree of active and passive motion and strength compared with the

uninvolved side should be noted. In cases of suspected leg injuries, the child's gait should be observed, if possible. Assessment of neurovascular function distal to the injury includes evaluation of capillary refill, peripheral pulses, and motor and sensory function.

Laboratory Tests

A complete blood cell count and erythrocyte sedimentation rate (ESR) may be considered for children with leg pains that do not resolve. Rheumatologic screening tests can be ordered based on abnormalities in these tests (eg, elevated ESR or white blood cell count). Laboratory tests, if obtained, should be normal if a child is diagnosed with growing pains. Routine laboratory studies are not necessary in the evaluation of nursemaids' elbow or fractures. However, because fractures of the femur are often associated with significant blood loss, it is important to monitor the hematocrit in these patients.

Imaging Studies

If leg pains persist and interfere with routine activity, radiographs or a bone scan of the legs may be considered. Radiographic evaluation is not required for children with nursemaids' elbow if presentation is typical and reduction is successful. Radiographs, if taken in such children, are usually completely negative because the dislocation is often corrected during positioning for radiographs. However, radiographs should be obtained in children with suspected fractures. Fractures involving the growth plate, especially type I and V Salter-Harris fractures, may be particularly difficult to diagnose radiographically because the growth plate is primarily cartilaginous and, hence, radiolucent. A bone scan or follow-up radiograph may be used to diagnose suspected fractures when initial radiographs are negative.

Management

Parental education and reassurance regarding the benign nature of **growing pains** are important. The pains themselves usually respond to **supportive measures** such as heat, massage, and analgesia. Stretching exercises for the legs have also been recommended. Referral to an orthopedist should be considered if the pain is severe and persistent and physical examination and laboratory workup fail to reveal a specific diagnosis.

Nursemaids' elbow is one of the few medical conditions that has a dramatic, immediate cure. To treat the elbow, the annular ligament must be reduced back to its anatomical position, and there are 2 common methods of reduction. In both methods the elbow is stabilized with application of pressure laterally over the radial head with the thumb of the medical provider. In the first method, there is rapid, firm hyperpronation of the forearm. In the second, the forearm is firmly supinated then the elbow is flexed. While both methods of reduction have high success rates, several studies suggest superiority of the hyperpronation method. A click may be heard or felt as

the radial head is reduced, and relief of pain is usually immediate for those children treated shortly after the injury. Return of function may require up to 30 minutes, however. If treatment is delayed, such rapid relief of symptoms may not be seen. Following reduction, the parents should be advised that the child may need mild pain medication. Some providers recommend short-term immobilization in a sling or splint to facilitate soft tissue healing. If reduction is unsuccessful, consider the possibility of obtaining radiographs and referring the patient for orthopedic consultation.

Most **fractures** should be referred to an orthopedic surgeon for evaluation and treatment unless the primary care physician is experienced in reducing and casting fractures. Several techniques are used in fracture management. **Closed reduction** is the nonoperative reduction or realignment of fracture fragments. **Open reduction** implies that an incision has been made to expose the fracture and proceed with manipulating the bone fragments into place. Fixation, or stabilization of the fracture with any type of device, may be required following the reduction. This is termed **internal fixation** if the device is under the skin and **external fixation** if the device begins outside of the skin but passes through the skin to bone. Indications for open reduction include failure of closed reduction, need for precise anatomical reduction, and complex multisystem trauma.

Certain fractures are common in pediatrics. Most clavicular fractures do not require reduction and can be treated with immobilization in a sling for 4 to 8 weeks. Elbow fractures (eg, lateral condyle and supracondylar humeral fractures) are at particular risk for neurovascular compromise and often necessitate open reduction to achieve anatomical reduction. Distal forearm fractures are usually managed with closed reduction and casting, but forearm fractures in the middle and proximal thirds of the bone may be harder to reduce in the office setting. Stable metacarpal and phalangeal fractures can be either splinted in an aluminum splint or be taped to an adjacent finger ("buddy taping"). The metacarpophalangeal joints should be maintained in 50 to 90 degrees of flexion, and the interphalangeal joints should be in about 20 degrees of flexion to minimize stiffness. Unstable finger fractures may require open reduction and pin fixation.

Femoral shaft fractures in infants and children can be managed with closed reduction and spica cast placement. As children become older, a fixation device may be required in addition to the closed reduction. Open reduction is necessary on rare occasions. Closed reduction and cast immobilization are usually used in the management of tibial shaft fractures. Short cast immobilization may be required for metatarsal fractures, and buddy taping is used for stable toe fractures.

Because of the potential for infection, open fractures are orthopedic emergencies that require immediate attention and orthopedic consultation. Careful debridement of the wound is required. Antibiotics should be administered, and tetanus immunization may be given based on a review of the immunization history.

Prognosis

Growing pains resolve over time without sequelae. Recurrence of nursemaids' elbow is common, occurring again in up to a third of patients. Therefore, parents should be cautioned regarding pulling children's arms or lifting them by one hand. Fractures in children generally heal faster and remodel (the spontaneous correction of deformity) better than equivalent fractures in adults. Vascular and nerve injuries and growth disturbances are potential complications of fractures and their management. Compartment syndrome, a potentially serious vascular injury, may also develop.

Growth plate injuries require special attention because of the potential for subsequent growth abnormalities of the affected bone. Prognosis of growth plate fractures depends on the type of injury sustained. Salter-Harris type I and II fractures generally have a good prognosis for long-term healing and growth. The severity of the injury and the accuracy of reduction determine the prognosis of type III and IV fractures. Growth arrest is common following type V fractures because the physis itself is injured.

CASE RESOLUTION

The child presented in the opening scenario has the benign condition commonly referred to as growing pains. Management involves parental education and reassurance. Local heat, massage, and analgesia (using ibuprofen) may be recommended.

Sports-Related Acute Injuries

Monica Sifuentes, MD, and Andrew K. Battenberg, BS

CASE STUDY

A 15-year-old female basketball player complains of 6 months of intermittent pain in her left knee. Occasionally the knee gives out while she is playing ball. The teen denies any associated swelling or erythema over the joint. She is able to walk with no problem and reports no history of direct trauma to the area. She is otherwise healthy.

On physical examination, she is a well-developed, well-nourished teenaged female in no acute distress. The examination is normal except for mild pain to direct palpation of the left patella. No swelling, erythema, or effusion of the knee joint is evident, and the left hip, knee, and ankle have full range of motion. The back is straight.

Questions

1. What are some of the most common orthopedic complaints in adolescent patients, and why do they occur in this age group?
2. What is the pathophysiology of overuse syndromes?
3. What is the purpose of the preparticipation sports physical examination?
4. What conditions disqualify adolescents from participation in competitive sports?
5. What are the current recommendations for the treatment and rehabilitation of acute soft tissue injuries?

Many adolescents with varying degrees of athletic ability participate in sports during their junior high and high school years. Some choose to continue this participation at the college level. Regardless of the ultimate goal, team sports are an important means by which children and adolescents can experience both winning and losing. Individuals learn the importance of group participation and develop interactive skills with other team members. They are exposed to the concept of physical fitness, which can improve body image as well as self-esteem.

Participation in athletics carries significant risks, however. Injuries, inappropriate coaching, and aggressive training sessions are not uncommon occurrences that may have long-term sequelae for young athletes. Primary care practitioners are responsible not only for the evaluation of children prior to their participation in sports but also for the diagnosis, treatment, and prevention of athletic injuries.

Epidemiology

Estimates indicate that as many as 7 million adolescents per year participate in organized sports activities in the United States. Several studies have attempted to quantify the overall injury rate associated with athletic participation. In general, the rate of injury for 13- to 19-year-olds is 7% to 11%. Approximately 20% of those injured sustain a significant injury. For boys, the sport with the highest injury rate in all age groups is football, followed by basketball and soccer. In girls, roller skating and gymnastics accounts for the most injuries. Gender differences between boys and girls have been found in some studies depending on the sport. Overall, boys tend to have more shoulder-related injuries, whereas girls tend to have more knee and

ankle injuries and more problems with overuse syndromes. Reports also indicate that the severity of sports-related injuries increases with age.

Preparticipation Physical Evaluation

The goal of the preparticipation physical evaluation (PPE) is the identification of any physical conditions or abnormalities that may predispose young athletes to injury. Examples include a history of concussion with head trauma or an incompletely healed sprain.

The PPE consists of 2 parts: (1) a review of the patient's current health and medical history, including sports injuries and family history relating to participation in strenuous exercise, and (2) a complete physical examination with a focus on the musculoskeletal system. Known as a "2-minute orthopedic examination," the musculoskeletal examination is a detailed assessment of all muscle groups, assessing their strength, tone, and function. Congenital or acquired deformities should also be noted. The American Academy of Pediatrics (AAP) has developed a form specifically for the PPE visit (see Chapter 33).

Disqualification from participation in specific sports is appropriate in certain situations. Competitive sports are classified according to their degree of contact or impact and how strenuous they are. Recommendations differ depending on the adolescent's medical condition and the type of sport the athlete desires to play. For details of these recommendations, see Selected References. Fortunately, many young athletes are healthy and rarely need to be restricted from participation.

Clinical Presentation

Older children and adolescents with sports-related injuries usually present to the practitioner with specific complaints of pain or swelling in a particular joint (Dx Box). In addition, they may complain of nonspecific musculoskeletal pain occurring in certain areas, such as the lower back or shoulder. Other complaints may include a limp, decreased range of motion of an extremity, or an inability to participate in a desired activity without pain.

Dx Orthopedic Injury

- Joint pain or swelling
- Tenderness to palpation of the affected joint
- Decreased range of motion of the affected joint or extremity
- May or may not have associated bruising of the skin overlying the injury

Pathophysiology

Adolescents, unlike adults, are particularly susceptible to injury because their bones and joints are not fully mature. Most injuries during adolescence involve the epiphysis, which is the weakest point of the musculoskeletal system. In addition, the presence of congenital anomalies, such as leg length discrepancies or hip rotation abnormalities, puts the young athlete at further risk for injury. Biomechanical and neuromuscular factors, hormonal influences, and anatomical differences have also been proposed reasons for higher rates of some injuries in young female athletes compared to young male athletes. For example, patellofemoral pain syndrome, which presents as knee pain exacerbated by activity, is a very common problem in adolescent females, affecting nearly 1 in 10 of those that are active. Contributing biomechanical factors include tight ileotibial bands, weak gluteal strength, and a relative genu valgum due to wider female hips. This combination leads to valgus stresses at the knee, internal rotation of the femur, and abnormal patellar tracking, which puts the athlete at greater risk for patellofemoral syndrome.

Most orthopedic injuries are the result of either macrotrauma or microtrauma. Sprains are an example of macrotrauma, whereas overuse syndromes can be considered microtrauma. **Macrotrauma** occurs from complete or partial tearing of muscle, ligaments, or tendons and is often associated with acute injuries. In contrast, **microtrauma** is usually produced by chronic repetitive trauma to a particular area, leading to inflammation and ultimately to pain. This most commonly occurs in soft tissues such as the muscle and tendon but can occur in the bone as well.

Definitions

A **sprain** is a stretching injury of a ligament or the connective tissue that attaches bone to bone. A **strain** is a stretching injury of a muscle or its tendon, which is the connective tissue that attaches muscle to bone. **Tendinitis** is an inflammation of the tendon. **Apophysitis** is an inflammation of the apophysis, which is the site of ligament or tendon attachment to growth cartilage (eg, Osgood-Schlatter disease

[apophysitis of the tibial tubercle], Sever disease [calcaneal apophysitis]). A **stress fracture** is an incomplete fracture often occurring in the bones of the legs and feet from repetitive trauma to the area. It is believed that the pain associated with shin splints may be due in part to atypical stress fractures of the distal tibia.

Overuse syndromes occur from repetitive microtrauma to the musculoskeletal system secondary to excessive or biomechanically incorrect activity. They are usually the result of training errors in which athletes are “trying to do too much too fast.” Common syndromes in adolescents include Osgood-Schlatter disease, shin splints, and patellofemoral syndrome (chondromalacia patellae).

Grading of Sports Injuries

Sprains can be classified according to the degree of injury and most commonly occur in the knee or ankle. Assigning a grade that describes the injury is useful when considering the prognosis of a particular injury. Consultants also find these grades helpful. Grade I through III is the usual classification used for sprains: Grade I generally refers to stretching of the ligament, Grade II a partial tearing of the ligament, and Grade III a complete tearing of the ligament. Stability of the joint, range of motion, and degree of pain and swelling determine the grade of the sprain. The grading system for **strains**, on the other hand, is based on an assessment of strength. Because strains do not usually cause joint instability, criteria for grading strains are different than for sprains and may be more subjective. A description of these 2 grading systems appears in Table 104-1.

Table 104-1. General Classification of Sprains and Strains

	<i>Joint</i>	<i>Range of Motion</i>	<i>Weight Bearing</i>	<i>Pain</i>	<i>Swelling</i>
Sprains					
Grade I	Stable	Normal	Normal	+	+
Grade II	Stable	↓	↓	++	++
Grade III	Unstable	↓↓	↓↓	+++	+++
	<i>Strength</i>	<i>Palpable Defect</i>	<i>Pain</i>		
Strains					
Grade I	>4/5	–	+		
Grade II	3/5–4/5	+/-	++		
Grade III	<3/5	+/-	+++		

Differential Diagnosis

The differential diagnosis of orthopedic conditions depends on the anatomical site of the injury or complaint and the mechanism of injury. Box 104-1 lists some of the more common orthopedic conditions by location. Anomalies of skeletal development, such as congenital angular deformities of long bones and soft tissue abnormalities like Ehlers-Danlos syndrome, should be considered as

Box 104-1. Differential Diagnosis Based on the Site of Injury

Back Injuries

- Muscle strain
- Spondylolysis
- Epiphyseal injury
- Herniated disks

Injuries to the Upper Extremity

- Acromioclavicular sprains
- Sternoclavicular sprains
- Glenohumeral dislocation
- Glenohumeral subluxation
- Impingement syndrome
- Acute elbow injuries
- Olecranon bursitis
- Lateral epicondylitis
- Flexor-pronator tendinitis
- Wrist sprains
- Scaphoid fractures
- Hamate fractures
- Finger injuries

Injuries to the Lower Extremity

- Iliac crest contusion
- Iliac apophysitis
- Quadriceps contusion
- Femoral stress fracture
- Medial/lateral ligament sprains
- Anterior cruciate ligament sprain
- Posterior cruciate ligament sprain
- Patellar dislocation/subluxation
- Prepatellar bursitis
- Patellofemoral stress syndrome
- Patellar tendinitis
- Osgood-Schlatter disease
- Shin splint syndrome
- Ankle sprains
- Achilles tendinitis
- Calcaneal apophysitis
- Plantar fasciitis

possible etiologies for overuse syndromes. Other non-orthopedic conditions, such as collagen-vascular diseases, infections, and tumors, may present with joint or bone symptomatology.

Evaluation

History

The history should focus on the musculoskeletal system and how the injury occurred (Questions Box).

Physical Examination

The physical examination should focus on the musculoskeletal system. If, however, teenagers have not had a physical examination within the past year, a complete physical examination should first be performed to exclude any systemic condition that might manifest itself initially as musculoskeletal pain. This is especially important in adolescents with chronic or systemic complaints, such as intermittent extremity pain, swelling of an affected joint, and fever.

In general, any pain or swelling of an affected joint or muscle should be noted. If there is history of acute trauma, an area of ecchymosis or joint effusion may be seen. The affected joint should be tested for range of motion and joint laxity in order to determine the degree of sprain. Special testing for ligament laxity should be used (Figure 104-1). For the knee, the most common method is the drawer test for anterior and posterior movement of the knee joint. However, the Lachman Test is gaining popularity as it has been shown to be a more sensitive and specific test for anterior cruciate ligament injuries. The patient is examined in a prone position on an examining table and the knee, ligaments, and tibia are assessed.

Questions

Sports-Related Injuries

- What is the acuity of the injury?
- What activity or sport was the patient engaged in at the time of the injury?
- How often has the patient engaged in this sport or particular activity in the past?
- Were there any new additions to the routine this time?
- Did the pain begin after a single injury or after repetitive activity?
- If the injury is related to a repetitive activity, does the pain occur at a specific time during this activity?
- What was the mechanism of injury?
- Is the pain incapacitating?
- Has a similar injury ever occurred in the past?
- How was the injury treated?
- Was there any pain following the previous injury?
- Does the patient feel as if he or she has completely recovered?
- How was this current injury managed acutely?
- Has the patient altered daily activity in any way to compensate for this problem?

Figure 104-1. Maneuvers used to determine stability of the knee joint. **A. Anterior drawer test: Anterior force is applied. B. Posterior drawer test: Posterior force is applied. C. Medial ligament stability: Lateral force is applied.**

Muscle spasms and diminished range of motion in an adjacent joint should be noted as these may be signs of a strain injury. Strength of the strained muscle(s) should be assessed, and any pain with palpation or range of motion should be noted. A palpable defect of the muscle suggests complete rupture of the muscle, whereas muscular contusions are associated with localized pain, soft tissue swelling, or hematoma. Pinpoint tenderness over a particular bone may indicate a fracture or, if at the site of a tendon insertion, inflammation. Reviewing the mechanism of injury and the timing of the symptoms is often helpful in differentiating between a fracture and tendinitis.

Laboratory Tests

A complete blood cell count and erythrocyte sedimentation rate may be helpful in adolescents with a history of chronic joint pain or swelling. If the results are abnormal, further workup is indicated to distinguish between a collagen-vascular disease such as systemic lupus erythematosus, an infection such as osteomyelitis or, rarely, an arthritic disorder such as juvenile idiopathic arthritis.

Imaging Studies

A plain radiograph of the involved joint or bone is often the only necessary diagnostic study to perform. Because ankle sprain is such a common occurrence, it is important to understand when a radiograph is needed to rule out fracture: The Ottawa Ankle Rules are guidelines for obtaining radiographs in acute ankle injury, are approximately 100% sensitive, and have been validated for use in children older than 6 years (Box 104-2). Plain radiographs of joints above and below the symptomatic area are also sometimes indicated. One example is the Maisonneuve fracture, a fracture of the proximal fibula near the knee that can occur with serious ankle injury; this fracture can be missed if a knee radiograph is not obtained in addition to ankle views. In general, advanced diagnostic tests such as computerized tomography scanning have limited value in the evaluation of an acute soft tissue injury. Magnetic resonance imaging may be indicated for injuries that do not improve despite adequate treatment and rehabilitation. See Chapter 105 for a discussion of imaging studies used to evaluate a child presenting with limp.

Box 104-2. Ottawa Ankle Rules

- Obtain ankle radiograph if ANY of the following:
 - Bone tenderness at posterior edge or tip of lateral malleolus
 - Bone tenderness at posterior edge or tip of medial malleolus
 - Bone tenderness along distal 6 cm of tibia or fibula
 - Inability to bear weight both immediately after injury AND in emergency department for 4 steps
- Obtain foot radiograph if ANY of the following:
 - Bone tenderness at base of the fifth metatarsal
 - Bone tenderness at navicular bone
 - Inability to bear weight both immediately after injury AND in emergency department for 4 steps

Management

With soft tissue injuries, the aim of acute management is to limit the extent of bleeding and inflammation that occur in the first 48 to 72 hours following the injury. The mnemonic RICE (rest, ice, compression, elevation) is helpful. Rest should be explained as “relative rest” because the athletes should be allowed to do whatever they want as long as they are pain-free during or within 24 hours of the activity. Ice should be placed in a plastic bag and applied directly to the skin for a continuous 20 minutes. Longer periods of icing are discouraged because this can result in peripheral nerve palsy from cryoinjury. Patients should ice the injury 3 to 4 times a day for the first 48 hours, and then at least once daily until the swelling or pain is gone. Compression is especially important and should be started as quickly as possible. When applying compression bandages, wrapping should begin distal to the injury and should proceed proximally; this prevents trapping of edema and swelling distal to the compression wrap, allowing proper drainage of injured tissue. Elevation of the injured extremity should occur as often as possible. The use of this plan for soft tissue injuries facilitates early healing and allows rehabilitation to proceed more quickly.

Anti-inflammatory or analgesic medications, such as ibuprofen, aspirin, and naproxen, are useful in controlling the symptoms of pain and swelling. For adolescent patients, dosages are similar to those used in adults: aspirin, 650 to 1,000 mg every 6 hours; ibuprofen, 400 to 800 mg every 6 to 8 hours; naproxen, 500 mg twice daily. To minimize gastrointestinal side effects, the medication should be administered with a snack or milk. Ideally, these drugs should be used for 7 to 10 days. Corticosteroids, either oral or parenteral, are not indicated in the management of overuse injuries or acute trauma to the extremities.

After the acute phase, therapy is aimed at rehabilitation and resolution of any edema or hematoma (Box 104-3). Athletes should slowly begin range-of-motion exercises as tolerated. Full tissue healing may take 6 to 8 weeks, but most young athletes do not have to wait that long to return to athletic activity.

Modified activity, depending on the degree of tissue damage, should initially be recommended in athletes who have suffered from overuse syndromes. Complete rest is rarely indicated. Participation in another sport such as swimming or cycling is often preferable to complete immobilization. In addition to the use of anti-inflammatory agents, physical therapy is another important therapeutic modality.

Box 104-3. Principles of Rehabilitation

- Resolution of hematoma
- Resolution of edema
- Regain full range of motion or flexibility
- Regain full muscle strength and endurance
- Regain agility and coordination
- Regain cardiovascular endurance

Cryotherapy, whirlpool, or alternating heat and ice treatments can be helpful. Reconditioning should be continued after 3 to 12 weeks of modified activity, depending on the degree of recovery. This entails gradual strengthening and flexibility training as well as reevaluation of previous modes of training to minimize the risk of reinjury (Box 104-4). Additional aspects to consider are strength imbalances and biomechanics such as those that occur in patellofemoral syndrome. By identifying specific musculoskeletal imbalances, the clinician can suggest stretches and strengthening exercises specific to the patient's deficits.

Box 104-4. Rehabilitation of Musculoskeletal Injuries^a

Four Phases of Rehabilitation

- Limit additional injury and control pain and swelling (RICE mnemonic).
- Improve strength and flexibility (range of motion) of the injured structures.
- Progressively improve strength, flexibility, proprioception, and endurance training until near-normal function is attained.
- Return to exercise and sports symptom-free.

^aModified Hergenroeder AC. Prevention of sports injuries. *Pediatrics*. 1998;101:1057–1063.

Prevention

Injury prevention is an important aspect of sports medicine with which the primary practitioner should be familiar. Because most injuries are the result of “trying to do too much too soon,” proper physical **training and conditioning** are essential, no matter how fit the athlete appears. Stretching, warm-up and cool-down exercises, and the type of equipment used for the sport, should be reviewed with the athlete during the sports physical visit. The type of sport to be played should also be reviewed and, if participating in a contact sport, the adolescent should be **matched with other athletes** based on weight and pubertal development rather than age. Some studies suggest that such matching will greatly reduce the risk of injury to the smaller, less mature athlete. Because an old or incompletely healed injury is a significant risk factor for reinjury, all **previous injuries should receive proper treatment and rehabilitation** before the athlete returns to play. **Protective equipment**, especially for collision and contact sports, as well as for those involving a ball or racquet, also should be emphasized to athletes and their parents. In addition, the AAP recommendation of **avoiding strength and weight training** until the athlete reaches sexual maturity rating (Tanner stage) 5 of pubertal development should be endorsed to prevent the risk of serious injury. **Education regarding the hazards of anabolic steroid use and creatine** also may be indicated.

Prognosis

Orthopedic injuries in young athletes and active adolescents have a great capacity for healing if given the opportunity. Early medical intervention to prevent irreversible tissue damage ensures complete recovery in most cases. Long-term sequelae are associated with

repeated trauma, incompletely treated cases, and chronic inflammatory changes. Some conditions, however, such as Osgood-Schlatter disease, will resolve even without treatment and do not lead to any permanent damage to the joint.

CASE RESOLUTION

In the case presented at the beginning of the chapter, the teenager has symptoms and physical findings consistent with patellofemoral pain syndrome (traditionally referred to as chondromalacia of the patella). Because plain radiographs are usually not helpful in confirming the diagnosis, none are necessary at this time. Management should include strength training for the quadriceps muscles, activity modification, nonsteroidal anti-inflammatory medication, and ice compresses after activity.

Evaluation of Limp

Paul Bryan, MD

CASE STUDY

A 6-year-old boy who has a 2-day history of right knee pain and limp is brought to the office. No history of knee trauma, swelling, redness, or associated fever is present. The medical history is unremarkable. The boy is afebrile, and his height and weight are at the 10th percentile for age. Examination of the right leg reveals decreased abduction and internal rotation of the hip; the knee is normal. The boy limps when he walks and favors his right leg.

Questions

1. What is the differential diagnosis of painful and painless limp in children?
2. What is the differential diagnosis of knee pain in children?
3. What laboratory and radiographic tests are indicated in the evaluation of children with limp?
4. What is the appropriate management of children with suspected infectious causes of limp?

A limp is a gait disturbance that occurs when an effort is made to minimize weight bearing on an affected leg so that pain and instability are reduced. The disturbance may be secondary to muscle weakness, deformity, pain, or a combination thereof. Muscle weakness may be due to primary muscle disease, neurologic conditions, or disuse atrophy. Structural causes of limp include leg length discrepancy and joint stiffness, while painful causes of limp include trauma, synovitis, infection (ie, bone, joint, or soft tissue), or neoplasm. A limp can be a sign of significant underlying disease, and accurate diagnosis and appropriate management are essential to prevent potentially serious morbidity, including long-term disability.

Epidemiology

A limp may be due to pain originating in a leg or to pain referred from the abdomen or spine. Age often defines the diagnostic possibilities because certain disorders are seen more frequently in particular age groups. Infectious causes of limp occur more frequently in infants and young children, and noninfectious causes are more common in school-aged children and adolescents (Box 105-1).

Clinical Presentation

A painful limp usually has an acute onset and may be associated with systemic signs such as fever or irritability, especially when the etiology is infectious. Toddlers may simply refuse to walk or walk with a slow, cautious gait when they are in pain rather than limp. Non-painful limp often has an insidious onset and is commonly due to weakness (eg, muscular dystrophy) or deformity (eg, leg length discrepancy).

Box 105-1. Differential Diagnosis of Limp in Children

CHILDREN AGES 1–3 YEARS

Painful Limp

- Septic arthritis/osteomyelitis
- Transient synovitis
- Intervertebral diskitis
- Juvenile idiopathic arthritis (JIA)
- Neoplasia (leukemia, metastatic disease)
- Trauma (toddler's fractures)
- Child abuse

Painless Limp

- Developmental hip dysplasia
- Neuromuscular disease (cerebral palsy)
- Leg length discrepancy

CHILDREN AGES 4–10 YEARS

Painful Limp

- Septic arthritis/osteomyelitis
- Transient synovitis
- Trauma
- Legg-Calvé-Perthes disease (LCPD) (acute phase)
- Intervertebral diskitis
- JIA
- Sickle cell pain crisis
- Neoplasia (leukemia, primary bone tumor, metastatic disease)

Painless Limp

- LCPD (chronic phase)
- Developmental hip dysplasia
- Neuromuscular disease (cerebral palsy, muscular dystrophy)
- Leg length discrepancy

CHILDREN AND ADOLESCENTS AGES ≥11 YEARS

Painful Limp

- Trauma
- Septic arthritis/osteomyelitis
- Slipped capital femoral epiphysis (SCFE)
- Osgood-Schlatter disease
- JIA
- Sickle cell pain crisis
- Neoplasia (leukemia, primary bone tumor, metastatic disease)

Painless Limp

- SCFE
- Leg length discrepancy
- Neuromuscular disease (cerebral palsy, muscular dystrophy)
- Scoliosis

Pathophysiology

Normal gait has 2 phases: stance and swing. During the stance phase, either one or both feet are on the ground; during the swing phase, one foot is not touching the ground as the limb is moved forward. Stance phase is shortened in limp to decrease the amount of time spent in bearing weight on the affected side or to minimize instability.

Normal adult gait is smooth and efficient, requiring the coordinated actions of the muscles of the legs and pelvis. Normal gait in children varies according to age and developmental maturity. Toddlers typically walk with a broad-based, tiptoe, “bouncing” gait with arms abducted for balance. They may initiate the stance phase with either toe or heel strike. By 2 years of age, children should initiate the stance phase consistently with heel strike. Children who are 3 to 4 years of age should exhibit normal adult gait with reciprocating arm swing most of the time.

Several types of abnormal gaits are recognized. A shortened stance phase due to pain is characteristic of an **antalgic gait**. Weakness of the hip abductors (gluteus medius) leads to a **Trendelenburg gait**, where the pelvis dips down during stance phase, producing a swaying type of gait. A tiptoe or **toe-to-heel** gait is normal in children for several months after they learn to walk. Persistence of such a gait beyond 2 years of age is abnormal and may result from either idiopathic heel-cord contracture or contracture secondary to cerebral palsy.

Differential Diagnosis

Trauma is a frequent cause of limp in children and adolescents. Toddlers may simply refuse to walk and have an occult fracture, such as a **toddler's fracture**. This is an oblique or spiral fracture of the middle or distal tibia, which occurs after a fall or jump involving a twisting motion. Toddlers are at risk for such injuries because of their unsteady gait. Standard anteroposterior (AP) and lateral radiograph views can initially be normal, and oblique views may be helpful. Follow-up radiographs or a bone scan may be necessary to make the diagnosis. Older children will usually be able to recall a specific injury and localize pain to a specific area. Radiographs are usually obtained to determine if a fracture is present. Individuals who have tenderness over open growth plates should be splinted and warrant close follow-up even with normal radiographs, as there is a possibility of a Salter-Harris type I fracture, which occurs through the growth plate and may not be radiographically apparent.

Painless limp in toddlers may be due to **developmental hip dysplasia**, **cerebral palsy**, or **leg length discrepancy** (anisomelia). As a result of developmental hip dysplasia, children may have a Trendelenburg gait secondary to leg length discrepancy or to weakness of the hip abductors. Children with spastic cerebral palsy often walk on their toes because of increased tone or heel-cord contractures. Functional or apparent leg length discrepancies may result from pelvic obliquity or spinal deformity. Children with true leg length inequality compensate by either walking on tiptoe on the shorter side or bending the knee on the longer side; in either case, their gait is abnormal. Limb discrepancies may be managed with

orthotics (eg, heel lifts) for mild cases, and surgical lengthening or shortening procedures may be necessary for more severe cases.

Transient synovitis of the hip is a benign self-limited inflammatory process involving the synovial lining and is one of the most common causes of limp in the young child. The exact cause of the inflammation is not known. There has been an association with certain upper respiratory infections, but no infectious agent has been identified. Trauma has also been implicated as a potential factor in initiating the inflammatory response because the contusion triggers a chemical synovitis. Age varies, but it typically affects children 3 to 8 years old. Individuals usually present with acute onset of unilateral hip pain associated with a limp. There can be referred pain to the anterior thigh or knee. Most children are either afebrile or have low-grade temperatures (<38.5°C [101.3°F]). The leg may be held in a position of abduction, flexion, and external rotation to reduce intracapsular pressure and associated pain. Symptoms are usually unilateral, but in up to 5% of cases there is bilateral involvement, often with one side being more symptomatic than the other.

Laboratory evaluation typically consists of complete blood cell count (CBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). The laboratory results are usually within normal limits or slightly elevated. Radiographs are often obtained, which are usually normal or show signs suggestive of an effusion. An ultrasound is often performed to look for the presence of an effusion within the joint, which is often present in this condition. If an arthrocentesis is performed, the fluid in transient synovitis usually has a white blood cell (WBC) count of less than 50,000/mm³ and a negative Gram stain. Individuals with normal laboratory values or with a fluid aspirate not suggestive of septic arthritis (when arthrocentesis has been performed) are typically managed with supportive care and close follow-up within 24 to 48 hours. Rest and nonsteroidal anti-inflammatory agents are the mainstays of therapy. Virtually all children recover within 3 to 10 days with no significant sequelae. Recurrence rates vary from 4% to 17% within the first 6 months following an episode of synovitis.

Septic arthritis occurs when there is an infection within the joint space. In children, this usually occurs in the face of bacteremia, with hematogenous spread to the highly vascular synovium. It can also occur from contiguous spread of an adjacent infection (eg, osteomyelitis) or by direct inoculation (eg, surgery or penetrating trauma). *Staphylococcus aureus* remains the most common pathogen identified across all age groups, with increasing incidences of community-acquired methicillin-resistant strains. Infants younger than 2 months can also be infected by neonatal pathogens, such as *Streptococcus agalactiae* (eg, group B streptococcus [GBS]) and gram-negative enteric organisms (eg, *Escherichia coli*). *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and *Kingella kingae* are the main organisms identified in the 2-month to 5-year age group. Children older than 5 years will usually have infections caused by *S aureus* or *S pyogenes*. *Neisseria gonorrhoeae* infections can be seen in sexually active adolescents.

Infants and children will often present with fever, decreased use of the affected extremity, limp, and refusal to walk. The most

commonly affected joint is the hip, which is classically held in a position of abduction, flexion, and external rotation to reduce intracapsular pressure and associated pain. Passive range of motion typically elicits significant discomfort and resistance. Parents of infants may notice considerable crying with manipulation of the legs with activities such as diaper changing.

Subtle or early cases can often present a diagnostic challenge because there can be significant clinical and laboratory overlap with transient synovitis. Unfortunately there is no highly sensitive or specific laboratory test that can readily distinguish these 2 entities. Fever higher than 38.5°C (101.3°F) was shown to be the single best predictor of septic arthritis in one study, with no children diagnosed with transient synovitis having a temperature above 38.5°C. Other predictors include refusal to bear weight, ESR greater than 40 mm/hour, a CRP greater than 2.0 mg/dL, and serum WBC count greater than 12,000/mm³. Unfortunately, with the exception of high fevers, one or more of these factors can also occur with transient synovitis. The presence of one of these 5 factors was associated with a probability of having septic arthritis of around 37%, while the presence of all 5 factors was associated with a probability of 98%. Imaging often consists of radiographs and ultrasound. Radiographs usually are non-diagnostic but may demonstrate joint-space widening suggestive of an effusion. Ultrasound will usually demonstrate the presence of an effusion.

Analysis of synovial fluid remains the gold standard for the diagnosis of septic arthritis, and arthrocentesis of any effusion under sedation or anesthesia is indicated if there is a clinical suspicion of septic arthritis. A WBC count greater than 50,000/mm³ within the fluid aspirate is generally considered diagnostic of septic arthritis; however, elevated counts can be seen in certain rheumatologic conditions. The presence of bacteria on Gram stain of joint aspirate regardless of WBC count suggests infection. Routine cultures of joint aspirate as well as peripheral blood cultures should be sent. In addition, with the increasing recognition of *K kingae* as a causative agent in septic arthritis, joint aspirations should be directly inoculated into blood culture bottles to enhance isolation because this organism is difficult to recover with standard culture techniques. In most studies, only around 50% of joint aspirate cultures grew out an identifiable pathogen. In one recent study, close to 50% of the aspirates that were sterile on standard culture media grew out *K kingae* from blood cultures.

Complications occur in 10% to 25% of all cases, increasing when delays of 5 days or more have passed before initiation of therapy. These complications include abnormal bone growth, permanent limp, unstable articulation of the affected joint, and decreased range of motion.

Osteomyelitis is an infection of the bone that is typically caused by a bacterial organism. Close to 50% of pediatric cases of osteomyelitis occur in children younger than 5 years. Most cases of osteomyelitis in children occur from hematogenous deposition of bacteria into the bone marrow during a transient episode of bacteremia. Other cases may be caused from contiguous spread of an adjacent infection or direct inoculation. Osteomyelitis most commonly

begins in the highly vascularized metaphysis of long bones of young children. The femur, tibia, and humerus account for most cases. As with septic arthritis, *S aureus* remains the most common organism identified across all age groups. Other organisms include *S pyogenes*, *S pneumoniae*, and *K kingae*. Young infants can also be infected by neonatal pathogens such as GBS and enteric gram-negative organisms. Individuals with sickle-cell disease are commonly infected with *Salmonella*. Individuals who have suffered a puncture wound through the foot can be infected with *Pseudomonas aeruginosa*, resulting in osteochondritis.

Children often present with fever and pain at the affected site. Younger children may present with limp or refusal to bear weight. If there is subperiosteal spread, there may be erythema, warmth, and swelling at the affected site.

Laboratory tests can be supportive of a diagnosis of osteomyelitis, but are usually not specific. Typically a serum CBC, ESR, and CRP are obtained along with blood cultures. Leukocytosis may be present, but in more than half the cases, the WBC count can be normal. Inflammatory markers are elevated in up to 90% of cases. Blood cultures are positive in up to 55%. Radiographs are often normal or show only soft-tissue changes early in the course of the disease. Periosteal reactions and lytic lesions are usually not present until day 10 to 21 into the disease. Bone scans can be helpful in the preverbal child or in individuals who cannot localize their pain. Magnetic resonance imaging (MRI) has become the study of choice, with a reported sensitivity of 97%. It is very useful for distinguishing between bone and soft-tissue infections.

Diskitis refers to an inflammatory process involving the intervertebral disks. This disease typically occurs in children younger than 5 years. It occurs almost exclusively in the lumbar region, causing progressive limp, back pain, and refusal to walk. Most children are afebrile. It is thought to occur in younger children because of the presence of vascular channels in the cartilaginous region of the disk space as well as an abundant intraosseous arterial anastomoses. These vascular channels disappear with age. Laboratory studies are often nonspecific, with slight elevations in the peripheral WBC count and ESR. Radiographs are abnormal in most cases (75%), with decreased vertebral disk space and erosion of adjacent vertebral endplates being the most common abnormalities seen. Bone scans will demonstrate nonspecific increased marker uptake in the affected area. Computed tomography scans rarely provide a specific diagnosis and are not generally used. Magnetic resonance imaging will demonstrate characteristic inflammatory changes and allow for differentiation from other conditions, such as vertebral osteomyelitis.

The exact etiology of diskitis is not known, and the treatment is somewhat controversial. Several authors propose that it is the result of an infectious process and warrants antibiotic therapy. Others propose that it is simply a benign self-limited disease because most cultures are sterile and patients can recover without any antimicrobial therapy.

Legg-Calvé-Perthes disease (LCPD) is an idiopathic avascular necrosis of the femoral head. The exact etiology is unclear but involves some disruption in the vascular supply of the capital femoral

epiphysis. This is most commonly seen in children 3 to 12 years old (median age 7 years). It is usually unilateral, but can be bilateral in up to 15% of cases. Children typically present with a chronic intermittent limp that can be either painful or painless. It is not uncommon for the child to be symptomatic for months before a diagnosis is made. Pain is usually worsened with internal rotation and abduction.

Laboratory tests are usually normal. Radiographs early in the course of the disease may either be negative or show widening of the joint space. In later stages, radiographic findings include an increased density and decreased size of the femoral head (necrosis), patchy areas of radiolucency near the epiphysis (fragmentation), and flattening of the femoral head (reconstitution).

Slipped capital femoral epiphysis (SCFE) is a displacement or slipping of the femoral head from the neck of the femur through the open physis (growth plate). This is the most common hip disorder affecting adolescents. It is more common in boys than girls and occurs more frequently among African Americans and Hispanics than whites. Typical age of onset is 9 to 16 years. Individuals are often noted to be overweight and frequently present with a chief complaint of knee pain. They will often have an antalgic gait. The foot is noted to be externally rotated in severe slips but may be neutral or intoed in mild slips. The examination of the knee will be normal without discomfort, despite the complaint of knee pain. Passive flexion of the hip will often result in obligate external rotation. There will usually be pain with internal rotation. An SCFE is stable when the individual can walk with or without crutches, an unstable SCFE occurs when the child cannot walk. Laboratory testing is not indicated. Radiographs of the hip in the AP and frog-leg positions reveal the diagnosis in approximately 80% of the cases. Both hips should be viewed because up to 20% of SCFEs are bilateral. Ultrasound in experienced hands has been shown to be an effective diagnostic tool (sensitivity of 95%). Computed tomography scan and MRI can both reveal the presence of a slip. The MRI is much more sensitive and can detect physeal widening in the pre-slip condition.

Osgood-Schlatter disease (OSD), or traction apophysitis of the tibial tubercle, is an overuse injury of the knee seen most commonly in adolescent athletes. Repetitive microtrauma causes partial avulsion of the patellar tendon at its insertion on the tibia. Individuals will typically present with a localized bony prominence, swelling, and tenderness over the tibial tubercle at the insertion of the patellar tendon. Radiographs are commonly performed to rule out other pathology and will typically demonstrate soft tissue swelling/edema of the skin and tissues, as well as ossific fragments within the tendon. Computed tomography, MRI, and ultrasound will show characteristic changes consistent with OSD, but are generally not indicated.

A limp can also result from certain systemic disease processes, such as **juvenile idiopathic arthritis**, **sickle cell disease (SCD)**, and **neoplastic disease**. Juvenile idiopathic arthritis may involve multiple joints, and there is usually evidence of inflammation (eg, warmth, swelling/effusion, redness). The pain is usually worse in the morning and improves throughout the day. **Sickle cell disease** is now detected on newborn screen, and most patients know of their diagnosis. Acute pain crises with SCD can affect multiple areas,

resulting in significant discomfort, limp, and refusal to walk. Careful consideration for infectious etiologies (ie, osteomyelitis) is necessary in the highly febrile or ill child with SCD who presents with a limp or bone pain. In addition, SCD patients are at risk of avascular necrosis of the hip secondary to vasoocclusive episodes. Neoplastic disease processes such as leukemia or primary bone tumors (eg, Ewing sarcoma or osteosarcoma) can present with bone pain and limp. The presence of pallor, petechiae, disseminated lymphadenopathy, or hepatosplenomegaly may suggest the presence of leukemia. The peripheral CBC will usually show the presence of blasts and varying degrees of involvement of the various cell lines (ie, anemia, thrombocytopenia). Primary bone tumors may present with bony deformities or overlying soft-tissue swelling. Radiographs will often reveal characteristic bony lesions, which may require an MRI to ascertain involvement. Computed tomography scans may be necessary to look for metastases. Individuals may require referral to an orthopedist for biopsy to ascertain a definitive diagnosis and possibly for amputation. Referral to an oncologist will be necessary to initiate appropriate therapy, including possibly chemotherapy or radiation.

Evaluation

History

The history should focus on the time of onset of the limp, its chronicity, and the degree of disability it produces. Often a history of trauma is provided, even when a non-traumatic cause is present. Young toddlers are often falling as they learn how to walk, and parents will frequently relay some trivial or unrelated injury. Delayed motor development may be a sign of neuromuscular disease such as cerebral palsy, whereas a history of loss of motor milestones may indicate muscular dystrophy or spinal cord tumor. It is important to remember that pelvic pathology may be referred to the hip, and hip pathology is often referred to the knee or thigh.

Physical Examination

Physical examination begins with observation for any overt deformities (eg, leg length discrepancy, deformity, joint swelling). All joints should be palpated, and the presence of swelling, tenderness, erythema, or warmth should be noted. A thorough evaluation of the hips is essential in children with knee pain. The type of gait abnormality may be determined by observing children walk or run.

Children should also be examined both supine and standing, if possible. Standing children can be assessed for pelvic obliquity and spinal deformities. Range of motion of the hips, knees, ankles, and feet can be checked in supine children, comparing the affected side with the non-affected side. Deep tendon reflexes and muscle strength should be assessed, and leg length measurements should also be made as indicated. Children should be supine for a true measurement of leg length, taken as the distance from the anterosuperior iliac spine to the medial malleolus. A discrepancy of more than 2 cm is considered significant in adults. The significance of discrepancies can be confirmed by imaging studies.

Laboratory Tests

Laboratory procedures are usually necessary in children with an acute onset of limp. Complete blood cell count, CRP, and ESR are useful markers of systemic disease or significant inflammation. There can be significant overlap between the differing etiologies, and no single screening test reliably distinguishes between the various inflammatory and infectious causes of limp. Blood and local cultures (eg, joint or bone fluid) may be useful in the evaluation of suspected infectious entities. Additional testing for rheumatologic causes may be clinically indicated, such as antinuclear antibody or rheumatoid factor (see Chapter 144).

Imaging Studies

Radiographs are the most commonly used imaging study. Usually 2 views are obtained. Examination of the hip involves imaging in the AP view as well as the frog-leg position. Both hips should be radiographed for comparison and to assess for the presence of bilateral disease. Ultrasound is helpful if there is concern about an effusion within the joint space and can also be used to guide diagnostic and therapeutic interventions (eg, arthrocentesis). Computed tomography scan can sometimes provide useful information, but MRI is being used with increasing frequency because of its superior resolution and lack of radiation. Bone scans may be helpful in the early stages of disease when radiographs are typically normal or when there is difficulty establishing a localized area of involvement.

Management

The management depends on the etiology. Management of septic arthritis consists of surgical drainage and intravenous (IV) antibiotics. Empiric therapy typically consists of a semisynthetic penicillinase-resistant penicillin (eg, nafcillin or oxacillin). If there are high rates of community-acquired methicillin-resistant strains of *S aureus* in the region, then clindamycin or vancomycin may be necessary until sensitivities can be performed. The addition of a third-generation cephalosporin is indicated in the newborn period pending Gram stain and culture results or when *N gonorrhoeae* is suspected in adolescents. Length of therapy is typically 2 to 4 weeks of IV antibiotics. Prognosis is generally good with prompt diagnosis and management within 4 days of symptom onset.

Management of osteomyelitis also consists of IV antibiotics. Occasionally surgery may be indicated, particularly if there is a subperiosteal or soft-tissue abscess or sequestra present. Empiric antibiotic therapy consists of a semisynthetic penicillinase-resistant penicillin (eg, nafcillin or oxacillin). In areas where community-acquired methicillin-resistant organisms are of concern, clindamycin or vancomycin may be necessary. Neonates and individuals with SCD require the addition of a third-generation cephalosporin pending culture results. In individuals with a presumed pseudomonas infection, an extended spectrum β -lactam (eg, ceftazidime, cefepime, or piperacillin/tazobactam) plus an aminoglycoside are indicated. Four to 6 weeks of antibiotic therapy is recommended. Some studies have shown that switching to an oral antibiotic may

be acceptable following a week of parenteral therapy if good compliance is likely, an organism has been identified, clinical improvement is noted, the patient is afebrile, and the inflammatory markers have begun to normalize. Oral dosages 2 to 3 times those normally recommended for non-bony infections are often used for β -lactam antibiotics. Other oral antibiotics (eg, clindamycin, trimethoprim-sulfamethoxazole, fluoroquinolones) have excellent bioavailability, and the usual oral dosages may be used. Consultation with an infectious diseases specialist is often indicated.

Supportive measures with nonsteroidal anti-inflammatory agents are generally indicated for the management of diskitis. Anti-staphylococcal antibiotics should also be considered. A brace may be helpful for support and pain relief. Most patients recover without any complications.

Prompt referral to an orthopedist is indicated in cases of LCPD. The goal of treatment of LCPD is to maintain full joint mobility and prevent deformity of the femoral head. Bed rest and immobilization decrease the pain and help restore range of motion. Traction and abduction casts/braces are used to contain the femoral head within the acetabulum in an effort to maintain its spherical shape. Surgical correction of gross deformities of the femoral head may be necessary in severe cases.

Treatment for SCFE consists of surgical reduction and stabilization with placement of screws through the epiphysis. The screws are typically left in place and do not need to be removed. Non-weight bearing is maintained until early callus is seen on the posterior-inferior metaphysis and the pain has resolved. Gradual and progressive weight bearing is allowed, and progression to full weight bearing usually occurs 3 to 4 months after fixation. No running or jumping is allowed until the physis closes.

Treatment of OSD consists of rest, ice, nonsteroidal anti-inflammatory agents, and strengthening exercises of the quadriceps and hamstring muscles. Surgical treatment is rarely indicated and is reserved for those patients who do not respond to conservative therapy.

Prognosis

The prognosis depends on the etiology of the limp, rapid diagnosis, and appropriate therapy.

The prognosis is good in most cases of septic arthritis and osteomyelitis if the infection is diagnosed early and treated appropriately. Prognosis of osteomyelitis is usually good, with less than 2% of patients who receive at least 3 weeks of antibiotic therapy developing chronic osteomyelitis. Treatment of chronic disease can be difficult, often necessitating prolonged courses of antibiotics (up to 6–12 months) and multiple surgeries for debridement. Rare complications include disturbances in bone growth, limb length discrepancies, arthritis, abnormal gait, and pathologic fractures. Prognosis is also good if diagnosis occurs at a young age (<8 years old). The main complication is degenerative arthritis of the hip.

Prognosis of LCPD is related to the degree of femoral head involvement and age at onset of the disease. Children younger than 6 years have the best prognosis. The risk of development of

degenerative arthritis in adulthood increases in children whose disease is more extensive and whose condition is diagnosed later (ie, after 8 years of age).

If patients with SCFE are untreated, the potential for further slipping of the femoral head remains until the growth plate closes. Potential treatment-related complications of SCFE include chondrolysis of the femoral head and acetabulum, avascular necrosis, and fracture at the site of pin placement. In general the prognosis is good and is based on the degree of slippage. The main complication is the development of avascular necrosis of the femoral head, which typically leads to degenerative hip disease later in life. This occurs in up to 15% of slips and is more common in an unstable SCFE. Only 7% of patients in the moderate-slip category have a poor outcome compared with 24% of patients in the severe-slip category.

In about 5% to 10% of cases, OSD may become chronic, with persistent swelling and tenderness. In such cases a radiograph may show the formation of an ossicle over the tibial tubercle; this ossicle may require surgical resection.

CASE RESOLUTION

In the case described at the beginning of the chapter, the child's history and physical examination seem to be consistent with LCPD. The child's knee pain is actually secondary to hip pathology. The diagnosis may have been missed if the physician had not examined the hips and noted the abnormality in range of motion. Both AP and frog-leg radiographs of the hips were taken, which showed widening of the joint space. Orthopedic consultation was obtained, and hospitalization for bed rest and ensured immobilization were recommended.

Musculoskeletal Disorders of the Neck and Back

Carol D. Berkowitz, MD, and Andrew K. Battenberg, BS

CASE STUDY

A 4-week-old male infant is brought to the office by his mother, who complains that her son always holds his head tilted to the right. She reports that he has held it in this position for about 1 week and prefers to look mainly to the left. The infant is the 8-lb, 8-oz product of a term gestation born via forceps extraction, and he had no complications in the neonatal period. He is feeding well on breast milk and has no history of fever, upper respiratory symptoms, vomiting, or diarrhea.

On examination, the head is tilted toward the right side with limited lateral rotation to the right and decreased lateral side bending to the left. Except for the presence of a small mass palpable on the right side of the neck, the examination is within normal limits.

Questions

1. What laboratory or radiologic studies are indicated in infants with torticollis?
2. What is the differential diagnosis of torticollis in infants?
3. What are some of the common musculoskeletal abnormalities that may be seen in association with torticollis?
4. What are other common musculoskeletal problems in children and adolescents?
5. What is the current recommended management of children and adolescents with idiopathic scoliosis?

Children with disorders of the spine can present with deformity, back pain, or occasionally both. Non-traumatic congenital and developmental deformities of the spine are frequently encountered in pediatric practice. Torticollis and scoliosis are 2 of the most common disorders in children that present as spinal deformity. **Torticollis**, or wry neck, is a positional abnormality of the neck resulting in abnormal tilting and rotation of the head. **Scoliosis** refers to any lateral curvature of the spine that measures more than 10 degrees as determined by an anteroposterior (AP) radiograph of the spine. Scoliosis can be divided into 3 categories: infantile (birth–3 years), juvenile (3–10 years), and adolescent. **Back pain** is a far less common complaint in children than in adults. When such pain occurs in children, it usually signals the presence of organic disease. However, in adolescents, musculoskeletal strain is a common etiology.

Epidemiology

Some degree of spinal asymmetry is seen in about 2% to 5% of the population.

The most common type of **torticollis** seen in children is congenital muscular torticollis. The incidence is estimated to be between 1% to 2%, and is increased in breech presentations (1.8% vs 0.3% in vertex presentation). It is associated with developmental dysplasia of the hip (DDH) in as many as 10% to 20% of affected infants. Family history may be positive in up to 10% of cases.

Acquired torticollis is much more common in older children and is usually secondary to trauma or infection, including cervical lymphadenitis, retropharyngeal abscess, myositis, and even upper respiratory tract infections. Episodes of benign paroxysmal torticollis, which often begin in the first year of life and generally resolve by 5 years of age, may have a familial basis. An association with benign paroxysmal vertigo and migraines has been noted.

Infantile scoliosis is rare in the United States and usually spontaneously resolves. The prevalence of juvenile **scoliosis** among school-aged children is 3% to 5%. A right thoracic single curve is the most common curve seen by physicians. Seventy-five percent to 80% of cases of structural scoliosis are idiopathic, 10% are due to neuromuscular causes, 5% are congenital, and the remaining 5% to 10% are due to trauma or miscellaneous causes. Scoliosis that begins in childhood affects boys and girls equally, and affected boys actually outnumber girls during the first 3 years of life. However, idiopathic scoliosis that develops after the age of 10 years is more common in girls than boys, with a ratio estimated between 5 and 7:1. In children with cerebral palsy, the incidence of scoliosis is increased, and it is found in about 20% of all cases.

Back pain is quite uncommon in preadolescent children. Unlike in adults, where it is often difficult to identify the cause of back pain, most cases of back pain in children have an identifiable etiology.

Clinical Presentation

Although **torticollis** may be noted at birth, it usually manifests at 2 to 4 weeks of age. Infants with congenital muscular torticollis present with a characteristic head tilt toward the affected side with the chin pointing toward the opposite side; this positioning is secondary to unilateral fibrosis and contracture of the sternocleidomastoid muscle (Figure 106-1). Unrecognized or untreated cases of torticollis may present as plagiocephaly (see Chapter 70) or facial asymmetry during infancy. Benign paroxysmal torticollis of infancy may present as recurrent episodes of head tilt that may be associated with vomiting, ataxia, agitation, or malaise (Dx Box).

No obvious deformity may be noted in mild **scoliosis**. Asymmetry of shoulder heights, scapular prominence or position, and waistline or pelvic levelness may all be signs of scoliosis (see Dx Box) (Figure 106-2A). Back pain is reported in 25% of adolescents with idiopathic

Figure 106-1. Torticollis. Infant with congenital muscular torticollis showing head tilt.

Dx

Torticollis and Scoliosis

Torticollis

- Head tilt
- Limited range of motion of the neck
- Contracture of the sternocleidomastoid muscle
- Plagiocephaly (congenital torticollis)
- Firm, non-tender, mobile mass within the body of the sternocleidomastoid muscle (congenital torticollis)

Scoliosis

- Lateral curvature of the spine
- Some pain
- Back or truncal asymmetry

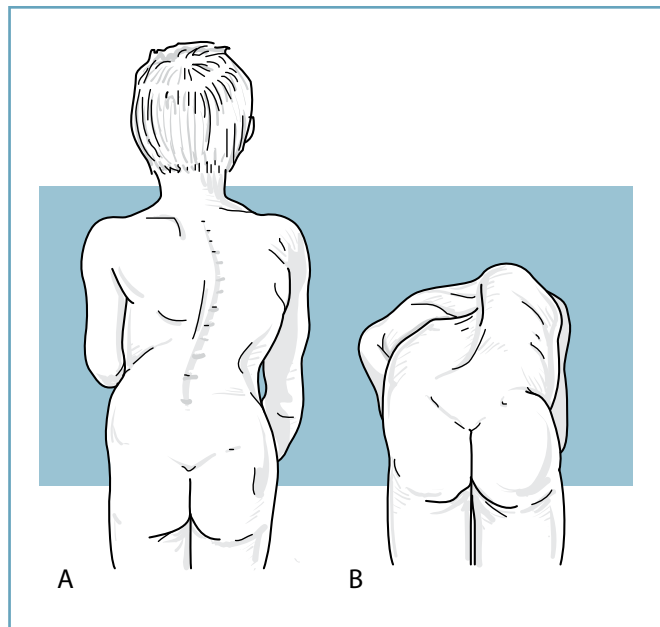

Figure 106-2. Scoliosis. A. Child with scoliosis (rear view). B. Child with scoliosis performing bend test.

scoliosis. Scoliosis may be detected during school-based screening programs or preparticipation sports physicals.

When pain is present, further examination for some other cause (eg, bone tumors, spondylolysis, spondylolisthesis) is warranted.

Preverbal children with **back pain** may present with limp or refusal to bear weight or walk.

Pathophysiology

Torticollis may be either congenital or acquired. The etiology of congenital muscular torticollis is unknown. It is believed to be due to intrauterine positioning or trauma to the soft tissues of the neck during delivery, which results in venous occlusion and ischemia of the sternocleidomastoid muscle. This leads to edema and degeneration of the muscle fibers with eventual fibrosis of the muscle body. Deformities of the face and skull may result if the condition is left untreated. Plagiocephaly (cranial asymmetry), with flattening of the face on the affected side and flattening of the occiput on the contralateral side, is seen most commonly.

Unlike kyphosis and lordosis, which are curves in the AP plane, **scoliosis** is a lateral curvature of the spine occurring in the frontal plane. Scoliosis can be either functional (nonstructural) or structural. In functional scoliosis, there is no fixed deformity of the spine and the apparent curvature disappears with lying down or with forward flexion. Individuals with leg length discrepancies appear to have scoliosis but have no spinal abnormality. Structural scoliosis may be idiopathic or caused by various underlying disorders. The cause of idiopathic scoliosis is unknown, and there appears to be a higher incidence of scoliosis in other family members. In addition, there are reports of lower levels of melatonin in patients with scoliosis, compared with age-matched controls. This finding has

not been confirmed and its relationship to the scoliosis is unclear. Abnormalities of fibrillin have also been seen in some patients with scoliosis, a finding also reported in patients with Marfan syndrome. In structural scoliosis, as the spine curves laterally it forces the vertebrae to rotate, resulting in deformity of attached structures. For example, a “rib hump” may be produced due to scoliosis in the thoracic spine (see Figure 106-2B). Pelvic obliquity or flank prominence may be produced when the curvature is in the lumbar spine.

Differential Diagnosis

The differential diagnosis of congenital and acquired **torticollis** is presented in Box 106-1. Congenital muscular torticollis is the most common cause of congenital torticollis. Acquired torticollis is seen primarily in older infants and children, and may appear in association with nystagmus and head nodding, a clinical triad referred to as spasmus nutans. Cervical lymphadenitis is a common cause of acquired torticollis in children 1 to 5 years of age, whereas trauma to the soft tissues or muscles of the neck is seen more frequently in school-aged children. Acute episodes (eg, benign paroxysmal torticollis of infancy) must be differentiated from chronic conditions (eg, Sandifer syndrome, rheumatoid arthritis).

Box 106-1. Common Causes of Torticollis

Congenital

- Congenital muscular torticollis
- Pterygium coli (skin web)
- Occipitocervical spine anomalies (eg, Klippel-Feil syndrome)

Acquired

- Infectious
- Cervical lymphadenitis
- Retropharyngeal abscess
- Osteomyelitis of cervical vertebrae
- Traumatic
- Atlanto-occipital, atlas-axis (C1–C2), or C2–C3 subluxation
- Cervical musculature injury (spastic torticollis)
- Cervical spine fractures
- Neurologic
- Tumors (posterior fossa or cervical cord)
- Dystonic drug reactions
- Syringomyelia
- Ocular disturbances (strabismus, nystagmus)
- Other
- Spasmus nutans
- Sandifer syndrome (hiatal hernia with gastroesophageal reflux)
- Benign paroxysmal torticollis of infancy
- Rheumatoid arthritis
- Hysteria
- Soft tissue tumors of the neck

Functional or nonstructural **scoliosis** may be secondary to poor posture, leg length discrepancies, or muscle spasm. Structural scoliosis can be classified into idiopathic, congenital, neuromuscular, and miscellaneous forms (Box 106-2). Idiopathic scoliosis, which is by far the most common type of structural scoliosis, may be divided into 3 categories based on age: infantile (0–3 years), juvenile (3–10 years), and adolescent (>10 years). The adolescent form occurs most frequently, accounting for up to 85% of cases.

Congenital scoliosis results from anomalies of the spine such as hemivertebrae or failure of vertebral segmentation. The incidence of cardiac and renal anomalies is increased. Although neuromuscular scoliosis is most often seen in children with spastic cerebral palsy, it may also be apparent in other conditions, such as poliomyelitis, meningomyelocele, muscular dystrophy, Friedreich ataxia, and spinal muscular atrophy. The miscellaneous causes of scoliosis are uncommon and include trauma, metabolic disorders, and neurocutaneous diseases.

The most common causes of **back pain** in children may be classified into 5 categories (Box 106-3). When pain is significant enough that a child presents to the emergency department, common causes include trauma (25%), muscle strain (24%), sickle cell crisis (13%), idiopathic cause (13%), urinary tract infection (5%), and viral syndrome (4%). Other infectious causes, such as diskitis, occur much more frequently in children than adults. Because the spine of children is smaller and has greater flexibility and ligamentous strength, children have a lower risk of traumatic injury than adults. Common causes of back pain in adults, such as musculoskeletal back pain (ie, muscle strain) and herniated disks, are uncommon in children. Predisposed individuals often experience their first episode

Box 106-2. Common Causes of Scoliosis

Functional Scoliosis

- Poor posture
- Leg length discrepancies
- Muscle spasm
- Herniated disk
- Back injury

Structural Scoliosis

- Idiopathic
- Congenital
- Neuromuscular
- Miscellaneous
- Trauma (eg, fractures or dislocations of the vertebrae)
- Intraspinal tumors
- Metabolic disorders (eg, juvenile osteoporosis, osteogenesis imperfecta, mucopolysaccharidosis)
- Neurocutaneous syndromes (eg, neurofibromatosis)
- Marfan syndrome

Box 106-3. Common Causes of Back Pain in Children

Infectious

- Myalgias (eg, influenza)
- Diskitis (more common in children <5 years of age)
- Vertebral osteomyelitis (pyogenic, tuberculosis [Potts disease])
- Referred pain (pyelonephritis, pneumonia)

Inflammatory

- Rheumatologic diseases (juvenile rheumatoid arthritis, ankylosing spondylitis)
- Crohn disease/ulcerative colitis/psoriatic arthritis
- Disk space calcification

Neoplastic

- Primary vertebral and spinal tumors (eg, Ewing sarcoma, osteosarcoma, neuroblastoma)
- Metastatic disease (eg, neuroblastoma)
- Benign tumors (eg, eosinophilic granuloma, osteoid osteoma)

Developmental

- Spondylolysis, spondylolisthesis (adolescents)
- Scheuermann kyphosis (adolescents)

Traumatic

- Herniated nucleus pulposus (disk herniation)
- Ligamentous or muscle strain (eg, overuse syndromes)
- Compression fracture of vertebrae

Other

- Sickle cell crisis
- Osteoporosis (eg, rickets, osteogenesis imperfecta)
- Child abuse
- Psychogenic

of musculoskeletal back pain during adolescence or young adulthood, and children, as a whole, account for only 1% to 4% of all herniated disks.

Evaluation

History

A careful history may provide clues to diagnosis and etiology (Questions box). Back pain is reported in about 25% of adolescents with scoliosis.

Physical Examination

In children with suspected **torticollis**, a thorough examination with specific attention to the head and neck region should be performed. Limited head rotation toward the affected side with decreased lateral side bending to the opposite side may occur. During the first 4 to 6 weeks of life, a firm, non-tender mobile mass (or pseudotumor) may be palpated within the body of the sternocleidomastoid muscle; the mass gradually regresses by 6 months of age. Because torticollis is associated with DDH, the hips should be examined for stability.

Questions

Torticollis, Scoliosis, and Back Pain

Torticollis

- Is there any family history of torticollis?
- What type of delivery did the mother have (eg, cesarean or vaginal)? Were forceps required?
- When was the head tilt first noticed?
- Does the infant move his or her neck in all directions, or does he or she always prefer to look in one direction?
- Does the infant have any recent history of trauma to the head or neck area?
- Is the head tilt persistent or does it come and go?
- Has the infant been sick or febrile?
- Does the child have nystagmus or head bobbing?

Scoliosis

- Is there a family history of scoliosis?
- Have the parents noticed the curvature of the spine? If so, how old was the child when the condition was first noted?
- Has the curvature increased since it was first noticed?
- Does the child have any back pain?
- Has the child had any previous treatment for the condition?
- (If appropriate) Has the child begun menstruating?

Back Pain

- How long has the child had the pain?
- Where is the pain localized?
- Is the pain persistent or does it come and go?
- Does the pain radiate anywhere (eg, down the legs)?
- Is the child limping or having difficulty walking?
- Has the child lost any motor milestones (eg, skills such as walking or standing that he or she could previously perform)?
- What makes the pain better? What makes it worse?
- Has there been any recent history of trauma or has the child begun participating in a new sport or physical activity?
- Has the child had a fever?
- Has the child had any problems with bowel or bladder function?
- Is the child taking any medication?

A neurologic examination should also be performed to look for any neurologic deficits that may be signs of an underlying tumor. Fever or signs of inflammation point to infectious causes. Because torticollis may be secondary to visual disturbances such as strabismus, a careful eye examination is warranted. The presence of nystagmus or head nodding suggests spasmodic torticollis.

Screening for **scoliosis** should be part of the routine health maintenance examination of school-aged children and adolescents. Children should be examined with the back fully exposed. The posture should be observed. The presence of any skin lesions such as café-au-lait spots should be noted. Any midline skin defects such as dimples or hair patches should also be noted because they are often associated with underlying spinal lesions. The spine should be palpated for any signs of tenderness, and a complete neurologic examination should be performed.

The back should be observed for asymmetry of the shoulders, scapulae, or pelvis. Physicians should have children bend forward at the waist to an angle of 90 degrees. This maneuver accentuates the curvature of structural scoliosis and emphasizes the rotational deformity of the spine. For example, in thoracic scoliosis, a characteristic rib hump is apparent on the convex side of the curve. A scoliometer can be used to determine the degree of scoliosis. More than 7 degrees of angulation correlates with a Cobb angle of 20 degrees and warrants referral to an orthopedist.

Scoliosis is described in terms of the primary or major curve, which is predominantly thoracic. The major curve may be accompanied by a secondary or minor curve, which is predominantly lumbar and often compensates the primary curve. The location is defined by the apical vertebra (eg, T2–T11 = thoracic, T12–L1 = thoracolumbar), the direction of the curvature by the side of convexity, and the severity indicated by the degree of curvature as measured on the spinal radiograph. Curves greater than 15 degrees are abnormal. Mild scoliosis is defined as curvature of less than 20 degrees, moderate as 20 to 40 degrees, and severe as greater than 40 to 45 degrees.

The evaluation of **back pain** begins with observation of children's posture and gait. Any midline skin lesions should be noted. A thorough general physical examination is important because referred pain (eg, pancreatitis, pyelonephritis, nephrolithiasis) may be causing the symptoms in the back. The spine should be palpated for any signs of tenderness. A complete neurologic examination should be performed, and any motor or sensory deficits should be noted. The motor examination should emphasize evaluation of the hips and the lower extremities, including range of motion and strength.

Laboratory Tests

In cases of **congenital torticollis**, laboratory studies are rarely necessary. In acquired torticollis, if any infection is suspected, a complete blood cell count (CBC) and blood and local cultures may aid in the diagnosis.

No specific laboratory tests are required in the evaluation of idiopathic **scoliosis**. Specific laboratory studies may be performed in the evaluation of other forms of scoliosis as indicated by the history and physical examination (eg, a urine metabolic screen for suspected metabolic disturbances).

Laboratory assessment for **back pain** depends on the history and physical examination. A CBC, blood culture, and erythrocyte sedimentation rate may be useful in the evaluation of suspected infectious etiologies. Rheumatologic studies such as a rheumatoid factor or human leukocyte antigen typing may help in the diagnosis of rheumatologic conditions. If the back pain is of acute onset, studies such as a urinalysis or serum amylase would help determine if the pain is referred, for example, in pyelonephritis or pancreatitis.

Imaging Studies

Radiographs are generally not useful in children with suspected **torticollis** unless bony anomalies are suspected. Magnetic resonance imaging (MRI) of the sternocleidomastoid muscle mass may be

considered if an underlying condition (eg, a branchial cleft cyst) is suspected. Computed tomography scan or MRI of the head or cervical spinal cord would be indicated if a neurologic tumor is suspected.

Routine radiographs are not required in the evaluation of all children with mild scoliosis (ie, minor degrees of curvature noted on physical examination). It may be best to obtain radiographs after orthopedic evaluation is complete. A standing AP spine radiograph is used to determine the location and direction of the curvature, measure the degree of asymmetry (Cobb angle), and evaluate the vertebrae. Repeat radiographs of the spine are used to follow the progression of the curvature over time. Because the risk of curve progression before skeletal maturity is a primary concern, hand and wrist radiographs should be taken to assess bone age in prepubertal children with scoliosis. Magnetic resonance imaging is recommended in individuals with rapid progression of their curve at more than 1 degree per month. Magnetic resonance imaging should include cervical, thoracic, and lumbar spine to identify deformities such as an Arnold-Chiari malformation or a tethered cord.

As with scoliosis, routine radiographs are not indicated in all cases of **back pain**. Various radiologic studies may be ordered depending on the suspected diagnosis. Radiographs may be useful in the evaluation of suspected vertebral abnormalities such as spondylolysis and spondylolisthesis. However, these conditions may represent incidental findings and not be the source of the back pain. If diskitis is suspected, a bone scan may be more appropriate than radiographs. Similarly, a bone scan or MRI is useful in the evaluation of suspected vertebral tumors.

Management

Treatment of congenital muscular **torticollis** consists of **passive stretching exercises** of the neck. With the neck in a neutral position (ie, not hyperextended), the head is bent to one side so that the ear on the side opposite to the contracted muscle is brought to the shoulder, or the chin is lowered to touch the shoulder on the affected side. In addition, **changing the placement of the crib** in relation to the nursery door and **repositioning toys and mobiles** in the crib stimulate children to look toward the side opposite the preferred gaze. Torticollis resolves spontaneously in most infants. When the deformity persists beyond the age of 1 to 2 years, **surgical release** of the contracted muscle may be indicated.

Management of acquired torticollis depends on etiology. The evaluation and treatment of many of these conditions can be complex and often require consultation with specialists in head and neck surgery, neurology, and orthopedic surgery.

Management of **scoliosis falls into 3 groups: observation, bracing, and surgery**. **Observation** involves **close follow-up** with careful repeat examinations and radiographic studies. Children who have not undergone their rapid growth phase are at greatest risk of marked progression of their curve. The Risser sign is used to assess the degree to which skeletal maturation has progressed. The sign is based on the degree of ossification of the iliac apophysis, with a Risser 0 signifying no ossification and a Risser 5 representing full

ossification. An initial consultation with an orthopedic surgeon is generally advisable, even in minor degrees of curvature. The goal of follow-up is early detection of curvature with implementation of treatment to prevent or reduce curve progression. Children with curves less than 20 to 25 degrees should be monitored for progression. Curves between 25 to 45 degrees do not require bracing in skeletally mature individuals (Risser 4 or 5) but should be braced (eg, with Milwaukee brace) in growing children. The goal of **bracing** is not to correct any existing curvature but to prevent further curve progression. The efficacy of bracing is determined by adherence to the regimen. **Surgery** (eg, the Harrington rod or posterior spinal fusion) may be indicated for children with curves greater than 40 to 45 degrees. These curves have a high likelihood of progression regardless of the patient's age and skeletal maturity. The development of pedicle screws has advanced the process of spinal fusion.

Although the management of **back pain** is diagnosis dependent, **rest** and **immobilization** are principles of treatment that apply in many instances. In the management of diskitis, antistaphylococcal antibiotics may be necessary in addition to immobilization. If spondylolisthesis and spondylolysis do not respond to rest and immobilization, operative stabilization may be required. In adolescents with low back pain related to muscular injury, conservative treatment, including bed rest, heat, and anti-inflammatory medications, may be tried for 1 to 2 weeks followed by a gradual return to normal activity. It is not advisable to institute such treatment in younger children without pursuing a more extensive evaluation or consultation with an orthopedic surgeon because the risk of serious disease is significant in this age group.

Prognosis

Congenital muscular **torticollis** responds to conservative management in about 90% of infants. The asymmetry of the face and skull also corrects over time once the contracture of the sternocleidomastoid resolves. Spasmus nutans, a condition that develops between 4 and 12 months of age, usually resolves spontaneously by 3 years of age.

The direction and location of the curvature in **scoliosis** do not change with age, but the degree of curvature may remain stable or progress. Factors associated with a high risk of curve progression include female gender, positive family history for scoliosis, younger age at diagnosis (especially before the adolescent growth spurt), and a larger curve at the time of diagnosis. In addition, a double curve is more likely to progress than a single curve, and a thoracic curve is more likely to progress than a lumbar curve. Left untreated, severe scoliosis can produce cardiopulmonary impairment or cosmetic deformity, which may lead to low self-esteem and poor body image. Decreased exercise tolerance has been reported in individuals with curves as small as 20 degrees. Individuals with infantile and juvenile scoliosis experience increased mortality from pulmonary and cardiac conditions during their 40s and 50s.

Most cases (80%–90%) of low **back pain** in adolescents and young adults resolve spontaneously in 2 to 8 weeks. It is important for patients to learn how to prevent recurrence by improving posture, learning how to lift heavy objects appropriately, and instituting a program of exercises to help strengthen the abdominal and back muscles.

CASE RESOLUTION

The history of the infant presented in the opening case scenario is consistent with congenital muscular torticollis. Physical examination helps confirm the diagnosis. The hips should be evaluated thoroughly because of the association of congenital muscular torticollis with DDH. A program consisting of neck stretching exercises and repositioning of interesting toys and objects in the infant's crib to the side opposite the preferred gaze should be instituted. The infant can be reevaluated in 2 to 3 weeks to monitor progress.

Vomiting

George Gershman, MD

CASE STUDY

A 6-week-old male infant who has been vomiting after each meal for 3 days is brought to the office. He is breast-fed, afebrile, and otherwise well. The history of the pregnancy and birth are normal. His birth weight was 3,500 g, and his current weight is 4,500 g. The physical examination is unremarkable. The mother nurses the infant in the office. Although he feeds hungrily and well, he vomits about 5 minutes after the feeding. The vomiting is projectile, and the vomitus shoots across the room. The vomitus contains curdled milk. On reexamination of the abdomen, a small mass is felt in the right upper quadrant.

Questions

1. What is the mechanism of vomiting, and how does it differ from regurgitation and rumination?
2. What are the common causes of vomiting in infants?
3. What are the common causes of vomiting in older children?
4. What is the significance of bilious vomiting?
5. What are the unique features of vomiting related to increased intracranial pressure?
6. What are some strategies for the management of vomiting in older children?

Vomiting is a common complaint of infants and children, and led Thomas Phairst to write, “Many times the stomake of ye child is so feble that it cannot retayne eyther meate or drynke” (*The Boke of Chylidren*, 1553). Vomiting is defined as the forceful ejection of the stomach contents through the mouth. The mechanism involves a series of complex, neurologically coordinated events under the control of the central nervous system (CNS). In contrast, regurgitation is the effortless bringing up of 1 or 2 mouthfuls of food without distress or discomfort. This is a frequent symptom of gastroesophageal reflux in infants (see Chapter 108). Rumination, a form of autostimulation, is the voluntary induction of regurgitation. It is most often noted in infants between the ages of 3 and 6 months. Rumination occurs in infants with developmental retardation or with a disturbed mother–infant relationship. It is said that affected infants always smell like vomitus, which is on the clothing, but that the vomiting is rarely seen because the presence of another person provides distraction.

Rumination should be considered in infants from deprived environments (eg, neglectful homes). Cases of rumination have been described in premature infants who were maintained in a neonatal intensive care unit after they no longer needed vigilant care from the nursing staff. Incubators, which were cut off from the outside environment, contributed to the isolation and subsequent rumination. The condition resolved once the infants were held and nurtured.

Epidemiology

Fifty percent of infants have spitting up or vomiting as an isolated complaint and less than 5% of these infants have significant underlying disease. Vomiting occurs less frequently in older children, who often experience acute, self-limited illnesses, such as gastroenteritis.

Clinical Presentation

Infants and children may present with vomiting as an isolated complaint or in association with other symptoms, including faintness, diaphoresis, sweating, pallor, tachycardia, fever, anorexia, abdominal pain, or diarrhea (Dx Box). When vomiting has persisted over a period, weight loss or failure to thrive (FTT) may occur. Neurologic symptoms, including headache and gait disturbances, may be noted in children with CNS problems. Other neurologic symptoms of altered muscle tone, lethargy, seizures, or coma in young infants suggest inborn errors of metabolism.

Dx Vomiting

- Vomiting
- Nausea
- Abdominal pain
- Anorexia
- Diarrhea
- Headache
- Fever
- Lethargy

Pathophysiology

Vomiting is a reflex reaction that occurs in response to numerous stimuli: enteric infections, toxins, drugs, chemotherapy, radiation, etc. The final common pathway involves expulsion of food from the relaxed stomach into the mouth due to coordinated contraction of the abdominal wall, respiratory muscles, increased intra-abdominal

and thoracic pressure, and relaxation of the lower and upper esophageal sphincters.

Anything that delays gastric emptying may be associated with vomiting. Gastric emptying may be retarded by a high-fat meal, swallowed mucus (eg, maternal mucus after birth, nasal mucus with an upper respiratory infection), fever, infection, and malnutrition. Delayed gastric emptying may develop with long-standing diabetes mellitus.

Vomiting can be divided into 3 phases: nausea, retching, and emesis. However, nausea may occur without retching and vomiting, and retching may occur without vomiting.

Nausea is a significant and difficult to define discomfort related to the sensation of a need to vomit. It can be produced by various stimuli (eg, bacterial toxins, drugs, intestinal distention, visceral pain, unpleasant memories, labyrinthine stimulation, noxious odors, visual stimulations, unpleasant taste, and increased cerebral pressure). Peripheral receptors in the stomach and the small and large intestines detect emetic stimuli; distention and contractions are recognized by mechanoreceptors and toxins are sensed by chemoreceptors. Emetic stimuli may also originate from the obstructed or inflamed bile ducts, peritoneal inflammation, mesenteric vascular occlusion, the pharynx, and the heart. Vagal pathways mediate emetic responses to a variety of peripheral stimuli. Most afferent vagal fibers project to the nucleus tractus solitarius and some to the area of postrema or the dorsal vagal motor nucleus. The serotonergic pathway plays the central role in nausea induced by peripheral stimuli.

The area postrema on the dorsal surface of the medulla close to the fourth ventricle is considered the chemoreceptor trigger zone to a variety of neurochemical stimuli. Bacterial toxins, drugs, toxic products of metabolic disorders, and radiation therapy may induce nausea by stimulation of numerous central receptors: dopamine D₂, muscarinic M₁, histaminergic H₁, serotonergic 5-HT₃, and vasopressinergic subtypes located in the area postrema. However, afferent excitation of multiple brain sites, including nucleus tractus solitarius, the dorsal vagal and phrenic nuclei, the medullary nuclei controlling respiration, the hypothalamus, and the amygdala, is responsible for coordinated activities of various organs and muscles and the induction of retching and emesis.

Retching is the second phase of vomiting. It is produced by concurrent contractions of inspiratory thoracic, diaphragmatic, and abdominal muscles against the closed glottis. The generated high positive intra-abdominal pressure forces gastric contents into the esophagus and herniates the gastric cardia into the thorax. At this phase, the high negative thoracic pressure prevents emesis of gastric fluids.

Emesis is the final stage of vomiting. Synchronous contractions of the inspiratory and expiratory muscles generate high positive intrathoracic pressure sufficient to produce expulsion of gastric contents into the mouth. Oral propulsion of the vomitus is facilitated by the elevation of the hyoid bone and larynx. Airways are protected from aspiration by glottis closure. Elevation of the soft palate prevents

passage of the vomitus into the nasal cavities. Hyperventilation may occur before emesis. During vomiting, breathing is suppressed.

With emesis, retrograde giant contractions originate from the middle of the small intestine. Intestinal contents move into the stomach causing enterogastric reflux. Within the stomach, the fundus remains flaccid, but the antrum and pylorus contract. Relaxation of the lower esophageal sphincter also occurs.

In children with pyloric stenosis, enterogastric reflux is prevented by hypertrophy of the pylorus. Projectile vomiting is facilitated by giant, often-visible contraction of the antrum and relaxation of the proximal stomach and low esophageal sphincter. Nausea is not associated with vomiting related to pyloric stenosis, and affected infants are frequently eager to eat immediately after vomiting.

Vomiting induced by increased intracranial pressure (ICP) is also not associated with nausea. In addition, such vomiting frequently occurs first thing in the morning on awakening and on an empty stomach. Regurgitation is a return of undigested food back up the esophagus to the mouth without the force and displeasure associated with vomiting. It could be manifested by visible spitting up after feeding or could be silent. Clinical evidence of regurgitation is not always associated with gastroesophageal reflux disease (GERD).

Differential Diagnosis

Vomiting could be a manifestation of gastrointestinal (GI), renal, metabolic, allergic, and CNS disorders. Some of them respond to medical management, and others mandate surgical intervention (Box 107-1). The presence of bile in the vomitus, referred to as bilious vomiting, is a serious sign, usually indicative of intestinal obstruction distal to the major duodenal papilla and of the need for surgical intervention. Bilious vomiting can also occur in children with pseudo-obstruction syndrome or acute pancreatitis and other conditions leading to paralytic ileus.

The presence of blood in the vomitus is another ominous sign and is discussed in Chapter 109.

The most common cause of vomiting is acute viral or bacterial gastroenteritis. Acute gastroenteritis is discussed in greater detail

Box 107-1. Differential Diagnosis of Vomiting in Infancy

Medical Conditions

- Gastroenteritis
- Ingestion of maternal blood or mucus
- Overfeeding
- Food allergies
- Inborn errors of metabolism
- Congenital adrenal hyperplasia
- Parenteral infections (eg, otitis media, urinary tract infection)

Surgical Conditions

- Atresia/stenosis of gastrointestinal tract
- Pyloric stenosis
- Ulcers
- Intussusception
- Volvulus
- Appendicitis

in Chapter 110. In cases that are not related to acute gastroenteritis, considering the age of the patient is the best approach to the differential diagnosis of vomiting.

Infants

Vomiting in neonates may be associated with the ingestion of irritants such as maternal blood or mucus. Either of these substances delays gastric emptying. Structural anomalies of the GI tract may also cause vomiting in neonates. The onset of symptoms is directly related to the level of obstruction, the higher the structural obstruction, the earlier the onset of vomiting. Lesions of the esophagus, such as esophageal atresia, may be evident in the delivery room, with an unsuccessful attempt to pass a nasogastric tube. Lower GI lesions, such as ileal atresia, may not present for several days. These lesions require surgical intervention. Infants with atretic lesions may also have a history of polyhydramnios or a single umbilical artery.

Overfeeding is the most common reason for spitting up in young infants. Frequently, infants who present with vomiting are actually experiencing spitting up or regurgitation. Overfeeding is less likely to occur in breastfed infants, because they have better control of their satiety. The physician should approach breastfed infants who are vomiting with care and concern.

Mothers of bottle-fed infants may feel that the volume of formula consumed by their infants is insufficient. Some non-nursing mothers feel the need to reinsert a nipple in the infant's mouth, and infants who are still interested in sucking (nonnutritive sucking) continue to feed, often exceeding the capacity of the stomach.

Food allergies are another common cause of vomiting during infancy. Infants with cow's milk formula intolerance may experience vomiting. At least 30% of these infants are also allergic to soy protein. Associated symptoms such as diarrhea, rhinorrhea, eczema, and growth failure frequently occur.

Gastroesophageal reflux is a common cause of regurgitation. It is described in detail in Chapter 108.

Achalasia is a rare cause of vomiting during infancy. It is defined as an absence of effective esophageal peristalsis and coordinated relaxation of the low esophageal sphincter. Ingested food that is unable to pass into the stomach may be regurgitated. Children with achalasia usually do not present until later in childhood, although they may have a prenatal history of polyhydramnios, a sign suggesting an abnormal swallowing pattern, even in utero.

Metabolic disorders, including inborn errors of metabolism and endocrine problems, may also be associated with vomiting. For example, children with galactosemia may present with vomiting as well as with jaundice, dehydration, cataracts, and hepatomegaly. Other inborn errors of metabolism include methylmalonic acidemia, disorders of the urea cycle, phenylketonuria, maple syrup urine disease, renal tubular acidosis, hypercalcemia, and diabetes insipidus. Some of these disorders induce symptoms suggestive of sepsis, such as lethargy and seizures.

Male infants with congenital adrenal hyperplasia (CAH) may present with vomiting and electrolyte disturbance, symptoms indicative of adrenal insufficiency. Affected male infants usually present at

about 10 to 14 days of age with vomiting and hyperkalemia (which should not be attributed to hemolysis of the specimen); hyponatremia develops later. In females, CAH is usually detected in the newborn nursery because of ambiguous genitalia. Diagnosis of this potentially lethal condition is critical to ensure the institution of replacement therapy and survival of affected infants.

Vomiting may be induced by infection in parts of the body other than the GI tract. Most notably, urinary tract infections (UTIs) in infants may cause projectile vomiting, a symptom highly suggestive of pyloric stenosis. These infants are usually febrile and the diagnosis is considered when the urinalysis or culture is positive. Otitis media may also be associated with vomiting.

Vomiting, especially if unrelated to meals, may occur with increased ICP. In young infants, this suggests the possibility of an intracranial hemorrhage as occurs with abusive head trauma.

Pyloric stenosis, a condition caused by hypertrophy of the muscle surrounding the pyloric channel, is the most common surgical condition associated with vomiting in infancy. The condition affects males significantly more frequently than females and usually appears in infants between the ages of 2 weeks and 2 months. Factors that are known to increase risk of pyloric stenosis include being firstborn, male, and a greater birth weight, and early exposure to erythromycin. The emesis is projectile and non-bilious, and frequently contains curdled milk, which reflects delayed gastric emptying, a problem caused by failure of the hypertrophied pylorus to relax. Affected infants have an intact appetite and are eager to eat. In some infants, starvation leads to few bowel movements and constipation; in others there may be small, frequent, mucus-laden stools (starvation diarrhea) that represent succus entericus. If pyloric stenosis is not diagnosed promptly, infants may fail to gain weight or may exhibit FTT. Symptoms suggestive of pyloric stenosis may result from an antral web or duplication of the GI tract.

Children

Vomiting in children is frequently associated with gastroenteritis. Infections elsewhere in the body, particularly UTIs, streptococcal pharyngitis, and otitis media, are also associated with vomiting. Labyrinthitis presents with vomiting associated with dizziness. Older children with new-onset diabetes mellitus may present with vomiting. Vomiting may also appear in children who are already known to be diabetic. This is particularly true when ketosis is present. Slow gastric emptying (gastroparesis) is a complication of long-standing diabetes mellitus. Vomiting is also a component of peptic ulcer disease, which is described in more detail in Chapter 112.

Vomiting may be a major symptom of CNS-related problems, such as tumors, infections, hydrocephalus, malformations, and other causes of increased ICP. As previously noted, vomiting in CNS-related conditions is often unrelated to meals and may not be associated with nausea. Autonomic epilepsy and migraine headaches are also associated with vomiting. Cyclic vomiting is an unusual condition characterized by recurrent episodes of vomiting with intervals of complete wellness between attacks. Emotional upset can precipitate events, and there may be a history of migraine headaches.

Vomiting is one of the hallmarks of Reye syndrome, a disorder that involves an encephalopathy in association with fatty infiltration of the liver. The etiology of the condition is unclear, but the root of the disorder seems to be related to mitochondrial dysfunction. Affected children usually have a history of an antecedent viral illness, most commonly influenza or chickenpox. Following a period of recovery, they experience altered consciousness with vomiting. Hepatic enzymes and serum ammonia are elevated. Aspirin, which uncouples oxidative phosphorylation, is apparently linked to Reye syndrome, both epidemiologically as well as theoretically. There has been a marked reduction in the incidence of Reye syndrome related to the decrease in the use of aspirin and vaccination of children against varicella and influenza.

Certain medications, including theophylline, erythromycin, and digitalis, may also be associated with vomiting. Some of these medications cause transient relaxation of the lower esophageal sphincter and others affect the chemoreceptor trigger zone.

Familial dysautonomia, Riley-Day syndrome, a rare condition that affects Jewish individuals, results in vomiting. The disorder is inherited in an autosomal-recessive manner and consists of an imbalance in the autonomic nervous system. Children experience intractable vomiting in addition to excess perspiration, inability to produce tears, difficulty swallowing and chewing, and cold hands and feet. They also have hyperpyrexia and hypertension. These children require fluid replacement and management with antiemetics.

Surgical conditions such as appendicitis, gall bladder disease, and twisted ovarian cysts are discussed in Chapter 112.

Adolescents

Vomiting during the adolescent years may be caused by any of the previously mentioned conditions. In addition, adolescents may develop vomiting in association with intentional ingestion of illicit drugs or alcohol. Many adolescents have incorrect notions of the sexual activity needed to initiate pregnancy. Teenaged girls, who have been vomiting, especially for a time, should be evaluated for pregnancy, regardless of their disclosed sexual activity status.

Adolescents with eating disorders, particularly bulimia, vomit but may not disclose their vomiting. They may ingest emetics, such as ipecac, to help control their weight (see Chapter 133).

Evaluation

History

A complete history is essential for correct diagnosis (Questions Box). A positive family history of vomiting may suggest a diagnosis of food intolerance/allergy, gastroesophageal reflux or peptic ulcer disease, migraine, or familial dysautonomia.

Physical Examination

The examination shows the impact of vomiting on children's growth. The weight may provide evidence of the chronicity of the process; weight loss suggests a protracted course. Evidence of other infections,

Questions

Vomiting

- What is the nature of the vomiting (projectile, bilious, non-bilious)?
- How long has the child been vomiting?
- Are any symptoms such as fever, diarrhea, dizziness, or lethargy associated with the vomiting?
- What is the relationship of the vomiting to meals?
- Does the vomiting occur at night, indicating possible hiatal hernia and gastroesophageal reflux?
- Is there a family history of vomiting?
- Is the child taking any medications?
- Have any measures been taken to relieve the vomiting?

such as otitis media or pneumonia, may also be apparent. An abnormal neurologic examination would suggest a CNS process or an inborn error of metabolism. The fundi of the eyes should be assessed for the presence of papilledema or retinal hemorrhages. Nystagmus may be noted in children with labyrinthitis or CNS disturbances. The examination of the abdomen may show abdominal distention due to surgical or non-surgical conditions such as Hirschsprung disease; malrotation; adhesions after previous surgery; pancreatitis; celiac sprue; chronic idiopathic constipation; and abdominal, pelvic, or retroperitoneal masses.

Laboratory Tests

The laboratory assessment is determined by the differential diagnosis. If gastroenteritis or enterocolitis is suspected, an examination of the stools for leukocytes and occult blood is appropriate. Specimens for bacterial or viral cultures or viral antigen detection can be submitted. A complete blood cell count may support the diagnosis of infection or reveal signs of anemia. In breastfed neonates and infants, vomited blood should be evaluated using the Apt Downey test to determine whether it came from the mother or infant.

Electrolytes should be obtained in infants or children with a history of significant vomiting and may confirm dehydration, acid-base imbalance or electrolyte disturbance. Infants with pyloric stenosis who vomit stomach contents develop a hypochloremic-hypokalemic alkalosis. A urinalysis also may show evidence of dehydration as well as signs of a UTI. Tests for inborn errors of metabolism, such as urine for acid analysis, are appropriate if this is suspected.

Imaging Studies

Radiographic procedures, such as esophagram or upper GI series, are the procedure of choice for diagnosis of esophageal and duodenal atresia and intestinal malrotation. An abdominal ultrasound is most effective in the diagnosis of pyloric stenosis or intussusception. A flat plate of the abdomen may show stomach distention, a "double bubble" (air in the stomach and duodenum), or a paucity of intestinal air in cases of high-level obstruction. Consultation with a pediatric gastroenterologist may lead to additional diagnostic tests, such as endoscopic evaluation.

Management

The initial step in the management of vomiting infants or children is to ensure adequate hydration and integrity of the cardiovascular bed. This may require the administration of intravenous fluids. Oral rehydration is the mainstay of therapy in infants and children whose vomiting is related to gastroenteritis. Small, frequent feedings with clear fluids are better tolerated than large, infrequent feedings, although the latter may be necessary in infants with diarrhea because each feeding may result in a bowel movement. Antiemetics such as phenothiazines are discouraged in children because of the high incidence of side effects, including dystonic posturing. Drugs commonly used in pediatric practice include antihistamines, dopamine D₂, and serotonin 5-HT₃ receptor antagonists. Oral ondansetron is frequently used as a single dose to manage the vomiting seen in acute viral gastroenteritis in the pediatric emergency department or as repeated doses for hospitalized children with other conditions associated with vomiting.

Further management depends on the diagnosis. Bacterial infections should be treated with the appropriate antibiotics. Surgical conditions, such as pyloric stenosis or intussusception, should be managed operatively. Inborn errors of metabolism require consultation with a geneticist and dietary manipulation. Congenital adrenal hyperplasia should be managed in consultation with an endocrinologist. This condition necessitates replacement hormonal therapy.

Prognosis

Most cases of acute vomiting resolve spontaneously or are readily managed once the underlying condition is diagnosed. The overall prognosis is therefore quite good.

Protracted vomiting may result in starvation and FTT, however. Severe vomiting may cause tears in the esophagus and lead to hematemesis. Obstructive causes of vomiting in infants respond to surgical intervention.

CASE RESOLUTION

The infant in the case history exhibits the signs and symptoms consistent with pyloric stenosis. The boy is a healthy, vigorous breastfed infant, and his weight gain of 1,000 g in 6 weeks (average: 25 g/d) is normal. The vomitus is curdled indicating that it has been in the stomach for more than 3 hours. Gastric emptying is delayed. The presence of a mass in the right upper quadrant is also consistent with the diagnosis. An ultrasound would confirm the finding. It would be equally appropriate to feed the infant nothing by mouth, start intravenous fluids, and obtain surgical consultation.

Gastroesophageal Reflux

Jeremy Screws, MD

CASE STUDY

A 22-month-old boy presents with a history of vomiting small amounts of food twice weekly. The emesis occurs most often after meals or periods of being very active. There does not seem to be any pain or discomfort with the vomiting. He has been otherwise healthy, with an uneventful course as an infant, good weight gain, and no hospitalizations. He has had mild respiratory symptoms beginning at 6 months with some nighttime cough and occasional wheezing. There is no history of pneumonia, dysphagia, or abdominal pain. Physical examination is normal, with no anemia or urinary tract disease noted on laboratory assessment.

Questions

1. What are the characteristics of gastroesophageal reflux (GER)?
2. What is the difference between GER and gastroesophageal reflux disease (GERD)?
3. What groups of children are at risk for GER?
4. What is the appropriate workup for an infant with suspected GER?
5. What is the appropriate management of infants and children with GER and GERD?
6. What is the natural history of GER in children?

Gastroesophageal reflux includes a spectrum of disease from physiological phenomena to pathologic disease. It involves the retrograde movement of gastric contents into the esophagus. Reflux episodes often follow meals and are brief. Gastroesophageal reflux may manifest as **regurgitation** to the oral pharynx with re-swallowing or vomiting with expulsion from the mouth. Gastroesophageal reflux is common in infants beginning at 2 to 3 months of age and resolving in most individuals by 18 months.

Although this process is common in the first year of life, it typically does not pose a problem unless it fails to resolve by 18 to 24 months. In contrast, GERD denotes a more severe pattern involving injury to the esophagus as well as the presence of extra-intestinal disease. This term is used when there are symptoms present such as pain, feeding or swallowing difficulties, cough, wheezing, or poor weight gain. Complications including pneumonia or esophagitis are also part of reflux disease. While GER may require only anticipatory guidance and monitoring, GERD necessitates further evaluation and medical therapy. Although GER and GERD are defined separately, there is sometimes confusion in the medical community. It must be emphasized that GERD involves symptomatic disease.

Epidemiology

Gastroesophageal reflux has a heterogeneous presentation, making it difficult to study longitudinally. We must be careful to make the distinction between GER and GERD as opposed to using these terms synonymously. Most infants with either condition who are brought for medical care will present by 6 months of age. Regurgitation occurs at least once daily in half of infants younger than 3 months and in nearly two-thirds of infants by 4 months. By 12 months only 5% of

infants will continue to have symptoms. Gastroesophageal reflux disease is considerably less common, with the prevalence depending on the type of symptom studied. It is reported at less than 10%. Most infants with reflux will need little to no medical intervention.

High-Risk Groups

Patients with neurologic injury have a higher prevalence of GERD. The management of these individuals requires a more aggressive approach. They are more likely to have esophagitis or aspiration, and anti-reflux surgery should be considered early in the treatment regimen. Infants who have undergone repair of esophageal atresia also have more severe disease, with at least one-half requiring anti-reflux surgery. Chronic respiratory disease such as cystic fibrosis is associated with GERD. It is described in two-thirds of patients with asthma, but this association is controversial. It is not clear whether the altered physiology of these diseases causes reflux, or if reflux exacerbates the pulmonary dysfunction. Similar triggers for asthma and GERD are described, so it may be that they are coexisting and unrelated. Recent studies with intraluminal impedance monitoring (see Evaluation) show that non-acid reflux occurs frequently in asthmatics. This would help to explain the lack of success of therapy aimed at acid suppression in this group of patients.

Clinical Presentation

The most frequent presentation for infants with GER is recurrent vomiting that is non-forceful and small in volume (Dx Box). Vomiting typically occurs after feeding and does not seem to disturb the patient. Some parents report a link between fussiness or crying with feeding, but this is not reproducible in trials comparing

Dx Presenting Signs and Symptoms of Gastroesophageal Reflux Disease

- Regurgitation
- Vomiting
- Fussiness or sleep disturbance
- Poor weight gain
- Hematemesis or anemia
- Odynophagia or dysphagia
- Asthma/apnea/aspiration

symptoms with pH studies. Further symptoms such as poor weight gain, anemia, or swallowing difficulties are characteristic of GERD. Nighttime cough, asthma, and recurrent pneumonia are respiratory presentations that may be seen. Older children can have recurrent emesis but may also complain of chest or abdominal pain. The adult symptoms of heartburn and regurgitation with epigastric or chest pain may not be noted in children until 8 to 12 years of age. Sandifer syndrome is a rare presentation in infants, with characteristic paroxysmal movements involving arching of the back that may be mistaken for seizures.

Pathophysiology

There are many factors felt to be involved in the pathophysiology of reflux disease. Many of these change as the child grows. This helps explain the improvement in infant GER over time. Motility and pressure differentials between the esophagus and stomach control the flow of gas and liquid across the lower esophageal sphincter (LES). Refluxate is allowed into the distal esophagus multiple times daily in all ages by *transient lower esophageal sphincter relaxations*. Increased frequency or duration of these relaxations, rather than low LES pressure, is felt to be a major cause of GERD. Transient lower esophageal sphincter relaxations are mediated by a brain stem reflex involving the vagal nerve and the release of nitric oxide.

The position of the gastroesophageal junction and its relationship to the diaphragmatic crura play an important role. The opposed crura have a “pinchcock” action that works with the esophagogastric angle, or angle of His, to prevent reflux. As this angle becomes more open or obtuse, reflux may increase. Disruption of this anatomical association, as seen with *hiatal hernia*, predisposes individuals to reflux.

Relaxations of the LES that are too frequent or prolonged expose the esophageal mucosa to noxious material. Secretions from the esophagus and salivary glands neutralize the refluxate and sweep it into the stomach. Appropriate peristalsis of the esophagus is therefore necessary for clearance. Inflammation in the distal esophagus exacerbates this process by decreasing peristalsis. Position influences gravity, with the upright position favoring antegrade movement. The composition of the refluxate influences the damage that can occur. Hydrochloric acid, pepsin, bile acids, and pancreatic enzymes have all been implicated in mucosal injury. The mucosa must combat this exposure with its own defense.

Before food or secretions can move out of the esophagus, the stomach must be ready to accept it. The fundus normally relaxes without an increase in pressure. Dysfunction of this fundic accommodation or delay in gastric emptying can increase pressure in the stomach and exacerbate reflux. The volume of ingested feedings is noted to be a factor in infants. Based on the size of their stomachs, infants typically take twice the volume of older children. This leaves more material in the stomach at any given time, potentially increasing intragastric pressure.

Differential Diagnosis

A diverse group of symptoms, each with its own list of potential diagnoses, are associated with reflux disease. Regurgitation and vomiting are the most commonly reported symptoms. Many of the causes of vomiting in the newborn can be separated from reflux with a history and physical examination (Box 108-1). Forceful, bilious, or bloody emesis is not typical of reflux. Fussiness and crying are nonspecific symptoms with etiologies ranging from infantile colic to meningitis. Esophagitis has many other etiologies of which eosinophilic

- Self-induced vomiting

esophagitis must be considered. This condition presents more typically in the atopic child with dysphagia. It may also present with food impaction in the esophagus, which is secondary to strictures and a small-caliber esophagus. However, the pain and vomiting of eosinophilic esophagitis may mimic GERD. An esophageal biopsy reveals the presence of intra-epithelial eosinophils. Management focuses on dietary manipulation and the elimination of identified foods that the child is allergic to.

Evaluation

Separating the mildly symptomatic “happy spitter” from the child with very apparent, painful erosive esophagitis may not prove difficult. However, deciding how much vomiting is too much may prove vexing. The presence of certain risk factors in the initial history should prompt further evaluation. These factors include poor weight gain, food avoidance, respiratory disease, unexplained anemia or frank hematemesis, or significant chest or abdominal pain.

History

Targeted questions about the timing and volume of feedings and their relationship to regurgitation can help build the case for reflux. Specific attention should be paid to respiratory symptoms such as nighttime cough or previous episodes of pneumonia. Difficulties with feeding and swallowing should be outlined carefully. Gagging or dysphagia with different consistencies should be noted. Family history of reflux, especially as an infant, may be helpful. A history of atopy in the family, including asthma and food allergies, will assist when considering eosinophilic esophagitis. Clinical questionnaires, including the Infant Gastroesophageal Reflux Questionnaire, have been validated but do not predict prognosis or severity. They are more useful in the research setting.

Physical Examination

One should perform a full physical examination, including an observation of feeding. Neurologic deficits or delay should be noted. The abdomen should be carefully palpated for masses or distension. Growth parameters should be reviewed longitudinally and the child's body habitus, particularly the amount of subcutaneous tissue, should be noted.

Laboratory Tests

Most patients with reflux will need no laboratory testing. Urinary tract infections may present in infants with only vomiting so a urinalysis and culture is reasonable. Children with large volume emesis or weight loss should be assessed for acidosis or other electrolyte abnormalities. Markers of kidney and liver function are reasonable to obtain. If anemia is suspected based on the physical examination or the presence of hematemesis, hematologic studies should be obtained.

Intra-esophageal pH Monitoring

Currently measurement of the intra-esophageal pH for periods of 24 to 48 hours is considered the gold standard for the diagnosis

of GERD. This is performed by placing a catheter transnasally into the distal esophagus to measure the intraluminal pH as the patient records the symptoms of interest, such as cough and pain. Meals are also recorded. Monitoring of pH can be performed safely in all age groups, and certain parameters of this study do correlate with esophagitis. It does not detect non-acid reflux, making its utility in linking respiratory disease to GERD questionable. It may be combined with multichannel sleep studies to investigate apnea or nighttime symptoms. A wireless device that attaches to the esophageal mucosa has been used in children. The device can be placed with or without endoscopy, but the size of the capsule may prohibit its use in smaller children.

Upper Gastrointestinal Series (UGI)

Contrast radiography of the upper gastrointestinal (GI) tract is often employed early in the evaluation of reflux. The utility of the test is not for screening; however, its sensitivity and specificity are both low. The brief duration of the examination misses episodes of reflux. Conversely, if episodes are seen it must be noted that the positioning of the patient and the pressure applied to the abdomen are not physiological. This test should be used only to identify anatomical anomalies that could cause vomiting, such as malrotation, esophageal or intestinal webs, pyloric stenosis, or hiatal hernia. Large volumes of refluxate to the level of the proximal esophagus or pharynx, if seen, are more likely to indicate GERD.

Scintigraphy

Nuclear medicine studies may be employed in the evaluation of reflux. In general they involve the administration of an age-appropriate feeding of technetium-labeled food. For infants this would be labeled formula at a volume that approximates a typical feeding. For older children this would include a mixed meal of liquids and solids. Scans are taken serially to mark the location of the tracer. There are 3 questions that can be answered with these studies. The first use of this method is to quantify the rate at which the stomach empties. This may be expressed as half time ($T_{1/2}$), which refers to the time taken to empty 50% of the tracer from the stomach. Alternatively, it may be expressed as percentage emptied at 90 minutes. For children younger than 1 year the $T_{1/2}$ should be less than 60 minutes for liquids. For older children a $T_{1/2}$ of 90 minutes has been accepted. The second use for scintigraphy is measurement of tracer in the esophagus, indicating a reflux episode. Shorter intervals between scans are required, and both acid and non-acid reflux are measured. As with the UGI, this test has a low sensitivity for reflux disease, making it unacceptable as a screening examination. However, the specificity is higher and multiple episodes may be supportive for the diagnosis of GERD. The third use for this modality is detection of aspiration. Delayed scans up to 24 hours later may be employed, which can show tracer in the pharynx or lung fields. This use is also limited due to low sensitivity. However, a positive test is helpful in linking reflux to pulmonary pathology.

Endoscopy With Biopsy

Endoscopy of the upper GI tract is moderately invasive but allows direct visualization of the esophagus. The presence and severity of esophagitis can be documented. Other disease processes causing esophagitis, including infection, *eosinophilic infiltration*, and Crohn disease, can be diagnosed. Biopsies should always be taken, even in the absence of macroscopic findings, as histologic esophagitis may be responsible for symptoms. Basal zone hyperplasia and increased papillary length are found in reflux esophagitis. Mucosal breaks are most suggestive of pathological reflux. Eosinophilic esophagitis may have specific endoscopic findings of linear or circular furrowing or white specks. However, the location and number of eosinophils on biopsy are necessary to separate this diagnosis from GERD. Traditional pH monitoring catheters or wireless devices can be placed at the time of endoscopy.

Multichannel Intraluminal Impedance

Impedance monitoring is increasing in clinical use as smaller, less expensive equipment becomes available. This technology involves the placement of a catheter transnasally into the distal esophagus, similar to traditional pH monitoring. However, these catheters have multiple sensors arranged from proximally to distally that can detect the flow of liquid or gas and determine the direction of movement of this bolus. Liquids moving from the distal catheter to the proximal (retrograde) catheter are noted to be reflux. Typically a pH sensor at the distal end is included so that boluses may be described as acid or non-acid. This study is especially attractive in small infants where frequent feedings buffer acidity and in respiratory diseases where non-acid reflux has been implicated. Normal values for all pediatric age groups are currently in press.

Management

Infants that are thriving with no symptoms other than regurgitation or vomiting will benefit primarily from alleviation of parental anxiety. Discussion involving the normal course and benign nature of GER may be all that is required. The infant should be followed for changes in feeding, weight, or respiratory complaints and the regurgitation should begin to resolve by the end of the first year. Referral to a pediatric gastroenterologist should be considered when there is poor weight gain or hematemesis, or when there is respiratory disease (coughing, wheezing, or apnea).

Lifestyle Changes

Life in recumbency has its disadvantages for infants, namely allowing the esophagus and stomach to reside at the same level. This concept has led to the use of positioning in infants. There are multiple positions used including prone, prone at a 30-degree angle, or supine at a 30-degree angle. The only proven position seems to be prone. Unfortunately this position has been associated with a higher rate of sudden infant death syndrome (SIDS) in infants. The practitioner must balance the risk of GERD with that of SIDS in the individual

patient. The 30-degree supine position does not seem to be more effective in decreasing reflux than the flat supine position, but there is conflicting evidence on this point.

Infants with reflux are often put through “formula roulette.” Cow’s milk or soy-based formulas are employed and some progress to partially digested or elemental formulas. There is a select group of infants with regurgitation that have cow’s milk protein intolerance who may respond to a 2-week trial of hypoallergenic formula. This is more likely in the patient with a family history of atopy. Nearly half of infants intolerant of milk protein will also exhibit symptoms with soy, thus protein hydrolysate formulations may be of more use. There is no indication for lactose-free cow’s milk formulas in this patient population. Rice cereal may be used as a thickening agent. This does not change findings on esophageal pH monitoring, but it may decrease the frequency of regurgitation. Patients with poor weight gain will benefit from the increased caloric density of the thickened formula. One tablespoon of rice cereal per 2 ounces of formula will increase the content from 20 to 27 cal/oz. Increasing amounts of rice cereal will increase the viscosity and caloric density, but this also increases osmolarity. Excessively concentrated formulas may worsen vomiting. Nipples used with thickened formula will need to be tailored by crosscutting, but this may lead to increases in coughing or gagging. Formulas containing commercial “antiregurgitant” agents are now available. Although no more effective than rice cereal for regurgitation they do not increase the caloric density and may require less energy to pull from the nipple. This must be balanced with the unknown long-term risks of these newer ingredients as well as the increased cost.

Environmental and dietary factors have been studied in the older child and teenager. Currently only caffeine, chocolate, and spicy foods that provoke symptoms should be avoided. Obesity and exposure to tobacco smoke have also been implicated.

Medications

The pharmacologic agents that are used in reflux disease are felt to be safe and, therefore, sometimes used empirically without diagnostic confirmation (Table 108-1). Although this may be useful in adolescents for up to 4 weeks, it should be used with much caution in infants or young children. There is emerging evidence of harm from acid suppression, especially proton pump inhibitors (PPI). Acid suppression is the mainstay of treatment. The goal is to reduce exposure of the esophagus to acid. There are 3 main types of drugs that can be used: antacids, histamine-2 receptor antagonists (H2RA), and PPIs. The only clinically effective antacids are those that contain aluminum, which has been associated with bone and nervous system toxicity, especially in infants. Histamine-2 receptor antagonists inhibit acid production in the gastric parietal cell. They are effective in the healing of esophagitis; however, tachyphylaxis has been seen as early as 1 week after initiation. Further complicating this class of medications are side effects such as fussiness that may appear to be reflux symptoms. Cimetidine and famotidine have the most evidence for use in pediatrics.

Table 108-1. Pharmacologic Agents Used for Reflux Disease

<i>Drug</i>	<i>Pediatric Dose</i>	<i>Adverse Effects</i>
Cimetidine	20–40 mg/kg/d, divided 3–4 times per day	Hypotension, gynecomastia, reduced hepatic metabolism of other drugs, neutropenia, agranulocytosis, thrombocytopenia
Famotidine	0.5–1 mg/kg/d divided every day to twice per day	Headache, dizziness, constipation, diarrhea
Omeprazole	0.7–3.3 mg/kg/d divided every day to twice per day	Headache, diarrhea, abdominal pain, nausea, rash, vitamin B ₁₂ deficiency, constipation
Lansoprazole	15 mg (weight <30 kg) 30 mg (weight >30 kg)	Headache, nausea, constipation, diarrhea, abdominal pain, proteinuria, hypotension, elevated transaminases
Metoclopramide	0.1 mg/kg/dose 4 times per day before meals	Drowsiness, restlessness, dystonia, gynecomastia, galactorrhea
Erythromycin	3–5 mg/kg/dose 3–4 times per day before meals	Diarrhea, vomiting, cramps, antibiotic effect, pyloric stenosis

Proton pump inhibitors bond and deactivate hydrogen, potassium-adenosinetriphosphatase pumps and reduce meal-induced acid production. They should be taken 30 minutes prior to a meal so that the drug is in the bloodstream in the largest concentration at mealtime. Omeprazole and lansoprazole have been studied the most in children, although no PPI is approved for infants younger than 1 year. Proton pump inhibitors may be used as the initial drug, or following failure by H2RAs. There are 2 approaches that are used in initiating these medications. **Step-up** therapy involves beginning with H2RAs or low-dose PPI and escalating therapy until symptoms have improved. **Step-down** therapy progresses from high-dose PPI to resolve symptoms then low-dose PPI or H2RA to maintain remission. Healing of esophagitis at higher doses takes 4 to 8 weeks, with symptoms resolving in this time frame. Histamine-2 receptor antagonists are more effective than PPIs in the fasting state. Therefore, they may be effective for nighttime symptoms that persist through high-dose PPI therapy when taken at bedtime.

There are emerging studies in children and adults showing adverse effects from long-term acid suppression. Up to 14% of patients can have side effects of headache, diarrhea, constipation, or nausea. Increased rates of community-acquired pneumonia gastroenteritis and necrotizing enterocolitis have been described. Adult studies have shown increased hip fractures and vitamin B₁₂ deficiency, suggesting malabsorption secondary to hypochlorhydria, but these have not been reproduced in children. Further studies are

needed to understand the significance of these adverse effects, but we must use caution with empiric therapy when accurate testing such as pH studies or endoscopy is available.

Prokinetic agents are indicated in the patient with evidence of delayed gastric emptying. Effects on LES tone and esophageal peristalsis seem to be less important than accelerated gastric emptying. Cisapride, a mixed serotonergic agent, was the model drug for this class. It has been shown to improve reflux symptoms and pH parameters in infants. However, it has been associated with QT prolongation and arrhythmia with some deaths. The use of cisapride has been severely restricted since 2000. Other drugs in the group are less likely to improve reflux but are still widely used. Metoclopramide also has mixed serotonergic effects, in addition to anti-dopaminergic and cholinomimetic actions. Adverse effects including central nervous system complications limit the use of this drug. This drug now carries a black box warning from the US Food and Drug Administration. Erythromycin is a motilin receptor agonist that is also used less commonly in GERD. There is evidence that its use in pregnancy or in young infants may increase the risk of pyloric stenosis. Many interactions have been seen with this macrolide antibiotic, which also limits its use.

Barrier agents include sodium alginate, which is not readily available in the United States, and sucralfate, which contains aluminum. The former is not effective in most cases of GERD and the latter should be reserved for short-term treatment of erosive lesions in the esophagus.

Anti-Reflux Procedures

Patients that continue to have reflux on maximum medical therapy or those that have serious extra-esophageal manifestations such as recurrent aspiration or Barrett esophagus should be considered for surgery. Patients requiring long-term drug therapy may also be selected for surgery. The most popular procedure is the Nissen fundoplication. The laparoscopic approach to fundoplication is used widely and entails a full wrap of the fundus of the stomach around the esophagus to increase LES tone and create a more acute angle of His. More than 90% of patients remain symptom-free up to 11 years postoperatively. Complications including gas bloat, dumping syndrome, and dysphagia are reported at variable frequencies. Failure rates are higher in neurologically impaired children and those with esophageal atresia repair. There are several other fundoplication procedures that have variable degrees of wrapping.

Significant delay in gastric emptying may require an additional surgical procedure at the gastric outlet. Antroplasty or pyloroplasty enlarges the exit from the stomach. There is some theoretical concern that fundoplication itself results in accelerated gastric emptying. The additive effects of pyloroplasty might result in dumping of gastric contents into the duodenum too rapidly. This has not been shown to be a significant problem, and this procedure should be given strong consideration in infants or children with moderate or severe gastric-emptying delay noted clinically or by scintigraphy.

Endoscopic anti-reflux procedures have mixed results in adults. Endoscopic transesophageal plication involves placing sutures through the gastroesophageal junction, pleating the mucosa and reducing the size of this opening. Endoluminal application of radio-frequency energy has been used to remodel the tissue of the LES to reduce reflux episodes. Pediatric experience is limited. Other options include endoscopic placement of inert barriers into the tissue of the LES. All of these endoluminal techniques need further clinical data, especially in children, before they can be recommended broadly.

Prognosis

Complications arising from untreated GERD include esophagitis, Barrett esophagus, strictures, and esophageal adenocarcinoma. However, most infants with GER have a more favorable outcome. Regurgitation resolves in most children by 18 months and is absent by 24 months in 98%. There is some evidence that a portion of patients that become asymptomatic will continue to have abnormal histology in the esophagus at follow-up endoscopy. Therefore, it is unclear if the disease process continues into later childhood. Future studies that follow infants with reflux longitudinally into adulthood will be of great benefit. There is much to be learned in the area of non-acid reflux and its role in respiratory disease as intraluminal impedance becomes more widely used.

Children with persistent reflux symptoms into later childhood have a worse prognosis. Patients with a history of esophageal atresia repair or severe neurologic injury may have a poor prognosis, often requiring high-dose medication or anti-reflux surgery. They are more likely to suffer from complications of GERD.

CASE RESOLUTION

This toddler continues to have frequent emesis at almost 2 years of age with extra-esophageal manifestations including wheezing. He should be referred to a pediatric gastroenterologist for evaluation of GERD. He is unlikely to have spontaneous symptom resolution at this age.

Gastrointestinal Bleeding

George Gershman, MD

CASE STUDY

A 4-year-old boy is evaluated for intermittent passing of bright red blood from the rectum for 2 weeks. Blood either coats the stool or appears as a spot after a bowel movement. The mother reports no vomiting, diarrhea, loss of appetite, weight loss, fever, or abdominal pain. The boy has no history of constipation, straining, or pain with defecation and is taking no medications. The family has no pets and has not traveled recently.

On physical examination, the boy is a well-appearing, energetic, interactive youngster. Weight and height are at the 75th percentile for age. The abdomen is soft, flat, and non-tender, and bowel sounds are normally active. No organomegaly or masses are evident. No rashes, bruising, or hemangiomas are present. No tags, fissures, or fistulas are seen on close visual inspection of the perianal area. Digital rectal examination reveals normal sphincter tone, and a small, mobile, pea-like mass is palpable in the rectal

vault. A film of bright red blood is present on the glove after the examination. A complete blood cell count with platelet count and a prothrombin/partial thromboplastin time determination yield normal results.

Questions

1. What is involved in the assessment of children with gastrointestinal (GI) bleeding?
2. How are upper and lower GI tract bleeding differentiated?
3. What conditions usually account for upper and lower GI tract bleeding?
4. What management options are available for GI bleeding?
5. How does the physician decide what type of management is appropriate for each individual patient?

Bleeding from the GI tract in infants and children is always stressful and frightening for patients and their parents and challenging for a physician, especially if bleeding is severe.

Fortunately, life-threatening GI bleeding is rare in pediatric practice. However, a pediatrician or emergency department (ED) physician should be prepared to initiate effective resuscitation and diagnostic workup focusing on common age-specific causes of GI bleeding.

The primary goal of this approach is a reduction of morbidity associated with significant hemorrhage.

Epidemiology

The incidence of bleeding from the upper GI tract (upper GI bleeding) among infants and children is unknown. Clinical experience suggests that the incidence in children is significantly less than in adults. It is supported indirectly by epidemiological data from the United Kingdom and United States, which indicate that the incidence of upper GI bleeding in adults younger than 29 years is approximately 18 to 23 per 100,000 adults per year, which is almost 4 to 5 times lower than among older age groups. However, the risk of upper GI bleeding is higher (between 6.2% and 10.2%) in infants and children admitted to pediatric intensive care units.

Despite the fact that rectal bleeding is quite common in pediatric practice, the epidemiology of this problem is not well established.

According to published data, rectal bleeding was a chief complaint of 0.3% of all visits to a tertiary ED during a 10-month period.

Clinical Presentation

There are 4 presentations of blood loss from the GI tract: hematemesis, melena, occult bleeding, and hematochezia.

Hematemesis is the term that applies to the vomiting of bright-red “fresh” blood or “coffee-ground” emesis of dark-brown “old” blood exposed to hydrochloric acid. Usually hematemesis reflects acute bleeding from the esophagus, stomach, or proximal duodenum. Swallowing of maternal blood in neonates, and epistaxis in older children, should be ruled out to avoid unnecessary invasive procedures.

Melena is defined as liquid, coal black, shiny, sticky, tarry, foul-smelling stool. It suggests bleeding from the upper GI tract. Occasionally the site of bleeding can be located in the ileum or right colon. However, in this case stool is black but not tarry. Melena suggests a minimum loss of 50 to 100 mL in adults or 2% of blood volume in children. Stool may remain black or tarry for a few days after massive hemorrhage even though active bleeding has ceased.

Occult bleeding implies the presence of an invisible quantity of blood in stool detected by a special technique. It is a synonym for chronic, recurrent losses of small amounts of blood, which often lead to severe microcytic anemia. The most commonly used technique for detection of blood in stool is the hemoccult stool test. This test

is based on the chemical reaction of a dye (guaiac) with peroxidase-containing substances and hydrogen peroxide. It is not specific for presence of blood (hemoglobin) in stool.

False-positive results could be secondary to peroxidase activity in food products such as cantaloupe, radishes, bean sprouts, cauliflower, broccoli, grapes, and red meat or iron preparations. False-negative results of the hemocult test are associated with prolonged colonic transit time and bacterial degradation of hemoglobin to porphyrin, which does not have peroxidase activity.

Hematochezia is the passage of bright red or maroon-colored blood from the rectum. This may be pure blood, bloody diarrhea, or blood mixed with stool. As a rule, it is a sign of lower GI bleeding from the distal colon or less frequently from the right colon or the distal ileum. Rarely hematochezia may occur in children with massive bleeding from the duodenum.

Pathophysiology

Compensatory responses to acute bleeding facilitate a restoration of depleted intravascular volume, maintenance of a normal cardiac output (CO) and adequate oxygenation of vital organs (brain, heart, lungs, and adrenal gland), and mobilization of internal energy stores.

Two parameters determine the degree of compensation: volume of blood loss and velocity of bleeding.

Mild Blood Loss (<15% of Circulatory Volume) or Class 1 Bleeding

Relatively slow blood loss of less than 15% of blood volume triggers (1) redistribution of depot blood from the venous system to systemic circulation and (2) shift of extracellular fluids into the vascular space. Adequate CO without changes in heart rate and blood pressure is maintained and there are no hemodynamic abnormalities. However, a rapid blood loss (even <10% of blood volume) may compromise CO and trigger tachycardia and other compensatory mechanisms to restore normal blood circulation.

Moderate Blood Loss (Between 15%–30% of Circulating Volume) or Class 2 Bleeding

Blood loss of more than 15% of blood volume leads to tachycardia, an increased systemic vascular resistance (SVR) due to activation of the sympathetic nervous system and hypothalamic-pituitary-adrenomedullary axis. In children, CO depends on heart rate rather than stroke volume due to smaller ventricular mass. With hemorrhage, tachycardia is the principal mechanism for maintenance of an adequate CO in pediatric patients; however, prolonged tachycardia increases myocardial oxygen demand and decreased diastolic-dependent coronary perfusion. This eventually leads to cardiovascular decompensation if fluid resuscitation is delayed or insufficient.

Normal blood pressure and adequate perfusion of vital organs in children with moderate bleeding is maintained by increased SVR and redistribution of blood from skin, muscle, splanchnic organs, and kidney to the brain, heart, lungs, and adrenal gland due to local

production of adenosine, nitric oxide, and prostaglandins. Therefore, blood pressure is a poor indicator of cardiovascular homeostasis in children with moderate GI bleeding. In contrast, persistent tachycardia is the red flag of pending cardiovascular collapse.

Severe Blood Loss (>30% of Circulating Volume) or Class 3 Bleeding

Failure of compensatory mechanisms and decreased CO leads to hypotension and tissue hypoxia. Compensatory tachypnea contributes to respiratory alkalosis in the initial phase of severe bleeding. Tissue hypoxia compromises mitochondria functional capacity to generate energy as adenosine triphosphate. This leads to metabolic acidosis due to excessive production of lactic acid and cellular death.

Hypoperfusion of the kidney causes acute spasm of the preglomerular arterioles and acute tubular necrosis and renal failure. Hypoxia and excessive cytokine production can induce liver failure: sudden onset of jaundice due to hepatocellular necrosis, elevation of transaminases, coagulopathy, hypoglycemia, and encephalopathy. Myocardial ischemia is a common consequence of severe bleeding. Sepsis, thrombotic microangiopathy, and a systemic inflammatory response syndrome may occur in the late stages of uncontrolled or inadequately treated severe hemorrhage.

Evaluation

Initial assessment of the child with suspected GI bleeding should be focused on hemodynamic stability and clues for etiology of bleeding. Four major questions must be answered promptly.

1. Is the patient stable?
2. Is the bleeding real?
3. Where is the source of bleeding?
4. What is the best approach to hemostasis?

The first and the most important step in the initial assessment of the child with suspected GI bleeding is determination of hemodynamic stability. Box 109-1 outlines procedural management of GI bleeding, focusing on restoring hemostasis.

A prompt assessment of estimated blood loss and the degree of hemodynamic instability should be done using objective criteria, such as mental status, skin color, capillary refill, pulse, blood pressure, and orthostatic maneuvers (Table 109-1). Special attention should be focused on tachycardia and narrowed pulse pressure, which are the earliest signs of impending shock. Hypotension usually occurs in the late phase of shock in children and is an ominous finding. The value of the initial hematocrit may not accurately reflect the severity of blood loss. First, the hematocrit does not fall immediately with hemorrhage due to proportionate reductions of plasma and red cell volumes. Second, the hematocrit begins to fall due to compensatory restoration of the intravascular volume by the shift of extra vascular fluids into the vascular bed. This process begins shortly after the onset of bleeding; however, it is not complete for 24 to 72 hours. At this point, plasma volume is larger than normal and the hematocrit reaches its true nadir assuming that bleeding has stopped.

Box 109-1. Procedural Management of Gastrointestinal Bleeding

Endoscopic Hemostasis of Non-Variceal Bleeding

Indications

- Active bleeding from a gastric or duodenal ulcer
- Stigmata of recent bleeding: a non-bleeding visible vessel in the ulcer base and a densely adherent clot
- Bleeding arteriovenous malformation
- Bleeding after polypectomy

Methods

- Injection of vasoconstrictive agent
- Thermal coagulation
 - Bipolar coagulation
 - Heater probes
 - Argon plasma coagulation device
- Metal clips

Endoscopic Hemostasis of Variceal Bleeding

Indications

- Active bleeding from esophageal or gastric varices
- History of bleeding secondary to portal hypertension
- Failure of shunting procedure

Techniques

- Sclerotherapy
- Endoscopic variceal ligation

Polypectomy

Indication

- Juvenile polyps less than 3 cm
- Multiple polyps less than 2 cm

Differential Diagnosis

There are 3 essential components of the diagnosis of GI bleeding

- Confirmation that bleeding is real
- Allocation of the bleeding area to the upper versus lower GI tract
- Detection of the specific cause of bleeding

Red staining of emesis or stool can be induced by cranberries, cranberry juice, cherries, strawberries, beets, tomatoes, candies, amoxicillin, phenytoin, and rifampin. Bismuth preparations, activated charcoal, iron, spinach, blueberries, and licorice can simulate bleeding by staining emesis and coloring stool black. An appropriate history, a normal physical examination, and guaiac-negative stool are sufficient to rule out a true bleeding episode.

It is important to remember that hematemesis and/or melena can be secondary to epistaxis. History of recent tonsillectomy and adenoidectomy, nasal allergies, dry environment, or nose-picking habits increases the probability of epistaxis. Thorough examination of the nose and oropharynx can help to establish the right diagnosis.

Detailed history and physical examination help narrow the diagnostic workup. For example, treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) is a risk factor for acute gastric ulcers and bleeding from the stomach. Jaundice, hepatomegaly, spider hemangiomas, prominent vessels of the abdominal wall, or ascites are the signs of chronic liver disease and suggestive of portal hypertension. However, GI bleeding in a febrile child with hemodynamic instability and jaundice could be secondary to sepsis-related coagulopathy and acute ulcer of the stomach or the duodenum and cholestasis.

Careful assessment of the perineum can reveal the anal fissures, fistulas, or perianal inflammation.

If the source of bleeding is not obvious, the placement of a nasogastric tube is very useful. A tube with the largest bore tolerable should be placed for adequate gastric lavage: a 10F to 12F sump tube is a reasonable choice for small children; 14F to 16F for older patients. Room temperature saline is the optimal fluid for irrigation. Iced saline lavage is no longer recommended because it compromises platelet function at the bleeding site and may induce hypothermia (especially in infants) with subsequent clinically significant arrhythmia. A bloody or coffee ground aspirate indicates upper GI bleeding if epistaxis was ruled out. The absence of blood in the stomach does not exclude upper GI bleeding because the source of hemorrhage can be in the duodenum. The presence of coffee-ground fluid in gastric aspirate, which promptly clears by gastric lavage, suggests that bleeding has stopped. Failure to obtain clear return on gastric lavage indicates ongoing bleeding.

The results of blood tests give some clues to the nature of bleeding. Low hemoglobin and hematocrit with normal mean corpuscular volume (MCV) are typical for acute blood loss. An elevated blood urea nitrogen (BUN) suggests volume depletion and absorption of the blood proteins in the small intestine, which support the diagnosis of upper GI bleeding. Very low hemoglobin, hematocrit, and MCV in a hemodynamically stable patient is consistent with chronic GI blood loss.

Table 109-1. Clinical Manifestations of Gastrointestinal Bleeding According to Blood Loss Volume

Symptoms and Signs	Blood Loss		
	<15%	15%–30%	>30%
Normal appearance	+	–	–
Anxiety	–	+	+
Disorientation	–	–	+
Lethargy	–	–	+
Tachycardia	–	++	+
Pallor	–	+	++
Livedo reticularis	–	+	++
Cold extremities	–	+	+
Capillary refill >2 seconds	–	+	+
Hypotension	–	–	+
Narrowed pulse pressure	–	+	+
Elevated diastolic pressure	–	+	–
Low diastolic pressure	–	–	+

Knowledge of common causes of GI bleeding in an age-specific group of children helps with the diagnostic strategy (Table 109-2).

In general, endoscopy is the method of choice for the diagnosis of the specific causes of acute and chronic GI bleeding related to mucosal and submucosal lesions of the GI tract. The choice of the particular type of endoscopic procedure is related to suspected pathology. Upper and lower GI endoscopy and enteroscopy are routine methods for diagnosis of such diseases as acute or peptic ulcers, esophagitis, gastritis, esophageal varices, vascular malformations, ulcerative colitis, Crohn disease, polyps, and other causes of GI bleeding. Capsule endoscopy is the new method with the unique ability to assess the entire small intestine. It is used for diagnosis of GI bleeding of obscure origin usually after negative results of conventional endoscopic procedures.

Table 109-2. Common Causes of Gastrointestinal (GI) Bleeding in Children

Age	Upper GI Bleeding	Lower GI bleeding
Neonates (0–30 days)	<ul style="list-style-type: none"> Swallowed maternal blood Stress ulcers/sepsis Hemorrhagic gastritis Hemorrhagic disease of the newborn 	<ul style="list-style-type: none"> Necrotizing enterocolitis Midgut volvulus Hirschsprung disease Vascular malformation
Infants (30 days–6 mo)	<ul style="list-style-type: none"> Cow's milk or soy protein allergy Esophagitis Prolapse gastropathy 	<ul style="list-style-type: none"> Anal fissure Allergic proctitis or enterocolitis Intestinal lymphoid hyperplasia Intussusception
Infants and children (6 mo–6 y)	<ul style="list-style-type: none"> Epistaxis Esophagitis Prolapse gastropathy Portal hypertension Drug-induced ulcers Gastritis Mallory-Weiss tear 	<ul style="list-style-type: none"> Anal fissures Intussusception Meckel diverticulum Intestinal lymphoid hyperplasia Polyps Infectious colitis Hemolytic uremic syndrome Henoch-Schönlein purpura
Children and teenagers (7–18 y)	<ul style="list-style-type: none"> Epistaxis Drug-induced gastropathy and acute ulcers Peptic ulcer Esophagitis Gastritis Portal hypertension 	<ul style="list-style-type: none"> Infectious colitis Ulcerative colitis Crohn disease Anal fissure Polyps

Radiograph and abdominal ultrasound are useful for diagnosis of structural abnormalities such as intussusception, necrotizing enterocolitis, and malrotation.

Technetium (Tc)-99m pertechnetate scan is the diagnostic procedure of choice in children with suspected Meckel diverticulum. It is 85% sensitive and 95% specific.

A tagged red blood cell scan and angiography are alternative methods used in children with active GI bleeding of obscure origin, especially when vascular anomalies or hemobilia are suspected.

Age-Associated Causes of GI Bleeding

Neonates

In healthy breastfed neonates and infants, hematemesis could be caused by swallowed maternal blood. In such cases, careful examination of maternal breast and areola can lead to correct diagnosis. In addition, the Apt-Downey test can be useful especially in the first 3 to 4 weeks of postnatal life while concentration of fetal hemoglobin is still high. The test is based on the chemical reaction of adult hemoglobin with sodium hydroxide, which leads to a color change from bright red to yellow or crusty brown. Fetal hemoglobin is resistant to hydroxylation, and blood from the infant remains bright red.

Acute gastric or duodenal ulcers should be suspected in sick premature or full-term asphyxiated or septic newborns or patients with intracerebral bleeding, raised intracranial pressure, congenital heart disease, respiratory failure, or hypoglycemia. The typical scenario includes sudden onset of hematemesis or melena and signs of hemodynamic instability. Occasionally, severe upper GI bleeding can occur in healthy, full-term neonates within the first few days of life.

Gastrointestinal bleeding is a common manifestation of necrotizing enterocolitis (NEC).

The warning signs of NEC are abdominal distention, feeding intolerance with increased gastric residuals, mild diarrhea, hematochezia, or stool positive for occult blood.

Plain radiographs reveal nonspecific distribution of bowel gas, pneumatosis intestinalis, or gas in the portal vein, depending on the severity of bowel ischemia.

Rare causes of GI bleeding in the first month of life include Hirschsprung enterocolitis, midgut volvulus, duplication cyst, vascular malformation, and hemorrhagic disease of the newborn, particularly in breastfeeding neonates who did not receive vitamin K.

Infants Up to First 6 Months of Age

One of the leading causes of GI bleeding in infants younger than 6 months is cow's milk or soy protein allergy. The spectrum of symptoms includes recurrent vomiting, hematemesis, failure to thrive, and diarrhea with guaiac-positive stools or hematochezia.

Exclusively breastfeeding infants may develop similar symptoms on rare occasions. Elimination of cow's milk, eggs, peanuts, shellfish, and tree nuts from maternal diet may lead to resolution of allergic symptoms in the breastfeeding infant. For infants with persistent symptoms or whose mothers are unable to restrict their diet

according to current recommendations and for formula-fed infants with cow's milk protein allergy, hypoallergenic (extensively hydrolyzed and free amino acid–based) formulas can be used to relieve the symptoms. Most infants with GI manifestations of cow's milk protein allergy will improve within the first 2 weeks of treatment.

An anal fissure is another common cause of bleeding in infants. The diagnosis is made by careful examination of the anus.

Intermittent rectal bleeding with streaks of frank blood mixed with normal-appearing stool can be secondary to intestinal lymphoid hyperplasia of the colon or terminal ileum. During endoscopy, multiple hemispheric smooth nodules of less than 4 mm can be found in clusters or diffusely throughout the GI tract. It results from an excessive reaction of the GI tract lymphatic tissue (lymphoid follicles and Peyer patches) to food-related or other antigens. Spontaneous regression of lymphoid follicles is quite common. In addition to parental reassurance, an elimination diet for breastfeeding mothers is a reasonable initial treatment. Feeding with extensively hydrolyzed protein formula is the next therapeutic step. Corticosteroid therapy is restricted to infants with a severe form of this disease: recurrent abdominal pain, significant anemia, persistent rectal bleeding, diarrhea, and failure to thrive. In such cases, immunodeficiency has to be excluded.

Esophagitis should be suspected as a cause of bleeding in infants with a history of recurrent emesis and interrupted feeding patterns associated with crying, irritability, or arching. The patients with repaired esophageal atresia with or without tracheoesophageal fistula are at higher risk of severe reflux disease and esophagitis. Bleeding induced by esophagitis is usually recurrent and not intensive. The patients may have hematemesis with streaks of blood or guaiac-positive stool.

Infants or older children can develop minor bleeding due to prolapse of gastric mucosa into the esophagus through the gastroesophageal junction (prolapse gastropathy). This condition is manifested by recurrent emesis with food and appearance of flecks of denatured blood at the end of vomiting. The presence of large amounts of frank blood or clots at the end of recurrent emesis suggests a more serious problem such as Mallory-Weiss tear.

Infants and Children Younger Than 7 Years

Several diseases have a higher incidence in this age group compared to other children.

The signs and symptoms of **portal hypertension** are a large-volume hematemesis; history of omphalitis associated with catheterization of the umbilical vein; presence of splenomegaly or hepatosplenomegaly; and other stigmata of chronic liver disease, such as jaundice, spider angiomas, caput medusa, and ascites. Esophageal varices are the most common site of bleeding in children with intrahepatic-sinusoidal and extrahepatic-presinusoidal forms of portal hypertension. Two-thirds of children with portal hypertension will bleed before 5 years of age. The diagnosis is based on the presence of esophageal or gastric varices or hypertensive gastropathy during an upper GI endoscopy.

Intussusception, which is more common in the first 2 years of life, is strongly considered in infants and children with sudden onset of severe, cramping abdominal pain intercepted with pain-free episodes and currant jelly stools. A lead point is often present in children older than 2 years. Diagnosis is confirmed by ultrasonography (positive: “concentric circles” or the “target-shaped” sign) or barium enema. Hydrostatic reduction of intussusceptions is successful in more than 90% of children.

Meckel diverticulum is the most common congenital anomaly in children. It is estimated that approximately 2% of infants have a remnant of the omphalomesenteric duct. However, less than 5% of children will develop complications, including GI bleeding. The predominant location of Meckel diverticulum is the distal ileum (40–60 cm above the ileocecal valve). Ectopic tissue is present in up to 80% of symptomatic patients. Gastric mucosa is the most common type of ectopia. The cause of bleeding is peptic ulceration at the junction of the ectopic gastric mucosa and normal ileum, the so-called marginal ulcer. Bleeding can be massive, but it may cease spontaneously secondary to contraction of the splanchnic vessels in response to hypovolemia. This phenomenon explains the intermittent nature of bleeding from Meckel diverticulum. Bleeding is usually painless, but sometimes coincides with recurrent abdominal pain.

The diagnostic procedure of choice is a Tc-99m pertechnetate scan.

Juvenile polyps may occur in as many as 1% of children, with peak incidence from 2 to 5 years of age. The common clinical presentation is recurrent, painless bleeding with a small amount of blood on formed stool. Diarrhea and tenesmus can occur when the polyp is large and located in the left colon.

Typical juvenile polyps are smooth, rounded, and red. Polyps of less than 1 cm are usually sessile; polyps larger than 1 cm have short or long stalks. Juvenile polyps are composed of normal and cystically dilated crypts embedded in an abundant lamina propria. Colonic mucosa adjacent to the large polyp has a distinguished, so-called chicken skin appearance. Colonoscopy is indicated due to the high incidence (almost 50%) of coexisting polyps in the descending and more proximal portions of the colon.

Endoscopic polypectomy is the treatment of choice. There is a general consensus that a single juvenile polyp is not a premalignant condition. Therefore, removal of a solid juvenile polyp is curative. Surveillance colonoscopy is not indicated unless the child develops a new episode of rectal bleeding.

Hemolytic uremic syndrome (HUS) should always be suspected in infants and toddlers with bloody diarrhea, which is present in three-quarters of children with epidemic HUS. In two-thirds of these children, *Escherichia coli* 0157:H7 can be isolated. Bloody diarrhea in HUS results from hemorrhagic colitis caused by the presence of endothelial damage produced by verotoxin and Shiga toxin and submucosal hemorrhages. Tenesmus is common. Diffuse, severe abdominal pain with peritoneal signs can occur.

The presence of the so-called thumbprinting sign on a barium enema or a computed tomography scan reflects a submucosal hemorrhage of the colon. Colitis-related symptoms last no longer than a week, followed by signs of hemolytic anemia and oliguria. Known GI complications of HUS are intussusception, pancreatitis, and intestinal obstruction. Small or large bowel perforation may occur during peritoneal dialysis, which may be performed to manage the acute renal failure that can accompany HUS.

Henoch-Schönlein purpura is most common in children younger than 7 years. The median age is 4 years. Henoch-Schönlein purpura should be suspected in children with sudden onset of severe diffuse abdominal pain, vomiting, and hematochezia following a viral illness during the winter and early spring and about a week after the appearance of purpuric-type skin lesions on the buttocks or lower extremities.

On rare occasions, GI manifestations may precede the skin rash. Severe anemia is uncommon. The small and large bowels have different degrees of hemorrhagic lesions. These may be apparent on a small bowel radiograph series or barium enema with coarsening of folds and thumbprinting. Abdominal pain and hematochezia are self-limited. Treatment with corticosteroids is controversial, although it may shorten the course of GI symptoms of abdominal pain by 1 or 2 days.

Children 7 Years and Older

The common causes of GI bleeding in this age group are listed in Table 109-2.

Drug-induced gastritis or acute ulcer should be strongly suspected in children treated with NSAIDs or oral steroids. The degree of bleeding ranges from mild to moderate. The typical clinical presentation is the sudden onset of abdominal discomfort followed by hematemesis or melena. Two types of lesions can occur: gastropathy or acute gastric ulcers due to alteration of the mucosal microcirculation and the mucosal cytoprotection related to suppression of local synthesis of prostaglandins. The incidence of NSAID-related GI bleeding is much higher in patients with *Helicobacter pylori* gastritis. Therefore, eradication of *H pylori* infection is recommended before long-term therapy with NSAIDs.

Although **peptic ulcer disease** (PUD) is relatively rare in pediatric patients, it accounts for at least a third of the cases of upper GI bleeding in school-aged children. Most bleeding ulcers are located in the duodenal bulb. At least 80% of bleeding episodes from duodenal ulcers cease spontaneously. However, if the bleeding is arterial, it may become life-threatening. Urgent endoscopy is necessary as soon as the patient becomes more stable after fluid resuscitation.

The risk factors for recurrent bleeding are large ulcer (>2 cm), location of the ulcer on the posteroinferior wall of the duodenal bulb, blood spurting from the base of the ulcer, a visible vessel, or an adherent clot. In these circumstances the risk of recurrent bleeding is relatively high even after initially successful endoscopic hemostasis and acid suppression with intravenous (IV) infusion of proton pump inhibitors. The most critical time for re-bleeding is the first 3 days following the initial hemostasis.

The risk of recurrent bleeding is minimal in children with a clear base ulcer or a pigmented spot sign, a small flat thrombus in the center of an ulcer. Endoscopic hemostasis is not indicated in these cases. Hemodynamically stable children without the endoscopically identified risk factors can be managed safely on an outpatient basis.

Colitis is the most common cause of rectal bleeding in older children and teenagers. Infectious colitis is by far more common than inflammatory bowel disease.

In general, bacterial colitis is an acute, self-limited disorder manifested by sudden onset of fever, tenesmus, and bloody diarrhea lasting from 5 to 7 days.

Chronic diarrhea (lasting ≥ 2 weeks) is usually associated with chronic inflammatory bowel disease. Rare causes of chronic infectious colitis are *Yersinia enterocolitica*, tuberculosis, *Entamoeba histolytica*, *Strongyloides stercoralis*, and opportunistic infections in immunocompromised patients.

Clostridium difficile colitis should be ruled out, especially in children treated with antibiotics or hospitalized patients.

Ulcerative colitis usually presents with insidious onset of diarrhea, nocturnal diarrhea, and subsequent hematochezia. Clinical manifestations of moderate to severe forms of ulcerative colitis include bloody diarrhea, abdominal cramps, urgency to defecate, malaise, anorexia with weight loss, intermittent low-grade fever, and some degree of anemia and hypoalbuminemia.

Crohn disease has a more indolent onset associated with abdominal pain, diarrhea, poor appetite, and weight loss. Diarrhea is not grossly bloody unless there is bleeding from an anal fistula or colitis that is diffuse or left-sided.

Differentiation between bacterial colitis and the early stage of chronic inflammatory bowel disease is always a challenge. A high index of suspicion and negative bacterial stool culture results, including *Yersinia* species and other rare pathogens, are essential parts of early diagnosis. The definitive diagnosis of chronic inflammatory bowel disease is based on the results of upper and lower GI endoscopy, including multiple biopsies.

Management

Resuscitation

It is imperative to initiate resuscitation of the hemodynamically unstable patient almost immediately before any diagnostic procedure is considered. Two large-bore peripheral IV lines or a central line should be placed and secured. Blood has to be typed and cross-matched and sent for baseline laboratory assessment of hemoglobin, hematocrit, MCV, platelet count, electrolytes, creatinine, BUN, liver enzymes, and clotting factors. Oxygen supplementation and large boluses of saline target restoration of circulation and tissue oxygenation. The volume of isotonic solution should be sufficient to improve tachycardia and reverse narrow pulse pressure. Blood transfusion is indicated for patients with

- Persistent tachycardia, abnormal pulse pressure, or orthostatic hypotension after replacement of 15% to 20% of blood volume with isotonic solution

- Estimated blood loss of 30% or more
- Hemoglobin 6 g/dL or less
- Uncontrolled bleeding
- Hemorrhagic shock
- Hemoglobin of 7 g/dL to 9 g/dL in children with chronic heart and lung diseases and signs of hypoxia

Packed red cells are the product of choice for replacement of blood loss. Matched whole blood is preferred for patients with massive bleeding. Fresh-frozen plasma is indicated for children with suspected or documented clotting factor deficiency including those with acute or chronic liver disease. Platelet transfusion is indicated in rare cases of severe bleeding with estimated blood loss of more than 50% of the patient's blood volume or children with active hemorrhage and platelet count less than 50,000/mm³. Early blood transfusion is reasonable for children with active bleeding and known chronic heart or lung diseases. Monitoring of vital signs is a more accurate way to assess the effect of blood transfusion than monitoring of hematocrit soon after transfusion. It is reasonable to wait 6 hours before checking a posttransfusion hematocrit.

Octreotide (a synthetic somatostatin analogue) is effective adjunct medical therapy of severe bleeding from esophageal or gastric varices. It should be given to the child with active hemorrhage and any evidence of chronic liver disease or previously diagnosed portal hypertension. The initial bolus of 1 µg/kg of IV octreotide is followed by continuous infusion of octreotide 1 µg/kg/hour. The dose can be increased every 6 hours up to 5 µg/kg/hour.

The definitive therapy of moderate to severe upper GI bleeding related to PUD or varices (esophageal or gastric) and lower GI bleeding from polyps or vascular malformation relies on endoscopic hemostasis.

Surgery should be reserved for children with severe uncontrolled bleeding from a known source or specific disorders, such as Meckel diverticulum.

Prognosis

The prognosis for infants and children with GI bleeding depends on the condition causing the bleeding. Early, aggressive treatment of the consequences of blood loss is essential to decreasing morbidity and mortality. Generally the prognosis is good, and overall mortality is less than 5%.

CASE RESOLUTION

The young child in the case history with episodic, painless rectal bleeding has a juvenile polyp. The polyp was palpable on digital rectal examination. A colonoscopy was negative for additional polyps. Polypectomy was performed without complications. Histological examination of the removed neoplasm confirmed the diagnosis of juvenile polyp.

Diarrhea

George Gershman, MD

CASE STUDY

An 8-month-old male infant is evaluated for a 2-day history of fever and blood-streaked, mucus-laden stools. His appetite is reduced, and he is only taking sips of diluted apple juice. He has had a single episode of vomiting. There are no ill contacts. On examination, the patient is irritable with a temperature of 102.2°F (39.0°C), a pulse of 180 beats/min, a respiratory rate of 58 breaths/min, and a blood pressure of 90/65 mm Hg. The mucous membranes are dry, the fontanelle is depressed, and the skin turgor is reduced. The abdomen is soft and bowel sounds are active.

Questions

1. What are the 4 major categories of diarrhea?
2. What are the common infectious agents that cause diarrhea in infants and children?
3. What are the characteristics of diarrheal stools caused by different etiologies?
4. What conditions lead to prolonged diarrhea in infants and children?
5. How is diarrhea managed in infants and children?

The word *diarrhea* is derived from Greek and means “to flow through.” Diarrhea is characterized by increased volume of stool, which is associated with a looser consistency and an increased frequency of bowel movements. The frequency of defecation and consistency of stool vary from individual to individual. For example, wide variations in frequency of bowel movement may be seen under certain conditions such as breastfeeding. Some breastfed neonates have a bowel movement once a week, whereas others may pass stool up to 10 times a day.

Diarrhea has several causes, which include infection, inflammation, and exposure to foods and drugs that affect the absorption of water from the small and large intestines.

Epidemiology

Acute diarrhea is very common throughout the world. In the United States, acute gastroenteritis is second in frequency only to upper respiratory infections. According to the World Health Organization, 2.5 million children in Latin America, Asia, and Africa die annually from dehydration secondary to diarrhea. In contrast, approximately 400 children die from this condition in the United States each year. These children often come from lower socioeconomic classes.

In the United States, each child experiences an average of 0.9 episodes of diarrhea per year unless enrolled in a child care facility. In that case, the number increases to up to 3.2 episodes per year, a figure similar to that of children in developing nations. The leading cause of diarrhea in children in developing nations is infection with viruses, bacteria, or parasites. The severity of the infection is influenced by the underlying state of nutrition. An episode of acute gastroenteritis can precipitate severe malnutrition in marginally intact children. The fecal-oral route is the major path for the spread of infectious diarrhea. In developing nations, poor sanitation and contaminated

drinking water perpetuate the problem. In the United States, contaminated food supply, such as the contamination of eggs and poultry with *Salmonella*, is associated with the spread of bacterial gastroenteritis. Puppies have been found to be a reservoir of *Campylobacter*.

Definitions

Diarrhea is defined as stool weight more than 10 g/kg/day in infants and more than 200 g/day in older children.

Acute diarrhea comprises 2 criteria: (1) sudden onset and (2) resolution of diarrhea within 2 weeks.

Persistent diarrhea implies an acute onset of diarrhea that lasts at least 14 days. The definition is based on acute onset diarrhea that continues beyond the expected duration of an infectious etiology.

Chronic diarrhea is defined as diarrhea lasting at least 14 days and associated with specific causes (eg, celiac disease or inflammatory bowel diseases).

Clinical Presentation

The presenting symptoms include frequent, watery stools, which may contain blood or mucus. Affected children may experience fever, vomiting, bloating, and abdominal pain. Signs and symptoms of dehydration, such as decreased skin turgor, dry mucous membranes, depressed fontanel, diminished tearing, and tachycardia, may be present. Persistent diarrhea may be associated with weight loss and failure to gain weight at an appropriate rate (Dx Box).

Pathophysiology

The consistency of stool depends on the stool's water content. The movement of water through the wall of the intestine is always related to the movement of electrolytes, because no active transport of water occurs. The absorption of water is associated with the active

Dx Diarrhea

- Frequent stools
- Blood in stool
- Mucus in stool
- Fever
- Poor weight gain or weight loss
- Dehydration
- Vomiting
- Abdominal pain

transport of sodium, and the secretion of water is associated with the electrogenic transport of chloride. Regulatory mechanisms of water and electrolyte transport across the intestine require integration of the enteric nervous system, cells in the lamina propria, and epithelial cells. This complex system works through the generation of hormone peptides, active amines, arachidonic acid metabolites, and nitric oxide. The bulk of absorbed water crosses the intestinal epithelium between the cells (tight junctions) following the osmotic gradient generated by the transport of nutrients and electrolytes. Thus diarrhea is the reversal from the normal status of absorption to exaggerated secretion. This can be induced by 2 processes: (1) excessive osmotic load generated by ingestion of nonabsorbable sugars such as lactulose or malabsorption of lactose, or other nutrients, which generates an abnormal osmotic pressure inside the lumen of the intestine and water leak into the gut and (2) active secretion of enterocytes secondary to direct action of viral or bacterial products/toxins and different substances on the cells, particularly in the crypt areas.

Osmotic diarrhea occurs whenever digestion and/or absorption are impaired. In general, it is relatively small-volume diarrhea, which is dependent on oral intake and abolished with fasting. The most common causes of osmotic diarrhea are (1) malabsorption of carbohydrate due to excessive consumption (eg, concentrated formulas or carbonated beverages) or decreased production of brush-border enzymes or the presence of non-absorbable substances such as lactulose, sorbitol, or magnesium salts in the intestinal lumen; (2) decreased absorptive capacity of the intestine due to acute or chronic inflammation of the small bowel mucosa (eg, acute viral gastroenteritis, cow's milk protein allergy, bacterial overgrowth, giardiasis, or celiac disease); (3) lack of pancreatic enzymes or bile acid; and (4) decreased absorptive capacity of the small intestine secondary to congenital or acquired short bowel syndrome.

Recent data suggest that disruption of the differentiation of intestinal enteroendocrine cells has profound effects on the nutrient absorption by the small intestine.

In general, nonabsorbed nutrients create an osmotic load that stimulates water leak into the intestinal lumen across the tight junction. In addition, unabsorbed nutrients, such as carbohydrates, are the substrate for fermentation by colonic bacteria with liberation of

short-chain organic acids, which create a secondary osmotic load in the large intestine and exacerbation of osmotic diarrhea.

Secretory diarrhea can be induced by any process, which creates a state of active intestinal secretion. In general, secretory diarrhea is associated with intestinal loss of large volumes of fluids, which continues despite cessation of eating. Secretory diarrhea can be induced by bacterial, viral (eg, rotavirus and HIV), or protozoan (*Cryptosporidium parvum* in immunocompromised children) infection or excessive secretion of several hormones and neuropeptides such as serotonin, histamine, cholecystokinin, etc. Secretory diarrhea is also seen with certain tumors, such as ganglioneuroblastoma, and congenital disorders of fluid and electrolyte metabolism, such as congenital chloride diarrhea. The classic example of secretory diarrhea is infection with enterotoxigenic *Escherichia coli* and *Vibrio cholerae*. Both bacteria produce toxins that bind to specific enterocyte membrane receptors and activate adenylyl cyclase, and production of cyclic adenosine monophosphate (by cholera toxin and heat-labile toxin from enterotoxigenic *E coli*) or cyclic guanosine monophosphate (by heat-stable toxin produced by *E coli*). The ultimate pathway involves the opening of chloride channels and massive water loss. Secretory diarrhea is particularly common in the developing nations, where it is related to infection with organisms such as enterotoxin *E coli* and *V cholerae*. In the United States, the most common cause of secretory diarrhea is rotavirus infection. Vasoactive intestinal peptide-secreting tumors such as ganglioneuroma and neuroblastoma must be considered in the diagnosis in children with persistent secretory diarrhea.

In reality, both osmotic and secretory components are present in many cases of diarrhea.

Motility disorders such as Hirschsprung disease or pseudo-obstruction syndrome can be associated with persistent nonspecific diarrhea.

Inflammatory diarrhea occurs acutely with certain infections or chronic inflammatory bowel disease. **Steatorrhea** refers to the presence of an excessive amount of fat in the stools. Approximately 95% of the fat content of food should be absorbed. In infants younger than 12 months, 10% of ingested fat may appear in the stool. Fat malabsorption occurs with problems of the small intestine, including giardiasis, chronic liver and pancreatic disorders such as biliary atresia, and cystic fibrosis.

Differential Diagnosis

Acute Diarrhea

The major cause of diarrhea in children and infants in developed countries is **acute viral gastroenteritis**. The most common virus is rotavirus, which usually occurs during the winter months. The disorder was referred to as *winter vomiting syndrome*. Infants present with a history of antecedent mild upper respiratory symptoms, followed by fever and vomiting. Watery diarrhea, which is usually free of blood or mucus, then occurs. About 10% of infected infants have signs of otitis media. Dehydration may also occur secondary to

rotavirus infection. It is typically mildly hypernatremic, with serum sodium values of about 150 mEq/L. Enteric adenovirus is the second most common viral pathogen causing diarrhea. In the summer months, enteroviral infections may produce similar diarrheal illness.

The most common **bacterial agents** associated with gastroenteritis in the United States are *Shigella*, *Salmonella*, and *Campylobacter*. *Aeromonas*, a common pathogen in developing countries, is recovered in less than 1% of cases of diarrhea in the United States.

Campylobacter produce signs of colitis, with blood and mucus in the stools. Patients are usually febrile and experience abdominal cramps. As a rule, children infected with *Shigella* are sicker, with higher levels of fever and more marked leukocytosis. In addition, infants and toddlers are particularly prone to seizures. Infection with *Salmonella* may also be associated with high fever. Stools may be mucus-laden, and inflammation of the small intestine may be evident. Parasitic infections, particularly with *Giardia lamblia*, *Entamoeba histolytica*, and *Cryptosporidium parvum*, may be associated with diarrhea and may follow a more protracted course. Infestation with these organisms does not usually result in fever.

Infectious conditions that do not affect the gastrointestinal (GI) tract (otitis media and urinary tract infection) may also be associated with diarrhea. Sixty percent of children with hepatitis A develop diarrhea in the first week of illness. Other conditions may also result in diarrhea. In newborns, infection with *E coli* may produce epidemic outbreaks of large, explosive, watery, green stools without blood. These outbreaks may result in closure of newborn nurseries. Watery stools may herald the onset of **necrotizing enterocolitis**; blood is usually present, however. Necrotizing enterocolitis most often affects preterm infants with respiratory distress syndrome. The pathogenesis of necrotizing enterocolitis remains largely unknown. One of the risk factors appears to be hypoxia and ischemia related to pulmonary immaturity. The mechanism of disease production seems to be related to hypoxia of the intestinal mucosa. Feeding intolerance, bloody stools, pneumatosis intestinalis, and air in the portal vein are the hallmarks of the disorder. Enterocolitis may also occur in infants with Hirschsprung disease. Adrenal insufficiency, as well as certain inborn errors of metabolism, such as galactosemia, may lead to diarrhea. In general, other symptoms such as vomiting occur. Infants may present in shock because of hypovolemia related to dehydration.

Food intolerance may result in diarrhea in infants as well as in older children. Overfeeding or the ingestion of large quantities of fruit juices, dried fruits, or sorbitol-containing products can produce osmotic diarrhea. Food allergies may also be associated with malabsorption. In infants, cow protein intolerance can produce diarrhea, growth retardation, anemia, hypoproteinemia, edema, respiratory symptoms, and eczema. Eosinophilia and elevated levels of immunoglobulin E are uncommon in infants with cow's milk protein allergy. Because 25% to 50% of cow protein-allergic children are also soy protein-allergic, symptoms of diarrhea may not abate when soy formula is offered. However, soy formula does help infants with lactase deficiency. Congenital lactose intolerance is an extremely rare disorder. Acquired lactase deficiency is fairly common, especially in certain racial groups; it is reported in 10% of whites, 70% to 80%

of African Americans, and 90% of Asians. The disorder is associated with diarrhea, cramping, bloating, and abdominal pain after consumption of lactose. The stool has an acid pH, floats because it contains air, and is positive for reducing substances. Lactase deficiency may occur following an episode of acute gastroenteritis, when the brush border of the small intestine has been disrupted.

Persistent Diarrhea

Infants and children may have a protracted course of loose stools following an episode of acute gastroenteritis.

Risk factors for persistent diarrhea are

- Caloric and protein malnutrition
- Vitamin A and zinc deficiency
- Prior infection such as measles
- Male gender and young age between 6 and 24 months
- Young maternal age

In most cases, no cause for persistent diarrhea can be detected, but infestation with *Shigella* or enterotoxigenic *E coli* may be a contributing factor. The possibility of infection with HIV should be considered in infants and children with protracted diarrhea, especially in geographic areas where disease prevalence is high. Certain children with acute diarrhea have such a modified diet (eg, clear fluids) that they develop starvation stools. These slimy, dark green or golden stools represent succus entericus, the secretion of the small intestine. Starvation stools do not have a fecal odor. Insufficient fat in the diet may contribute to starvation diarrhea.

Chronic Diarrhea

Inflammatory bowel disease, which occurs more commonly in older children and adolescents, is associated with chronic diarrhea. Ulcerative colitis presents with infiltration of the lamina propria with inflammatory cells, distortion of the glands, and crypt abscesses. Fever, weight loss, and anorexia are often present. Diarrhea is the hallmark of the disease, and patients experience tenesmus as well as mucus-laden and bloody stools. Inflammation always affects the rectum. It can be localized in the left colon (left-side colitis) or spread out through the entire large intestine (pancolitis).

Crohn disease may also lead to chronic diarrhea, although lower abdominal pain aggravated by defecation may be a more prominent part of the medical history. Affected individuals frequently experience extraintestinal manifestations of the disease, such as fever, anorexia, weight loss or growth retardation, recurrent stomatitis, uveitis, arthralgia and arthritis, and clubbing. Perianal disease, such as fistulas, may be noted in 30% of patients.

Irritable bowel syndrome may lead to chronic diarrhea in infants and children. Affected children do not suffer from diarrhea at night, which is the sign of infectious or secretory diarrhea. Partially formed first stool in the morning and increased frequency during the day is the classic history. Bowel movement tends to occur after each meal, suggesting a prominent gastrocolic reflex. Children may have 3 to 10 stools per day, which may be mucus-laden and contain undigested vegetable fiber. Alternating periods of constipation may

occur. Affected children appear well throughout this illness, without weight loss, growth impairment, fever, leukocytosis, steatorrhea, or protein malabsorption. Their appetite remains good. Treatment of this type of chronic diarrhea involves the use of a high-residue diet to add bulk to the stool and thereby prevent small, frequent stools. Other conditions that lead to chronic diarrhea include intestinal polypoidosis; the use of certain medications, such as antibiotics; and the use of heavy metals, such as iron.

Chronic diarrhea may also be associated with **maldigestion**, as with cystic fibrosis, or **malabsorption**, as with celiac disease or gluten enteropathy.

Newborns with **cystic fibrosis** may present with meconium ileus or rarely with acute appendicitis. Failure to thrive is common among patients with cystic fibrosis despite the fact that many of them have voracious appetites. Stools are large, bulky, and foul-smelling secondary to the steatorrhea. Isolated GI complaints are reported in 15% to 20% of patients with cystic fibrosis, but most affected children are also prone to pulmonary infections. Rectal prolapse is another complication.

Celiac disease is related to an immunologic reaction to the gliadin portion of the wheat protein, gluten. This protein is also found in barley, rye, and oat. Characteristically, villous flattening is apparent on small intestinal biopsy. This flattening restricts the absorptive capacity of the intestine and leads to malabsorption. Children with the classic form of celiac disease have short stature, pale skin, sparse hair, protuberant abdomen, and wasted buttocks. In recent reports, subtle signs of celiac disease have been recognized and usually reflect the growth failure or anemia. Symptoms appear a few months after grains are introduced into the diet, usually between the ages of 9 and 12 months. Stools are mushy, bulky, and foul-smelling. Fat content in the stool may be 2 to 3 times the normal level.

Evaluation

History

A careful history should be obtained (Questions Box).

Physical Examination

Children should be assessed for the presence of dehydration as evidenced by altered vital signs, delayed capillary refill, decreased skin turgor, a sunken fontanelle, dry mucous membranes, and reduced tearing. Skin changes in the perianal area or evidence of diaper dermatitis would indicate the irritative nature of the stools. Perianal fissures may be present in Crohn disease. Evidence of growth retardation should be determined by assessing the growth parameters, particularly weight. Failure to gain weight over a period of months should trigger the workup of GI disorders such as chronic inflammatory bowel disease, celiac disease, or cystic fibrosis.

Laboratory Tests

Stool assessment, a major component of the evaluation, involves 4 steps. First, the stool is evaluated for its quantity as well as its gross appearance. Undigested pieces of fruits and vegetables in the stool

Questions

Diarrhea

- How long has the diarrhea been present?
- How frequent is the stooling?
- What is the consistency of the stools?
- Is stooling related to eating, which is a sign of osmotic diarrhea, or does it occur even if the child does not eat, which is a sign of secretory diarrhea?
- Do the stools contain any blood or mucus, which suggests a bacterial or parasitic infection?
- Is the child febrile?
- Does the child have any symptoms associated with the stooling problems?
- Does the child have a recent history of travel or exposure to animals?
- Is anyone at home ill?
- Has the child experienced any change in the frequency of urination, which is an important measure of the state of hydration?
- What is the child's diet now? What has it been?

of toddlers are often a sign of poor chewing. Small, thread-like bodies that resemble worms are concretions of bile and are common in the stool of infants. The change in stool volume with fasting can also be checked. Reduced volume in the face of fasting is consistent with osmotic diarrhea.

Second, the stool is subjected to chemical and microscopic analyses to detect the presence of unabsorbed nutrients such as carbohydrates and fats. The presence of carbohydrates may be detected using a small amount of stool liquified in about 1 mL of water. A Clinitest tablet is added to the sample, and a change in color from blue to green or orange is indicative of the presence of undigested carbohydrate. If the main source of dietary sugar is sucrose, as determined by the history, the specimen must be hydrolyzed by heating with hydrochloric acid. If the specimen sits around for too long, the presence of bacteria in the stool may break down the carbohydrate and lead to a false-negative result. The presence of fat can be determined both qualitatively and quantitatively. The stool may be examined under a microscope with just water or using a Sudan or Carmine red stain. If there are 10 or more globules of fat per high-power field, a quantitative fat analysis over a 3-day period should be undertaken. Ten percent of children with abnormal stool fat on microscopic assessment have a normal 3-day quantitative stool fat value. Quantification of fecal elastase-1 is an accurate alternative approach for diagnosis of exocrine pancreatic insufficiency in children with cystic fibrosis.

Third, the stool is examined for the presence of blood and leukocytes. Blood may be present in the stool but originates from excoriations in the diaper area rather than from the GI tract. To assess for leukocytes in the stool, the mucus component of the stool should be smeared on a glass slide and stained with methylene blue. More than 2 to 4 leukocytes per high-power field is abnormal and suggests a bacterial infection. The sensitivity of the fecal leukocyte test is 85% but the specificity is only 50% to 60%. Absence of leukocytes

or erythrocytes in the stool signifies a very low probability of an invasive bacterial infection (predictive value of a negative test is 95%). A stool specimen should be submitted for culture and may be evaluated for ova and parasites. Stool analysis using Rotazyme will detect rotavirus. Fourth, stool is assessed for levels of sodium and potassium and stool osmolality to calculate the so-called ion gap (ion gap = stool osmolality - [(Na+K) × 2]). Ion gap exceeding 100 mOsm/kg and low sodium concentration in stool (<40 mEq/L) is typical for osmotic diarrhea. On the contrary, ion gap equal to or lower than 100 mOsm/kg and sodium concentration in stool higher than 70 mEq/L is consistent with secretory diarrhea.

Additional studies, especially in the face of dehydration or fever, include serum electrolytes, complete blood cell count, urinalysis, and urine culture. Serological markers such as tissue transglutaminase and antiendomysial antibodies are good screening tests of gluten enteropathy. Upper GI endoscopy with a small bowel biopsy is indicated for confirmation of celiac disease or diagnosis of other causes of persistent or chronic malabsorptive diarrhea. Colonoscopy should be considered after consultation with a gastroenterologist if inflammatory bowel disease or familial polyposis is suspected.

Management

Initial management of children with gastroenteritis involves **adequate hydration and replacement of any fluid or electrolyte deficits** (see Chapter 66). Bolus therapy may be necessary in children with significant dehydration. Children with significant dehydration may require admission to the hospital and the administration of intravenous fluids. Less severely affected children may be managed as outpatients using oral rehydrating solutions such as Pedialyte or Infalyte. Alternatively, parents can be advised to make oral rehydrating solutions by using water (1 liter), sugar (4–8 teaspoons), and salt (½ teaspoon).

Dietary manipulation in the treatment of diarrhea is somewhat controversial. Traditionally, affected children have been placed on clear fluids for 1 or 2 days, with a gradual return to a more regular diet with time. A **BRAT diet** (bananas, rice or rice cereal, applesauce, tea or toast) was often recommended because of the intrinsic binding properties of the particular food. Recent studies recommend a full resumption of a normal diet, including dairy products, as the way to ensure adequate nutrition during the acute illness. A high-fat, low-carbohydrate diet accelerates improvement. A lactose-free diet is beneficial for infants and children with persistent diarrhea.

Antimicrobial therapy is indicated for infection with certain pathogens such as *Campylobacter*, *E histolytica*, *G lamblia*, and *Shigella*. Antimicrobial agents are used to treat *Salmonella* infection in certain populations such as neonates, immunodeficient children, and children with sickle cell anemia. **Antidiarrheal agents** are not usually recommended for the management of diarrhea in children. Diarrhea is believed to be the body's way of eliminating a toxic

substance that has been ingested. In addition, the diarrhea often progresses in spite of the medication, which has its most binding effect after the illness has subsided, leading to constipation.

Children with chronic diarrhea secondary to a specific condition should be managed as dictated by the particular disorder.

Prognosis

Most cases of diarrhea in infants and children in the United States are self-limited and resolve without problems. More chronic cases may lead to malnutrition. Enteral feedings or hyperalimentation may be used to ensure a good outcome. Some children require consultation with a pediatric gastroenterologist.

CASE RESOLUTION

In the case history, the presence of blood and mucus in the stool suggests a bacterial etiology. The stool should be examined microscopically for leukocytes using methylene blue. Their presence supports a bacterial etiology. A stool specimen as well as a blood specimen should be sent for culture. Because the infant appears dehydrated (ie, sunken fontanelle, poor skin turgor, tachycardia), admission to the hospital should be considered to allow for rehydration and the administration of parenteral antibiotics.

Constipation

Doron D. Kahana, MD, and George Gershman, MD

CASE STUDY

A 6-year-old child is brought to the office by her mother who reports 6 months of episodic belly pain. The mother states that the child complains mostly in the afternoon and evening and rarely at night or morning. The pain will last a few minutes and is sometimes severe. She notes that her daughter vomited once and had soiled her underwear on a few occasions. She believes the child toilets daily but has not asked or supervised her directly. The mom reports that the toilet was plugged a few times after the child defecated. The child has a great appetite and eats an age-appropriate diet that is high in pastas, breads, cow's milk, and cheese. The child at times is gassy and looks bloated. Otherwise the child is healthy, growing and developing normally, and is in first grade. On examination, vital signs are normal, she is at the 75th percentile in height and 90th

percentile in weight. On questioning the child as to the specific location of her pain, she points to her umbilicus. On deep palpation there is a firm mass in the left lower quadrant; it is non-tender and the abdomen is otherwise soft. A rectal examination reveals hard, dry stool in the vault. The rest of the examination is normal.

Questions

1. What is the definition of constipation?
2. How is the stooling pattern related to diet?
3. What diseases and medical conditions are associated with constipation?
4. How do familial factors influence stooling patterns?
5. What is the management of chronic constipation?

Introduction

Constipation is a common and significant complaint that accounts for approximately 3% of visits to pediatric clinics and up to 25% of pediatric gastroenterology visits. Clinically, it is defined by stools that are dry, hard, and/or difficult to pass. Reduced *frequency* of stooling is a common characteristic of constipation, but is not universal or definitive. The guidelines of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition define constipation as “a delay or difficulty in defecation, present for two or more weeks and sufficient to cause significant distress to the patient.” Normal stooling frequency averages 3 to 4 per day during the first weeks of life and decreases to 1 to 2 per day with introduction of table foods by 1 year of age. After age 4 and into adulthood, normal stool frequency ranges from 3 per day to 3 per week.

Many factors influence the frequency of stooling in normal infants and young children, including diet, familial pattern of intestinal motility, personal sensitivity, hygiene habits, hydration status, variable stressors, and intake of medications. Exclusively breastfed infants may have long intervals (sometimes several days) between normal bowel movements.

Functional constipation is defined as constipation in the absence of organic disease; however, it is important to note that chronic constipation is also a condition that begets disease and, thus, must be treated appropriately. Constipation is one of a number of unique medical conditions that create a positive feedback loop; stool withholding results in worsening constipation as stretch receptors

accommodate a distended rectum and contractile forces fail to result in complete evacuation.

In infancy, peristaltic motility may be weak or poorly coordinated, and the lack of physical mobility/ambulation requires the infant to exert a physiological effort (ie, Valsalva maneuver) to allow passage of stool. Parents may interpret “straining” as a sign of constipation despite the passage of soft, normal stools. Therapy in such cases, if necessary, is usually non-medical and involves manual stimulation of the anal sphincters and mobilization of the infant. Older infants and toddlers may have constipation secondary to food intolerance, such as cow's milk protein allergy, and removal of the inciting agent may result in complete resolution. Toilet training can prove to be a challenge, especially in constipated toddlers, and stressful parent-child interactions may result in resistance on the part of the child.

Commonly, chronic constipation in childhood is triggered by a painful evacuation that results in an unpleasant experience. School-aged children may elect to withhold stool because of fear of toileting outside the home or because of social stressors (eg, parental divorce, bullying). Assessment of the etiology of constipation requires a careful medical history to determine the age of onset, the characteristic of the stool, and the presence of contributing factors. After all, regular toileting is a sign of good health.

Epidemiology

Prevalence of constipation in infants is less than 3% and increases between the ages of 2 and 4 years. Onset often coincides with toilet

training and dietary changes, as well as increased colonic transit time. Longer transit allows for more extensive colonic fermentation of food residue, salvage of micronutrients, and greater resorption of water, but it is associated with firmer, drier stools that may trigger abdominal and rectal discomfort. Defecation may become unpleasant and lead to stool withholding behavior.

Prevalence of constipation in infants and toddlers is equal among males and females, but it becomes 3 times more frequent in boys than in girls by age 5 years. Fecal soiling, or encopresis, a significant comorbidity, is reported in up to one-third of females and half of males with severe, chronic constipation (see Chapter 53).

Clinical Presentation

Infants often present with infrequent stooling. Some parents report facial grimacing and grunting during defecation as well as apparent discomfort or fussiness with bowel movements. History of delayed passage of meconium, recurrent vomiting, or poor weight gain indicates the need for further evaluation. Toddlers usually present complaining of abdominal pain and reporting the passage of hard or large stools. School-aged children may have fecal soiling, which usually represents overflow incontinence (only 10%–15% of all cases of encopresis are non-fecal retentive). Parents describe a stool withholding posture, where the legs are clamped together and the gluteal muscles are contracted in an effort to suppress defecation (Figure 111-1). Poor appetite and episodic vomiting in severe cases are secondary to a persistent sense of fullness from a dilated and impacted colon. Hydronephrosis, urinary tract infections, and enuresis are also associated with chronic constipation and an impacted colon.

Pathophysiology

What Is the Colon?

The colon is a muscular organ that processes dietary residue through bacterial fermentation, salvaging nutrients and reabsorbing more than 90% of the water that enters, and prepares stool for transient storage and eventual excretion (Figure 111-2). Fermented food residue produces gas (eg, hydrogen, methane) and short-chain fatty acids; the latter provide colonocytes with readily available fuel (via butyric acid) and enter the portal circulation for calorie salvage in the liver (eg, propionic and acetic acids). The fermentation process may release other micronutrients and vitamins and is thus an important component of colonic function.

Normal Physiology

Digested food normally takes about 2 to 6 hours to reach the cecum from the duodenum (gastric emptying half-time is normally 60–90 minutes). The propagation of food in the small intestine occurs via peristaltic waves called the migrating motor complex. Once chyme is in the cecum, peristalsis slows down and it may take several hours or days for it to be expelled as stool. The longer

Figure 111-1. Child exhibiting retentive posture.

Figure 111-2. Diagram of anus, rectum, and sigmoid colon.

the transit time, the more extensive the water resorption and the more likely it is for the stool to be dry and hard. The rectosigmoid is the sensing organ that initiates the process of defecation and can store stool until it is socially acceptable to expel it. Contraction and emptying of the rectosigmoid is stimulated by eating, a process called the *gastrocolic reflex*. In the rectum, the pelvic floor muscles (levator ani, puborectalis) regulate fecal retention and defecation. The puborectalis suspends the rectosigmoid and imposes constraints that facilitate voluntary stool retention (continence). Continence is also promoted by contraction of the internal and external anal sphincters.

Defecation

The urge to defecate is signaled by the propulsion of feces from the sigmoid colon to the rectum. Distention of the rectum causes relaxation of the internal anal sphincter; the external anal sphincter and puborectalis must voluntarily relax under parasympathetic conditions. The pelvic floor muscles descend, permitting straightening of the anus and rectum (see Figure 111-2). Thus defecation is facilitated by squatting or sitting and by increasing intra-abdominal pressure. The urge to defecate can be consciously repressed by voluntary contraction of the external anal sphincter and likely subconscious sympathetic reflex inhibition and contraction of the puborectalis muscle. The process of defecation is learned early in childhood and remains spontaneous throughout life. The spontaneity of this process may be lost for a variety of reasons, including secondary to trauma, pelvic floor dysfunction (dyssynergia), pseudo-obstruction, or surgical resection.

The Vicious Cycle of Constipation

If the urge to defecate is suppressed, the rectosigmoid and eventually the entire colon will become dilated and impacted, and defecation may become difficult. The increased caliber of the colonic lumen makes contractions weaker and less effective in propagating stool. Moreover, the constipated child may become desensitized to rectal distention. Eventually, delayed defecation leads to formation of hard, bulky stool, which makes defecation difficult and painful. The child learns to tighten the external anal sphincter and gluteal muscles, pushing feces higher into the rectal vault and suppressing the urge to defecate—this is the vicious cycle of constipation (Figure 111-3). In children, the initiating event may be a painful evacuation, possibly after an acute illness (eg, cold, respiratory infection). Intentional and prolonged suppression of defecation is an important factor in the pathogenesis of chronic constipation.

Familial Factors

Some families are predisposed to constipation. Concordance for constipation is 4 times more common in monozygotic twins than dizygotic twins. It may be related to increased absorption of water or an unusually long or poorly motile colon. Poor sensitivity to a critical rectal volume or the need for a particularly large rectal volume may delay the initiation of defecation in genetically predisposed individuals.

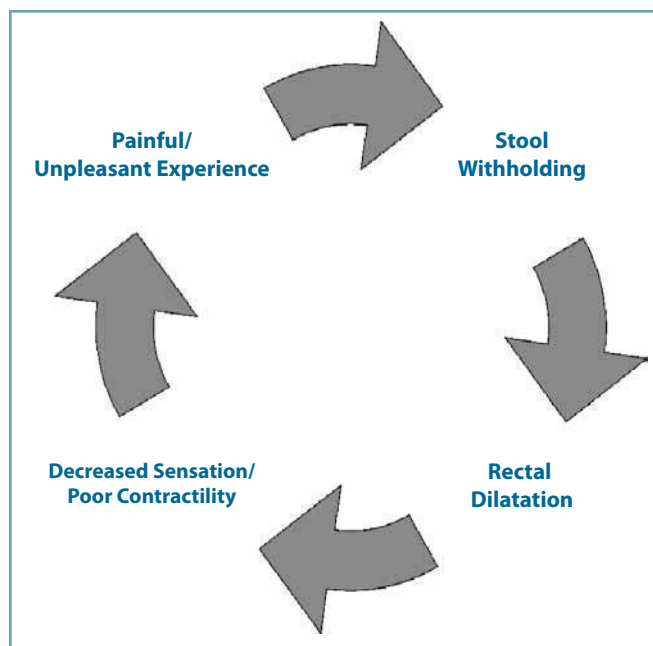

Figure 111-3. The vicious cycle of constipation.

Differential Diagnosis

The differential diagnosis of constipation can be divided into congenital versus acquired and then into the following etiologic categories: anatomical; neurologic; hormonal; infectious/toxic; drug-induced/metabolic; functional or other, such as genetic or allergic (Box 111-1). Functional constipation is supported by a characteristic history that includes poor dietary and hydration habits, stool withholding behavior, and a normal physical examination. Dietary history may reveal high consumption of cow's milk (>24 oz/day), cheese, or sugary fruit juice, as well as poor intake of fruits, vegetables, and whole grains. Stool withholding is most commonly seen in young, school-aged children and often is a product of a stressful environment such as a new sibling, a move, parental struggles, or a new school environment.

Chronic constipation that is resistant to medical therapy should not be ignored. Conditions such as Hirschsprung disease and congenital intestinal malrotation can present past the neonatal period and may lead to intestinal devastation (eg, volvulus and ischemia). Several conditions are particularly important to consider when evaluating constipation in infants, including Hirschsprung disease, hypothyroidism, anal stenosis/atresia, meningomyelocele (occulta), and cerebral palsy. Failure to pass meconium, or a delay in the passage of meconium (meconium ileus) beyond 24 hours, should also raise suspicion for a congenital or genetic aberration (eg, Hirschsprung, cystic fibrosis).

Hirschsprung disease is an intestinal motility disorder resulting from aganglionosis of the myenteric plexus that usually affects the rectosigmoid. However, the entire colon can be involved in a distal to proximal distribution. The severity of the disease and complexity of surgical treatment is directly proportional to the length of the affected colon. When ganglion cells are missing in the very distal

portion of the rectum, the disorder may resemble chronic idiopathic constipation, often recalcitrant to medical therapy. The prevalence of Hirschsprung disease is about 1 in 5,000 live births and may account for up to 3% of all cases of constipation referred to a gastroenterologist. Physical examination of a patient with Hirschsprung disease may reveal some degree of abdominal distention and an empty rectal vault. In infants, a rectal examination frequently induces explosive stool due to distention of the internal anal sphincter. Early recognition of this condition is important to prevent the development of toxic megacolon and enterocolitis, a condition that carries high morbidity and mortality. Hirschsprung disease may be seen in conjunction with syndromes such as trisomy 21, Smith-Lemli-Opitz, and Waardenburg syndromes, and several genetic mutations in the receptor tyrosine kinase gene *RET* have been described as responsible for the pathogenic mechanism.

Infants with hypothyroidism secondary to hypopituitarism may also present with constipation and are not diagnosed through the newborn screening process because of normal (ie, low) levels of thyroid-stimulating hormone. These children may either appear clinically normal or display some of the features of hypothyroidism (eg, large fontanel, umbilical hernia, coarse facies, macroglossia).

Anal stenosis, imperforate anus with a perineal fistula, or an anteriorly displaced anus may not be recognized immediately in the newborn period because the condition may be subtle. Anorectal malformations occur in about 1 in 7,000 live births, which reinforces the need for a perianal and rectal examination with every constipated child.

Severe constipation that begins prior to toilet training is more suggestive of an organic etiology, such as Hirschsprung, malrotation, or pseudo-obstruction. Pseudo-obstruction may present in older children with a history of intermittent constipation, abdominal distention, pain, nausea, and vomiting. Onset of constipation around the time of toilet training, when stooling had been normal in the past, suggests functional constipation.

Constipation may develop in some children in association with the use of medications such as iron or bismuth (Pepto-Bismol), codeine or other narcotics, chemotherapeutic agents (eg, vincristine),

and agents with anticholinergic properties (eg, pseudoephedrine, imipramine).

Evaluation

History

Commonly associated historical signs and symptoms of constipation include abdominal pain (especially during and after meals), abdominal distention, excessive flatulence, hard stools, dyschezia (painful evacuations), bright-red blood per rectum, toilet plugging episodes, and urinary symptoms (eg, enuresis, recurrent infections) (Questions Box). Overflow incontinence may mislead the clinician to a differential diagnosis for chronic diarrhea. Fecal soiling due to stool retention and overflow is noted in many children with severe, chronic constipation, although a complete physical examination in such a

Questions

Constipation

- What is the child's stooling pattern? How often does the child have a bowel movement? What is the appearance and consistency of the stool?
- What was the child's age when the problem began?
- What makes up the child's diet?
- Does the child take any medications?
- Does the child have any symptoms associated with constipation, such as recurrent abdominal pain? If so, how long have these been occurring?
- Has the child been sick recently with any illnesses that might cause constipation?
- Has the child recently experienced any changes in routine that could cause constipation?
- Is there a family history of constipation?
- How old was the child when he or she was toilet trained?
- Is there any bleeding with stooling?
- Is there pain with stooling?
- Have any remedies such as laxatives, enemas, or suppositories been used to relieve the symptoms?

setting should reveal both a stool mass in the lower left abdominal quadrant and an impacted colon or rectum on digital manipulation. As with all conditions that present with abdominal pain, it is important to screen for the presence of recurrent mouth sores, skin rashes, joint pain, weight loss, bloody or mucousy stools, incomplete evacuations, and tenesmus (rectal spasm accompanied by a strong urge to defecate, often with the passing of blood and/or mucus). Family history of inflammatory bowel disease, celiac disease, irritable bowel syndrome, constipation, and atopy (eg, food allergy) should also be noted with every child presenting with abdominal pain.

Physical Examination

The physical examination in cases of functional constipation is usually normal. If the child is complaining of abdominal pain, ask the child to indicate the area of greatest pain with one finger. In functional disease, the child most often will point directly to the umbilicus. Palpation may reveal a firm stool mass in the left lower quadrant that is classically non-tender. Consistency and color of the stool in the rectum will vary, but a hard and dry stool is strongly suggestive of stool impaction. An empty rectum should raise suspicion for an organic etiology. Digital manipulation followed by an “explosive” passage of stool is suggestive of Hirschsprung disease. The back of the child should be inspected for a sacral dimple or a hair tuft, especially in infants, as this may be a sign of occult spinal cord anomaly.

Signs of pallor, mouth sores, hepatosplenomegaly, arthritis, or skin rashes may suggest another underlying disease process.

Laboratory Tests

Malnourishment is possible if the child consumes a restricted diet (eg, more than 24 ounces of cow’s milk or soda per day) or has a suggestive physical examination (eg, pallor, dry skin). Iron-deficiency anemia and mineral deficiencies (eg, calcium, zinc) are signs of poor nutritional intake. A lipid panel may reveal high triglycerides (from excessive sugar intake) and low high-density lipoprotein (from poor quality fat intake). Thyroid function may require evaluation in certain cases.

Imaging Studies

A flat plate of the abdomen is usually not indicated, but may help on a clinical level by showing the child and/or parents the significant amount of stool present. Anatomical studies such as a barium upper gastrointestinal series evaluate for malrotation, a congenital stricture, imperforate anus, or Hirschsprung disease. It is recommended for barium enema to be performed without a prior clean-out, in order to sensitize the study for the presence of a transitional zone.

Further Tests

Anorectal manometry and a suction rectal biopsy may be carried out by a gastroenterologist to help diagnose Hirschsprung disease; however, only a full-thickness rectal biopsy will confirm the presence or absence of aganglionosis and must be performed by a surgeon. Colonic manometry can also measure colonic peristaltic waves and help diagnose pseudo-obstruction and other dysmotility disorders.

Management

In the Primary Care Setting

Most cases of constipation can be evaluated and managed by primary care physicians. In functional constipation, the mainstay of management involves a 3-pronged approach of dietary therapy, behavioral modification, and medications (Figure 111-4).

Diets that predispose to constipation are rich in simple carbohydrates (eg, sugar), refined and processed carbohydrates (eg, pasta), saturated fat (eg, fried food), processed meat (eg, hotdogs), and dairy (especially milk and cheese). Dietary therapy should begin by decreasing the intake of these food items and increasing the intake of fruit, vegetables, whole grains, legumes, and tree nuts. Prune juice and fruit nectars (eg, pear, peach, apricot) may be supplemented and are well tolerated, effective, and may be mixed with the child’s favorite drink. Most fruit, such as pears, papaya, and cantaloupe, as well as vegetables, roots, and tree nuts are high in beneficial fiber. Dried fruit (eg, raisins, cranberries) are rich in sorbitol and thereby cathartic. It is important to continuously introduce new food items to the diet, especially fruit and vegetables. Introduction of certain foods, such as whole grain breads and brown rice, may need to be gradual and require some adjustment, but will render life-long benefits (Box 111-2).

Behavior modification can also be challenging, but absolutely essential to breaking the vicious cycle. Teaching of proper “toilet hygiene” to the child should be done in a firm and consistent manner, and engaging the child with a sticker or star chart may help. In short, it is recommended that the child sit on the toilet once or twice daily for 8 to 10 minutes at a time, preferably after a meal (taking advantage of the gastrocolic reflex). Longer toilet sitting should be discouraged as it may lead to perianal disease such as a fissure or hemorrhoids. Even if the child fails to have a bowel movement with each toilet sitting, good toilet hygiene will make the experience a routine and hopefully help prevent further reluctance to use the toilet. Biofeedback is useful when available, especially

in children with encopresis and/or paradoxical contraction of the external anal sphincter.

Medications are generally safe and largely over the counter (Box 111-3). The 2 most commonly used medications are polyethylene glycol (PEG-3350), a nonabsorbable high molecular weight synthetic polymer (non-fermentable), and lactulose, a nonabsorbable high molecular weight sugar (fermentable). Both work by helping the colon retain water and thus prevent the complete dehydration of stool. Lactulose is a prebiotic that is fermented into short-chain fatty acid and can beneficially lower stool pH; however, the process may cause gassiness and bloating in some patients and therefore dosing may need to be increased gradually. Suppositories or enemas are largely avoided nowadays, as is manual disimpaction, with high-dose polyethylene glycol administration showing equal efficacy with less invasiveness. Mineral oil is useful in lubricating hard stool and may decrease the pain associated with disimpaction; however, it should not be given to infants or neurologically impaired patients due to risk of aspiration and chemical pneumonitis. Dietary fiber supplements (ie, prebiotics), such as psyllium husk, guar gum, inulin, and fructans, are helpful for maintenance therapy. Probiotics, notably the strains *Lactobacillus reuteri*, *L plantarum*, *Bifidobacterium longum*, *B breve*, and *B animalis* subsp. *Lactis*, have also shown usefulness in the therapy of constipation.

The most important element in the management of functional constipation is persistence and longevity. Several months of therapy (eg, 6–12) are often needed and considered safe, as the colon needs to heal from a chronic injury in order to regain regularity. Dietary changes and toilet hygiene should be incorporated into a healthy lifestyle and practiced into adulthood.

When to Refer to a Gastroenterologist

Constipation that is resistant to medical therapy should not be ignored. Although uncommon, anatomical aberrations (eg, malrotation), Hirschsprung disease, and intestinal pseudo-obstruction may present after infancy and lead to toxic megacolon or intestinal/colonic volvulus, resulting in intestinal ischemia and devastation. These conditions may require surgical intervention and long-term follow-up and thus should be referred to a specialist.

Special attention should be paid to infants with persistent constipation because of the high risk of serious conditions such as Hirschsprung disease or malrotation.

Prognosis

The prognosis varies with etiology. Functional constipation is usually amenable to routine management, but treatment failures are reported in 20% of children with functional fecal retention and some long-term studies suggest persistence of symptoms for 25% to 50% of children. A long delay in presentation increases the risk of poor clinical outcome. Age at presentation and stooling frequency are also strong predictors of clinical outcome. Relapse rate at 1 year, after a successful initial intervention, is less than 5%, but increases to 10% to 40% after 5 to 7 years, with significantly higher rates for women. Long duration of symptoms, poor self-esteem, and prior sexual abuse are among risk factors for a poor prognosis. Nonetheless, long-term studies largely show 2 important conclusions: (1) prolonged laxative use is important and (2) dietary and behavioral modifications are ultimately successful in weaning laxative use (Figure 111-5).

Figure 111-5. Clinical outcomes of patients according to follow-up year, divided into the 4 defined outcome categories. Numbers in the upper row above the bars show the numbers of patients due for follow-up evaluation each year. Numbers in the second row show the numbers of patients reached for follow-up evaluation each year. (Reproduced from Bongers MEJ, van Wijk, Reitsma JB, Benninga MA. Long-term prognosis for childhood constipation: clinical outcomes in adulthood. *Pediatrics*. 2010;126:e156–e162.)

CASE RESOLUTION

The child in the case scenario has functional constipation. The belly pain is visceral and related to gas distention and stool retention. The relation of her pain to meals is a reflection of the gastrocolic reflex. A single episode of vomiting may be coincidental and is not overly concerning. Soiling may occur with fecal impaction and overflow incontinence. Parents are often unaware of their children's toileting habits. Gassiness implies stool retention and fermentation in the colon. It is essential to note normal appetite and growth parameters. The rectal examination helps confirm the diagnosis. No further testing is necessary for this child at this point, and the primary care physician should initiate therapy.

Abdominal Pain

George Gershman, MD

CASE STUDY

An 12-year-old boy has a 3-month history of intermittent abdominal pain. The pain is present prior to eating and is alleviated by food. The pain also occurs at night. As a result of his symptoms, the child has missed 1 to 2 days of school each week. The family moved to the area 6 months ago, and initially the child seemed to be adjusting to his new school and environment. In addition, the boy has a history of a 5-lb weight loss. He has a positive family history of abdominal pain; his father has been diagnosed with a peptic ulcer. On physical examination, the vital signs are normal. The weight is at the fifth percentile and the height is at the 25th percentile. There are no abnormal physical

findings, and the patient is quiet and cooperative. The rectal examination is normal, and the stool is negative for occult blood.

Questions

1. What are the different types of abdominal pain?
2. What characteristics distinguish functional from organic abdominal pain?
3. What are the common organic causes of recurrent abdominal pain in children?
4. What are 2 etiologies for functional pain?

Abdominal pain is one of the most common symptoms of childhood. It may be acute or chronic. Acute abdominal pain resolves within 4 weeks from the onset of symptoms. Most children with acute abdominal pain have self-limiting conditions such as viral or bacterial gastroenteritis. However, a sudden onset of abdominal pain can be caused by serious, life-threatening conditions (eg, acute appendicitis, intussusception, or hemolytic uremic syndrome). Chronic abdominal pain is defined as pain that persists at least for 2 months. Most children with chronic abdominal pain suffer from so-called functional abdominal pain (FAP). The criteria for childhood FAP must include all of the following criteria: presence of abdominal pain at least once per week for 2 or more months prior to diagnosis; episodic or continuous nature of abdominal pain; insufficient criteria for other functional gastrointestinal disorders; and absence of anatomical abnormalities, and inflammatory and metabolic and neoplastic processes related to patient's symptoms. Children with FAP suffer equally from intermittent or continuous non-localized abdominal pain. Onset of pain is usually not associated with defecation. Children with FAP and loss of daily function fall into the category of FAP syndrome (FAPS). The term *functional abdominal pain* should not suggest that affected children are malingerers or their symptoms are fictitious.

An organic etiology is found in less than 10% of school-aged children with chronic or recurrent abdominal pain (RAP). However, failure to recognize and/or delayed therapy can have devastating effects.

Epidemiology

According to community- and school-based studies, up to 38% of children and adolescents experienced abdominal pain weekly, with

up to 24% of children reporting symptoms persisting for longer than 8 weeks. Abdominal pain is the essential part of several functional gastrointestinal disorders such as irritable bowel syndrome (IBS), functional dyspepsia, and abdominal migraine, as well as organic disorders, which occur with variable frequency in different age groups.

Pathophysiology

There are 3 main reasons for acute or chronic organic abdominal pain: inflammation, distention of the viscera, and ischemia.

Abdominal pain can originate from abdominal viscera (visceral pain), parietal peritoneum, abdominal wall, retroperitoneal skeletal muscles (somatic pain), and extra-abdominal sites (so-called referred pain). Impulses of visceral pain are carried out primarily by small, unmyelinated, slow-conducting afferent C fibers incorporated into the autonomic sensory pathways. Each visceral organ receives dual sympathetic and parasympathetic innervations. Sensory fibers associated with the sympathetic nervous system traverse both pre-vertebral (celiac, superior, and inferior mesenteric ganglion) and paravertebral ganglion and terminate in the spinal cord. Sensory fibers contained in the vagus and pelvic nerves (parasympathetic branch of the autonomic nervous system) terminate in the brain stem and lumbosacral spinal cord respectively. Sensory fibers from visceral organs that connect with the spinal column terminate within the 4 to 5 spinal segments. This explains why visceral pain is poorly localized and often perceived along the midline as a dull or aching sensation. For example, the onset of acute appendicitis is usually manifested by pain in the periumbilical or epigastric areas before the pain migrates to the right lower quadrant. It

is frequently accompanied by symptoms of autonomic disturbance (eg, nausea or pallor).

Somatic pain is induced by irritation of parietal peritoneum and supportive tissue. The signals from the pain receptors (nociceptors) are transmitted for the most part by rapid conducting myelinated A-delta fibers responsible for tactile, thermal, and chemical stimulation and discrimination of location and intensity of stimuli. As a result, somatic pain is well localized, intense, and sharp. The important characteristic of somatic pain is aggravation by movement. Therefore, the child with somatic abdominal pain is likely to lie still in contrast to the restless patient with visceral pain.

The classic example of referred pain is abdominal pain induced by inflammation of parietal pleura at the onset of pneumonia as the result of shared central projections of the parietal pleura and abdominal wall.

The location of abdominal pain is determined by the level of spinal cord connection with the corresponding visceral organs through the afferent sensory fibers. The structures of the foregut origin, such as distal esophagus, stomach, duodenum, liver, and pancreas, are innervated by the nerves that enter the spinal cord at the level T5 to T9 segments. Pain from these organs is perceived between the xiphoid and umbilicus. The structures related to the primitive midgut (small intestine, appendix, and right colon) project the afferent fibers to the T8 to T9 segments of the spinal cord. As a result, the associated pain affects the periumbilical area. The structures related to the embryonic hindgut, including the left colon and the rectum, share the innervations, which involve the spinal segments T10 to L1 and allocate the pain between the umbilicus and symphysis pubis.

Radiation of the pain may be helpful in diagnosis (eg, pain related to acute cholecystitis or biliary colic often refers to the area just under the inferior angle of the right scapula or above the right clavicle). Another example of referred pain is pain between the scapulas and middle back region in patients with pancreatitis.

The pathophysiology of functional abdominal pain is different from acute or chronic organic abdominal pain. The genesis of functional abdominal pain is related to abnormalities in the enteric nervous system and dysregulation of the brain–gut interaction. It is now believed that children with functional abdominal pain may have abnormal responses to the normal physiological functions related to meals as well as intestinal distention during peristalsis, associated hormonal changes, and psychological conditions like anxiety and parental separation.

Research data suggest that visceral hyperalgesia is the key element in the pathophysiology of functional abdominal pain. This theory implies sensitization of the various receptors associated with afferent innervation of the gastrointestinal (GI) tract by an infectious or allergic process or abnormal processing of afferent signals by the central nervous system.

Clinical Presentation

Children who experience abdominal pain may present with pain that may be characterized as persistent or intermittent, waxing and waning or steady and unrelenting, sharp or dull, and worsened or

unaffected by movement. They may have associated complaints, including vomiting, diarrhea, constipation, fever, weight loss, headache, and anorexia (Dx Box).

Pain from distention of smooth muscle also waxes and wanes, is poorly localized, and is unaffected by motion. Distention of any hollow viscus, including the stomach, intestines, biliary tree, fallopian tubes, or ureters, can result in such symptomatology. A classic example of such pain is renal colic, where the patient is writhing because of the discomfort.

Dx Abdominal Pain

- Abdominal pain
- Abdominal wall rigidity
- Abdominal tenderness
- Vomiting
- Alterations in bowel sounds
- Diarrhea or constipation
- Anorexia
- Fever

Differential Diagnosis

In assessing the possible disease entities that may account for abdominal pain, patient age and duration of symptoms are the key differential components. The location of the pain may provide a clue to the etiology. Disease affecting the stomach is usually appreciated in the epigastrium. Duodenal problems are noted between the xiphoid and the umbilicus, small intestinal pathology is appreciated in the periumbilical area, and cecal inflammation may be felt from the epigastrium to McBurney point. Disease in the colon is less specifically noted but is usually felt in the hypogastrium. Bladder and colon problems may be suprapubic or sacral. Pain may also be referred to the back. Renal colic is also noted in the back, but more in a lateral or costovertebral angle (tenderness) site.

Acute and Chronic Abdominal Pain

Young Infants: Medical Conditions

A unique disorder of infants, **colic** has been referred to as paroxysmal fussiness of infancy (see Chapter 46). The onset of symptoms is usually between 2 and 4 weeks of age, with resolution by 3 to 4 months. Although recurrent abdominal pain seems to be present, abdominal pain has never been established as the cause of colic. Colic is characterized by fussiness and crying. Symptoms usually appear after feeding, particularly late in the day around dinnertime. Infants cry, clench their fists, and flex their legs. A gas–cry–air–swallowing cycle seems to occur. The symptoms may respond to a number of measures, including rhythmic motion and anti-gas medications. Infants with colic usually appear well otherwise and often have accelerated weight gain secondary to repeated feeding made in efforts to quiet them.

Abdominal pain may also occur with **food allergy**, particularly cow's milk protein allergy. Generally, symptoms such as vomiting,

diarrhea, hemoccult-positive stools, failure to thrive, rhinitis, eczema, pallor, irritability, and a positive family history of allergies are associated with food allergies. Disaccharidase deficiency may result in abdominal pain, but diarrhea is also usually present.

Young Infants: Surgical Conditions

Intussusception occurs in infants 3 months of age and older. The child may have been previously well or have experienced a recent bout of diarrhea. Vomiting is reported in about 50% of patients, and pallor is frequently present. Lethargy is not an uncommon associated symptom. An etiology is noted in less than 2.5% of affected infants, although a lead point (lymphoma or Meckel diverticulum) may be found in 5% to 10% of older children. The intussusception most often involves the area around the ileocecal valve. Compression of the vessels within the bowel wall may lead to necrosis and gangrene. The presence of blood and mucus in the stools gives a “currant jelly” appearance, although the initial stool is often normal, having been the stool that was present in the rectum prior to the intussusception.

The abdominal examination of affected children may be benign except for pain over the area of the intussusception or may reveal the presence of a mass. Bowel sounds may be increased secondary to the obstruction. The rectal examination may reveal blood and the presence of a mass. Fever and leukocytosis may also be noted. A flat plate of the abdomen is usually nonspecific. Intussusception is diagnosed by abdominal ultrasound or barium enema. Hydrostatic reduction is the treatment of choice of intussusception. It is successful in almost 90% to 95% of children. Failure of hydrostatic reduction or associated complications are related to delayed diagnosis and severe edema and necrosis of the affected bowel.

School-Aged Children: Medical Conditions

Functional Abdominal Pain

As noted previously, most children with RAP suffer from functional gastrointestinal disorders (FGID). According to the clinical presentation, FGID can be subdivided into 5 categories: FAP, FAPS, functional dyspepsia, IBS, and abdominal migraine. Children with FAP usually do not have association of pain with eating, defecation, menses, or exercise. It is occasionally triggered by new environment, difficulties at school, or domestic problems. The pain is usually periumbilical and quite severe. It can be recurrent or continuous and may affect daily activity.

Irritable bowel syndrome in children is characterized by abdominal discomfort or pain associated with 2 or more symptoms: improvement after defecation, onset of pain associated with a change in frequency, and change in form of stool. Symptoms that cumulatively support the diagnosis of IBS are 4 or more stools per day or 2 or less stools per week, lumpy/hard or loose/watery stool, straining, urgency or feeling of incomplete evacuation, passage of mucus, bloating, or a feeling of abdominal distention. Children with IBS are often anxious and express multiple somatic complaints.

Although many children seem to outgrow the FAP and IBS, long-term follow-up studies suggests that a significant number remain symptomatic into adulthood.

Children with functional dyspepsia experience persistent or recurrent abdominal pain or discomfort centered in the upper abdomen (above the umbilicus). Pain is not relieved by defecation or associated with the onset of change in stool frequency or form. Dyspeptic symptoms may follow a viral illness. The pain is often relieved by medical inhibition of gastric secretion. Children with functional dyspepsia may suffer from nausea, early satiety, postprandial fullness, vomiting, and a sense of bloating.

Abdominal migraine is characterized by paroxysmal episodes of intense, acute periumbilical pain that lasts for one or several hours. Pain is often incapacitating. Children return to their usual state of health for weeks to months between the paroxysms of pain. When present, the pain interferes with normal activities and is often accompanied by pallor, anorexia, photophobia, headache, nausea, and vomiting. There is an increased incidence of maternal migraine in children with abdominal migraine.

As mentioned previously, an organic etiology is found in less than 10% of school-aged children with RAP. The alarming symptoms and signs of organic diseases are persistent right upper and right lower quadrant pain; pain that wakes the child from sleep; dysphagia; persistent vomiting; arthritis; perirectal disease; GI blood loss; nocturnal diarrhea; involuntary weight loss; deceleration of linear growth; delayed puberty; unexplained fever; and family history of inflammatory bowel disease, celiac disease, or peptic ulcer disease.

Peptic ulcers may develop in children in 3 situations. Acute infantile ulcers may occur in newborns secondary to stress and hypoxia. Stress ulcers may occur in children who are the victims of trauma, including burns and hypoxia (eg, after submersion). The routine use of histamine H₂ receptor antagonists or proton pump inhibitors has reduced the incidence of ulcers in hospitalized critically ill children.

The most common type of ulcers in children is acute, drug-induced ulcerations of the stomach and the duodenum due to non-steroidal anti-inflammatory drugs or corticosteroids. Chronic or peptic ulcers may develop in prepubertal children and teenagers with no apparent precipitating factors. A positive family history of peptic ulcer disease is reported in 25% to 50% of affected children. Unlike the classic ulcer symptoms of adults, in which pain occurs on an empty stomach and is relieved by eating, children may find that ulcer-related pain is without a specific clinical pattern. Positive family history, microcytic anemia, and hemoccult-positive stools should raise a clinical suspicion and prompt referral of the child to the pediatric gastroenterologist. There is clear evidence linking ulcer disease and infection with *Helicobacter pylori* in adults. The relationship between *H pylori* and peptic ulcer disease in children is not so strong, though two-thirds of pediatric patients with endoscopic evidence of peptic ulcer disease have infection with *H pylori*.

Mesenteric adenitis may produce symptoms indistinguishable from appendicitis, although affected children may not be so ill-appearing. Nausea and vomiting and a history of an antecedent upper respiratory infection are often present.

Parenteral infections such as tonsillitis or pneumonia may present with fever and abdominal pain. In addition, hepatitis may result

in pain and tenderness localized to the right upper quadrant in association with anorexia. Hepatitis in children is usually due to hepatitis A, and many infected young children are anicteric (see Chapter 114).

Pancreatitis produces abdominal pain that is often referred to the back. In the past, mumps was the most common cause of pancreatitis. Other infections such as hepatitis B, Epstein-Barr virus and coxsackievirus B, and *Mycoplasma pneumoniae* are the common infectious etiologies of acute pancreatitis.

Acute pancreatitis can be induced by some medications (eg, steroids, chemotherapeutic agents). Familial and recurrent forms of pancreatitis are also reported. Trauma, particularly from injuries sustained as a result of an impact against handlebars of bicycles, is a common cause. In children with pancreatitis and no apparent etiology, trauma related to child abuse should be considered.

Parasitic infestations, particularly with *Giardia lamblia*, may produce abdominal pain, often with bloating and diarrhea.

Genitourinary problems may result in abdominal pain. An abnormal urinalysis provides clues to the etiology. Renal stones occur infrequently in children, and boys are more often affected than girls. In two-thirds of affected children, stones are detected incidentally or in association with a urinary tract infection (UTI). Stones may be composed of calcium phosphate or oxalate, magnesium, uric acid, cystine, or xanthine. In addition to flank or abdominal pain, patients may also experience hematuria, fever, recurrent UTI, and persistent pyuria.

Hematologic and vascular disorders such as sickle cell disease, rheumatic fever, and Henoch-Schönlein purpura may also present with abdominal pain. Sickle cell anemia should be considered in African American children with abdominal pain. Pain may be related to vaso-occlusive events including bowel ischemia and splenic infarction or cholecystitis. Henoch-Schönlein purpura, which is also referred to as anaphylactoid purpura, is characterized by a hemorrhagic skin rash, joint pain, and renal abnormalities in addition to abdominal pain. This pain may result from a number of processes, including vasculitis and ischemia of the bowel wall, edema of the bowel wall, and intussusception of the small intestine.

Diabetes mellitus may lead to abdominal pain secondary to cramping of accessory muscles of respiration during a bout of ketoacidosis.

Acute intermittent porphyria is an uncommon cause of abdominal pain in children. The pain is often colicky and may be associated with constipation, nausea, and vomiting. Neurologic symptoms such as pain or paresthesia in the extremities may be present. Often symptoms are precipitated by the ingestion of medications (eg, barbiturates, sulfa drugs). Some antispasmodic medications, such as Donnatal elixir, contain phenobarbital and can precipitate an attack. The diagnosis is made by evaluating the urine for the presence of protoporphyrins.

Primary peritonitis is secondary to infection with *Streptococcus pneumoniae* and is seen in children with nephrotic syndrome, cirrhosis, and sickle cell disease, and in young girls with fever, abdominal pain, and vaginal discharge.

School-Aged Children: Surgical Conditions

Appendicitis is the most common surgical condition that produces abdominal pain in school-aged children. Appendicitis may even occur in newborns, where it is seen in association with conditions such as cystic fibrosis and Hirschsprung disease that lead to diminished passage of stool. The condition is frequently difficult to diagnose in children younger than 3 or 4 years for 2 reasons: (1) examination of such young children for pain is difficult and (2) symptoms are similar to those of acute gastroenteritis (ie, fever, abdominal pain, anorexia). Classically, patients complain of periumbilical pain that localizes to the right lower quadrant in 1 to 5 hours. They often have a low-grade fever, with a temperature of 100.4°F (38°C). Vomiting and increased urinary frequency may occur. Stooling is variable.

The physical examination may reveal guarding and localized pain as well as rebound tenderness. A positive psoas or obturator sign may be present, indicating inflammation of these muscles. Tenderness may also be noted on rectal examination. Leukocytosis over 10,000/mL is also usually present. A radiograph of the abdomen may reveal 1 of 4 signs: a fecalith in the appendix (appendicolith), air in the cecum (sentinel loop), blurring of the shadow of the psoas muscle, or edema of the abdominal wall on the right side. A chest radiograph is also useful to rule out the presence of pneumonia, which may produce symptoms that mimic appendicitis.

Meckel diverticulum may be responsible for abdominal pain in a number of ways. It may serve as the lead point for an intussusception, cause symptoms of ulcer disease (pain or hemorrhage) secondary to the presence of ectopic gastric mucosa, or become acutely inflamed as in appendicitis. Meckel diverticulum follows the rule of 2s: it affects 2% of the population, is 2 feet from the ileocecal valve, is 2 inches in length, and is 2 times more common in males than in females.

Adolescents

In female adolescents, **gynecologic problems** such as torsion of the ovary, mittelschmerz, dysmenorrhea, and pelvic inflammatory disease must be considered as causes of abdominal pain (see Chapter 98). In addition, pain may result from gall bladder disease secondary to cholelithiasis or cholecystitis. Cholelithiasis is also a consideration in previously pregnant adolescent patients with abdominal pain and fatty food intolerance.

Evaluation

History

A thorough history should be obtained (Questions Box). A detailed description of pain may suggest a specific etiology. For example, pain worsened by eating can occur in children with gastroesophageal reflux disease, gastritis, cholecystitis, or pancreatitis. Nocturnal pain or pain relieved by a meal is more common in children with peptic ulcer disease. Pain relieved by defecation is suggestive of IBS. Pain aggravated by defecation raises suspicion of chronic inflammatory

Abdominal Pain

Questions

- What is the nature of the pain? Is it sharp or dull, well or poorly localized, intermittent or relentless, worsened or unaffected by movement?
- How often does the pain occur?
- How long has the pain been present?
- Do any maneuvers, such as eating or lying down, reduce the symptomatology?
- Is the pain related to meals in any way? Is it worse after eating?
- Are any symptoms such as fever, weight loss, anorexia, vomiting, diarrhea, constipation, dysuria, or headache associated with the pain?
- Does anyone else in the family have similar symptoms?
- Does the pain occur at night and on weekends?
- Is there a history of travel?

bowel disease. Localization of abdominal pain is an important additional diagnostic clue; functional abdominal pain is usually localized along the midline or periumbilical area. Associated symptoms such as fever, weight loss, anorexia, vomiting, diarrhea, leukocytosis, and an elevated sedimentation rate also suggest an organic etiology.

Physical Examination

The physical examination should include an assessment of the severity of the pain. Children should be observed when they do not suspect that they are being watched. For example, a child who stands up and hops around when the physician leaves the room may have pain with a psychosomatic basis. Detection of abdominal tenderness may be ascertained during auscultation of the abdomen by pressing down with the stethoscope.

A rectal examination is also an integral part of the evaluation. In prepubescent girls with genitourinary symptoms or adolescent females, a genital assessment should be included.

Growth parameters should be evaluated for evidence of impairments, especially in children with RAP. Abnormal findings such as abdominal masses or perianal skin tags are clues to an organic etiology. Children who appear vigilant and keep their eyes open during the examination often have organic problems.

Laboratory Tests

The laboratory assessment is determined by the differential diagnosis. In general, laboratory tests include a complete blood cell count, a urinalysis, and an erythrocyte sedimentation rate (in recurrent cases). In children with suspected lactose intolerance, a hydrogen breath test is recommended by some physicians, although a trial of dietary manipulation or use of exogenous lactase (eg, Lactaid) may be more cost-effective. Other laboratory tests, such as serum amylase or liver function studies, are appropriate if pancreatitis or hepatitis is suspected. Detection of *H pylori* antigen in the stool supports the diagnosis of *H pylori*. Stool evaluation for occult blood and parasites is also helpful. Consultation with a gastroenterologist should be considered in patients suspected of having ulcer disease or inflammatory

bowel disease. Specialists may order diagnostic procedures such as endoscopy to arrive at the diagnosis.

Imaging Studies

In general, a flat plate of the abdomen should be obtained, especially if an acute surgical condition is suspected. Abdominal computed tomography can be useful in some children with right low quadrant pain to confirm the diagnosis of acute appendicitis. Abdominal ultrasound and a barium enema are indicated to diagnose intussusception. Technetium scans help detect Meckel diverticulum if ectopic gastric mucosa is present. Ultrasonography is useful in suspected cases of cholelithiasis and cholecystitis. It may also detect pancreatic edema or pseudocyst, hydronephrosis, or abdominal masses.

Management

Management depends on the suspected cause of the abdominal pain. Medical conditions warrant treatment with **pharmacologic agents**. Peptic ulcer disease requires H₂ blockers such as cimetidine, proton pump inhibitors such as omeprazole, or cytoprotective agents like sucralfate. Infection with *H pylori* is managed with a combination of different antibiotics with proton pump inhibitors and bismuth preparations. Urinary tract infections should be treated with antibiotics. Conditions such as appendicitis mandate **surgical intervention**.

The management of children with RAP is challenging. A 3-tiered empiric trial has been suggested for children in whom no distinct cause is identified. First, a high-fiber diet should be implemented. This helps alleviate the abdominal pain symptoms of children with IBS. Second, antacids, H₂ blockers, or proton pump inhibitors are used empirically to see if symptoms respond to decreased acid levels. Third, a trial of Lactaid or a lactose-free period may also be implemented. A low dose of tricyclic antidepressant (eg, amitriptyline 0.1 mg/kg–0.2 mg/kg) has been used successfully in children with functional abdominal pain.

Prognosis

In general, the prognosis for children with acute abdominal pain is good, although it varies depending on the condition. In 30% to 50% of children with RAP, the symptoms resolve within 2 to 6 weeks of diagnosis. Thirty percent to 50% of affected children experience abdominal pain as adults, although the pain does not limit their activities. As adults, these individuals may experience IBS or other chronic nonspecific complaints, such as headache, backache, and chronic pelvic pain.

CASE RESOLUTION

In the case history, the boy has the classic symptoms of peptic ulcer disease. His symptoms are alleviated by eating and exacerbated at night. In addition, the family history is positive for peptic ulcer. Further evaluation may include a stool test for *H pylori* antigen, and referral to pediatric gastroenterologists for further workup, including upper GI endoscopy.

Jaundice

Melissa K. Egge, MD

CASE STUDY

A 2-month-old male infant is brought to the office for a routine well-child checkup. He was the product of a full-term, normal, spontaneous vaginal delivery, with a birth weight of 3,600 g. He has been feeding well, exclusively at the breast. Loose stools follow each feeding. On physical examination, the infant weighs 4,900 g. The examination is normal except that the boy appears jaundiced. On further questioning, the mother states that her son has been jaundiced since shortly after birth, and she feels that his appearance has not changed. The color of the stool is yellow.

Questions

1. What are the common causes of unconjugated hyperbilirubinemia in young infants?
2. What are the common causes of conjugated hyperbilirubinemia in young infants?
3. What are the usual causes of jaundice in older children and adolescents?
4. What is the appropriate management of hyperbilirubinemia in breastfed infants?

Jaundice is a condition that occurs when bilirubin reaches a level in the blood that makes it visibly apparent. In newborn infants, this level is 5 mg/dL. In older children and adolescents, jaundice becomes apparent at serum bilirubin levels of 2 mg/dL. The term **physiological jaundice** is used to denote the jaundice that normally occurs following birth. In full-term infants, bilirubin reaches its peak of about 6 mg/dL between the second and fourth days of life. Levels above 10 mg/dL are probably not physiological. Bilirubin generally returns to a normal level (<1 mg/dL) by 12 days of age. Premature infants experience their peak level of bilirubin, which may be up to 10 to 12 mg/dL, between the fifth and seventh days of life. Levels over 14 mg/dL are probably not physiological. Levels may be elevated in premature infants for up to 2 months.

Although physiological jaundice, a benign finding, affects all infants, other more serious disorders may present with similar symptomatology. The physician must be able to differentiate between these conditions to ensure appropriate intervention and management. New-onset jaundice in older children and adolescents is caused by other disorders.

Epidemiology

Jaundice is nearly universal in neonates because of the rapid turnover of red blood cells and the relative immaturity of the liver. Breast milk jaundice affects about 1% of breastfed infants. Various illnesses, particularly bacterial infections, also may precipitate jaundice in newborns. Neonatal cholestasis (conjugated hyperbilirubinemia), which is seen in a small number of cases of neonatal jaundice, is due to neonatal hepatitis or extrahepatic biliary atresia 45% of the time. Genetic and metabolic diseases now comprise approximately 45% of the cases of neonatal cholestasis that were previously known as idiopathic.

Jaundice occurs much less frequently in the post-neonatal period and is most often secondary to viral hepatitis (see Chapter 114).

Clinical Presentation

Children with jaundice have yellow skin, conjunctiva, and mucous membranes. In newborns, the coloration may not be appreciated by parents because of its gradual onset and the parents' inexperience. The finding may be apparent in otherwise asymptomatic infants during routine health maintenance visits. In addition to the yellow color, children with jaundice may also present with symptoms related to the cause of the jaundice, including vomiting, anorexia, failure to thrive, acholic (white) stools, dark urine, fatigue, and abdominal pain or fullness (Dx Box).

Dx Jaundice

- Yellow skin, mucous membranes, and conjunctiva
- Tenderness in the right upper quadrant of the abdomen
- Hepatomegaly
- Anorexia
- Acholic stools
- Vomiting
- Pruritus

Pathophysiology

Bilirubin, a red pigment found primarily in bile, forms from the breakdown of heme-containing compounds, mainly hemoglobin, but also muscle myoglobin, cytochromes, catalases, and tryptophan pyrrolase. Blockage along any point in the physiological or

anatomical pathway may result in increased levels of bilirubin and the appearance of jaundice (Figure 113-1). After the breakdown of hemoglobin, unconjugated bilirubin is taken up by the hepatocyte plasma membrane carrier, bilitranslocase. Once within the hepatocyte, bilirubin is bound to intracellular proteins (Y proteins or ligandin). Uptake depends on hepatic blood flow and the presence of the necessary binding proteins. Once in the liver, unconjugated bilirubin is conjugated by the enzyme glucuronyl transferase. Conjugated bilirubin, which is water-soluble, can be eliminated through the kidneys. Following conjugation, bilirubin passes into the bile through the bile canaliculi. It then moves to the gastrointestinal (GI) tract, where some of it may be reabsorbed (enterohepatic circulation), or be acted on by bacteria to form urobilinogen and stercobilinogen, which may appear in the urine or stool, respectively.

In neonates, a number of factors contribute to physiological jaundice. Increased destruction of red blood cells occurs because the red blood cell survival in infants is only 70 to 90 days, as opposed to 120 days in older children. Hepatic uptake is lower, perhaps as a result of decreased levels of hepatic proteins as well as decreased hepatic blood flow. Levels of glucuronyl transferase do not reach adult values until the second week of life. These decreased levels of glucuronyl transferase mean that conjugation of bilirubin occurs at a slower rate.

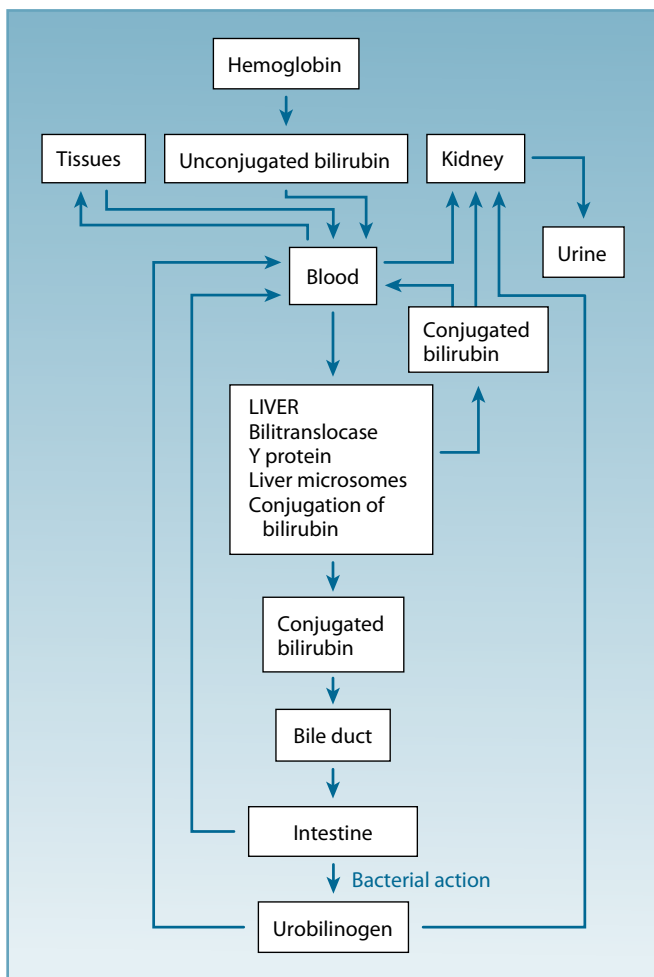

Figure 113-1. The bilirubin pathway.

In some infants, glucuronyl transferase levels remain low; these individuals remain prone to jaundice at times of illness, stress, and starvation (Gilbert syndrome). Some breastfed infants also experience prolonged jaundice. Jaundice in breastfed infants may be related to poor caloric or fluid intake, weight loss, slow passage of meconium, or the type or number of bacteria in the intestine. It is believed that some unknown substance in the mother's milk, perhaps pregnane-triol, blocks glucuronyl transferase. (See Chapter 24 for more information about breastfeeding.) Reabsorption of bilirubin is increased through the enterohepatic circulation because of the diminished number of bacteria in the GI tract in young infants.

In older children, similar mechanisms may act to cause an increase in the bilirubin level. Hemolytic anemias (eg, glucose-6-phosphate dehydrogenase [G6PD] deficiency or pyruvate kinase deficiency [PKD]) may lead to increased red blood cell destruction. Inflammatory or infectious processes involving the liver, such as hepatitis, may impair the ability of the liver to excrete bilirubin. Pharmaceutical and toxicological agents may also interfere with the ability of the liver to metabolize bilirubin.

Differential Diagnosis

The differential diagnosis of jaundice in children involves 3 criteria: (1) age; (2) the type of hyperbilirubinemia (conjugated or unconjugated); and (3) if the hyperbilirubinemia is conjugated, the nature of the obstruction (intrahepatic or extrahepatic). The latter 2 factors are particularly important in determining the etiology of jaundice in young infants. A diagrammatic representation of the differential diagnosis of jaundice in children is shown in Figures 113-2, 113-3, and 113-4.

Infants Younger Than 8 Weeks of Age

Unconjugated Hyperbilirubinemia

Jaundice occurs universally in all newborns, but marked elevation of bilirubin levels or presence of jaundice in the first 24 hours of life or beyond 2 weeks of age warrants assessment. When less than 15% of the total bilirubin is direct, unconjugated hyperbilirubinemia is present. This is best determined by measuring the levels of total and direct bilirubin in the blood. **Physiological jaundice** is associated with unconjugated hyperbilirubinemia. The hematologic workup of affected infants is normal. Jaundice related to inadequate breast milk intake is called *breastfeeding jaundice*, which may resemble physiological jaundice and occurs during the first week of life, whereas with *breast milk jaundice*, bilirubin levels rise during the second week of life when physiological jaundice is improving. In breastfed infants, levels may reach as high as 25 to 30 mg/dL. Breast milk jaundice usually peaks by the age of 4 weeks and can last up to 12 weeks.

Conditions associated with slow intestinal transit time and increased enterohepatic circulation, such as hypothyroidism, also may result in jaundice. As with physiological and breast milk jaundice, the hematologic workup is normal. High intestinal obstructions, such as pyloric stenosis, duodenal atresia, annular pancreas,

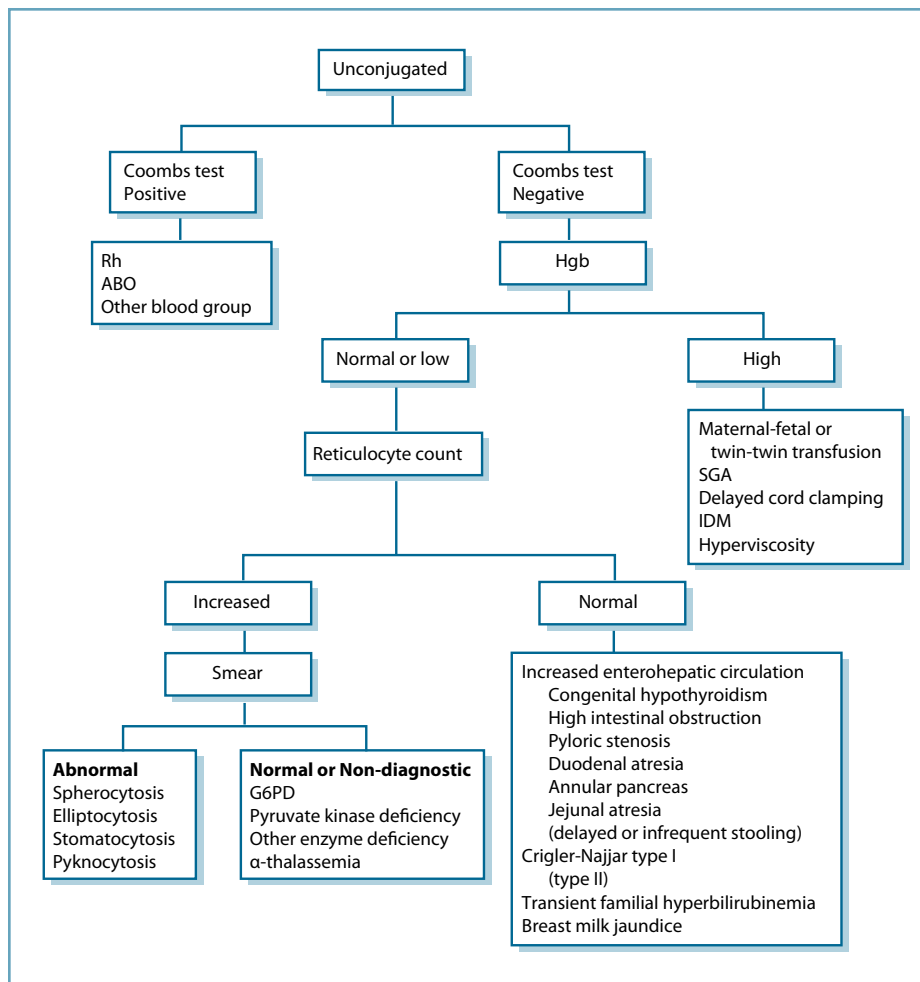

Figure 113-2. Differential diagnosis of jaundice in neonates (during the first 8 weeks of life). Unconjugated hyperbilirubinemia. G6PD, glucose-6-phosphate dehydrogenase; Hgb, hemoglobin; IDM, infant of diabetic mother; SGA, small for gestational age.

and jejunal atresia, may lead to jaundice, perhaps because of starvation and decreased levels of glucuronyl transferase.

Crigler-Najjar syndrome type I involves an absence of glucuronyl transferase in which bilirubin levels can approach 50 mg/dL at birth. An indirect hyperbilirubinemia on the order of 20 mg/dL that persists beyond 2 weeks in the absence of hemolysis is indicative of the type II version of this syndrome. Because of very high bilirubin levels, type I disease may lead to kernicterus unless managed with exchange transfusion. Phototherapy, cholestyramine, and eventual liver transplantation are additional therapies. The disorder is inherited in an autosomal-recessive manner and is extremely rare.

Hematologic problems may also produce jaundice in the neonatal period. Such problems are most often associated with blood group (usually Rh or ABO) incompatibility between mothers and infants, but some minor blood group determinants can precipitate similar problems. Jaundice occurs in affected infants because of the rapid destruction of red blood cells. Other infants may have a hemolytic anemia such as spherocytosis. Jaundice may also occur if excess blood is present in the infant's system. Situations in which

elevated hemoglobin is associated with jaundice include maternal-infant or twin-twin transfusions, infants who are small for gestational age, delayed clamping of the umbilical cord, infants of diabetic mothers, and infants with hyperviscosity syndrome.

Conjugated Hyperbilirubinemia

When more than 15% of the total bilirubin is direct, the jaundice is categorized as conjugated hyperbilirubinemia. Conjugated hyperbilirubinemia is always pathologic. Total parenteral nutrition is the most common cause of conjugated hyperbilirubinemia in the neonatal intensive care unit but does not usually present a diagnostic dilemma. The institution of oral feedings helps reverse the process. In other cases, determination of whether the problem is intrahepatic or extrahepatic is the major consideration. Some conditions of intrahepatic involvement represent a spectrum involving progression from inflammation of bile canaliculi (hepatitis) to their destruction (biliary atresia).

Inflammation of the hepatocytes is hepatitis. This disease may be caused by an infection in the liver or elsewhere in the body (eg, sepsis and urinary tract infections [UTIs] in young infants). Urinary tract infections are usually caused by *Escherichia coli*. The hepatic involvement resolves with appropriate antibiotic therapy of the primary infection.

Primary liver infection may be due to **TORCHS** (toxoplasmosis, other agents, rubella, cytomegalovirus [CMV], herpes simplex virus [HSV], HIV, syphilis) agents, the most common culprits being CMV and HSV. Infants infected prenatally often have low birth weights, hepatosplenomegaly, petechial rashes, and ocular findings such as cataracts and chorioretinitis. Hepatitis A may cause an acute infection, but rarely manifests as jaundice in neonates. Hepatitis B is a possible etiology of neonatal cholestasis, and hepatitis C is usually an asymptomatic infection. **Other infectious causes** include enteroviruses, reovirus 3, parvovirus B19, human herpesvirus 6, adenovirus 2, *Listeria monocytogenes*, and tuberculosis. Differentiating among these conditions is usually done on the basis of culture, polymerase chain reaction, or serology. Certain physical and epidemiological findings may help to distinguish these entities, however. Syphilis is more common in the developing nations of the world. Jaundice may appear within the first 24 hours of life or be of later onset. Infection with *L monocytogenes* infection may be associated with the presence

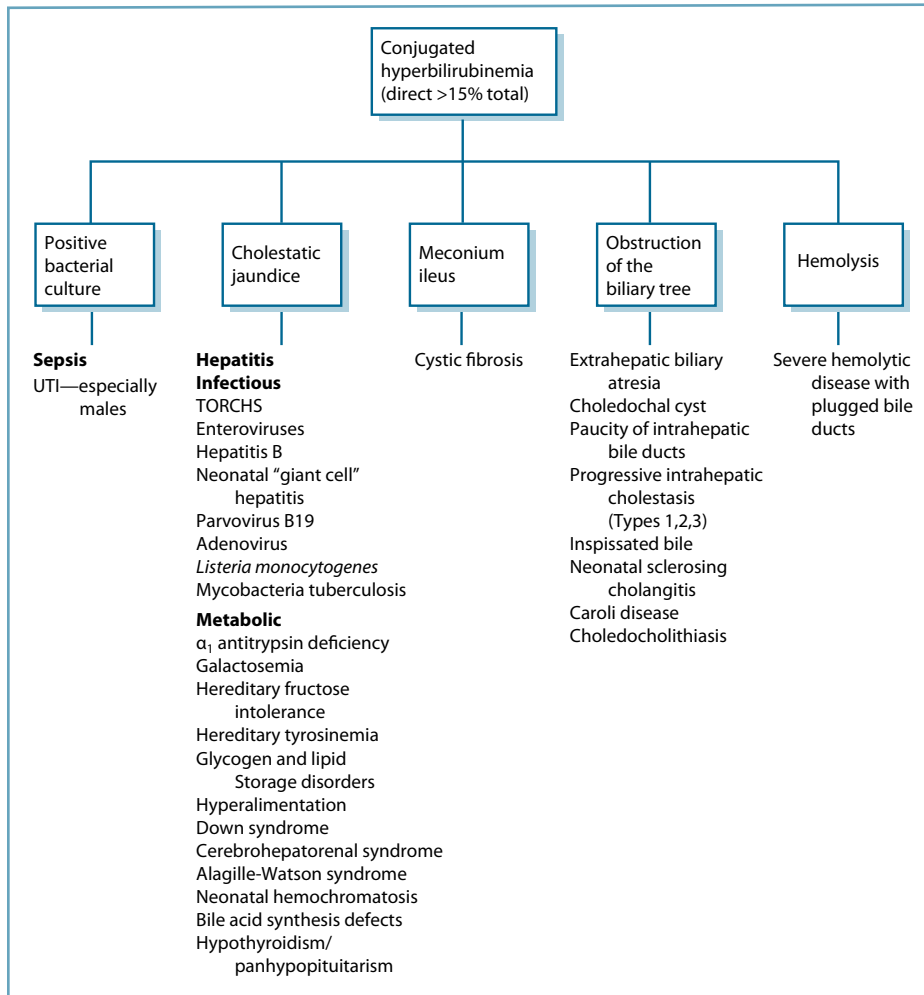

Figure 113-3. Differential diagnosis of jaundice in neonates (during the first 8 weeks of life). Conjugated hyperbilirubinemia. UTI, urinary tract infection.

of focal granulomas on the posterior pharynx. Similar granulomas in the liver are evident.

Metabolic diseases and **inborn errors of metabolism** may also lead to hepatitis. Most of these conditions are inherited in an autosomal-recessive manner. In addition to jaundice, infants may present with vomiting, irritability, lethargy, anorexia, hepatomegaly, hypoglycemia, failure to thrive, bleeding, or cataracts. Galactosemia may be detected through neonatal screening or may present earlier as *E coli* sepsis. Infants with hereditary fructose intolerance present after exposure to fructose, sucrose, or sorbitol. α_1 -antitrypsin deficiency may account for 20% to 30% of cases of idiopathic neonatal liver disease and for 10% of neonatal cholestatic disease. Inborn errors of metabolism generally present with a direct hyperbilirubinemia, while inborn errors of erythrocyte metabolism (PKD or G6PD) present with an indirect hyperbilirubinemia.

Genetic conditions that lead to jaundice in newborns include hereditary tyrosinemia, infantile Gaucher disease, Niemann-Pick disease, and Wolman disease. Cystic fibrosis may also cause cholestatic jaundice because of the presence of inspissated bile in the bile canaliculi. Fifty percent of these infants have meconium ileus,

meconium peritonitis, or intestinal atresia. “Plugged” bile ducts may be seen with severe hemolytic anemia where bilirubin production is markedly elevated. Drugs may also induce intrahepatic cholestasis. A number of syndromes are associated with persistent intrahepatic cholestasis. Alagille syndrome (arteriohepatic dysplasia) is characterized by unusual facies, skeletal and cardiovascular anomalies, and a paucity of intralobular bile ducts. The incidence is 1 in 100,000 live births. Progressive familial intrahepatic cholestasis and bile acid synthetic defect, together with Alagille syndrome, account for cholestasis in 10% of affected neonates. Not surprisingly, as the etiologies for more of these cases are identified through genetic and pathologic testing, fewer cases are labeled *idiopathic neonatal hepatitis*.

Extrahepatic biliary atresia accounts for about 25% of cases of cholestasis in newborns. Obliteration of the biliary tree is apparent. Infants are often well until 3 to 6 weeks of age, when they develop conjugated hyperbilirubinemia. The incidence is 1 in 14,000 live births. It has been postulated that some primary insults such as α_1 -antitrypsin, metabolic disorders, or viral infections such as CMV and HSV may incite biliary atresia. Choledochal cysts appear as dilatations of the biliary tree and obstruct the passage of bile.

Older Infants, Children, and Adolescents

The approach to the differential diagnosis of jaundice in older infants and children is similar to the process in young infants. Unconjugated hyperbilirubinemia is usually due to hemolysis, and the level of indirect bilirubin helps clarify the differential diagnosis. Patients whose indirect bilirubin is greater than 6 mg/dL may have **Crigler-Najjar syndrome type II** and respond favorably to phenobarbital. Patients with levels under 6 mg/dL may have hemolytic anemia. **Congestive heart failure (CHF)** and **hypothyroidism** may also produce unconjugated hyperbilirubinemia. **Gilbert disease**, a benign condition in which the bilirubin rises to about 5 mg/dL in response to stress and starvation, may result in jaundice. The prevalence of Gilbert syndrome, an autosomal-recessive disease, is 5%. **Drugs**, including rifampin and birth control pills, may also be associated with unconjugated hyperbilirubinemia.

Conjugated hyperbilirubinemia may result from 2 different processes: (1) cholestasis and (2) hepatocellular inflammation or injury. Signs of cholestasis are high levels of alkaline phosphatase (3 times

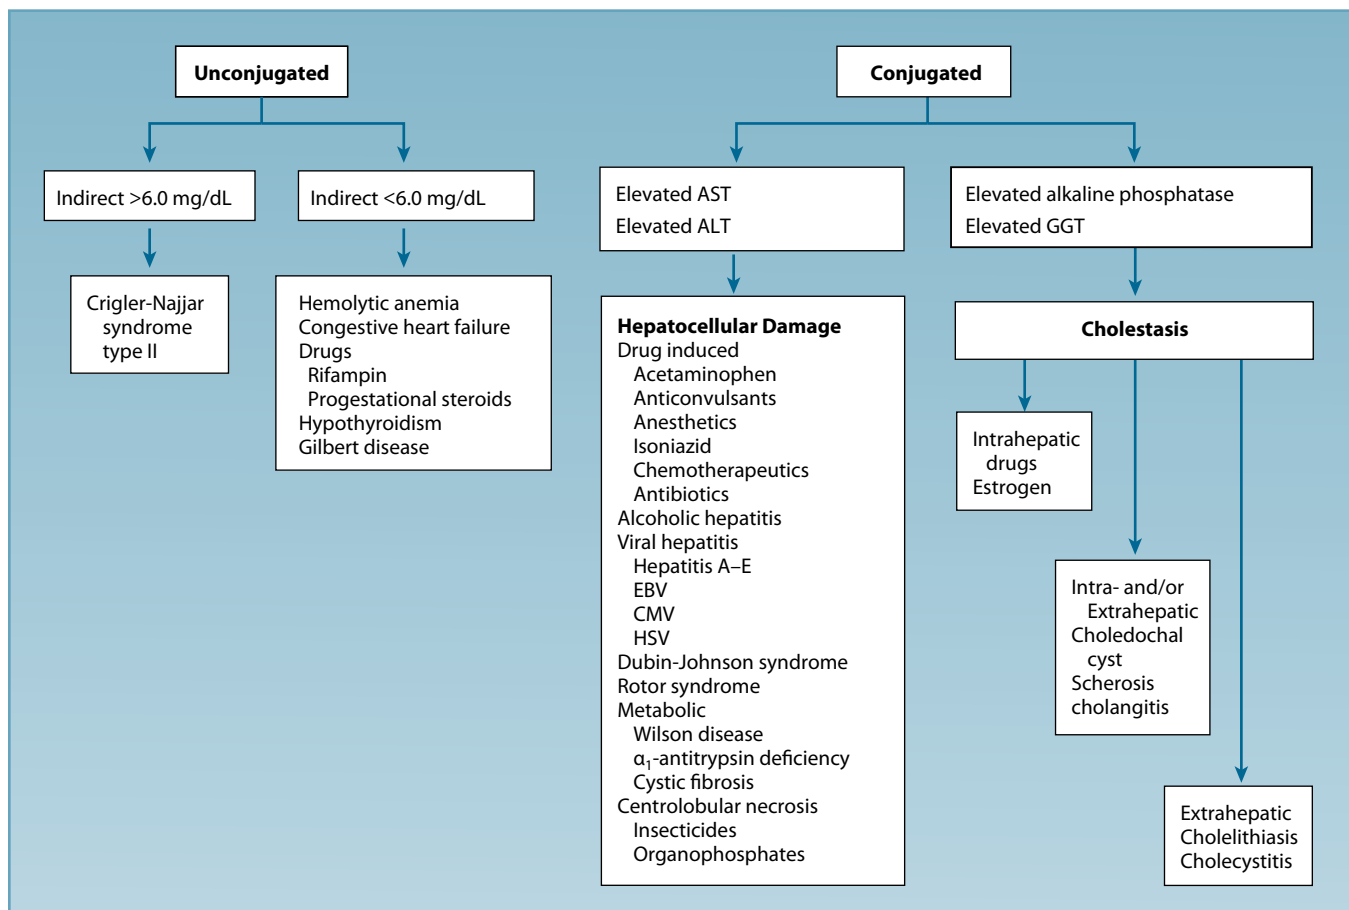

Figure 113-4. Differential diagnosis of jaundice in older infants, children, and adolescents. ALT, alanine aminotransferase; AST, aspartate aminotransferase; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GGT, gamma-glutamyl transferase; HSV, herpes simplex virus.

normal), mildly to moderately elevated transaminases, and increased γ -glutamyl transpeptidase. Cholestatic jaundice, related to drugs (estrogens) and alcohol, may occur on an intrahepatic basis. **Byler syndrome** is a familial disorder characterized by intrahepatic cholestasis. Extrahepatic cholestasis is seen with cholelithiasis or other obstructions of the biliary tree. Cholelithiasis may occur in individuals with hemolytic anemia and in adolescents who are overweight or postpartum. Hepatocellular injury most often results from hepatitis (see Chapter 114), including infectious, alcoholic, and drug-induced hepatitis. Rarer disorders include Dubin-Johnson syndrome and Rotor syndrome. Metabolic diseases such as Wilson disease, α_1 -antitrypsin deficiency, and cystic fibrosis should be considered in the differential diagnosis of every older child presenting with conjugated hyperbilirubinemia.

Evaluation

History

A careful history must be obtained (Questions Box).

Physical Examination

Patients should be evaluated for evidence of organomegaly, ocular anomalies, rashes, hearing deficits, and unusual facial features. The

Questions

Jaundice

- What associated symptoms are present?
- How long have the symptoms been present?
- Does the child have a fever, which may suggest the presence of an infection?
- What is the color of the stools (acholic stools suggest obstruction)?
- Does the child have a family history of jaundice or consanguinity?
- What makes up the child's diet? If the child is an infant, is he or she breastfed or bottle-fed?
- When did the parents first notice the jaundice?
- Has the child been jaundiced previously?
- Has the child been vaccinated against hepatitis A and B?
- Is there a history of foreign travel or shellfish ingestion?

unique facial features are pathognomonic for certain genetic disorders such as Byler or Alagille syndromes. Rashes and lymphadenopathy are associated with certain infectious conditions, including congenital infections (TORCHS) in newborns and infectious mononucleosis in adolescents. Patients should also be checked for the presence of any cardiac anomaly, which may suggest a genetic syndrome or CHF.

Laboratory Tests

In the newborn nursery, noninvasive methods are used to measure the level of jaundice. The “jaundice meter” uses reflectance spectrophotometry to determine the skin color and correlates highly with serum bilirubin levels. An icterometer is another noninvasive method, which uses an acrylic plastic color chart that is placed against an infant’s nose.

The aim of the laboratory assessment is to discover where the bilirubin metabolism is abnormal. The total bilirubin as well as the fractionated bilirubin levels should be determined. The presence of elevated levels of direct-reacting bilirubin represents conjugated hyperbilirubinemia. The demonstration of a yellow color to the foam of a shaken specimen of urine is a rapid test for conjugated hyperbilirubinemia. Urine test strips also readily detect conjugated bilirubin in the urine.

In children with unconjugated hyperbilirubinemia, a complete blood cell count with reticulocyte count and evaluation of the peripheral smear confirm hemolytic anemia. Serum haptoglobin levels are diminished in hemolytic disorders. In neonates, the Coombs test should be performed, and infant and maternal blood types should be determined. The hemoglobin should also be determined. A normal or low hemoglobin may be seen in the face of hemolytic anemia. An elevated reticulocyte count or an abnormal peripheral blood smear indicates hemolysis. Hemolytic anemias with abnormal peripheral smears include spherocytosis, elliptocytosis, stomatocytosis, and pyknotocytosis (see Chapter 83).

In children with conjugated hyperbilirubinemia, tests should be performed to determine if infections such as bacteremia, UTI, congenital infection, or hepatitis are present. Evaluation for metabolic diseases should also be obtained by assessing the urine for the presence of reducing substances, organic acids, and bile acid metabolites. A sweat chloride test and α_1 -antitrypsin level should be considered. The status of liver function can be determined by evaluating aspartate aminotransferase, alanine aminotransferase, γ -glutamyl transpeptidase, and alkaline phosphatase. To assess synthetic liver function, one should test prothrombin time, total protein, albumin, glucose, cholesterol, and ammonia.

Imaging Studies

The anatomy of the biliary tree can be evaluated using ultrasound. Choledochal cysts may be visualized using this modality. When a “triangular cord sign” is seen on ultrasound, the diagnosis of biliary atresia is almost certain. A triangular-shaped echogenicity demonstrates the atretic ductal remnant in the area cephalad to the portal vein bifurcation. Other imaging tests, including excretion studies (radioisotope scans) and cholangiogram, can be used to help differentiate hepatitis from biliary atresia. Consultation with a pediatric gastroenterologist may be appropriate.

Liver Biopsy

A histologic evaluation may be necessary if laboratory results have not defined an etiology. Detailed review by an experienced pathologist may be diagnostic and save the infant from an exploratory surgery.

Management

The management of jaundice depends on the cause of the condition. Physiological jaundice and jaundice secondary to breastfeeding frequently require no intervention. Primary prevention is the best strategy to combat breastfeeding jaundice. Educate the mother to initiate breastfeeding within 1 hour of life with continuous rooming-in, breastfeed every 2 to 3 hours, promptly respond to hunger cues, and prohibit supplementation with water or sugar water. However, if bilirubin levels are greater than 20, interrupting breastfeeding for 24 to 48 hours will successfully lower bilirubin levels, but support and counseling are mandatory to ensure that breastfeeding resumes. Studies suggest that the use of a casein hydrolysate formula such as Nutramigen may lead to a greater degree of reduction in the level of bilirubin than the use of a whey-predominant formula such as Enfamil. Some practitioners use **bilirubin-reducing lights**, but other clinicians believe that breastfed infants can tolerate bilirubin levels as high as 25 to 30 mg/dL without danger of kernicterus. Newer phototherapy techniques involve the use of woven fiberoptic pads that can be used in the home. Increasing the exposure of the infant to phototherapy by using standard phototherapy above and a fiberoptic pad below is more effective than either modality alone. Clinical trials are demonstrating the efficacy of a single intramuscular dose of Sn-mesoporphyrin in treating and preventing neonatal hyperbilirubinemia. Sn-mesoporphyrin, a **metalloporphyrin**, blocks heme oxygenase, the first step in the production of bilirubin. Sn-mesoporphyrin may be especially helpful in situations when blood transfusions are prohibited by the parents for religious reasons or when known hemolytic disease will put the infant at risk for kernicterus. Infants who are preterm, ill, or have jaundice as a result of hemolysis may be at a greater risk from elevated bilirubin levels. **Exchange transfusion** may be indicated in addition to placement under bilirubin-reducing lights. A rule of thumb: Preterm infants should receive exchange transfusions when the bilirubin reaches the infant’s weight (eg, 11 mg/dL in a 1,100-g infant). Intravenous immunoglobulin may prevent the need for exchange transfusion in babies with hemolysis due to blood group or Rh incompatibility by reducing hemolysis.

Diet and nutrition can be an integral part to supporting an infant with conjugated hyperbilirubinemia. Medium-chain triglyceride formulas such as Pregestimil or Alimentum allow for absorption independent of bile acids. Supplementation with fat-soluble vitamins A, D, E, and K is also beneficial. If galactosemia is suspected, switch to soy formula pending results of the newborn screen.

Medications play a limited role in the management of jaundice. **Phenobarbital** may speed up the liver’s excretion of bilirubin, even in cases of hemolytic anemia. This drug is also useful in the management of jaundice due to certain genetic conditions such as Crigler-Najjar syndrome type II. The appropriate **antibiotics** should be used to combat infections associated with jaundice. For relief of pruritus, ursodeoxycholic acid (15–30 mg/kg/day), or rifampicin may be offered.

Infants with biliary atresia may require **surgery**. Surgery links the surface of the liver to the intestinal tract, allowing for passage of

bilirubin directly into the lumen of the small intestine. Adolescents with gallbladder disease may also require surgical intervention (ie, a cholecystectomy).

Prognosis

Most infants with elevated bilirubin levels have physiological jaundice or breast milk jaundice. The prognosis is excellent in these children. In recent years, concern has arisen about a recrudescence of kernicterus, including cases in breastfed, healthy term infants. Early discharge from the nursery and late follow-up may have contributed to this debilitating complication. Physicians should pursue an appropriate assessment of hyperbilirubinemia in jaundiced infants and not ascribe the symptoms to breastfeeding. Conditions other than physiological jaundice or breast milk jaundice may be less amenable to therapy and may require ongoing medical or surgical intervention. Children with metabolic abnormalities usually require lifelong nutritional intervention, those with hepatic disease may succumb to their hepatic dysfunction, and those treated with surgical correction of biliary atresia may have recurrent episodes of cholangitis leading to cirrhosis and the eventual need for liver transplantation.

In contrast, older infants, children, and adolescents with jaundice often have self-limited conditions that spontaneously resolve.

CASE RESOLUTION

In the case history, the infant is breastfed, which raises the possibility of breast milk jaundice. Fractionated bilirubin and hemoglobin determination are appropriate to assess the bilirubin level and confirm the absence of hemolysis. One approach to the diagnosis of breast milk as the etiology of the jaundice is to stop breastfeeding for a day or two to see if the bilirubin level decreases. (Sometimes an infant may not resume breastfeeding.) Biliary atresia or metabolic or infectious hepatitis should also be considered because of the infant's age.

The presence of normal-colored stools is reassuring, however, and makes biliary atresia less likely. The urine should be checked for the presence of reducing substances, which is a noninvasive way of evaluating the infant for galactosemia. The birth record should be obtained. Knowledge of the maternal and infant blood types would allow evaluation for mother–infant blood group incompatibility.

Viral Hepatitis

ChrisAnna M. Mink, MD, and Monica Sifuentes, MD

CASE STUDY

A 15-year-old boy is brought to the office with a 1-week history of intermittent fever, vomiting, diarrhea, and diffuse abdominal pain. His mother reports the appearance of “yellow eyes and skin” on the day before the visit. Her son was previously in good health, and he has not seen a physician in several years. He is taking no medications and has no known ill contacts. He has no history of recent travel outside the United States and denies any unusual food ingestions. Mom reports that he frequently eats at a local fast-food restaurant with his soccer team, but his family does not eat there. He has one ear piercing and denies sexual activity, drug use, or tattoos.

The physical examination is significant for a temperature of 101.4°F (38.6°C), pulse of 100 beats/min, and blood pressure of 110/63 mm Hg. The teen is a well-developed, well-nourished male with yellow skin and sclera.

The abdomen is soft, with mild diffuse tenderness, most notably over the right upper quadrant, and normal bowel sounds. The liver edge is palpated 5 cm below the right costal margin, and no splenomegaly is present. The rectal examination is normal, with guaiac-negative stool.

Questions

1. What are the most common causes of viral hepatitis in children and adolescents?
2. What is the appropriate evaluation for children and adolescents with suspected hepatitis?
3. What complications are associated with viral hepatitis?
4. What treatments are currently available for viral hepatitis, and how does treatment differ depending on the specific etiology?

Hepatitis is an inflammation of the liver that can occur as the result of an exposure to a toxin, such as a chemical or drug, or an infectious agent. Viruses are the most common cause of hepatitis in children and adolescents, and previously, most cases in the United States were the result of hepatitis A virus (HAV), hepatitis B virus (HBV), or hepatitis C virus (HCV). With the advent of routine immunization for pediatric and adolescent age groups for HAV and HBV, the incidence of both infections has dramatically declined. Routine immunizations have reduced the occurrence of infection, as well as complications and long-term consequences, especially for hepatitis B. All 3 of these unrelated viruses can produce an acute illness characterized by nausea, malaise, abdominal pain, and jaundice. Hepatitis B virus and HCV also can produce a chronic infection that is associated with an increased risk for chronic liver disease and hepatocellular carcinoma.

Other common viruses that can cause hepatitis in children are Epstein-Barr virus (EBV), cytomegalovirus (CMV), varicella-zoster virus (VZV), adenovirus, enteroviruses, and herpes simplex virus (HSV); however, their contribution to the overall morbidity and mortality associated with infectious hepatitis is minimal.

Epidemiology

In 2008 nearly 7,500 cases of viral hepatitis were passively reported in the United States to the Centers for Disease Control and Prevention. Most cases were due to HAV or HBV, and fewer than 900 were attributed to HCV. This reflects a more than 80% decline in HAV and HBV from the peak incidence in 1995. The number of cases of HCV is

slightly increased. The total number of hepatitis cases is probably underestimated as a result of under-recognition and underreporting, but likely exceeds 25,000.

Although the incidence of HAV and HBV infections are declining, children younger than 15 years have the highest incidence of infectious hepatitis. Both genders are equally affected. Certain situations are associated with increased risk for infection with HAV. These include crowded living conditions, chronic care facilities, military institutions, prisons, child care centers, travelers to endemic areas, and high-risk sexual practices (eg, commercial sex workers and men who have sex with men). Poor personal hygiene and inadequate sanitation are also risk factors. In approximately 50% of hepatitis A cases, however, the source of infection is unknown. Hepatitis A is found worldwide, but specific locations are associated with an increased incidence of the disease, including Central and South America, Africa, the Mediterranean region, and Asia.

Groups at high risk for HBV infection include illicit parenteral drug users, commercial sex workers, men who have sex with men, heterosexuals with multiple sexual partners, health care workers, recipients of hemodialysis, household contacts of carriers of HBV, and immigrants from HBV-endemic areas. Individuals who live in crowded environments with poor hygienic standards, such as institutions for the developmentally disabled or correctional facilities, are also at risk for HBV infection. No risk factors are identified in 40% of cases. Worldwide, approximately 5% of the population (ie, 350 million people) is chronically infected with HBV. Areas with the highest

incidence of hepatitis B include Southeast Asia, most of Africa, the Pacific Islands, China, and parts of the Middle East.

Approximately 10% to 15% of primary infections with HBV result in a chronic carrier state. The younger children are when they are infected with HBV, the more likely they are to become chronic carriers. Between 70% and 90% of infants born to infected mothers become carriers, and at least 50% of children infected before the age of 5 years become carriers. Boys have a greater risk of becoming carriers than girls, though the reason for this disparity is not known.

Hepatitis C virus accounts for 20% to 40% of all viral hepatitis in all age groups. High-risk individuals are recipients of transfusions of blood or blood products, recipients of organ or tissue transplants, intravenous (IV) drug users, health care workers with blood exposure, hemodialysis patients and, infrequently, sexual or household contacts of infected persons. No identifiable source can be found in at least 35% of cases. In the pediatric population, recipients of blood and blood products before 1992, clotting factor concentrates before 1987 (eg, hemophiliacs), dialysis patients, institutionalized children, and high-risk infants (eg, maternal history of IV drug abuse, sexually transmitted infections [STIs], or HIV coinfection) are most likely to be at risk for HCV infection.

Because hepatitis D only occurs as a coinfection with HBV, high-risk groups are the same, with the exclusion of health care workers and homosexual males. High prevalence rates occur in Eastern Europe, Central Africa, southern Italy, and the Middle East.

Hepatitis E virus (HEV) infection is endemic in developing countries such as Mexico, Central and Southeast Asia, North Africa, China, and India. No cases of HEV infection acquired in the United States have been reported. In endemic regions, HEV is the most common cause of symptomatic hepatitis in children. Young and middle-aged adults are most commonly affected, and HEV infection is especially severe for pregnant women.

Clinical Presentation

Children with acute hepatitis generally present with complaints suggestive of a “flu-like” illness, including fever, malaise, decreased appetite, nausea, and vomiting. They may also report diffuse abdominal pain. Unlike adults in whom jaundice is a common finding, pediatric patients, particularly infants and young children, are frequently anicteric. Hepatomegaly is often found on physical examination though not universally, and there may be varying degrees of right upper quadrant discomfort (Dx Box). A nonspecific macular

Dx Hepatitis

- Diffuse abdominal pain
- Nonspecific symptoms (fever, malaise, anorexia, nausea, and vomiting)
- Jaundice (not necessarily in all cases)
- Dark urine and light-colored stool
- Pain or tenderness over the liver area
- Hepatomegaly

rash, papulovesicular acrodermatitis (Gianotti-Crosti syndrome), and arthralgias can also occur in the course of HBV infection.

Pathophysiology

Hepatitis A

Hepatitis A virus is a picornavirus composed of single-stranded RNA with only one serotype. The most common modes of transmission are through close personal contact and contaminated food and water. This generally occurs by fecal contamination and oral ingestion. Shellfish, such as raw oysters, clams, and mussels, are a frequent source of infection. Infected food handlers may also transmit the disease.

The average incubation period for hepatitis A is 28 to 30 days (range: 15–50 days). Peak viral secretion occurs before the onset of jaundice. The virus is shed in the stool 2 to 3 weeks before the onset of jaundice and up to 1 week after its appearance. However, most young children are anicteric, so infections often go unnoticed during this highly contagious period (Figure 114-1). The duration of illness is usually 2 to 4 weeks. A prolonged course or relapse occurs in 10% to 20% of adult cases. A chronic carrier state for HAV does not exist, though fulminant infections can occur. Lifelong immunity is conferred after a single infection. Mortality is rare, especially in children.

Hepatitis B

Hepatitis B virus is a double-stranded DNA virus in the Hepadnaviridae family. The disease is usually spread by contact with infected blood or blood products, but it can also occur through close interpersonal contact. Although hepatitis B surface antigen (HBsAg) is found in numerous body secretions (blood and blood products, feces, urine, tears, saliva, semen, breast milk, vaginal secretions, cerebrospinal and synovial fluid), only serum, semen, vaginal secretions,

Figure 114-1. Course of acute hepatitis A infection. HAV, hepatitis A virus; Ig, immunoglobulin. (Reproduced with permission from Tabor E. Etiology, diagnosis and treatment of viral hepatitis in children. In: Aronoff SC, Hughes WT, Kohl S, Speck WT, Wald ER, eds. *Advances in Pediatric Infectious Diseases*. Chicago, IL: Year Book Medical Publishers; 1988.)

and saliva have been proven contagious. No fecal-oral transmission occurs. Transmission is facilitated through percutaneous inoculation (eg, tattooing, IV drug use) and exposure of cuts in the skin and mucous membranes to contaminated fluids on objects such as razors and utensils. Sexual transmission occurs via semen, vaginal secretions, and saliva. Perinatal vertical transmission occurs in infants whose mothers are acutely infected or chronic carriers. Although the exact mode of transmission is unclear for household contacts, postnatal infection from household exposure has been reported.

The average incubation period for HBV infection is 3 to 4 months (range: 1–6 months). Figure 114-2 depicts the typical course of acute hepatitis B, along with the course of the chronic carrier state.

Figure 114-2. Course of hepatitis B infection. A. Acute hepatitis B infection. B. Chronic hepatitis B infection. In: Aronoff SC, Hughes WT, Kohl S, Speck WT, Wald ER, eds. *Advances in Pediatric Infectious Diseases*. Chicago, IL: Year Book Medical Publishers; 1988.)

Hepatitis C

Hepatitis C virus is a single-stranded RNA virus in the *Flavivirus* family, and it is able to mutate rapidly, thus escaping detection by the host's immune system. Like HBV, HCV can be spread through contact with contaminated blood and blood products. Conditions associated with HCV infection in children and adolescents include hemophilia and hemoglobinopathies such as thalassemia and sickle cell disease (possibly due to increased exposure to blood products), a history of malignancy, administration of hemodialysis or solid organ transplantation, and IV drug use. Vertical transmission can occur, but seems to be infrequent (1%–5% of infants born to HCV-infected mothers). Contaminated immune globulin (Ig) administered between April 1, 1993, and February 23, 1994, has been implicated as a source of HCV infection. Transmission of infection via household and sexual contact has been demonstrated as well.

The incubation period is variable, ranging from 2 weeks to 6 months, and averages 6 to 7 weeks. Most affected children are anicteric as well as asymptomatic. If symptomatic infection is present, it is usually mild, insidious, and indistinguishable from infections due to HAV or HBV. Jaundice occurs in only 25% of patients. Fulminant hepatitis is extremely uncommon.

Hepatitis D

Acute delta hepatitis, or hepatitis D, is caused by a distinct single-stranded RNA virus that requires HBsAg for replication. Both the virus and a delta antigen are enclosed in an envelope of HBsAg. Transmission is similar to HBV, but vertical transmission is uncommon. Hepatitis D occurs either as a coinfection with HBV or a superinfection in a chronic carrier of HBV. Acute disease is usually more severe and carries a higher risk of fulminant hepatitis than hepatitis B infection alone.

Hepatitis E

Hepatitis E virus is caused by an enterically transmitted RNA virus. Transmission is primarily through contaminated drinking water and fecal-oral spread, especially during rainy or monsoon seasons in endemic areas.

The incubation period ranges from 2 to 9 weeks, with most cases of acute infection being self-limited. Mortality is low in endemic populations, except in pregnant women. Nearly all cases of HEV infection in the United States have been reported in travelers to endemic areas.

Differential Diagnosis

The differential diagnosis of hepatitis depends on the patient's age, possible exposures, and immunization history. Possible infectious causes in neonates include overwhelming bacterial sepsis, VZV, and congenital infections (TORCHES [toxoplasmosis, rubella, CMV, HSV, HIV, enteroviruses, and syphilis]), in addition to HBV infection. Perinatal transmission of HAV is rare. Genetic disorders and anatomical abnormalities causing biliary obstruction (eg, biliary atresia) should also be considered (see Chapter 113).

In older infants and children, in addition to HAV, HBV, and HCV, other viral etiologies include EBV, CMV, enteroviruses (including coxsackieviruses), adenovirus, VZV, HSV and, less commonly, rubella, rubeola, and HIV. Acute or chronic anemias such as sickle cell disease can also cause hepatomegaly and jaundice. Noninfectious conditions to consider include drug-induced hepatitis (eg, treatment with prescribed medications such as isoniazid or phenytoin); toxin ingestion (eg, acetaminophen, herbal remedies); and conditions such as cystic fibrosis, α_1 -antitrypsin deficiency, Wilson disease, and other congenital disorders such as Caroli disease (intrahepatic dilation of the bile ducts).

In adolescents, viral etiologies to consider are similar to those listed for children. Other infectious processes to consider in the adolescent age group include biliary tract infections, bacterial sepsis, Fitz-Hugh–Curtis syndrome (liver inflammation associated with pelvic infections, especially with *Chlamydia trachomatis* and *Neisseria gonorrhoea*, and *Mycoplasma hominis*.) The list of prescribed and illicit drugs that may cause liver toxicity is extensive and includes oral contraceptives, seizure medications, alcohol, inhalants, acetaminophen, and tetracycline.

Evaluation

History

A comprehensive history should be obtained in children of all ages (Questions Box). A dietary and travel history is essential, especially when considering HAV and HEV.

For young infants, a complete maternal and obstetrical history should be obtained and include the following questions: Does the mother have any history of IV drug use? Does the mother come from an area where hepatitis is highly endemic, such as Southeast Asia?

Questions

Hepatitis

- Does the child have any history of fever, malaise, anorexia, or weight loss?
- Has the child experienced any vomiting or diarrhea?
- Is any abdominal pain or discomfort present? If so, in what location?
- Are yellow eyes or any changes in skin color apparent? If so, for how long?
- Is the color of the urine dark and the stool light?
- What is the child's recent travel history?
- Has the child ingested any shellfish in the previous 1 to 2 months?
- Has the child been in contact with any individuals with hepatitis or jaundice (including sexual contacts)?
- Is the child taking any medications (eg, isoniazid)?
- Does the child have a history of transfusion with blood or blood products?
- Is the adolescent sexually active, or has the adolescent had any known exposure to sexually transmitted infections (STIs)?
- Does the adolescent have a history of intravenous (IV) drug use?
- Does the mother have a history of hepatitis, IV drug use, STIs, or multiple sexual partners?

Did the mother receive prenatal care? Was hepatitis B screening performed prenatally or at delivery? Did the mother have any known STIs or sexual contacts with hepatitis B–infected individuals, or did she have multiple sexual partners?

The physician should ask adolescents about sexual activity, STIs, and the number of sexual partners. In addition, it is important to inquire about parenteral drug use and tattoos.

Physical Examination

Most children with viral hepatitis are asymptomatic and generally do not present for medical evaluation. For symptomatic children, there are no clues on examination to aid in differentiating the causes. However, a complete physical examination should be performed to help rule out other etiologies. All vital signs should be recorded. The temperature is important, especially if children have a recent history of fever. In children who are vomiting, signs of dehydration (eg, tachycardia, evidence of orthostatic hypotension, dry mucous membranes, tenting of the skin, sunken eyes, and lethargy) should be noted. Growth parameters, particularly weight, should be obtained and compared with previous measurements if available.

The skin should be examined for jaundice; evidence of pruritus (eg, excoriations), which may be associated with elevated bilirubin; or a nonspecific rash. Icterus of the sclera, tympanic membranes, and palate should also be noted. The abdomen should be palpated for tenderness and organomegaly, particularly hepatomegaly. The liver span should also be determined by percussion because it will help monitor the patient's progress. Splenomegaly, which is not typically found in hepatitis, indicates a different diagnosis, such as leukemia, or another infectious cause, such as EBV or CMV. A rectal examination should also be performed to look for masses or blood in the stool, which may suggest a neoplastic etiology.

A neurologic examination is important to document any signs of encephalopathy from hyperammonemia, which occurs more commonly in chronic liver disease or fulminant hepatic failure.

Laboratory Tests

The initial laboratory tests needed are directed by the severity of illness in the child at presentation. At a minimum, these include liver function tests (LFTs) (alanine aminotransferase, aspartate aminotransferase, γ -glutamyltransferase, and total and direct bilirubin) and coagulation studies (prothrombin time [PT]/partial thromboplastin time). Monitoring PT is particularly useful because of its rapid turnaround time and predictive utility; if the value is greater than 3 seconds above the upper limit of normal (international normalized ratio >1.5), the prognosis is poor. Serologic testing for hepatitis A (HAV-IgM and HAV-IgG) and hepatitis B panel (HBsAg, HBs antibody, hepatitis B e antigen [HBeAg], HBe antibody, and hepatitis B core antibody) should also be performed. Diagnostic antibody patterns for HAV and HBV are shown in Figures 114-1 and 114-2.

Serum antibody to HCV (anti-HCV) should be sent, especially for individuals with risk factors for infection. A confirmatory test such as a recombinant immunoblot assay, which measures antibody to various regions of the HCV genome, is generally performed if a

screening enzyme immunoassay (EIA) is positive, as false-positive EIAs may occur. Hepatitis C virus serologic assays detect IgG anti-HCV antibody; IgM tests are not available. Hepatitis C virus RNA polymerase chain reaction (PCR) has generally replaced the immunoblot for confirmatory testing, and PCR can also be used in other situations (eg, testing an immunocompromised individual who may not make antibodies). Serologic markers for hepatitis D (IgM and IgG anti-hepatitis D virus [HDV]) can be sent when concurrent HBV infection is evident. Isolation of the hepatitis D antigen in the liver, however, is the gold standard test for diagnosis of hepatitis D. Other serologic testing may be performed as indicated by history (eg, testing for syphilis with rapid plasma reagin for sexually active teens). A complete blood cell count and comprehensive metabolic panel may be needed in ill-appearing children, especially with signs of dehydration. A urinalysis for bilirubin should be done. In severe or complicated cases of viral hepatitis, additional testing such as liver biopsy or ultrasound may be indicated. For these cases, consultation with specialists in infectious diseases and hepatology is needed.

Management

For most cases of acute HAV, HBV, or HCV infection, therapy consists of **supportive care**. These illnesses are usually self-limited, and no specific therapy is indicated. Adequate nutrition and hydration are of primary importance. Therefore, the **intake of sufficient food and fluids** should be ensured. A low-protein diet during the acute phase of the illness may be considered. The use of **antipyretics** such as acetaminophen or ibuprofen for fever usually does not pose a problem in patients with mild disease and acutely elevated LFTs. However, because it is metabolized by the liver, it is preferable to limit the use of acetaminophen. Physical activity should be limited until patients feel better and LFTs return to normal. Children and adolescents can return to school when they are no longer jaundiced; they may also resume a normal diet at that time.

In children with more severe symptoms, IV hydration and an antiemetic may be indicated. Hospitalization is required for children who are moderately to severely dehydrated, are unable to tolerate fluids, or have evidence of fulminant liver failure. Treatment is aimed at correcting any metabolic abnormalities or electrolyte disturbances, including hypoglycemia. Coagulopathies should be corrected with vitamin K, fresh frozen plasma, and cryoprecipitate. Total parenteral nutrition may be required to maintain caloric needs.

Consultation with a pediatric gastroenterologist is important for management of children with acute fulminant liver failure or chronic, active hepatitis. Although no specific treatments are available for fulminant acute viral hepatitis, a few treatment options are now approved for treating children with chronic infection with HBV and HCV. Treatment options for both infections include immunomodulators such as interferon- α [IFN- α , available as IFN- α -2b and pegylated recombinant interferon- α -2a and anti-viral agents (eg, lamivudine for HBV and ribavirin for HCV) generally given in combination regimens. Variables for choosing to treat and with what regimen depend on the child's age, underlying health status, and

degree of viral activity. All treatment regimens are associated with adverse effects. Most pediatric patients with chronic HCV infection are asymptomatic and do not usually warrant treatment.

Children and adolescents with HBV and HCV chronic infection and their parents should be counseled to avoid hepatotoxic medications and alcohol. Their parents should be informed of the possibility of transmission to others, and patients should refrain from donating blood, organs, tissue, or semen. In addition, sexually active adolescents should be informed of the possible risk to sexual partners. Toothbrushes and razors should not be shared among household contacts. Most children with chronic HBV and HCV should not be excluded from child care centers because of their infection. Possible reasons for exclusion of HBV-infected children include biting behaviors, bleeding disorders, and generalized dermatitis. Because children with chronic HBV and HCV infection are at risk for the development of serious liver disease, they should be followed regularly by their physician in conjunction with a pediatric gastroenterologist experienced in caring for these children.

Prevention

All children should routinely receive immunizations for HBV (starting as early as birth) and for HAV (starting at 12 months of age). For older children and adolescents, review of their immunization records should be performed at all medical encounters, and catch-up doses of hepatitis A and B vaccine should be provided. In the United States, some states require proof of HBV vaccination for school enrollment.

Hepatitis A

Routine **immunization** for children starting at the age of 12 months has been recommended by the Advisory Committee on Immunization Practices and American Academy of Pediatrics since late 2006. In 1995 target groups were given hepatitis A vaccine, which led to a more than 85% decline in disease incidence. **Hand washing** by food handlers, medical personnel, and child care workers is one of the primary methods for prevention of the spread of HAV. **Contact precautions** should be used for hospitalized patients for at least one week after onset of symptoms. Active immunization with hepatitis A vaccine and/or passive immunization with Ig is recommended as postexposure prophylaxis for all people who have had intimate exposure to infected individuals. The hepatitis A vaccine and Ig may be administered at the same time in different sites. Postexposure Ig is generally not indicated for contacts at school or work, but Ig is indicated for HAV-exposed infants younger than 12 months, as they are not candidates for HAV vaccine. The dose of Ig is 0.02 mL/kg within 48 hours of exposure, given no later than 2 weeks after exposure. Immune globulin is 80% to 90% effective in prevention of clinical HAV disease. Pre-exposure prophylaxis with vaccine and/or Ig is recommended for travelers to endemic areas. If the stay is less than 3 months, the dose of Ig is 0.02 mL/kg; for longer stays, the dose is 0.06 mL/kg every 5 months. Two inactivated hepatitis A vaccines have been licensed in the United States for use in children 12 months of age and older, as well as for adults. The vaccine efficacy is over 94%

for preventing clinical HAV disease. The 2 licensed vaccines seem to be interchangeable. Two doses of the vaccine are recommended and should be given initially and 6 to 12 months later. Combination vaccine against HAV and HBV (Twinrix, GlaxoSmith Kline) is licensed for individuals older than 18 years.

In addition to routine childhood immunization, specific other groups for whom hepatitis A vaccine is recommended include travelers to endemic areas who are older than 12 months of age, individuals with chronic liver disease, men who have sex with men, users of injection and illicit drugs, and those at occupational risk of exposure. Other potential recipients include child care center staff and attendees, hospital personnel, food handlers, and individuals with hemophilia.

Hepatitis B

Preventive strategies for hepatitis B include universal immunization of all infants beginning shortly after birth and pre-exposure and post-exposure prophylaxis. In addition, the vaccination of selected individuals at increased risk and “catch-up” vaccination for unimmunized adolescents, especially those at high risk, is recommended.

Passive immunization with **hepatitis B immunoglobulin (HBIG)** is recommended for infants born to known HBsAg-positive mothers or mothers whose status is unknown. Passive immunization is also recommended for susceptible individuals who are sexual partners of persons with acute hepatitis B infections, household contacts (including children <1 year who have received <2 doses of vaccine), and those who experience mucosal or percutaneous exposure to HBsAg-positive blood. Unimmunized victims of sexual assault or abuse should receive HBIG if the offender is known to be HBsAg-positive. Simultaneous active immunization with the hepatitis B vaccine is recommended in these cases.

Immunization with the hepatitis B vaccine (active immunization) is currently recommended for all infants, adolescents not previously immunized, IV drug users, men who have sex with men, children receiving blood or blood products regularly (eg, hemophiliacs), children in chronic care facilities, household contacts of chronic carriers, and health care professionals. The standard schedule consists of 3 doses. Infants should receive the first dose before discharge from the nursery or shortly thereafter, the second dose 1 to 2 months later, and the third dose at 6 to 18 months of age. Infants should not receive the 3rd dose before 6 months of age. Intervals for other individuals are similar.

Perinatal vertical transmission of HBV can be prevented by giving newborns HBIG (0.5 mL intramuscularly) within 12 hours after birth and hepatitis B vaccine concurrently (at a different site) prior to discharge. This practice prevents approximately 90% of chronic infections in infants born to mothers with HBsAg and HBeAg. Post-immunization serologic screening is recommended, however, for these infants at 1 year of age because approximately 5% become

carriers despite appropriate preventive vaccination. Special schedules for active and passive immunizations against HBV should be consulted for premature infants who weigh less than 2,000 g.

Hepatitis C

No vaccine exists for the prevention of HCV infection. Because Ig is manufactured from plasma that is HCV-antibody negative, it is not recommended for prophylaxis.

Current recommendations include screening individuals with risk factors for HCV infection (see Pathophysiology), infants born to HCV-infected women, recipients of Ig between April 1993 and February 1994, and children with clinical hepatitis found not to have hepatitis A or B.

Hepatitis D

Prevention of HBV infection through universal vaccination is the most important means of controlling HDV infection.

Prognosis

The prognosis for children with viral hepatitis depends on etiology, as well as the child's age and underlying health status, at the time of infection. For HAV infection, the outcome is generally good, with an uneventful recovery. Infants and children infected with HBV, on the other hand, are at high risk of becoming chronic carriers, especially if infected at a young age. Approximately 25% of carriers develop chronic, active hepatitis, which often progresses to cirrhosis. In addition, the risk of developing hepatocellular carcinoma is 12 to 300 times higher in these patients compared with the rest of the population.

Chronic hepatitis also occurs with HCV infection, though it is unknown whether chronic infection and subsequent complications are higher for neonates. Autoimmune complications such as arthritis, serum sickness, and erythema multiforme are common with chronic disease. Approximately 70% of patients with acute HCV infection later develop chronic hepatitis, and 10% to 20% progress to cirrhosis and hepatic failure. Hepatocellular carcinoma has also been described in a small proportion of patients.

Likewise, complications of hepatitis D, such as cirrhosis and portal hypertension, are not uncommon. They occur more frequently than with hepatitis B alone and progress more rapidly. Infection with HEV does not result in a chronic condition. Fatal hepatitis A is a rare occurrence. The overall mortality associated with HBV, HCV, and HEV is also low (approximately 1%–2%), though HEV can be fatal in 20% of infected pregnant women. For hepatitis D, mortality it is more variable, ranging from 2% to 20%. Figures increase to 30% for HBV with coinfection with hepatitis D.

CASE RESOLUTION

In the case history, the teen has a classic presentation of viral hepatitis despite no history of travel to an endemic area. Statistics point to probable infection with hepatitis A, and exposure possibly occurred at the fast-food restaurant. Because he does not appear to be dehydrated or seriously ill, he can be managed as an outpatient. Serologic testing for hepatitis A, B, and C should be performed, in addition to LFTs and coagulation studies. The parents should be informed of the probable diagnosis and if confirmed as hepatitis A, all household contacts should receive hepatitis A vaccine and/or prophylaxis with Ig. They should also be educated regarding the infectivity of the disease and counseled about supportive therapy. Public health officials should be consulted for management of other individuals who were possibly exposed. The boy should have limited physical activity while symptomatic and he should be scheduled for a follow-up visit in a few days for repeat LFTs and coagulation tests. The prognosis is good.

Hypotonia

Kenneth R. Huff, MD

CASE STUDY

A 6-month-old girl is brought to the office because she does not reach for her toys anymore. The pregnancy was full term, but the mother remembers that the fetal kicking was less than with an older brother. Delivery was uncomplicated, and the infant fed well from birth. The girl began to show visual attention at 2 to 3 weeks, smiled socially at 1 month, and pushed up while prone at 2 months. Although she turned over at 4 months, she has not done this in the last month. She no longer reaches up to the mobile over her crib.

On examination, the girl lies quietly on the table and watches the examiner intently. Her growth parameters, including head circumference, are normal. After she has been undressed, it is apparent that she “seesaw” breathes (ie, abdomen rises with inspiration) and has a “frog-leg” posture. Her cranial nerve examination is normal except for head-turning strength. When she is pulled to a sitting position, her head lags far behind and her arms are

straight at the elbows. She cannot raise her arms off the table. When a rattle is placed in her hands, she manipulates the toy, which she regards from the corner of her eye. Her deep tendon reflexes are absent, but her pain sensation is intact.

Questions

1. How is the level of nervous system involvement determined in infants with hypotonia? What levels of the nervous system are usually involved in the infant with hypotonia?
2. What is the significance of a loss of developmental milestones or abilities?
3. How are clinical management issues related to prognosis?
4. When is genetic counseling appropriate for children with hypotonia?

Infants with decreased tone are referred to as hypotonic or “floppy.” Hypotonia is most simply defined as lower than normal resistance to passive motion across a joint, but is also suggested by abnormal posture. Although the lack of resistance may have other components (such as connective tissue abnormalities suggested by an unusual range of joint mobility, blue sclera, hyper-elastic skin, or Down syndrome features), muscle strength is a key component. Tone can be used as a surrogate indicator of strength in infants who cannot cooperate with resistance testing. Weakness can also be inferred from functional observations and the inability to sustain limbs against gravity or the lack of a withdrawal response of a limb to a painful stimulus. Identification of the level of the nervous system affected (eg, upper motor neurons, spinal cord, anterior horn cell, peripheral nerve components, myoneural junction, or muscle fibers) is most important in determining the etiology of hypotonia in infants and children. Only after this localization is the likely pathology defined in most cases.

Epidemiology

Hypotonia is not unusual in neonates, and non-neuromuscular causes of hypotonia are more common than neuromuscular conditions. Non-neuromuscular causes include hypoxic-ischemic encephalopathy and brain lesions related to premature birth, such

as intraventricular hemorrhage and periventricular leukomalacia. Genetic abnormalities also are frequently present shortly after birth. Spinal muscular atrophy (SMA) is a common progressive genetic condition with an incidence similar to cystic fibrosis, about 1 in 5,000. Duchenne muscular dystrophy is the most common neuromuscular condition in childhood, with an incidence of 1 in 1,700 to 1 in 3,500 male births. The Duchenne gene has been found to spontaneously mutate in approximately 50% of the cases. Among non-genetic disorders, the incidence of acute postinfectious polyneuritis or Landry–Guillain-Barré syndrome is 2 to 8 per 100,000.

Clinical Presentation

Hypotonia in infants often presents as an unusual posture of the infant, diminished resistance to passive movements of limbs or trunk, or an excessive range of joint mobility. Hypotonic infants have delayed motor milestones, decreased movements, and poor head and trunk control (Figure 115-1). Older children may have decreased ability to resist with strength testing of individual muscle groups as well as impaired functional strength in sitting, standing, walking, climbing, or running (Dx Box). Swayback posture in standing may indicate hip girdle or proximal weakness. Pointed toes in the supine position may indicate an upper motor cause.

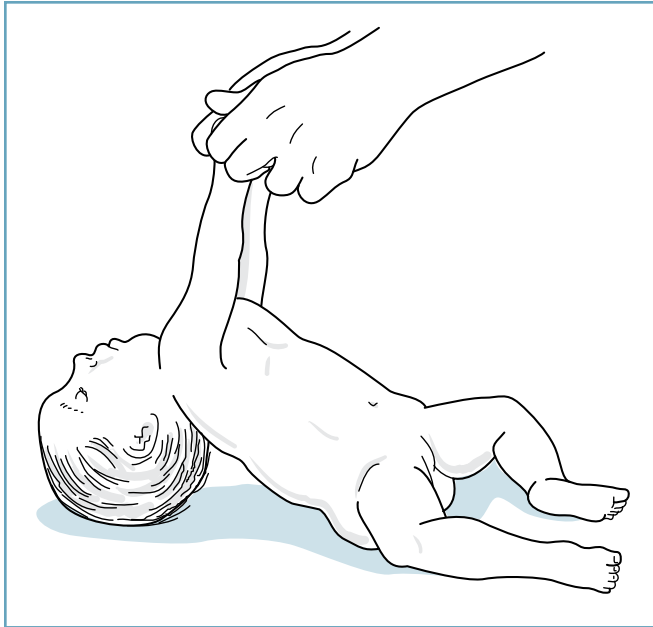

Figure 115-1. Hypotonic infant being pulled into sitting position. Arms are completely extended, head control is poor, and legs are abducted at the hip.

Dx Hypotonia

- Decreased resistance to passive movement of a joint
- Muscular weakness in older children
- Etiologic diagnosis related to the nervous system level of the lesion

Pathophysiology

Tone is a product of connective tissue structural elements, including ligaments, tendons, and joint capsules; muscle fiber number and integrity; and nerve fiber input to muscle. Nerve input to the muscle includes the number and myelination of axon fibers, trophic factors from the nerve, and the frequency of action potentials depolarizing the muscle membrane. The control of tone through the anterior horn cell is complex and involves more than just corticospinal tract (upper motor unit) but also other descending tract influences. Lesions of the neuromuscular apparatus (lower motor unit), which includes muscle, nerve, nerve sheaths, and anterior horn cell, can most directly decrease tone, but lesions of any of the other structures at many levels of the nervous system can also affect tone. The final common pathway of upper or lower motor unit modification of tone is through the gamma loop (fusimotor) system. Gamma motoneurons within the anterior horn of the spinal cord innervate the contractile muscle portions on each end of the intrafusal fiber and enhance the sensitivity of the sensory endings to stretch, which in turn transmit signals back to the alpha motoneurons in the anterior horn innervating the rest of the muscle. Different levels of the central nervous system (CNS) (motor cortex, thalamus, basal ganglia, vestibular nuclei, reticular formation, and cerebellum) can modify tone through their effect on the gamma motoneuron.

The nature of the lesion at different levels of the nervous system may be quite variable. For example, ultrastructural abnormalities occur in congenital myopathies, including those related to respiratory chain defects, anterior horn cell apoptosis occurs in SMA and may also occur with ischemic insults, and stripping of myelin by macrophages occurs with acute postinfectious polyneuritis.

Differential Diagnosis

Distinguishing clinical features in determining the level of the lesion in the nervous system include pattern of weakness, activity of muscle stretch reflexes, presence of fasciculations or sensory loss, cerebrospinal fluid findings, serum muscle enzyme levels, **electromyography (EMG)** pattern, nerve conduction studies, and histologic appearance of the muscle and/or nerve biopsy. It is useful when assessing the hypotonic child to separate upper motor neuron or brain causes from neuromuscular causes (Table 115-1). The former include perinatal hypoxia-ischemia, intracranial hemorrhage, and cerebral dysgenesis. These problems may present with hypotonia in infancy but later are evident as a static encephalopathy. A child with a CNS cause may have a below normal level or range of attention and may lack age-appropriate social skills. Seizures or hemiparesis also signify a likely CNS cause. Fine motor coordination, quality and repertoire of movements, and language may be affected in an older child. The deep tendon reflexes may be brisk or easily elicited. The Babinski

Table 115-1. Differential Diagnosis of Infantile Hypotonia

<i>Level</i>	<i>Specific Lesion</i>
Cerebral hemisphere	Static encephalopathy related to perinatal or prenatal insults Dysgenesis (eg, Down syndrome) Degenerative conditions (eg, storage disease)
Spinal cord	Traumatic transection Dysraphism or other malformation
Anterior horn cell	Spinal muscular atrophy Poliomyelitis
Peripheral nerve	Leukodystrophy Type III hereditary sensorimotor neuropathy Acute polyneuritis (rarely occurs in infancy)
Myoneural junction	Myasthenia gravis Toxin (botulism or “mycin” antibiotic)
Muscle	Congenital structural myopathy Congenital myotonic dystrophy Congenital muscular dystrophy Mitochondrial myopathy
Systemic	Amino and organic acidopathies, hypercalcemia, renal acidosis, rickets, celiac disease, hypothyroidism, collagen disease, congenital heart disease

reflex may be dorsiflexor. In infants, fisting of the hands, scissoring of the extended legs on vertical suspension, and movement through postural reflexes such as the asymmetrical tonic neck reflex are clues to an upper motoneuron process. Serum muscle enzymes, EMG, nerve conduction, and muscle biopsy will all be normal if assessed. However, neuromuscular causes include congenital myopathy, SMA, muscular dystrophy, and acute postinfectious polyneuritis. A child with one of the neuromuscular causes for the hypotonia that don't involve cranial innervated muscles may have an interested and visually attentive facial appearance in the presence of severe weakness that allows only sparse or nearly absent limb movements. Deep tendon reflexes may be difficult to elicit or absent in many neuromuscular lesions.

Older children may display a different pattern of weakness that gives a clue to the level of involvement. If the weakness is preferentially in upper extremity extensor and lower extremity knee flexor, ankle dorsiflexor, and ankle evertor muscle groups, the lesion may involve the upper motoneuron. Static bilateral hemiparesis may suggest severe hypoxic-ischemic insult; diplegia may suggest periventricular leukomalacia in a former prematurely delivered infant. This differential weakness from CNS causes may be present and contribute to hypotonia for a long period before spasticity intervenes and affects tone. If the weakness involves limb agonist and antagonist muscles equally, however, it may represent a neuromuscular process. It should also be remembered that hypotonia can result from disorders with combined lesions in levels above the lower motoneuron and in the motor unit. Examples include Krabbe leukodystrophy, Pompe disease, and hypoxic-ischemic insults involving both the upper motoneuron and the anterior horn cell during the acute phase.

Evaluation

A methodical assessment using clinical and laboratory features in children to localize the lesion to a level of the nervous systems can help anatomically narrow a wide differential diagnosis (Table 115-2).

History

Particular areas of the history are especially important (Questions Box). Level of fetal movements relative to other pregnancies and possibilities of toxic or infectious fetal exposures should be obtained. Relatively decreased fetal movements may signify an early

degenerative condition. Polyhydramnios can signal prenatal interference with swallowing. Birth events should be investigated for sources of possible trauma to the neonatal nervous system, such as prematurity or birth asphyxia. The physician should determine whether any developmental skills have been lost. Any associated loss of tone or strength could signify a progressive condition rather than a static problem as would occur with a birth injury. The acuity of the developing weakness also is an important clue in the differential diagnosis. Immediate-onset hypotonia accompanied by constipation, poor feeding, and other bulbar involvement may suggest botulism. Acute losses of tone and strength may also occur with enteroviral poliomyelitis, Landry–Guillain-Barré syndrome, myasthenia, and myositis. Relapsing-remitting courses of hypotonia may be seen with myasthenia, metabolic myopathies, and periodic paralysis in the older child. A progressive deterioration in intellectual functions might point to a leukodystrophy, storage disorder, or other degenerative disorders, such as one of the “Leigh syndromes,” particularly if ataxia, brain stem symptoms, and respiratory dysfunction subsequently develop.

In addition, the family history should be determined. The presence of weakness or hypotonia in other family members, or the presence of early unexplained neonatal deaths in the family, may indicate a genetic or maternal basis for the patient's hypotonia.

Physical Examination

Dysmorphic features should be noted in developmentally delayed children with hypotonia because they may suggest cerebral dysgenesis in some instances (eg, the characteristic stigmata of Down syndrome) or neuromuscular conditions in other instances (eg, hypoplastic mandible, high-arched palate, thin ribs with deformed rib cage, or pectus excavatum). Poor feeding with small male genitalia in the neonate may suggest Prader-Willi syndrome. A large tongue with decreased growth parameters may point to hypothyroidism. Hepatomegaly may be seen with Niemann-Pick and Zellweger syndromes. Signs of brain dysfunction, such as lethargy, unresponsiveness to the environment, and lack of social skills, should be noted. The neonate who acutely develops signs like those of sepsis along with generalized hypotonia may have an inborn error of metabolism that is decompensating and requires emergent intervention. Age-appropriate cognitive abilities should be assessed as a measure of cerebral function. This assessment may range from primarily

Table 115-2. Approach to the Diagnosis of Hypotonia

Clinical Feature	Anatomical Site				
	Cerebrum	Spinal Cord	Anterior Horn Cell	Neuromuscular Junction	Muscle
Alertness	Decreased	Normal	Normal	Normal	Normal
Cry	Decreased	Normal	Normal/weak	Weak	Normal/weak
Eye movements	Sometimes abnormal	Normal	Normal	Abnormal	Normal
Tongue fasciculations	Absent	Absent	Present	Absent	Absent
Muscle bulk	Normal	Normal	Decreased	Normal	Decreased
Deep tendon reflexes	Normal/increased	Decreased/increased	Absent	Normal	Normal/decreased

Hypotonia

- Were the fetal movements of the child abnormal or less than those of previous pregnancies?
- Was the pregnancy full term? Was the delivery complicated?
- Does the mother, any siblings, or other family members suffer from a similar weakness?
- Has the child lost any developmental skills? Is the problem getting worse?
- If the weakness is worsening, how rapidly is it progressing?

Questions

observation of visual attention in very young infants to evaluation of language and academic skills in older children. Cranial nerve examination with regard to eye movements, facial strength, and presence of tongue fasciculations is important, especially in the differential diagnosis of many neuromuscular conditions. Ocular muscle involvement may be part of mitochondrial myopathies, myotubular myopathy, and myotonic dystrophy. Blindness and hyperacusis responses may suggest Tay-Sachs disease. Facial muscle involvement is common in some congenital myopathies and myotonic dystrophy but not a part of SMA. Sucking and swallowing difficulty is a feature of SMA, congenital myotonic dystrophy, myotubular and nemaline myopathies, neonatal myasthenia, and Prader-Willi syndrome, in addition to birth asphyxia.

Tone and strength should be examined carefully in both trunk and limbs with the head in the midline. Passive pronation, supination, flexion, extension, and gentle shaking of hands and feet can demonstrate hypotonia, as can the traction maneuver for head control, horizontal prone suspension for trunk tone, scarf sign and axillary suspension for shoulder girdle tone, and popliteal angle for lower extremity tone. In premature infants there is normally a caudal-rostral progression of tone development, particularly flexor tone, correlated with age up to 40 weeks term. Individual joint movements should be observed and agonist-antagonist strengths should be tested bilaterally to look for asymmetries and focal discrepancies. There may be a paucity of spontaneous limb movements, and breathing may be paradoxical with chest lowering and stomach rising due to primarily diaphragmatic strength. Severe respiratory compromise along with profound hypotonia may be features of neonatal spinal cord injury as well as congenital myopathies. A loss of pain sensation (evidenced by facial grimace following a painful stimulation below the neck) would suggest the former cause rather than the latter. The plantar response should be obtained particularly in older children. The presence of contractures is common in congenital muscular dystrophy and congenital myotonic dystrophy. The older child may have developed scoliosis from gravity effects on a weak spine. The absence of deep tendon reflexes and or presence of percussion myotonia should also be carefully noted. Sensory testing is important in suspected neuropathies, radiculopathies, and myelopathies. The responses to be observed are latency, limb movement (more than stereotyped triple flexion), facial grimace and cry, and habituation. In the case of a hypotonic neonate, the mother may also need to be

questioned and examined particularly for the presence of symptoms or signs of myotonic dystrophy or myasthenia gravis.

Observation rather than formal individual muscle testing is often easier and more revealing, particularly in infants and preschool-aged children. Useful activities to observe include walking, running, climbing stairs or stepping onto a stool, lying on the floor and coming to a standing position unassisted, smiling, closing the eyes tightly, and speaking. The ambulatory child may have a waddling gait from hip girdle weakness, genu recurvatum from quadriceps weakness, or talipes planus from foot weakness. Arising from a prone position on the floor the child may demonstrate the Gower sign by first getting to the hands and knees, then walking the feet forward to the hands, and finally “walking” the hands up the trunk to gain an upright position, rather than quickly rising from squatting without using the hands.

Laboratory Tests

One purpose of laboratory tests in children with neuromuscular conditions is to confirm the level of the nervous system involved (Table 115-3). **Serum creatine phosphokinase (CPK)**, a screen for muscle fiber necrosis, should be requested when the history suggests a degenerative condition or the examination indicates the cause of the hypotonia is in the neuromuscular unit. Creatine phosphokinase is 10 to 100 times higher than normal in children with muscular dystrophy, and it may also be mildly elevated in female carriers of the mutant dystrophin gene in their first 3 decades of life. The serum CPK level may be less markedly elevated in children with inflammatory myopathies, such as dermatomyositis and polymyositis, and to some extent following muscle trauma. Severe hypotonia at birth can be a result of inborn errors of metabolism, such as peroxisomal disorders, non-ketotic hyperglycinemia, congenital lactic acidosis, organic acidemias, fatty acid oxidation disorders, maple syrup urine disease, molybdenum cofactor deficiency, and hyperammonemic syndromes, which can be screened using blood or plasma tests. The evaluation of the hypotonic depressed neonate should include an evaluation for infection (complete blood cell count and appropriate cultures) as well as an assessment of pH; blood gas; glucose; electrolytes; liver function tests; ammonia; amino acids in the blood; and sugars, organic acids, and ketones in the urine. Spinal

Table 115-3. Laboratory Tests Useful in the Diagnosis of Hypotonia Caused by Neuromuscular Lesions

Test	Anatomical Site

Muscle enzymes	Normal	Normal	Normal/ increased
Tensilon test	Normal	Abnormal	Normal
Electromyography	Neuropathic	Decremental/ incremental	Myopathic
Muscle biopsy	Group atrophy	Normal	Myopathic

fluid examination is sometimes helpful if there is an increase in white cells related to possible infection or inflammation or if there is an increased level of protein as seen in immune, storage, or necrotizing CNS conditions.

Useful information about the presence of neuropathic, myopathic, and neuromuscular junction disorders can be obtained from the nerve conduction velocity and EMG. Demyelinating neuropathies slow **nerve conduction** or produce signs of a segmental conduction block. If the problem is a motor neuropathy, an axonal neuropathy may have depressed amplitude of the nerve action potential or fibrillation potentials on EMG. In some myopathies, bizarre or small amplitude potentials and myotonia may be seen on EMG. Decremental response to stimulation and other abnormalities are evident with myasthenia gravis and neuromuscular junction blockade caused by the botulinum toxin. An intravenous (IV) edrophonium (Tensilon) test can confirm the diagnosis of myasthenia gravis in children with easy fatigability by history or on examination. Some neuromuscular conditions are associated with cardiomyopathies and, therefore, the electrocardiogram can help in diagnosis as well as bring to light potentially critical problems needing acute intervention such as heart conduction block.

When properly handled, the **muscle biopsy** gives useful diagnostic information about neuromuscular disorders that may cause hypotonia. A large portion of the tissue should be frozen for histochemical studies. Histochemistry can differentiate neuropathic changes from myopathic changes related to fiber type specificities as well as disclose structural abnormalities pointing to dystrophy or congenital myopathy. Histochemical stains can also give information about metabolic myopathic disorders. Another portion of the muscle should be fixed in glutaraldehyde for electron microscopy to determine if ultrastructural abnormalities such as those seen in specific congenital or mitochondrial myopathies are present.

Metabolic and molecular genetic studies can sometimes be done on blood or urine samples, such as thyroid functions if clinical suspicion of hypothyroidism persists, white blood cell enzymatic assays, very-long-chain fatty acid profiles, lysosomal enzyme screens, plasma amino acid levels, and urine organic acid levels. However, if a genetic disorder is preferentially expressed in muscle tissue and direct gene analysis is not feasible, a muscle biopsy specimen can be analyzed. Tissue can be subjected to other specific expression analyses such as dystrophin protein levels, glycolytic enzyme activity, respiratory chain enzyme complex assays, carnitine levels, or fatty acid transport assays to confirm the diagnosis. Cytogenetic analysis may be useful when Down syndrome or other chromosomal aberrations are suspected and DNA methylation analysis is done when Prader-Willi syndrome is suspected as a cause of non-paralytic hypotonia. Blood sample molecular techniques, including use of specific nucleic acid probes, comparative genomic hybridization, copy number variance, and exon sequencing screens can sometimes be used to help make specific diagnoses for genetic disorders (eg, Duchenne or other X-linked muscular dystrophies, myotonic dystrophies, mitochondrial cytopathies, and SMA). Often these blood tests have eliminated the need for more painful electromyography or muscle biopsy.

Imaging Studies

A magnetic resonance imaging scan is often helpful in at least 4 situations: (1) when deficits in mental status, cognitive function, or attention are apparent in children with hypotonia; (2) when the neurologic examination suggests an upper motoneuron component to the weakness or hypotonia such as active deep tendon reflexes or persistent ankle clonus; (3) when a progressive congenital muscular dystrophy is suggested by both myopathic signs and CNS signs; and (4) when children have hypotonia as part of a multiorgan system dysgenesis such as with a chromosomal aberration, because of the relatively higher likelihood of a CNS component to the dysgenesis. A computed tomography scan is also sometimes helpful in evaluating the presence of calcification in brain structures as might occur in metabolic abnormalities or necrotizing brain insults if these are part of the clinical differential.

Management

Specific management depends on diagnosis but ranges from supportive respiratory measures to anti-inflammatory therapies to physical and orthopedic therapy and devices to improve function. Sometimes the potential for recovery is an important factor in determining the degree of aggressiveness in the clinical management and therapy sessions for children with neuromuscular conditions. An infant with a congenital myopathy may gradually increase in strength and should, therefore, receive intensive supportive care including long-term ventilatory support and gastrostomy feeding. On the other hand, the family of an infant with a rapidly degenerative terminal condition such as the severe infantile type of Werdnig-Hoffmann anterior horn cell disease may elect not to undertake respiratory support after they understand the course of the disease and lack of curative therapy. Such families continue to benefit from the ongoing information provided by the physician and the support of paramedical personnel and lay groups. Affected children can also benefit from palliative therapies and hospice care.

Children with profound weakness easily succumb to respiratory infections and have difficulty with recovery from anesthesia; therefore, they require vigilance on the parent's or caretaker's part and early intervention because they may need intense **respiratory support**. Children with long-term neuromuscular weakness can sometimes benefit from **orthopedic** procedures to improve limb function by joint stabilization or equalizing of muscle strengths across joints or scoliosis stabilization to prevent respiratory compromise. **Physical and occupational therapy** can accelerate recovery after procedures and maximize function.

Children with acquired acute hypotonic weakness (Box 115-1) may require therapies more directed at the underlying pathophysiological process. Acute postinfectious polyneuritis requires careful, frequent monitoring of respiratory status and artificial ventilation when significant loss of vital capacity has occurred. In addition, children should be considered for **plasmapheresis** when their condition rapidly worsens early in the course of the disorder. Intravenous

Box 115-1. Specific Etiologies of Hypotonia Caused by Acute Generalized Weaknesses

- Acute postinfectious polyradiculoneuritis (Landry–Guillain-Barré syndrome)
- Postinfectious myositis
- Enteroviral poliomyelitis
- Acute myasthenia gravis
- Infantile botulism
- Tick paralysis
- Periodic paralysis (hyperkalemic, hypokalemic, and normokalemic)
- Metabolic myopathy

immunoglobulin is an alternative therapy that may be particularly useful in a child too small for the venous access required for pheresis. Specific antisera are used for botulinum intoxication. Dysimmune myasthenia can be treated with anticholinesterase medication, IV immunoglobulin, and/or thymectomy when it is resistant or only partly responsive to immunosuppressive medication. In addition to the more acute disorders, chronic relapsing polyneuritis and myositis can be treated effectively with various anti-inflammatory agents including prednisone and immunoglobulin during periods of exacerbation. Suspected metabolic disorders can be managed with semi-focused metabolic therapy such as stopping a toxic nutrient; using a high-energy alternative nutrient (glucose); treating hyperammonemia with benzoate, phenylbutyrate, or arginine; dialysis; administering insulin to control hyperglycemia; reducing periods of catabolism; and supplementing vitamin cofactors and carnitine. Metabolic myopathies are still often empirically treated with thiamine, riboflavin, nicotinamide, coenzyme Q10, biotin, l-carnitine, succinate, vitamins C or K, and medium-chain triglyceride oil, using these in some cases based on tissue analysis.

Treatment and care of children with muscular dystrophy is presently directed individually toward maintaining mobility and preventing contractures through physical therapy, bivalved casts, braces, and surgical repair. Inactivity increases disability. Adjunctive corticosteroid therapy is useful in children with Duchenne dystrophy, but beneficial effects are temporary and must be weighed against steroid toxicity. Presently new therapies for providing dystrophin expression are under active investigation, including “exon skipping” promoting drugs and dystrophin gene fragment-carrying viral vectors. Many new hardware technologies (eg, long leg braces, electric wheelchairs, battery-operated ventilators, and noninvasive positive-pressure ventilation for some cases of respiratory insufficiency) have allowed affected children to overcome previously insurmountable disabilities.

Prognosis

Spinal muscular atrophy type I generally progresses to death over a couple of years, and Duchenne muscular dystrophy generally progresses to full time artificial ventilation over 15 to 20 years. However, the course of many genetic conditions can be quite variable and is related to different alleles at the disease gene locus, the position of the critical base pair substitution or deletion, or other loci that may have a modifying effect on either disease gene expression or the pathophysiology of the disease. For example, both the SMA and dystrophin genes have multiple abnormal modes of expression with widely different prognostic implications for disease course. The weakness of congenital myopathies usually slowly improves. Toxin-mediated infant botulism and immune-mediated disorders, particularly Landry–Guillain-Barré, generally have a good outcome although long-term supportive measures may be necessary.

CASE RESOLUTION

The 6-month-old girl in the case history was judged to have hypotonia caused by a neuromuscular condition, in part because of her alert appearance and absent deep tendon reflexes. Neuropathic abnormalities on electromyography and muscle biopsy were also present. A blood test for the survival motor neuron genes did not detect any normal sequences, confirming the diagnosis of spinal muscular atrophy type I. The family received genetic counseling, became involved in a support group, and eventually reached a decision to forego intubation when respiratory failure overtakes their daughter. The physician coordinated hospice services for the family.

Headaches

Kenneth R. Huff, MD

CASE STUDY

A 12-year-old girl is brought in with a history of headaches. Although she has been sent home from school twice in the last 6 weeks, she has experienced headaches for at least a year. The last episode, 1 week ago, was typical. The headache began as a dull feeling over both eyes, radiated up to the top of her head, and eventually became pounding. She had no preliminary visual symptoms or other warning signs prior to the head pain. The episode began during an afternoon class after she had been outside on a hot, sunny day for physical education. The headache worsened after she walked home from school. Once she got home, she went to her room, drew the curtains, and lay down on her bed. She experienced some nausea and loss of appetite but no vomiting. She did not get up for dinner. She denied diplopia, vertigo, ataxia, or limb weakness, and her speech was observed to be articulate and coherent. She took two 80-mg children's acetaminophen

tablets without significant relief but eventually fell asleep. The following morning she felt fine.

Between headaches, her behavior has not changed, and she has continued to make above-average grades. She has not experienced any major changes in her home environment. When initially questioned, her mother denied having migraines, but she admits to needing to lie down because of headaches about once a month. A detailed **neurologic examination of the girl is completely normal.**

Questions

1. What are the major types of headache?
2. How do the symptoms help differentiate the types?
3. How does family history influence the etiology and help in the management of the headache?
4. What is the appropriate treatment for the problem headache?

Headaches, which are very common in adolescents and older children, frequently prompt parents to bring their children to the physician's attention. The physician must differentiate headaches that are symptomatic of a progressive intracranial process from those that may possibly be intermittently disabling but do not necessitate surgery. The cornerstone of this determination is obtaining key historical information and noting abnormalities on examination of the nervous system. Decisions about management strategies are most influenced by etiology and, if it has become a chronic problem, the impact the headaches are having on the child's life.

Epidemiology

The contribution of "symptomatic" headaches (those related to tumors, vascular abnormalities, or meningitis) to the overall prevalence of headache is relatively small. Chronic recurrent headaches in children that are not related to a self-limited condition are frequently lumped together as migraine, which includes classic and common migraine. The prevalence of migraine that comes to a physician's attention is about 3% to 10% for all children, but as many as 30% of children by age 15 admit to having experienced a headache in the last year. Although initial headache symptoms begin most often between ages 6 and 12 years, many patients come to medical attention for the first time during adolescence, especially girls whose headache prevalence is double that of boys. Headaches are also commonly associated

with trauma, acute intercurrent infection, or other systemic illness. A multigenerational family history of "sick headaches" is a frequent finding in the child with migraine. This history must be specifically elicited by the physician, however, because its significance is often discounted by the parents.

Clinical Presentation

Parents must interpret the nature and severity of their child's experience and symptoms, which may be difficult especially in younger children. Younger children may rarely complain of head pain or more commonly of stomachache or present with nausea or vomiting. Adolescents may report persistent, dull, aching, or pounding head pain. It may be increasing in intensity or frequency and be associated with neurologic signs, which may suggest an intracranial mass lesion, or the pain may be episodic, relatively stable in frequency over many months, and similar to that experienced by other family members either presently or in the past, which may suggest a migraine etiology (Dx Box). Classic migraine, which is relatively unusual in children, is distinguished from common migraine by the presence of an aura of specific sensory symptoms that precede the headache. Both types of headache may be associated with lethargy, slowness of movement and response, intolerance of intense sound or light, and loss of appetite.

Dx Headaches (Migraine)

- Head pain, often pounding in character, over the eyes, at the vertex, or in the occipital region
- Pain frequently accompanied by nausea, anorexia, photophobia, or phonophobia
- Pain sometimes preceded by visual symptoms such as scotomata
- Presence of trigger factors, including bright light, intercurrent illness, or stress
- Family history of headaches (often)

Pathophysiology

Pain fibers are carried in the trigeminal nerves from the scalp, skull, meninges, and vessel walls within the brain. Traction on these fibers or inflammation at the endings produces the pain that is associated with mass lesions or meningeal inflammation. The usual distinction between migraine and tension headache pathophysiology is more difficult to make in the younger child and may involve the types of trigger factors (Box 116-1) that occur at different ages. Several different mechanisms that involve one or more environmental factors may trigger headache in genetically predisposed individuals. The migraine generator probably resides in the brain stem and has input to the trigeminal nucleus. The pathogenic neurotransmitter at the nerve endings may be serotonergic (perhaps emanating from platelet stores), but release may be precipitated by a cascade of local cytokines, substance P, calcitonin gene-related peptide, and histamine in and around vessel walls leading to changes in vascular permeability and local swelling. The relative roles of genetic susceptibility and environmental agents are subjects of current investigation.

Box 116-1. Triggers of Migraine

- Glare, dazzle, bright sunlight, or fluorescent lighting
- Physical exertion, fatigue, lack of sleep, hunger
- Change in ambient temperature or humidity
- Allergic reactions, pungent odors
- Certain foods, alcoholic beverages, and cold foods or beverages
- Anxiety, stress, and worry
- Head trauma
- Menstruation and oral contraceptives
- Refractive errors (rare)

Differential Diagnosis

Acute Headaches

Emergent causes should be considered if headaches have an abrupt onset, develop rapidly, or are especially severe or if children describe them as a “thunderclap” or “the worst of my life.” **Intracranial hemorrhage** from a ruptured aneurysm, an arteriovenous malformation or, rarely, as a secondary effect of hypertension is foremost on the

list of such causes. If children have a condition that may potentially lead to stroke, such as coagulopathy, hemoglobinopathy, or heart disease, the stroke may become hemorrhagic and produce acute, severe headache.

Non-hemorrhagic meningeal irritation, such as the inflammation produced by bacterial or viral meningitis, may also cause acute headaches. These conditions may render patients confused and lethargic while still conscious and are often associated with fever. Both types of meningitis produce signs of meningeal irritation: nuchal rigidity (stiff neck) and Kernig and Brudzinski signs.

Chronic Progressive Headaches

Children with brain tumors, brain abscesses, or a block in cerebrospinal fluid (CSF) flow producing hydrocephalus frequently have a “crescendo” history of increasing severity or frequency of headaches. The headache may be consistently localized or may awaken the patient from sleep, presumably related to relative shift in intracranial traction forces due to gravity and the horizontal position. Many other children with brain tumors do not complain of a localized headache and may present with vomiting without headache as a prominent symptom. Idiopathic intracranial hypertension most often presents with headaches, and papilledema will be present when the eyes are examined. Standard imaging studies are normal, but CSF pressure is high when measured during a lumbar puncture. There may be a relationship to intracranial venous sinus obstruction in some cases. A serious sequela of idiopathic intracranial hypertension is an enlarging blind spot in visual fields and eventual loss of vision if pressure is not relieved. Therapies include CSF withdrawal, diuretics such as Diamox, and optic nerve fenestration or CSF diversion surgically.

Chronic Recurrent Headaches

The pain of **migraine headaches**, the most common chronic headache type, is dull in character, and if headaches are severe, patients shun other intense sensory stimuli. **Sinus infection** may be a cause of either chronically recurring headaches or acute headaches, especially if children relate that the pain is more facial than cranial. Symptoms of chronic nasal congestion, allergies, and postnasal drip may be associated with sinus headaches. Children with asthma also have recurring headaches possibly triggered by sinus involvement, generalized cytokine release, cerebrovascular smooth muscle reactivity, or medication side effect susceptibility.

Other types of headaches may recur. **Chronic daily headaches** (more than 15 headache days per month) in some cases may be transformed migraine or rebound headache due to abortive medication overuse. In other cases the history, though suggestive of migraine, is more consistent with **tension headaches** characterized by a feeling of a tightening band around the head; occurrence late in the day; and association with anxiety, depression, or a stressful environment. Adolescents, if they are susceptible individuals, may also have frequently recurring headaches due to irregular lifestyles such as not eating regularly or getting adequate sleep. **Posttraumatic headaches** may recur with gradually decreasing severity up to several months

following head trauma. **Cluster headaches** are associated with lancinating pain, unilateral tearing, nasal stuffiness, and nighttime pacing, but are exceedingly rare in children.

Evaluation

History

Information should be obtained from patients, parents, and other caregivers concerning the quality, intensity, and location of the headache as well as other associated symptoms before and during the headache (Questions Box). The duration, clinical course, and conditions that evoke, intensify, or alleviate the pain are also important. It is useful to have children describe a typical episode (perhaps the most recent), including the circumstances of when and where the headache began and how it affected activities at the time. The degree to which the headache problem affects the child's lifestyle influences the management plan for chronic recurrent headaches.

Physical Examination

The blood pressure should be noted even though primary hypertension is an unusual cause of headaches in children. A thorough neurologic examination is needed to determine if findings suggest an emergent problem such as meningitis or potential neurosurgical condition such as intracranial hemorrhage, or brain tumor. The examination should assess for the presence of sinus tenderness by palpation, nuchal rigidity, fundoscopic abnormalities such as papilledema or hemorrhages, and any focal neurologic signs. A brain tumor or other space-occupying lesion may present with ataxia and cranial nerve signs for a posterior fossa lesion; loss of visual fields or

hypothalamic dysfunction (endocrine abnormalities) for a suprasellar or third ventricular region lesion; and hemiparesis, hemisensory deficit, or language dysfunction for a cerebral hemispheric lesion. Personality changes or developmental regression should be especially noted. Increased intracranial pressure (ICP) may lead to papilledema, loss of upgaze, general hypertonicity, leg weakness, positive Babinski sign, spastic gait, loss of continence, or confusion or stupor owing to blockage of CSF by the tumor.

Rarely, children in the midst of a migraine headache may display confusion, aphasia, unilateral numbness or, less commonly, weakness, hemianopsia, or ophthalmoplegia. In these circumstances, the diagnosis of complicated migraine or a migraine syndrome is reached only after other diagnostic tests have eliminated more emergent conditions.

Laboratory Tests

If stiff neck is present and focal or lateralized neurologic signs are absent, an immediate CSF examination is indicated to diagnose the cause of meningeal inflammation. When hemorrhagic fluid is encountered, it is often useful to centrifuge a specimen to check for xanthochromia and to count cells in a subsequent sample to differentiate a traumatic spinal tap from subarachnoid hemorrhage.

Imaging Studies

Recent trauma, persistent vomiting, depressed alertness, crescendo history, change in pattern, or possibly even just recent onset of the headaches all may be indications for an immediate head magnetic resonance imaging (MRI) or computed tomography (CT) scan. Such decisions are also influenced by reliability of follow-up and ease of communication level with the child's caretaker. If signs or symptoms of increased ICP are apparent, a CT or MRI scan must be obtained to diagnose the etiology of the headaches. New focal or general neurologic signs also indicate the need for a CT or MRI scan. Cerebral angiography may be necessary in rare cases to locate a focal source of subarachnoid hemorrhage. Less emergent radiologic studies, but also including CT or MRI, are helpful with the diagnosis of chronic or recurrent sinus headaches.

Management

If a careful assessment has revealed no acute or progressive conditions, pain is not severe, frequency is low, duration is short, and effect on lifestyle or daily activities is minimal, the appropriate management is often just **reassurance**. Frequently, parental anxiety about a potential mass or hemorrhage far outweighs the morbidity produced by the headache symptom itself. Sometimes placing the child's headache problem in context with the parent's or other family member's headaches will help with reassurance, and sometimes in milder cases, non-pharmacologic or nonprescription medication strategies can be agreed on as a management plan. Education and sometimes a headache diary or log helps patients and their families take control and own their own problem (discern triggers and track intervention efficacy).

Questions

Headaches

- Where is the child, what time of day is it, and what is the child doing when a typical headache or the last recalled headache begins?
- Where is the pain located? How severe is the pain? How long does the pain last?
- Is nausea, vomiting, or photophobia associated with the headache?
- What does the child do after getting the headache? Does the episode require cessation of activities?
- Does the child take any medication for the pain? If so, was it successful? What else, if anything, allows the child to feel better?
- How long ago did the first headache occur? Are the headaches becoming more frequent or severe?
- Have headaches ever awakened the child at night?
- Have there been any changes in speech, vision, gait, or personality, or any loss of skills or abilities between headaches?
- Does the child have any warning symptoms before the pain? Does unilateral visual loss, weakness or numbness, diplopia, confusion, or loss of consciousness occur with the headache?
- How often does the child miss school because of a headache?
- Do other members of the family have headaches? Do they ever need to lie down or do they take medicine for these headaches?

However, it may be apparent that the headaches have produced significant discomfort or an effect on lifestyle for the child and treatment is warranted (Table 116-1). Interventions should weigh side effects against effectiveness of treatment. A goal is a reduction in headache frequency, severity, duration, or disability with improved quality of life. Both pain and nausea may need treatment. **Symptomatic treatment** should be taken as soon after the onset of prodromal or headache symptoms as possible, and often the first choice should be an adequate trial of **acetaminophen or nonsteroidal anti-inflammatory drugs**. Headaches in adolescents are often helped by **isometheptene mucate**. For severe, recurrent headaches, serotonin receptor agonists are useful, and **sumatriptan and other triptans** have relatively tolerable but occasionally anxiety-provoking side effects and patients need to be informed about them as with any new medication. Dihydroergotamine or sumatriptan given intranasally are also effective abortive treatments and work faster than the tablets, but they may have a disagreeable taste if they should enter the posterior oropharynx. Refractory very severe headaches may respond to prochlorperazine (Compazine) or intravenous (IV) **dihydroergotamine or dexamethasone along with a bolus of IV fluids**.

The decision to begin a **prophylactic medication** should be based on the frequency and severity of the headaches. Again, the benefits of potentially controlling headache-related symptoms must be weighed against the risk of daily side effects. Anticonvulsants such as **valproic acid and topiramate** have been found to be successful anti-migraine agents. The β -blockers, including **propranolol**, have demonstrated efficacy as prophylactic agents. The antihistamine **cyproheptadine** has also been successful in many patients. **Amitriptyline** is an effective preventive treatment in older children and adolescents; a single bedtime dose should be used at first. A 1- to 2-week trial is necessary before concluding the initial treatment has been ineffective. Amitriptyline can be combined with propranolol if necessary. Calcium channel blockers, such as **verapamil**, and serotonin reuptake inhibitors, such as **fluoxetine**, may also be useful in older children and adolescents. Chronic daily headaches may be successfully treated with education, use of prophylactic medication, avoidance of analgesics because of rebound potential, and helping the children work their way back into a functional daily routine. Healthy lifestyle changes have been beneficial, particularly in adolescents, and biofeedback-assisted relaxation training has had

Table 116-1. Drugs Useful in Childhood Headaches

Table 116-1. Drugs Useful in Childhood Headaches	
Abortive (Symptomatic)	
Acetaminophen, PO	325–975 mg every 4 h (15 mg/kg/dose) (max: 5 doses/24 h)
Ibuprofen, PO	200–800 mg every 6 h (10 mg/kg/dose) (max: 40 mg/kg/24 h)
Naproxen, PO	5–7 mg/kg/dose every 8–12 h (max: 15 mg/kg/ 24 h [age >2 y])
Sumatriptan, SC, IN, or PO	6 mg SC or 5–20 mg IN or 25–100 mg PO (may repeat after 1 h SC, 2 h IN and PO) (max: 2 doses/24 h)
Ergotamine, PR	¼ rectal suppository (2 mg), repeat ¼ suppository every 30 min as needed (max: 4 mg/day [older children and adolescents])
Rizatriptan, PO	5–10 mg orally disintegrating or regular tablets (may repeat after 2 hours) (max: 3 doses/24 h)
Isometheptene mucate with dichloralphenazone and acetaminophen, PO	1–2 caps at onset (may repeat every 1 h to 3–5 caps/day [adolescents])
Dihydroergotamine, IN or IV	4 mg IN (1 spray each nostril, repeat once after 15 min) or 0.25–1 mg at onset and 1 mg/h \times 2 (max: 6 mg/wk [older children and adolescents])
Dexamethasone, IV	4–16 mg single dose (0.25 mg/kg) or rapidly tapering every 6 h
Prochlorperazine, IV	5–10 mg single dose (older children and adolescents) 0.1–0.15 mg/kg/dose (younger children)
Prophylactic	
Propranolol	10–40 mg 2–4 times a day (max: 40–80 mg/24 h if \leq 35 kg 120–160 mg/24 h if >35 kg; no more than 320 mg/24 h)
Cyproheptadine	1–4 mg 2–4 times a day (0.25–0.5 mg/kg/24 h) (max: 16 mg/24 h)
Amitriptyline	10–75 mg at bedtime (max: 150 mg/24 h [older children and adolescents])
Verapamil	40 mg every 8 h (age 1–5 y); 40–80 mg every 8 h (age >5 y) (max: 240 mg/24 h)
Valproic acid	10–15 mg/kg/day initial, 30–60 mg/kg/day maintenance, divided twice a day or every day if ER (max: 60 mg/kg/day [follow clinical signs of toxicity and serum level])
Topiramate	50–200 mg/day divided twice a day after ramping from 25 mg twice a day over a few weeks
Fluoxetine	10 mg every morning initial (max: 40 mg/day [adolescents])

Abbreviations: ER, extended release; IN, intranasally; IV, intravenously; PO, orally; SC, subcutaneously; PR, rectally.

mixed results. If severe environmental stressors or psychological trauma is present as an ongoing headache trigger, patients may benefit from psychotherapy.

Prognosis

Many children with headaches have a good prognosis and do not require ongoing intervention after families are reassured of the benign nature of the problem. For other children, symptomatic medications are frequently effective. Prophylactic medication is necessary in a few cases. For patients receiving prophylactic therapy, periodic withdrawal of the medication should be attempted to establish that it is still necessary. Pediatric patients frequently experience remission of their headaches by late adolescence, and by adulthood, the incidence of headaches has decreased, particularly for males.

CASE RESOLUTION

In the case history, the child's symptoms and the circumstances of the headache suggest a diagnosis of migraine. No laboratory tests or imaging studies are necessary. The girl is begun on amitriptyline and instructed to keep a calendar of headache occurrences. She has 2 headaches in the first 2 weeks, which are aborted effectively with ibuprofen. Following these episodes, she has no further recurrences, and the amitriptyline is withdrawn successfully after 3 months.

Tics

Kenneth R. Huff, MD

CASE STUDY

An 8-year-old boy has unusual recurring behaviors that began 2 to 3 months ago. He stretches his neck or raises his eyebrows suddenly several times a day. Sometimes he is able to suppress these actions. The boy's parents report that in the last 2 years he has displayed several repetitive behaviors, including blinking, grimacing, rubbing his chin on his left shoulder, making a "gulping" sound, and sniffing. Originally they thought the sniffing was related to hay fever, but the boy has no other allergic symptoms. He does not use profane words. In conversations, he sometimes repeats the last phrase of a sentence that was just used whether by himself or someone else. In addition, he must touch each light switch in the hallway every time he leaves his room, and he must retie his shoelaces several times until they are exactly the same length. Although his schoolwork has not deteriorated, he has always had trouble completing tasks and finishing homework. Both his teacher and his best friend have asked about his strange

behavior. His mother has a "psychological" problem with her son's gulping sounds (ie, they recur in her own mind), and she recalls that her father had a habit of frequently looking over one shoulder for no apparent reason.

Although during examination the boy does not exhibit any unusual behaviors, he raises his eyebrows twice and places his hand over his crotch several times while his parents are interviewed. Except for mild fine motor incoordination, the neurologic examination is normal.

Questions

1. What are the characteristics of tics?
2. What are the social implications of tics?
3. Should pharmacologic treatments be part of the management of tic disorders?
4. What other problems are associated with the tic disorder that also should receive intervention?

Tics are brief, abrupt, non-purposeful movements or utterances. They occur in a background of normal activity and are repetitive and involuntary but can be suppressed. Tourette disorder is a common etiology of tics in children. It is defined by multiple types of tics displayed over time. These include both motor tics and vocal tics produced by some sudden movement of air or saliva within the larynx, nasopharynx, or oropharynx, causing a perceptible sound. Tourette disorder frequently manifests solely as a nondisabling movement disorder but may also be associated with other neurobehavioral problems, which may include attention-deficit/hyperactivity disorder (ADHD), obsessive-compulsive disorder, mood and rage disorders, anxiety, and personality and conduct difficulties that may be more disabling than the tics.

Epidemiology

Tics are relatively common in children but often go unrecognized as a movement disorder. The onset of tics associated with Tourette disorder is generally between 5 and 12 years of age but can be as late as 21 years of age. The prevalence of tics is 5 times higher in males than in females. By various estimates, the Tourette disorder prevalence is between 0.1% and 3%, but many cases of Tourette disorder are familial, and other family members may have symptoms so mild that they never seek medical attention. In addition, some family members may have only non-tic manifestations of the syndrome,

such as obsessive-compulsive symptoms, but data support a relationship between tics and obsessive-compulsive symptoms.

Clinical Presentation

Children with tics display sudden repetitive movements of the face, neck, shoulders, or hands in the context of normal behaviors, and normal behaviors are sometimes used to mask the tics. Sometimes tics can be suppressed for periods, such as when they would be embarrassing or during a time of intense physical activity, concentration, or performance, but they also may be worsened by stress or strong emotional feelings. Tics associated with Tourette disorder will vary in their manifestations over periods of weeks to months. Some examples of tics are blinking, eye rolling, grimacing, neck stretching, head turning or shaking, shoulder shrugging, and wrist flicking. Tics may either mimic normal, sometimes complex, movements or involve a series of orchestrated simple movements, such as sequential finger flexing, wrist bending, and arm stretching. Tics may include sudden repetitive sounds from the vocal apparatus (Dx Box). The sounds may include throat clearing, sniffing, sucking, or blowing. In addition, children with Tourette disorder may also have socially inappropriate words or gestures or repeat what they have just said or heard.

Children with Tourette disorder may have learning problems including easy distractibility and inability to finish schoolwork.

Dx Tics

- Sudden, brief uncontrolled movements
- Repetitive sounds from the vocal apparatus
- Behaviors occurring in the context of or mimicking normal behaviors but having no purpose

They also may have intrusive or repetitive thoughts, unfounded fears, or ritualistic actions that may involve touching, cleanliness or neatness, counting and exactness, symmetry or evenness, or irrational checking.

Classifications of tics according to the nature of the action can be helpful in understanding apparently widely different movements as being part of the same disorder because of ultimately shared central nervous system chemistry or circuitry (Box 117-1). Clonic tics are brief and dystonic tics are more sustained movements. In addition to simple tics, patients may rarely have other unusual behaviors (complex tics) including echopraxia (repetitive gestures), copropraxia (obscene gestures), and coprographia (obscene writing). Unusual speech patterns include irrelevant or nonsense words, palilalia

Box 117-1. Types of Tics Seen in Children With Tourette Disorder

Simple Tics

- Clonic
- Dystonic

Complex Tics

- Series of different or similar simple tics
- More complicated coordinated movement
- Copropraxia and coprographia

Vocal Tics

- Oropharyngeal, nasopharyngeal, or laryngeal sounds
- Consonants or syllables
- Meaningless or nonsense words or phrases
- Coprolalia
- Palilalia and echolalia

Sensory Tics

Box 117-2. Misconceptions in Diagnosing Tourette Disorder

- Attributing the unusual tic symptom to attention-getting or emotionally based behavior
- Diagnosing the episodic behavior as a seizure on the basis of inadequate historical information
- Attributing a vocal tic to an upper airway, sinus, or allergic condition
- Attributing an ocular tic to an ophthalmologic problem
- Requiring tics to be observed in the office before making the diagnosis
- Waiting for coprolalia to be present before making the diagnosis
- Assuming severe tics are necessary for the diagnosis, or assuming mild tics are a normal developmental phase

(repeating one's own words), echolalia (repeating another's words), and coprolalia (obscene speech). Many affected children describe a sensory tic, which is an indescribable, uncomfortable feeling that is relieved by a motor tic. Diagnosis is often delayed because of misunderstandings about the common and uncommon manifestations of Tourette disorder (Box 117-2).

Pathophysiology

Tics are thought to be generated from a functional abnormality in deep brain nuclei that might include the striate nuclei, the globus pallidus, the subthalamic nuclei, and the substantia nigra. The frontal cortex, thalamus, and limbic systems may also be involved.

Dopaminergic neurotransmission within these structures is likely to be part of the abnormal function because of one class of medication (stimulants) worsening the symptoms and another class (dopamine antagonists) effective as a treatment. In patients with Tourette disorder, the cerebrospinal fluid contains low baseline levels of homovanillic acid, a dopamine metabolite, which could result, as has been hypothesized, from a hypersensitive dopamine receptor. In addition, amphetamines and methylphenidate increase dopamine release, and in some instances, these agents precipitate tic symptoms. Haloperidol, an effective tic-suppressing medication, blocks the dopamine receptor and, therefore, may block a potentially hypersensitive receptor for dopamine. The observations of good clinical response with low doses of haloperidol and the finding of increased homovanillic acid levels remaining high long after disappearance of the neuroleptic drug due to receptor desensitization both support this hypothesis. The physiology may be more complex than that encompassed by this hypothesis, and other transmitters are probably involved as well because effective medications in other classes are also useful.

Recently an autoimmune hypothesis has been generated to explain an association of the sudden onset of tics and/or obsessive-compulsive symptoms with preceding group A streptococcal infections of the pharynx. This association has been termed PANDAS (pediatric autoimmune neuropsychiatric disease associated with streptococcus). It is intriguing that a clear relationship has been known for some time between the same bacteria and another movement problem, Sydenham chorea, but the evidence is conflicting and unconfirmed by large studies for the bacteria's role in common neuropsychiatric disease such as Tourette disorder or obsessive-compulsive disease and, therefore, routine screening has not been recommended.

Differential Diagnosis

The duration, frequency, and appearance of the movement and circumstances of occurrence of tics help distinguish them from several other episodic movement disorders. Myoclonus is a lightning-like, non-suppressible jerk of a small group of muscles, and chorea involves nearly constant, small amplitude movements of the fingers, hands, and feet that are often accompanied by grimacing movements of the face. Tremor is an oscillatory movement of an

extremity or the head. Hemiballismus is an uncontrollable episodic throwing movement of an extremity. Hyperexplexia is a hyperactive startle response provoked by touch or sudden noise. Torticollis, or neck writhing, may be paroxysmal but is generally part of either a benign transient disorder or a chronic degenerative disorder, such as familial dystonia. Paroxysmal kinesigenic choreoathetosis, an unusual episodic condition precipitated by a sudden movement, is characterized by a twisted trunk and limb posture lasting a few seconds (longer than tics, generally) and not accompanied by loss of consciousness. Hypnagogic jerks and bruxism are persistent normal variant behaviors that occur in sleep.

Other repetitive behaviors are sometimes confused with tics. Compulsions are complex actions that are done against one's will or better judgment. Stereotypies are persistent repetitive senseless movements. Perseverative behaviors are continued activity after the cause for it has ceased. Self-injurious behaviors are usually biting or banging of a body part during periods of agitation. Addictive behaviors occur with psychological dependence due to a reward system. Habits are fixed practices established by repetition. Mannerisms are stereotyped movements or habits peculiar to an individual and part of their personality. Anger outbursts are sudden emotion-generated behaviors occurring with relatively little provocation.

Tic disorders are sometimes divided into 3 groups: (1) **simple transient tics**, which are monomorphic (always the same appearance over a period of months), last less than 12 months, and may be caused by particular environmental situations or psychological states; (2) **chronic tics**, which last longer than 12 months but are a single type; and (3) the **tics of Tourette disorder** (Box 117-3). However, all 3 types of tic disorders are sometimes found in the same family.

Box 117-3. Conditions Necessary for Diagnosis of Tourette Disorder

- Multiple motor and vocal tics variably manifested over time
- Tics present for at least 1 year
- Onset of tics before 21 years of age
- Tics not due to another known condition or substance

Evaluation

History

A thorough history should be taken when evaluating children with potential tic disorders. The physician should find out as much as possible about the duration, circumstances of occurrence, and frequency of the movements (Questions Box). Parents may imitate the behavior or, if possible, bring in a videotape of the child's behavior. This may give the physician more telling information than verbal descriptions. The physician should describe suggested tic behaviors because the parent may not be aware these behaviors may be tics.

Questions

Tics

- How long and how often has the child been displaying the unusual behaviors?
- In what circumstances do the unusual behaviors occur? For example, do the behaviors occur when the child is eating or sleeping, engrossed in an activity, or excited? Or do they occur when attention is on the child or after a startle or other triggering behavior?
- Can the parents or other caregivers imitate the child's unusual behavior?
- Is the child having difficulty at school (cognitively or socially)?

Physical Examination

Frequently tics are not seen by the physician when observing the child directly because the child is able to suppress them, but the physician may still be able to see the child's tics. The physician might be able to observe the child unobtrusively while the child and family are still in the waiting room. The child can be observed for tics "out of the corner of one's eye" during the course of the parent interview and examination. As part of the examination, a screen of cognitive abilities and fine-motor coordination should be included because of the comorbidity of ADHD and other learning disabilities and associated fine motor dysmaturity.

Laboratory Tests

There are no definitive diagnostic or supportive laboratory tests for Tourette disorder or for confirming the presence of tics. Children with atypical or ambiguous movement disorders should be screened for potential metabolic abnormalities, including routine determinations of calcium, magnesium, glucose, liver function enzymes, and ceruloplasmin levels (for Wilson disease). Thyroid function tests may also be requested if there are other signs or symptoms of thyroid dysfunction.

Imaging Studies

Imaging has been largely used in research evaluations of Tourette disorder patients where it has demonstrated volumetric increases in primarily right frontal white matter and the anterior parts of the corpus callosum in magnetic resonance imaging (MRI) studies, reduced right basal ganglia activity in single-photon emission computed tomography studies, and increased right caudate and frontal cortex activity in functional MRI studies during tic suppression. These imaging modalities have not yet proven clinically useful in the care of individual patients, however.

Management

Goals of management should include (1) reduction in the frequency of tics during critical circumstances with a minimum of medication side effects and (2) attention to the other coexisting learning or behavioral disabilities. Before physicians prescribe drug treatment, they must consider the severity of the tic disorder and its potential

or actual production of psychosocial disability or lack of it. Some children do not need medication for the movement disorder, and they and their families can be reassured by an understanding of the problem. Other patients may experience remission for weeks or months, during which they can reduce or discontinue their medications. Several classes of drugs are useful in the treatment of tic disorders. A first-line medication because of its relatively good efficacy, side-effect profile, and convenience is the **Catapres** transdermal skin patch containing clonidine, an α_2 -adrenergic agonist. Dosage is titrated using the minimally effective size and strength of the patch. Guanfacine, an oral formulation in the same class, is also effective. The atypical antipsychotics, particularly risperidone, have also been effective with sometimes less sedation or potential for extrapyramidal side effects than tranquilizing dopamine blockers. Another useful medication is the neuroleptic **pimozide** (Orap). An electrocardiogram is recommended before beginning this medication because it has been associated with prolonged QTc. Concomitant use of inhibitors of CYP3A liver metabolism should not be given. **Haloperidol** has been useful in divided doses starting as low as 0.5 mg/day up to 2 to 6 mg/day. Children should begin with a low dose that is then titrated up to maximum efficacy or development of intolerable side effects. A potential disadvantage of haloperidol and other antipsychotics such as fluphenazine is cognitive sedation and the small possibility of tardive dyskinesia. **Botulinum toxin type A** injections may be useful for isolated persistent tics occurring in “needle-accessible” locations. Behavioral approaches including habit reversal training may be viable alternatives in some cases.

Treatment for children with Tourette disorder should be multimodal and prioritize, address, and monitor all problematic aspects of the syndrome (Box 117-4). Children with Tourette disorder should be assessed for learning disabilities including ADHD. Interventions may include organizational aids, homework time management, reduction in potential environmental distractions, and more **individualized instruction**. **Pharmacologic therapy** may include the Catapres patch, a tricyclic antidepressant, atomoxetine, or a stimulant. Long-acting methylphenidate or mixed amphetamine salt preparations are not necessarily contraindicated in children with Tourette disorder; these drugs do not worsen tics in all patients. Children with Tourette disorder are also susceptible to obsessive-compulsive symptoms. **Fluoxetine**, **sertraline**, and **clomipramine** are most useful for this comorbid problem.

Children with Tourette disorder and their families also frequently benefit from **lay educational materials** about the disorder. **Support groups** composed of other families that have children with the syndrome and local chapters of the Tourette's Syndrome Association may help. Referral for psychological or psychiatric counseling for patients and their families may be necessary because in its severe form, Tourette disorder may be socially devastating and may provoke secondary frustrations, low self-esteem, depression, and other emotional problems as well as the primary psycho-behavioral difficulties that may be part of the syndrome.

Box 117-4. Therapies Useful in Tourette Disorder

Tics

- Clonidine (Catapres transdermal patch): α_2 -adrenergic agonist
- Risperidone (low dose) serotonin dopamine receptor antagonist
- Haloperidol (low dose): dopamine receptor blocker
- Pimozide (Orap): dopamine receptor blocker
- Fluphenazine: dopamine receptor blocker
- Guanfacine (Tenex): α_2 -adrenergic agonist

Attention-Deficit/Hyperactivity Disorder and Learning Disability

- Clonidine (Catapres transdermal patch): α_2 -adrenergic agonist
- Methylphenidate: if tics are not worsened
- Atomoxetine: norepinephrine transporter inhibitor
- Desipramine: tricyclic antidepressant
- Education interventions: individualized or small-group instruction

Obsessive-Compulsive Disorder

- Fluoxetine (Prozac): serotonin uptake inhibitor (non-tricyclic)
- Clomipramine (Anafranil): tricyclic antidepressant

Depression and Adjustment Problems

- Psychotherapy (individual and family)
- Imipramine: tricyclic antidepressant
- Support group

Prognosis

The prognosis in most children with tics is good. Less than 20% of adults and older children who were symptomatic in grade school continue to manifest clinically significant tic symptoms. Some symptomatic children, however, have ongoing problems with a productive educational experience or developing appropriate peer relationships. Therefore, according to the severity of these issues early in childhood, the physician must individualize the management strategy to achieve a favorable prognosis later when educational and social problems may be harder to reverse. Because the movements may change or even remit over long periods, the psychological adjustments become very important in the long-term prognosis.

CASE RESOLUTION

The boy in the case history is diagnosed as having Tourette disorder. After a discussion with his family about the disorder, he is treated with Catapres patches. A questionnaire is sent to his teacher concerning ADHD symptoms at school. At a 6-week follow-up visit, he has fewer tics and is doing better in school (classroom situation of 15 students for most of the day).

Acne

Monica Sifuentes, MD

CASE STUDY

A 15-year-old adolescent male comes to your office for a preparticipation sports physical. He is healthy and he has no questions, complaints, or concerns.

The adolescent is well developed and well nourished, with normal vital signs, including blood pressure. The physical examination is entirely normal except for the skin. Multiple closed comedones (whiteheads) are noted along the hairline. Erythematous papules and pustules are present across the forehead and over both cheeks. Scattered open comedones (blackheads) are located over the nose and cheeks as well. The chest and back are clear, with no lesions.

Questions

1. What is the pathogenesis of acne vulgaris?
2. What are some contributing factors in the development of acne?
3. What are the different types of acne lesions?
4. What management options are available for the treatment of mild, moderate, and severe acne in adolescents?
5. What are the indications for the use of isotretinoin?
6. What is the prognosis for adolescent patients with acne?

Acne vulgaris is a common condition that most frequently occurs in adolescents. The spectrum of disease varies among individuals and is caused by a variety of factors. Regardless of the etiology and extent of acne, the disease can be devastating to adolescents both physically and psychologically. Primary care physicians should, therefore, acknowledge acne as a medical problem, even when patients do not mention it initially, and should treat the condition as a chronic disease.

Epidemiology

Most cases of acne that require treatment occur in individuals 9 to 19 years of age, although the condition can also affect young infants and adults. Boys and girls are equally affected, but the condition is usually more severe in males and typically lasts longer in females. Certain individuals may be genetically susceptible to acne. Caucasian teens are more likely to have acne than African American and Asian teens. Certain cultural practices, such as the use of oil-based hair care products by some African Americans, also can lead to a specific pattern of lesions along the forehead and temporal areas (pomade acne). Estimates indicate that more than 85% of adolescents in the United States are affected with acne and that more than \$1 billion is spent annually on acne treatments. And although acne is generally believed to be a pubertal event, a fair number of young adults continue to manifest lesions after 25 years of age.

Several factors contribute to the development of acne-like eruptions. Internal agents include endogenous hormones (eg, androgens, progesterone) and specific drugs (eg, progestin-only contraceptives, isoniazid, phenytoin, corticosteroids, anabolic steroids, lithium-containing compounds). External agents include skin bacteria, especially

Propionibacterium acnes; industrial chemicals (eg, petroleum, animal and vegetable oils); oil- or wax-containing cosmetics; greasy sunscreen or suntan preparations; and local pressure from objects such as headbands, shoulder pads, helmets, or chin straps. Excessive perspiration and emotional stress also can aggravate acne. Specific foods such as chocolate, caffeine-containing soda, pizza, and french fries have not been shown to cause or worsen acne, although this is controversial.

Clinical Presentation

The lesions of acne vulgaris primarily affect the face, especially the cheeks, forehead, and chin; the chest; the back; and the shoulders. Lesions can be non-inflamed or inflamed (Dx Box). Non-inflamed lesions, or comedones, can be opened or closed to the environment. Closed comedones (whiteheads) are small, flesh-colored bumps, and open comedones (blackheads) contain central, dark material. Inflamed lesions are typically erythematous papules, pustules, or nodules and may be more cystic in appearance.

Dx Acne

- Occurrence predominantly during puberty
- Lesions more severe in males
- Location on face, chest, back, and shoulders
- Non-inflamed, open comedones (blackheads) or closed comedones (whiteheads)
- Inflamed papules or pustules
- Nodules, cysts, or scarring may be present
- Possible exacerbation premenstrually or related to stress

Lesions are generally concentrated in the centofacial areas or “T-zone” early in the course of acne. The T-zone includes the forehead, nose, and chin areas, which are rich in sebaceous glands. Over time, lesions can develop in other areas of the body, such as the neck, chest, shoulders, and back.

Pathophysiology

Although the exact etiology of acne remains unclear, the pathogenesis of acne involves certain processes that occur within the pilosebaceous unit.

- 1. Abnormal follicular keratinization.** The earliest change in the formation of acne occurs in the horny cells that line the sebaceous follicle. A disturbance in the differentiation of these cells leads to excessive shedding of the cells into the lumen. Impaction of the follicle occurs as these horny cells stick together.
- 2. Overproduction of sebum.** The sebaceous gland is highly responsive to hormonal stimulation, namely androgens. With the rise in androgens during puberty, hypertrophy of the sebaceous gland occurs, and the production of sebum is increased. The flow of sebum is obstructed by the above follicular hyperkeratosis, resulting in retention of all material.
- 3. Proliferation of *P. acnes*.** The overproduction of sebum in acne provides a ripe environment for the proliferation of *P. acnes*, an anaerobic diphtheroid that, along with *Staphylococcus epidermidis* and *Pityrosporum ovale*, is part of the microflora of the sebaceous follicle. In addition, *P. acnes* possesses a lipase that hydrolyzes sebum triglycerides into free fatty acids. These acids irritate the follicular wall and cause inflammation.
- 4. Inflammation.** The expulsion of sebum into the dermal layer of the skin occurs as a result of the rupture of the pilosebaceous follicle. This initiates an inflammatory process and the formation of inflammatory lesions such as pustules and cysts. In addition, *P. acnes* produce biologically active extracellular materials, which increase the permeability of the follicular epithelium. The bacterium also produces chemotactic factors that are responsible for the migration of inflammatory cells to the area.
- 5. Comedones.** The above processes can lead to a number of noninflammatory and inflammatory lesions (Table 118-1). Comedones are early noninflammatory lesions made up of sebum, horny cells, and bacteria. They can be closed or open. A **closed comedo**, or **whitehead**, is a dilated plugged sebaceous follicle that is closed to the surface of the skin. An **open comedo**, or **blackhead**, occurs as a result of dilatation of the follicular orifice at the surface of the skin and open communication with the outside environment. The dark color at the surface of the skin, however, is not dirt and may be from a number of processes such as oxidation of melanin in the horny cells, interference with the transmission of light through compacted epithelial cells, or the presence of certain lipids in sebum.

Table 118-1. Classification of Acne

Category	Physical Findings
Grade I	Noninflammatory acne → open and closed comedones Closed comedones then lead to any of the next 3 levels of inflammatory acne
Grade II	Early inflammatory acne → presence of comedones and papules (obstructed follicles)
Grade III	Moderate, localized inflammatory acne → pustules or larger, more inflamed papules
Grade IV	Severe, more generalized inflammatory acne → cystic, nodular lesions

- 6. Pustules and papules** are inflammatory lesions. Pustules lie in the superficial epidermal layer of the skin, and papules occur in the lower dermal layer. Because of their deeper location, they are often accompanied by a more severe inflammatory reaction, and scarring may result. **Nodules** or **cysts** are suppurative inflammatory lesions located deep within the dermis. Associated with the most severe form of acne, nodules are the result of deep pustules that rupture and then become lined with epithelium. When nodules are present, significant scarring can be a major problem.

Evaluation

History

The primary historical issues to explore in patients with acne vulgaris are both medical and psychological (Questions Box). From a medical standpoint, practitioners should determine how long the acne has been present and if the condition has ever been treated. Psychological aspects should include questions to assess the patient's overall self-esteem. Expectations regarding treatment and recovery also should be assessed at the initial visit before therapy is begun.

Physical Examination

The physical examination should focus on the primary sites of acne: face, chest, back, and shoulders, although the entire skin should be inspected closely at the first visit. Individual lesions should be checked for signs of inflammation and infection at each follow-up visit. Their distribution also should be recorded along with their response to treatment. The presence or absence of scarring should be assessed as a measure of the severity of acne and a predictor of outcome. Young women with very irregular menses and obesity should be examined for hirsutism, which might indicate excessive adrenal or ovarian androgen production as a contributor to the development of acne.

Laboratory Tests

In general, no laboratory studies are needed either at the time of the initial evaluation or during the treatment of mild to moderate acne. If there is a history of abnormal menses and evidence of hirsutism

Questions

Acne

Medical Aspects

- How long has the adolescent had acne?
- Has the adolescent ever received treatment for acne?
 - How long did treatment continue?
 - What treatment methods were used?
 - For what reasons was the therapy discontinued?
- Is the adolescent currently using any treatment products?
 - Do the lesions seem to be getting better or worse?
- If the acne has never been treated, is treatment desired?
- Do any activities, medications, or environmental agents seem to exacerbate the lesions?
- Does the adolescent have a family history of acne?
- Is the adolescent taking any oral medications?
- Does the adolescent have any other medical conditions?

Psychological Aspects

- Is the adolescent bothered by the lesions?
- Is the adolescent embarrassed about his or her appearance? If so, does this embarrassment prevent the adolescent from participating in certain activities?
- Is the adolescent ever ridiculed by his or her peers because of the acne?

For postpubertal females

- Does the acne worsen prior to menses?
- Are menses regular?
- Is there any evidence of hirsutism?
- Is the adolescent sexually active?
- Is she using any hormonal contraception?

or virilization in the adolescent female, a free testosterone, early morning cortisol and 17-hydroxyprogesterone, and serum dehydroepiandrosterone sulfate (DHEAS) levels are indicated to differentiate between the various causes of hyperandrogenism. In the case of severe acne when isotretinoin is indicated, several pretreatment studies are necessary. A complete blood cell count, liver function tests, and a fasting lipid profile are recommended. In addition, a pregnancy test must be performed prior and to within 2 weeks of starting isotretinoin in female adolescents. These studies should be obtained in consultation with a dermatologist, who is generally responsible for prescribing isotretinoin.

Management

The general management of acne begins with counseling and should include patient education regarding the pathophysiology of the condition to dispel any myths regarding its etiology and treatment. In addition, the patient's motivation should be assessed to better individualize therapy. Realistic expectations regarding duration of therapy and likely outcome of treatment should be reviewed with the teenager. Parental involvement helps optimize care in cases of severe acne.

All adolescents with acne should follow these general recommendations:

1. Wash skin with mild soap and water once or twice daily. Frequent washing will not improve acne and may irritate the skin.
2. Use cosmetics, sunscreens, and moisturizers sparingly or switch to oil-free products that indicate they are noncomedogenic.
3. Avoid picking at lesions and excessive scrubbing, especially with abrasive cleansers. Traumatizing acne lesions may contribute to scar formation.
4. Note that dietary modifications generally are not indicated.
5. Use sunscreen and restrict ultraviolet therapy.
6. Follow the prescribed regimen carefully (Table 118-2) and understand that long-term treatment is often required.

Table 118-2. Treatment of Acne^a

<i>Classification</i>	<i>Recommended Treatment Regimen</i>
Grade I (mild)	Benzoyl peroxide (BP) 2.5%–5% every other day or at bedtime May increase to twice a day, if no response and tolerated, and/or topical retinoid at bedtime
Grade II (mild-moderate)	BP and/or topical retinoid as above plus topical antibiotics once or twice a day if inflammation present, or topical combination product (BP combined with antibiotic) and/or topical retinoid at bedtime
Grade III (moderate)	BP in the morning and topical retinoid at bedtime plus oral antibiotic
Grade IV (severe)	Above treatment for grade III acne, plus referral to a dermatologist for consideration for treatment with isotretinoin

^aCourtesy of Victor C. Strasburger, MD.

The specific therapies prescribed depend on the severity and duration of the acne, the type of lesions, and patients' ability to comply with the proposed treatment regimen. The patient's skin type should be taken into consideration when selecting the appropriate vehicle for the active ingredient, such as a cream, gel, lotion, solution, or ointment. Oily skin types tend to respond better to gels or solutions, whereas creams, lotions, and ointments are better for dry skin. The most effective regimens include topical products such as benzoyl peroxide, retinoic acid, and antibiotics; systemic antimicrobials; hormonal agents; and isotretinoin. Most often, however, combination therapy is used and later modified according to the patient's response. Physicians should remember to discuss with the adolescent that the acne often looks worse before it gets better and that the treatment is long-term. Noticeable improvement usually takes at least 6 to 8 weeks.

Topical Therapy

Several topical products are available for the treatment of acne. **Benzoyl peroxide (BP)** is bactericidal for *P acnes* and acts as a comedolytic agent as well. It should be considered as the first line of therapy for the management of both comedonal and mild inflammatory acne. Although over-the-counter products are available, the more effective gel preparations are preferable and available by prescription. The lowest concentration possible should be used initially (eg, 2.5% or 5% concentration). Higher concentrations may be used in cases in which the trunk or back are involved, however, increasing the concentration does not necessarily increase its efficacy and may just result in more irritation.

Therapy should be initiated gradually, especially if used in combination with retinoic acid, because BP is inherently irritating and drying. Initially, a thin application should be used once a day every other day, and the frequency should be increased as tolerated. Allergic contact dermatitis rarely develops, but if it does, treatment must be discontinued. A nonacneogenic, noncomedogenic sunscreen is recommended as well to protect against the photosensitivity associated with BP usage.

Tretinoin or retinoic acid (Retin-A, Avita) is the mainstay of therapy for noninflammatory or comedonal acne. This vitamin A derivative reduces microcomedo formation by normalizing follicular keratinization and decreasing the adhesiveness of horny cells shed into the follicular lumen. It also has some anti-inflammatory effects. It is available by prescription as a gel, cream, or liquid in several different concentrations. Recently, microsphere technology has become available, which is less irritating and allows the medication to be delivered slowly at higher concentrations. It seems to be as effective as the older formulations.

Like BP, retinoic acid can be very irritating and may cause some erythema, peeling, stinging/burning, and dryness, which are thought to be dose-dependent. Therefore, therapy should be initiated cautiously with a cream or gel, which is less potent and drying than the liquid preparation. To further reduce irritation, patients should be instructed to wash with a mild soap no more than 2 times a day and to wait at least 20 to 30 minutes for the skin to dry completely before applying the product. Physicians often recommend that patients apply retinoic acid before bedtime rather than in the mornings, which tend to be more hectic for the average teenager. A small, pea-sized dot of tretinoin should be used each time and divided into 3 smaller dots on the skin before rubbing a thin film gently to most of the face, concentrating on the affected areas but also applying it to some of the less affected skin. Patients also should be cautioned against excessive sun exposure while using retinoic acid because this agent lowers the sunburn threshold. Combined daily treatment with BP is warranted in cases of mild inflammatory acne; however, because BP inactivates tretinoin, the 2 drugs cannot be applied simultaneously. Most clinicians recommend BP in the morning and tretinoin at night.

Adapalene (Differin) and tazarotene (Tazorac) are 2 relatively new third-generation topical retinoids that have been used in the

treatment of acne. Adapalene is less irritating and has been shown to be more photostable than tretinoin; however, it is not approved for children younger than 12 years. It is available in an alcohol-free gel, cream, or solution. Tazarotene, originally created for the treatment of psoriasis, is the most effective of the topical retinoids, but is more expensive and irritating than the other retinoids, and there are concerns about its teratogenicity. It is therefore not widely prescribed for the treatment of acne.

Azelaic acid (Azelex), a naturally occurring derivative from wheat, has both antibacterial and anti-keratinizing activity. It inhibits the growth of *P acnes* and has an antiproliferative effect on keratinocytes. Although less potent than tretinoin, azelaic acid may be useful in patients with mild to moderate inflammatory and comedonal acne who cannot tolerate topical tretinoin or BP because it seems to be less irritating. Pruritus, burning, stinging, tingling, and erythema have been reported, however. It is available by prescription as a 20% cream and should be applied twice daily.

Antibiotic Therapy

Both topical as well as systemic antibiotics can be used in the treatment of mild to moderate inflammatory acne. The choice of which to use usually depends on the extent of skin involvement and severity of inflammation. **Topical antibiotics** are often useful in patients with mild inflammatory lesions that are unresponsive to BP or retinoic acid alone. Such antibiotics act by inhibiting the growth of *P acnes* and reducing the number of comedones, papules, and pustules. Erythromycin, tetracycline, and clindamycin are available as topical preparations. The **erythromycin gel** is most popular; the recommended dosage is twice daily. Allergic reactions from topical formulations rarely occur. Compared with systemic antibiotics, topical preparations have fewer systemic side effects because of decreased absorption. Topical antibiotics alone are not recommended as monotherapy because resistance generally develops with prolonged use and the therapeutic response can take a while. Both erythromycin and clindamycin are available in combination with benzoyl peroxide and are very effective against *P acnes*; however, combination preparations are generally more costly.

Systemic antibiotics are the mainstay of therapy in patients with nodular or cystic inflammatory acne and in patients who have not responded to topical antibiotics or who have inflamed lesions involving the trunk as well as the face. However, systemic agents have not been shown to be effective with comedonal acne. The success of oral antimicrobial therapy relates to the suppression of *P acnes* and the inhibition of bacterial lipases. As a result, free fatty acids and other by-products are reduced, thereby decreasing inflammation.

Tetracycline and its derivatives (**doxycycline and minocycline**) are the preferred first-line oral antibiotics for the treatment of moderate to severe inflammatory acne. Alternatives include amoxicillin, co-trimoxazole, and trimethoprim. Other systemic antibiotics such as erythromycin have been used in the past; however, antibiotic resistance is now a problem. In addition, clindamycin is used much less frequently because of its associated side effects

like pseudomembranous colitis. Doxycycline and minocycline are particularly beneficial when lesions fail to respond to tetracycline. However, tetracycline and doxycycline are not recommended in children younger than 9 years or in pregnant females. The most common side effects include candidal vaginitis, especially in females who also take oral contraceptives (OCPs); gastrointestinal (GI) disturbances; and photosensitivity. The ultimate goal of oral antibiotic therapy is use of the minimum dose to control lesions and minimize side effects. Most patients require prolonged or frequent intermittent courses of oral antibiotics, however, before remission occurs. In general, the dose of the antibiotic and the dosing interval should not be reduced before a significant clinical effect is seen, which may take 6 to 8 weeks. At that time the dose of the oral antibiotic may be gradually tapered and topical antibiotic treatment may be substituted.

Hormonal Therapy

Hormonal therapy is indicated in menstruating females who are unresponsive to other forms of treatment and who are candidates for isotretinoin. Oral contraceptives antagonize the action of circulating androgens by increasing the production of sex-binding globulin, which decreases biologically active free testosterone. In addition there is decreased androgen production by the ovaries through feedback inhibition of pituitary gonadotropin secretion. Clinical improvement in inflammatory lesions has been reported with ethinyl estradiol (35 µg) and the progestin norgestimate (Ortho Tri-Cyclen) and ethinyl estradiol/drospirenone (Yasmin). In general, OCPs must be taken for 2 to 4 months before any improvement is seen, with relapses occurring if treatment is discontinued. Ortho Tri-Cyclen and Estrostep have been approved by the US Food and Drug Administration (FDA) specifically for their antiandrogen effects, although other OCPs have shown similar efficacy in reducing acne lesions.

Specific endocrine disorders such as polycystic ovarian syndrome and the metabolic syndrome also may exacerbate acne and should be investigated in female adolescents with a history of oligomenorrhea, hirsutism, obesity, and insulin resistance. In these cases, hormonal therapy will treat the hyperandrogenism as well as the accompanying acne by decreasing adrenal androgen production.

Systemic Therapy

Because sebaceous glands are androgen-dependent, antiandrogens such as spironolactone can reduce sebum production, and therefore improve acne. However, this therapy is generally reserved for adult females. Doses range from 100 to 200 mg/d; however, lower doses may also be effective. Several months of spironolactone therapy are needed for maximum benefit, with prolonged therapy often required. Gynecomastia occurs not infrequently. Agranulocytosis is a rare complication.

Isotretinoin Therapy

Isotretinoin (Accutane, Claravis, Sotret, Amnesteem), a systemic oral analog of vitamin A, is currently the most effective treatment available for severe nodulocystic acne that is resistant to conventional

therapy. This agent is also useful in patients with a propensity for scarring. It influences all aspects of acne formation: sebum secretion, follicular keratinization, and inflammatory responses. For patients with severe forms of inflammatory acne, isotretinoin has been hailed as a “miracle drug,” despite its many side effects.

Given the numerous potentially serious adverse effects of the drug, referral to a dermatologist is strongly recommended for patients who require isotretinoin therapy. The most significant of these adverse effects is teratogenicity, although other issues include dryness and chapping of the skin and mucous membranes, musculoskeletal effects, GI issues, neurologic problems, and hematologic abnormalities. Isotretinoin can also elevate triglyceride levels, particularly in patients with diabetes mellitus, obesity, alcohol abuse, and familial hyperlipidemia. There also are psychiatric concerns regarding isotretinoin use, including aggressive and/or violent behavior, and an increased risk of depression or suicide, which has led to additional black box warnings by the FDA. Although an association has not been confirmed to date, clinicians are advised to be aware of the coexistence of a mental health disorder when prescribing isotretinoin and are urged to monitor patients closely for a psychiatric referral if indicated.

To minimize fetal exposure to isotretinoin, a special restricted distribution program called iPLEDGE is now administered by the FDA for physicians and pharmacists who prescribe systemic isotretinoin. This computer-based risk management program includes specific educational materials as well as policies and procedures that must be read and signed by the prescribing physician. In addition, informed consent is required of all patients for whom the medication is being prescribed. Two forms of birth control for female patients and documentation of a negative pregnancy test also is required prior to dispensing of the medication. An identifying qualification sticker also must be affixed to all isotretinoin prescriptions indicating the prescribing physician is appropriately registered with the FDA distribution program. Monthly follow-up by the prescribing dermatologist is mandatory.

Prognosis

Fortunately, most uncomplicated cases of acne (approximately 90%) resolve by the third decade of life. For those individuals with nodulocystic lesions, however, acne and significant scarring can continue to be a problem. Therefore, early and aggressive treatment is imperative.

CASE RESOLUTION

In the case history, the adolescent should be offered treatment for his mild to moderate comedonal and inflammatory acne. This may include BP, retinoic acid (Retin-A), and topical antibiotics. The common side effects of the medications (eg, dry skin, peeling) should be reviewed, and the teen should be instructed to use a noncomedogenic sunscreen. A follow-up appointment should be arranged after 3 to 4 weeks to assess compliance with and tolerance of the treatment regimen.

Disorders of the Hair and Scalp

Ki-Young Suh, MD; Kathy K. Langevin, MD, MPH; and Noah Craft, MD, PhD

CASE STUDY

A 6-year-old child presents with a 1-month history of a swelling on the right side of her scalp that is associated with hair loss. She has previously been in good health, and she has no history of fever. On examination, she is afebrile, has normal vital signs, and appears well. An area of nontender, boggy swelling 2 × 2 cm with associated alopecia is apparent over the scalp in the right temporal area. Small pustular lesions are scattered over the involved area. Generalized scaling of the scalp and occipital adenopathy are evident.

Questions

1. What are the common causes of circumscribed hair loss in children?
2. What are the common causes of diffuse hair loss in children?
3. What are the common causes of scalp scaling in children?
4. What features distinguish tinea capitis from alopecia areata?
5. What is the treatment for tinea capitis? Is there a role for topical antifungal agents?

Disorders of the scalp may be either congenital or acquired during childhood or adolescence. Conditions may be further classified according to the presence or absence of hair loss (alopecia), whether the hair loss is diffuse or circumscribed, and whether the hair loss results in scarring of the scalp.

Epidemiology

Acquired circumscribed hair loss is more commonly seen than diffuse hair loss. Most cases of acquired circumscribed hair loss result from tinea capitis, alopecia areata, or trauma due to traction or trichotillomania.

Tinea capitis is a fungal infection of the scalp most often caused by the dermatophytes *Microsporum canis* or *Trichophyton tonsurans*. *Trichophyton tonsurans* accounts for most cases in the United States, but in a given geographic area, the etiologic fungus may change over time. Tinea capitis, which is less common in infants and postpubertal adolescents, is seen primarily in school-aged children between the ages of 3 and 7 years. Prevalence is estimated to be between 3% and 13% in the pediatric population. Boys are affected more often than girls with *M canis*, though both are affected equally in epidemics caused by *T tonsurans*. African American and Latin American children are more vulnerable to infection. Human-to-human transmission is more common with *T tonsurans*, an anthropophilic fungus. Children who handle dogs or cats, which harbor *M canis*, a zoophilic fungus, are susceptible to infection. Carriers are most commonly adults exposed to affected children, and carriers are considered contagious. Up to 60% of affected children are asymptomatic. Tinea capitis can result in localized patches of hair loss and can result in scarring if the infection becomes inflammatory.

Alopecia areata is believed to be an organ-specific autoimmune disorder with a prevalence of 158 per 100,000 persons, occurring equally in males and females. Family history is positive in 10% to 50% of affected patients. Although alopecia areata may develop at any age, it is rare before the age of 1 year, and 40% to 50% of cases develop alopecia areata before the age of 21 years. It may be seen in association with atopic dermatitis, Down syndrome, and other autoimmune diseases.

Trichotillomania, or compulsive pulling at the hair, may be seen in association with other impulse disorders such as thumb sucking and nail biting (see Chapter 51). It results in hair loss due to self-induced trauma. Usually the scalp hair is involved, but eyebrows or eyelash hair may also be affected. Although trichotillomania may be seen at any age, onset is usually between the ages of 5 to 12 years. It is more commonly seen in girls and women rather than boys and men and in children rather than adults. **Traction alopecia** is more commonly seen in females whose hair-grooming practices result in excessive tension and trauma to the hair.

Clinical Presentation

Children may present with specific complaints, including localized baldness, pruritus, scaling, or inflammation (Dx Box). Occasionally, lymphadenopathy, particularly in the occipital area, is the major presenting symptom.

Pathophysiology

An understanding of the physiology of the normal hair growth cycle helps in the evaluation of hair and scalp disorders. The scalp of an average human being contains about 100,000 hairs. Individuals with

Dx Disorders of the Hair and Scalp

- Circumscribed or generalized hair loss (alopecia)
- Scaling
- Pruritus
- Erythema of the scalp
- Localized or generalized swelling of the scalp
- Occipital adenopathy

blonde hair generally have 10% more hairs and those with red hair have 10% less. Healthy terminal hair grows an average of 0.3 mm per day or approximately 1 cm per month.

The hair follicle is responsible for most disturbances of hair growth because the hair shaft itself is a nonliving structure. Normal hair growth is a cyclical process composed of 3 stages. The anagen phase, the period of active hair growth, lasts for an average of 3 years (range: 2–6 years). Normally, about 85% to 90% of scalp hair is in this phase at any one time. The catagen phase, the transition period, lasts for about 10 to 14 days. The telogen phase, the final resting phase, lasts for about 3 to 4 months. About 13% of scalp hairs are in this phase at one time. The average individual loses about 100 to 150 telogen hairs per day. The normal hair cycle results in replacement of each scalp hair every 3 to 5 years.

Tinea capitis is a communicable infection and can be acquired via interpersonal contact, contact with infected animals, and via fomites. There are 3 patterns of hair invasion. In endothrix infections (eg, *T tonsurans*), the fungus produces chains of spores within the hair shaft. In ectothrix infections (eg, *M canis*), spores are present around the exterior of the hair shaft. Favus, the most severe form of tinea capitis, demonstrates hyphae and air spaces within the hair shaft. This is usually caused by *Trichophyton schoenleinii*, a less common etiologic organism. Though dermatophytes have a relatively short incubation period (up to 3 weeks) they are viable in fomites for months. Subcutaneous invasion in conjunction with an exaggerated host response can result in kerion.

Alopecia areata is thought to be due to aberrant expression of class I human leukocyte antigens on early anagen follicles resulting in T lymphocyte recognition of these normally immune hairs. There follows an immunologic attack causing premature telogen. The hairs then break easily at the surface of the scalp. The hairs at the margins of alopecia are easily plucked and they have an “exclamation mark” appearance with the proximal end thinner than the distal end.

Differential Diagnosis

While some hair disorders can be easily recognized clinically, the differential diagnosis can be challenging at times. Familiarity with the appearance of these conditions is critical. The Internet can be valuable in providing access to images of many dermatologic conditions. Some sites such as VisualDx (accessible at www.visualdx.com) display pictorial representations and allow for searching by features such as by hair loss patterns, symptoms, exposures, skin color, scalp location, age, immune status, and many other factors.

Scalp Disorders Without Associated Hair Loss

These conditions are divided into those disorders seen most often in neonates and young infants and those seen more frequently in children and adolescents (Box 119-1). **Caput succedaneum**, a generalized edema involving the soft tissues of the scalp, and **cephalhematoma**, a subperiosteal hematoma, are 2 of the most common lesions of the scalp that occur during the neonatal period. A cephalhematoma does not extend beyond the suture lines of the affected bone, which distinguishes it from caput succedaneum. Both conditions result from birth trauma and generally resolve spontaneously within a few weeks to months without further complications.

Box 119-1. Common Disorders of the Scalp Without Associated Hair Loss

Neonatal Period and Early Infancy

- Birth trauma to the scalp (eg, caput succedaneum, cephalhematoma)
- Scalp abscess (at fetal scalp electrode site)
- Herpes simplex infection
- Cradle cap/seborrheic dermatitis
- Atopic dermatitis^a
- Scabies

Childhood and Adolescence

- Seborrheic dermatitis^a
- Atopic dermatitis^a
- Head lice (pediculosis capitis)
- Psoriasis^a

^aMay occur with or without associated hair loss.

Other neonatal scalp conditions include infections such as **scalp abscess** and **herpes simplex virus (HSV) infection**. Scalp abscess occurs most commonly as a complication of scalp electrode placement and has an incidence of 0.4% to 4.5%. The infectious agents are usually flora of the cervix and vagina. Management depends on the severity of the infection (eg, associated cellulitis or signs of systemic involvement). Although most cases are self-limited, the abscess can be complicated by intracranial infection. Herpes simplex virus infections of the scalp are not uncommon in neonates; 85% of neonatal HSV infections occur at time of delivery and the scalp usually has the longest contact with the cervix, one of the sites for transmission of infection. Herpes lesions are typically vesicular, but petechial, purpuric, or bullous lesions may also be apparent. Skin lesions typically develop at 1 week of life but may be present at birth or develop as late as 3 weeks later.

Atopic dermatitis and **seborrheic dermatitis** are the 2 most common diagnoses of scalp scaling among infants and children younger than 10 years. **Seborrheic dermatitis** is a red, scaly eruption that occurs mainly on the scalp (otherwise known as cradle cap), face, and postauricular and intertriginous areas (see Chapter 121). It is often seen in infants younger than 2 years. Additionally, the scale, often termed *dandruff* in children 2 to 10 years, is usually seborrheic dermatitis, and this is seen more in African American

children. Unlike atopic dermatitis, seborrheic dermatitis is generally non-pruritic. Occasionally the inflammatory process is severe enough to result in diffuse hair loss. Psoriatic lesions of the scalp and Langerhans cell histiocytosis can mimic seborrheic dermatitis. Skin biopsy may be required for definitive diagnosis. It is often seen in conjunction with adenopathy of the head and neck without associated tinea infection.

Atopic dermatitis on the scalp is also characterized by erythema and scaling of the scalp, and it can overlap with seborrheic dermatitis. Atopic dermatitis on the scalp can be associated with significant pruritus with rubbing and scratching that result in the secondary effects of crusting and lichenification. Severe atopic and seborrheic dermatitis, as well as psoriasis, can result in **tinea amiantacea** (not a fungal infection), which usually presents as a localized, thick, adherent, white or gray scale.

Head lice (pediculosis capitis) are an extremely common childhood infestation that affects girls more often than boys and is most common in children aged 3 to 11 years. Lice are spread by direct contact with infected individuals or infested clothing, combs, or other hair accessories. Pruritus is the primary symptom along with erythema and scaling, with secondary impetigo being common. The viable ova or nits may be visible as small, oval, tan to brown specks found most commonly in the hair above the ears and the nape of the neck. Hatched eggs are clear to white. Generally, only the ova closest to the scalp are viable. They are difficult to remove.

Scabies, a pruritic infestation commonly seen in children, generally does not affect the scalp, except in infants, the elderly, and the immunocompromised. On the scalp of infants, 2- to 3-mm erythematous papules are seen, with overlying excoriations and, often, secondary bacterial infection.

Scalp Disorders Associated With Hair Loss

Box 119-2 lists the common scalp disorders associated with hair loss. When evaluating hair loss in children, it is important to determine whether the loss is diffuse or circumscribed.

Nevus sebaceus is a congenital lesion that mainly occurs on the face and scalp, occurring in about 3 of 1,000 neonates. These lesions are characteristically hairless. In addition, they are usually solitary, well-circumscribed plaques on the scalp, yellow-orange in color, and ovoid to linear in shape. Nevus sebaceus can be associated with a small risk of malignant transformation, namely basal cell carcinoma, at a rate of less than 1% before the age of 18 years. Other growths within nevus sebaceus may also occur at a rate of approximately 1%. Therefore, regular monitoring or consideration of excision should be part of the management. Because of the relatively low risk and low metastatic potential, it is reasonable to postpone excision until later in life. **Aplasia cutis congenita** is a congenital skin defect with localized areas of epidermal, dermal, and/or subcutaneous tissue loss. Lesions can occur anywhere on the body, but most are found along the midline of the scalp. At birth, the lesions usually appear as punched out, round or oval defects that may have an overlying thin, glistening membrane. Erosion, ulceration, or a scar due to healing in utero can also be seen. A “hair collar” often surrounds the lesion.

Aplasia cutis congenita is a result of many possible etiologies, and it can be an isolated defect or in association with other congenital defects such as cleft lip or palate, syndactyly, or multiple other anomalies. Small defects generally heal well, whereas larger defects may require surgical excision and eventual skin grafting. Preoperative imaging studies may be required for extensive, severe cases.

Tinea capitis, a fungal infection of the scalp, is one of the most common causes of acquired hair loss in children. This condition is characterized by patchy alopecia with broken-off hairs and scaling of the scalp. *Trichophyton tonsurans* infection sometimes appears as a series of black dots within the affected area due to the presence of fragmented hairs. The diagnosis can be difficult in children with either diffuse scalp scaling or a diffuse pustular eruption without significant alopecia. Occasionally, an intense hypersensitivity response may result in a boggy swelling of the scalp known as a **kerion**. The surface of the kerion may be smooth or covered with small pustules, mimicking a bacterial infection. Uncomplicated tinea capitis leaves no scars, but kerions or favus may result in permanent, scarring hair loss.

Alopecia areata, which frequently leads to hair loss, is characterized by well-defined areas of complete hair loss without associated scaling, irritation, or inflammation of the scalp. Hairs at the periphery of bald patches can usually be easily plucked. The most common presentation is that of one or more round or oval bald patches. A less common subtype is the ophiasis pattern, in which hair loss is present in a band along the periphery of the temporal and occipital scalp. Associated nail defects, including nail pitting (most common) and ridging, may be seen. Occasionally, alopecia totalis (loss of all scalp hair) or alopecia universalis (loss of all body and scalp hair) may result.

Common traumatic causes of alopecia in children are traction alopecia and trichotillomania. **Traction alopecia** often occurs along the margins of the hairline secondary to having the hair pulled back in tight ponytails or braids. Short, broken hairs and follicular papules may be seen. Chronic, prolonged traction can result in permanent, scarring alopecia. **Trichotillomania** is a self-induced form of traction alopecia in which children twist or pull out their hair either consciously or subconsciously (see Chapter 51). Hair pulling is generally believed to occur in a younger population and usually resolves with minimal or no intervention needed. Trichotillomania is now classified in *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*, in the habit and impulse disorders category. Hair is generally plucked in a wave-like fashion across the scalp or centrifugally from a starting point. The occiput is generally spared. Trichotillomania may mimic other types of alopecia, but the diagnosis can usually be made on the basis of the bizarre patterns of hair loss with hairs broken at differing lengths. Children occasionally eat the hairs as they are pulled out, resulting in the formation of a **trichobezoar** (hair ball) in the stomach.

Discoid lupus erythematosus, **lichen planus**, and **secondary syphilis** are uncommon causes of localized hair loss from the scalp in children. The patches of alopecia in discoid lupus erythematosus often appear hypopigmented with hyperpigmentation at the periphery. Because adnexal structures are involved in discoid lupus,

scarring alopecia is commonly seen. Lichen planus, an idiopathic inflammatory disease of skin and mucous membranes, can result in both scarring and non-scarring alopecia. Secondary syphilis lesions appear as “moth-eaten” patches of alopecia that are non-scarring.

A variety of structural defects, endocrine and metabolic disorders, and toxins may be associated with diffuse loss of scalp hair (Box 119-2). **Intrinsic structural defects of the hair** may cause hairs to break, thus resulting in failure of hair growth. In some forms of **ectodermal dysplasia**, the number of hair follicles is reduced or the follicles are altogether absent, giving the appearance of sparse or thinning hair. Many of the ectodermal dysplasias have abnormalities of the teeth, nails, and sweat glands. **Monilethrix** is an autosomal-dominant condition that can appear in isolation or in association with other anomalies. Microscopic evaluation of hairs show a “beads on a string” appearance due to alternating nodes and internodes

Box 119-2. Common Disorders of the Scalp With Associated Hair Loss

CIRCUMSCRIBED HAIR LOSS

Congenital

- Aplasia cutis congenita
- Nevus sebaceus
- Epidermal nevus

Acquired

- Tinea capitis
- Alopecia areata
- Traction alopecia
- Trichotillomania
- Discoid lupus erythematosus
- Secondary syphilis
- Herpes simplex virus
- Lichen planus

DIFFUSE ALOPECIA

Congenital

- Congenital hypothyroidism
- Hair shaft defects (eg, Menkes syndrome, monilethrix)
- Ectodermal dysplasias and other genetic syndromes

Acquired

- Seborrheic dermatitis
- Psoriasis
- Telogen effluvium
- Anagen effluvium (secondary to toxins or chemicals)
- Endocrine (eg, diabetes mellitus)
- Hypothyroidism-hypoparathyroidism-hypopituitarism
- Medication-induced (isotretinoin)
- Androgenic alopecia (eg, male pattern baldness)
- Loose anagen syndrome

Other

- Nutritional (eg, acrodermatitis enteropathica, malnutrition, iron deficiency, rickets)
- Systemic lupus erythematosus

resulting in fractures between the nodes. Pili torti can be seen in several syndromes including **Menkes syndrome (kinky hair syndrome)**. Affected patients have twisted hair leading to premature breakage and, thus, chronically short hair. There is often baldness at sites of friction.

Telogen effluvium is a common cause of diffuse hair loss that may occur 2 to 4 months after a variety of events, including pregnancy, discontinuation of oral contraceptives, severe febrile illness, medications, severe diets, or significant emotional stress. Hair loss results from the abrupt conversion of numerous scalp hairs from the anagen (growth) phase to the telogen (resting) phase. Loss of more than 150 hairs per day is considered abnormal. Patients may complain of losing several hundred hairs a day, but the occurrence of clinically significant baldness is rare. Estimates indicate that individuals must lose about 25% of their hair before thinning becomes clinically apparent. The hair loss may continue for several weeks, but complete regrowth usually occurs within 6 to 12 months. **Anagen effluvium** results in the loss of growing hairs due to a sudden cessation of the growing phase. It occurs most commonly after systemic chemotherapy.

Loose anagen syndrome is a disorder in which the anagen hair follicle is anchored improperly, resulting in easy, painless plucking of the hairs. This can result in patchy diffuse hair loss or focal areas of alopecia. This is a familial condition, with fair-haired females more commonly affected. Often, these children will not need a haircut through early childhood. The hair is expected to spontaneously become normal by the teenage years without treatment.

Evaluation

History

The age of the child guides the differential diagnosis, because some lesions are more common at one age than another. See the Questions Box to review pertinent history that may be helpful in diagnosis.

Questions

Disorders of the Hair and Scalp

- Is the child losing any hair?
- If so, is the child losing hair from all over the scalp or only from localized areas on the scalp?
- Has the child lost any body hair (eg, eyebrows, eyelashes) in addition to the scalp hair?
- How long has the child been losing hair?
- Is the scalp pruritic or scaling?
- Have the parents noticed the child twisting or pulling the hair?
- Is the child's hair often in ponytails or braids?
- Has there recently been any significant stress in the child's life?
- Do any pets live in the home?
- Is the child taking any medications?
- Is anyone else in the home or anyone in close contact with the child having similar symptoms?

Physical Examination

The scalp should be examined to see if the hair loss is diffuse or circumscribed and whether scalp hairs can be plucked easily. Signs of irritation, inflammation, or scaling of the scalp should also be noted, as well as the presence of adenopathy, nail changes, or hair loss elsewhere on the body.

Wood light examination of the scalp for fungus is helpful if positive. A negative examination does not rule out the possibility of fungal infection, however, because *T tonsurans*, the most common cause of tinea capitis in the United States, does not fluoresce. *Microsporum canis* fluoresces yellow-green under the Wood light.

Laboratory Tests

Laboratory assessment is useful in some cases. If fungal infection is suspected, a KOH examination should be performed by the primary care physician. Scales and broken hairs can be obtained from involved areas by brushing, scraping (eg, with a No. 15 scalpel blade), plucking, or rubbing a moistened 4" × 4" gauze over affected areas and then removing broken hairs and scale from the gauze with forceps. The scrapings should be placed on a glass slide, dissolved in KOH solution, heated gently, and examined under the microscope. Hyphae and spores within the hair shaft (eg, *T tonsurans* infection) or surrounding the hair shaft (eg, *M canis* infection) should be noted.

In addition to microscopic examination, fungal cultures are recommended in all cases of suspected tinea capitis. Brushings using either a moistened sterile cotton swab or a sterile brush as used in Pap smears will yield the most reliable results. Hair or scalp scrapings are inoculated onto Sabouraud agar or dermatophyte test medium (DTM). Within 5 to 14 days, a distinctive growth seen on the Sabouraud agar or a color change from yellow to red in the DTM confirms the diagnosis. A negative KOH examination and fungal culture, in addition to a lack of inflammation and scaling, may be required for differentiating trichotillomania or alopecia areata from tinea capitis.

The diagnosis of telogen effluvium is usually suggested by the history and counting the number of hairs lost each day. If the diagnosis is in question, the patient may be referred to a dermatologist for examination of the involved hair roots via biopsy and determination of the anagen-telogen ratio, which is usually about 85:15. A telogen count of more than 25% is considered to be diagnostic of telogen effluvium. The ratio of anagen to telogen hairs is normal in trichotillomania.

A more extensive laboratory workup may be required if the hair loss is persistent or the history or physical examination is suggestive of systemic disease (see Box 119-2). Studies that may be considered include liver function tests, thyroid function studies, a serum Venereal Disease Research Laboratory test, antinuclear antibodies, and serum electrolytes.

Management

Management depends on the diagnosis. Herpetic infection in a newborn requires immediate attention and systemic antiviral therapy because the risk of systemic infection is significant. Scalp electrodes and vacuum-assisted vaginal deliveries should be avoided in neonates with mothers known to have HSV infections because these can increase the rate of infection transmission. Currently cesarean section delivery remains the standard of care, though most cases of herpes simplex in infants are in those born to mothers without known infection at time of delivery.

Children suspected of nevus sebaceus should be referred to a dermatologist. Excision may be considered, not only because of the risk, albeit low, of secondary neoplastic changes, but also because these lesions can become more prominent and warty in appearance and friable during puberty and adulthood.

Seborrheic dermatitis can persist into the pubertal years, contrary to previously held belief. Cradle cap, the greasy form of seborrheic dermatitis, can be treated with simple skin care measures such as bathing and the use of moisturizing emollients. Gentle shampoos, low-potency corticosteroids and, if needed, 2% ketoconazole cream can resolve most cases. Past infancy, seborrheic dermatitis may be treated with **shampoos containing tar, pyrithione zinc, ketoconazole, or selenium** in rotation. Topical, mild corticosteroid solutions can be used if pruritus is significant.

Head lice may be treated with **pyrethrin products**, such as permethrin 1% cream rinse (Nix) or the prescription 5% cream typically used for scabies. Other medications such as malathion and ivermectin can also be effective. All topical medications should be used twice, 1 week apart, regardless of package insert information. A fine-toothed comb or tweezers may be required after rinsing to remove the ova or nits of head lice. Other alternative treatments have been unsubstantiated, such as using mayonnaise or petroleum jelly. Heat, such as that associated with blow-drying the hair, also kills a large percentage of the lice.

Permethrin 5% cream is the preferred scabicide. It should be applied from head to toe in infants younger than 2 years, and from neck to toe for those older than 2 years, for 8 to 12 hours, washed off, and repeated in 1 week. Permethrin 5% cream can be used in infants as young as 2 months and pregnant women. For these patients, sulfur 6% ointment can be used. For both scabies and lice, the treatment of fomites is also important. Clothing, bed linens, and towels should be washed in hot water and machine-dried in high heat. Fomites that cannot be laundered should be sealed in plastic for 48 to 72 hours.

Oral griseofulvin administered for at least 6 to 12 weeks has been the long-held treatment of choice for **tinea capitis**. Although griseofulvin can have many side effects, including gastrointestinal disturbances, hepatotoxicity, and leukopenia, it is generally well tolerated by children and is available in suspension form. Hematologic, renal, and liver function studies can be monitored in children on high

doses or prolonged treatment. Higher dosing is occasionally required due to increasing resistance. Care should be made to use proper dosing when using micronized (20–25 mg/kg) or ultra-micronized (10–15 mg/kg) griseofulvin. Newer antifungal agents are also being used with great success, often for shorter durations than griseofulvin, which can increase compliance. **Itraconazole** can be given as either continuous or pulse therapy and is also available as a solution. **Fluconazole**, also available as solution, is usually administered for 3 to 6 weeks or at a higher dose once weekly for 8 to 12 weeks. **Terbinafine**, available in tablets or granules, has also been effective at shorter treatment times than griseofulvin. Monitoring of blood cell counts and liver and renal function are recommended monthly before and during treatment. Ketoconazole is contraindicated in this population due to its potential for adverse effects, especially in light of other available agents. Generally, longer courses of treatment are needed for *M canis* infection. Topical antifungal agents are not effective on the scalp for treatment of tinea capitis because the hair follicle must be penetrated, requiring the use of systemic therapy. Twice-a-week shampooing with ketoconazole or selenium sulfide shampoos has been shown to reduce carriage of spores and reduce infectivity. A course of oral **prednisone** may be required in conjunction with an oral antifungal if a kerion is present to minimize discomfort and permanent, scarring hair loss. Children with kerions are often misdiagnosed as having a bacterial infection of the scalp and treated with oral antibiotics. However, the pustules in kerions are generally sterile, and even when secondary bacterial infection is present (eg, about 30%–50% of patients), antibiotics do not alter the course of the condition.

Children believed to have alopecia areata should be referred to a dermatologist immediately. Therapy for **alopecia areata** consists of **both topical and intralesional corticosteroids**, topical anthralin, or minoxidil. Topical immunotherapy with a sensitizer such as squaric acid has also been used for the treatment of extensive alopecia areata. Occasionally oral steroids can be tried for extensive or rapidly progressing disease. Many psychosocial factors should be considered when treating children with this condition. Children with severe forms of the disease may benefit psychologically from wearing a wig. The National Alopecia Areata Foundation is available as a support group for affected children and their families.

Prognosis

Common disorders of the scalp, such as seborrheic dermatitis, head lice, and tinea capitis, generally respond well to treatment and rarely result in long-term sequelae. The course and prognosis of alopecia areata are quite variable and may be difficult to predict. Generally, the prognosis for regrowth is good if hair loss has occurred in only a few patches. The prognosis is usually poorer with younger age at onset, positive family history, nail involvement, and an ophiasis (band-like)

pattern of hair loss. It is important to pursue further workup if a condition does not respond to therapy because it is critical that a condition such as Langerhans cell histiocytosis, a mimicker of seborrheic dermatitis, not be missed. Many of the hair disorders are a result of syndromes that will not respond to therapy and, thus, education for patients and their families is important.

CASE RESOLUTION

The child presented in the case scenario exhibits physical findings of a kerion. Diagnosis can be made clinically on the basis of the appearance of the lesion. The diagnosis is established by microscopic evidence of hyphae and culture confirmation. Treatment with oral antifungals and possibly oral steroids should be initiated. Carriers should also be identified and treated. The child should be examined in 4 weeks to ascertain the response to therapy and check for any adverse reactions.

Diaper Dermatitis

Ki-Young Suh, MD; Kathy K. Langevin, MD, MPH; and Noah Craft MD, PhD

CASE STUDY

A 6-month-old infant has a 3-day history of a rash in the diaper area. The mother has been applying cornstarch, but the rash has gotten worse and has spread to the inner thighs and the abdomen. The infant has no history of fever, upper respiratory tract symptoms, vomiting, or diarrhea. He was seen in the emergency department 1 week ago for acute gastroenteritis, which has since resolved. On examination, a poorly demarcated, shiny, erythematous rash is noted over the convex surface of the buttocks, lower abdomen, and genitalia, with relative sparing of the intertriginous creases. The rest of the physical examination is within normal limits.

Questions

1. What are the common causes of rashes in the diaper area (diaper dermatitis)?
2. What are the features that distinguish one type of diaper dermatitis from another?
3. What systemic diseases may present with diaper dermatitis?
4. What are some common treatments for diaper dermatitis?

Diaper dermatitis is used to describe a wide variety of skin disorders that present with a rash in the area covered by the diaper. The most familiar form of diaper rash, irritant contact diaper dermatitis, is one of the most common skin disorders of infants and young children. Other infectious and inflammatory processes in the diaper area can also result in dermatitis. Successful management requires making the correct diagnosis and identifying the etiology and associated factors.

Epidemiology

Diaper dermatitis is the most common dermatologic disorder in infancy, with a peak incidence at 9 to 12 months of age, though some reports have shown a high incidence in the first month of life. Prevalence in infants is estimated at anywhere from 7% to 35%. This disorder is not limited to infants and small children but to any individual who wears diapers, though the incidence in adults is unknown.

Clinical Presentation

The lesions of diaper dermatitis primarily affect the skin of the buttocks, gluteal cleft, lower abdomen, perineum, and proximal thighs. **Irritant contact dermatitis**, the most common type of diaper dermatitis, appears as erythema and scaling papules and plaques or poorly demarcated, glistening erythema over the convex surfaces, with relative sparing of the intertriginous folds (Figure 120-1A). Candidal infection is another common form of diaper dermatitis and is characterized by a beefy red, sharply demarcated plaque with white scale at the border and/or small, satellite papules and pustules along the margins. Candidal infections may be primarily

concentrated within the skin folds (Dx Box) (Figure 120-1B). Other etiologic causes of diaper dermatitis can be challenging to distinguish from one another but can usually be differentiated by their distribution and response to therapy.

Dx Diaper Dermatitis

- Urinary or fecal incontinence requiring diaper wearing
- Erythematous rash over anogenital region
- Associated gastroenteritis, antibiotic therapy, or oral thrush

Pathophysiology

Many factors are involved in the pathophysiology of irritant diaper dermatitis. Prolonged contact with moisture, urine, feces, or irritating chemicals plays an important role in the initiation of these disorders. Friction generated as the infant tries to move around may further aggravate the condition and lead to maceration of the skin. Secondary infection, most often with *Candida albicans*, may be seen in many cases.

The cause of irritant diaper dermatitis is multifactorial, with prolonged exposure to moisture resulting in fragile skin and a compromised protective barrier, leading to increased irritant penetration and potential growth of microorganisms. Fecal enzymes (proteases, lipases, and urease) also weaken this barrier. Friction from a diaper can easily abrade this fragile skin. Diapers clearly play a role in this disorder; societies where diapers are not worn do not see this condition. Ammonia produced by bacterial breakdown of urea is no longer believed to be the causative factor in cases of irritant diaper dermatitis.

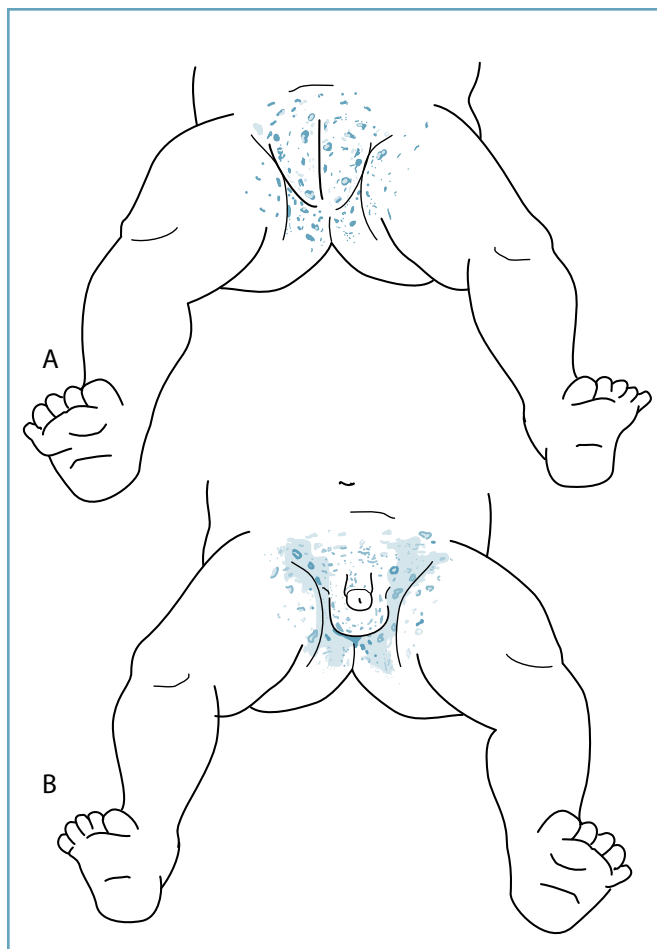

Figure 120-1. Diaper dermatitis. **A.** Diaper dermatitis secondary to contact. Convex surface areas are affected. **B.** Diaper dermatitis secondary to *Candida*. Intertriginous areas are affected, and satellite lesions are present.

Differential Diagnosis

While most cases of diaper dermatitis can be easily recognized clinically, the differential diagnosis can be challenging at times or when the condition fails to respond to therapy. Familiarity with the difference in appearance of these conditions is critical. The Internet can be valuable by providing access to images of many dermatologic conditions. Some sites such as VisualDx (accessible at www.visualdx.com) display a pictorial representation and allow for searching by features such as rash morphologies, symptoms, exposures, skin color, body location, and many other factors.

Diaper dermatitis is a general term to refer to a rash that occurs in the area covered by the diaper. Therefore, a specific diagnosis based on the etiology of the diaper dermatitis is important. The differential diagnosis of diaper dermatitis is presented in Box 120-1.

Irritant contact dermatitis, the most common cause of diaper dermatitis, is most prominent on the skin of the buttocks, perineum, lower abdomen, and proximal thighs. The skin of the creases is relatively unaffected. Exposure to proteolytic enzymes and irritant chemicals in the face of excessive heat or moisture is believed to lead to this condition. Friction with the diaper at sites of contact may

Box 120-1. Differential Diagnosis of Diaper Dermatitis

Most Common Causes

- Irritant contact dermatitis
- Candidiasis
- Seborrheic dermatitis

Less Common Causes

- Allergic contact dermatitis
- Impetigo
- Perianal streptococcal or staphylococcal disease
- Atopic dermatitis
- Psoriasis
- Zinc deficiency, including acrodermatitis enteropathica
- Biotin deficiency
- Langerhans cell histiocytosis
- Congenital syphilis

aggravate it. Such a rash is poorly demarcated and can give the skin a glistening, red appearance.

Granuloma gluteale infantum is a possible complication of irritant diaper dermatitis, presenting with violaceous nodules and plaques on the buttocks, vulva, scrotum, and perineum. Though alarming in appearance, these are benign and will resolve once the dermatitis is cleared, though scarring can result. The development of granuloma gluteale infantum does not necessarily correlate with the severity of the preexisting irritant dermatitis. **Jacquet erosive dermatitis** is another potential complication when the irritant dermatitis is severe. This form is characterized by small, well-demarcated erosions or ulcers that can also feature elevated borders. With chronic irritant dermatitis, children may also develop **perianal pseudoverrucous papules and nodules**, which are small bumps characterized by a flat-topped, moist, smooth, shiny surface. All 3—granuloma gluteale infantum, Jacquet's erosive dermatitis, and perianal pseudoverrucous papules and nodules—are considered to be on a disease continuum as less common manifestations of irritant contact dermatitis.

Candidiasis, due to infection with *C albicans*, typically begins in the creases (intertriginous areas) and then spreads to other surfaces. Sometimes associated with oral thrush, candidiasis is also a common sequela of systemic antibiotic therapy. The rash appears as bright, beefy red plaques with sharp, raised borders and many small satellite papules, vesicles, and pustules along its margins, often with desquamation. *Candida albicans* can be a cause of secondary infection of already inflamed skin as well as a primary causative factor in some cases of diaper dermatitis. Recurrent candidal diaper dermatitis can be associated with candidal colonization of the gut and oral cavity.

Seborrheic diaper dermatitis, like candidal diaper dermatitis, also primarily affects the intertriginous areas of the groin. The lack of pruritus, manifest as sleeping and feeding well, distinguishes it from atopic dermatitis. The rash has a characteristic salmon-colored, greasy appearance with a yellowish scale, though it can be acutely

inflamed. Satellite lesions can be seen. Seborrheic dermatitis of the face, scalp (including postauricular areas), neck, trunk, and proximal extremities is usually seen in association with seborrheic dermatitis of the diaper area.

Allergic contact dermatitis is a less common cause of diaper dermatitis but should be considered in patients who do not respond to standard therapeutic interventions. Allergens can be from the chemical makeup of the diaper itself or from topical preparations such as soaps, emollients, and baby wipes that are applied to the diaper area. For example, rubber additives such as mercaptobenzothiazole found in the elastics of disposable diapers have been shown to cause allergic diaper dermatitis on the hips and outer buttocks, a distribution reminiscent of a cowboy's gunbelt holster and hence the nickname "Lucky Luke" dermatitis. Other allergens to consider are emulsifiers in topical preparations, fragrances, disperse dye, and preservatives.

Bacterial infections can cause diaper dermatitis. **Impetigo**, especially bullous impetigo, is a not uncommon eruption in the diaper area. It is more commonly observed in neonates, often as epidemics. Bullous impetigo is caused by *Staphylococcus aureus* and is toxin-mediated. The rash presents as vesicles on the diaper area, as well as the trunk and face. These enlarge into 3- to 5-cm bullae that easily rupture, leaving superficial erosions with thick, honey-colored crusts. There can be associated systemic symptoms of fever and diarrhea. Perianal bacterial disease can result from group A beta-hemolytic streptococcus or *S aureus*. Classically, perianal streptococcal dermatitis manifests as well-demarcated, bright red, tender patches. Rectal bleeding and painful defecation may also be noted.

Congenital syphilis can present with diaper dermatitis findings in 30% to 60% of those born with this infection. Initially, there is usually a bright erythematous morbilliform eruption that fades to a coppery color, often with scaling. Pustules can develop later. Buttocks, face, extremities, palms, and soles are generally affected.

Diaper rashes that seem to persist despite seemingly adequate therapy should raise suspicion for other systemic diseases. Though less common, these include psoriasis, atopic dermatitis, zinc deficiency, biotin deficiency, and Langerhans cell histiocytosis. **Psoriasis** may occur anywhere on the body, but lesions typically occur on the scalp, face, elbows, and knees. In infants, generally between 2 to 8 months of age, psoriasis may involve the diaper area. Lesions elsewhere on the body are typically well-circumscribed, erythematous plaques with a thick, silvery scale. However, psoriatic lesions in the diaper area may be difficult to differentiate from seborrheic dermatitis or candidal infection. Plaques are brightly erythematous and sharply demarcated. Skin biopsy, family history of psoriasis, or nail involvement may help confirm the diagnosis.

Atopic dermatitis is rare in the diaper area, even in infants who have lesions elsewhere on the body. The relative sparing of the diaper area is perhaps a result of the increased moisture of the skin in this area. (See Chapter 121 for a discussion of atopic dermatitis.)

Zinc deficiency can cause dermatitis in a characteristic periorificial distribution (mouth, nose, ears, eyes, and anogenital area) and distal extremities. Zinc deficiency may result from an inherited

defect called acrodermatitis enteropathica or develop secondary to insufficient intake or malabsorption such as in patients with cystic fibrosis. **Acrodermatitis enteropathica** is a rare, autosomally recessive inherited disorder with mutations in *SLC39A* resulting in defective zinc transporters in the small intestine. In breastfed infants, the disease becomes manifest shortly after weaning, whereas in bottle-fed infants, signs and symptoms appear days to weeks after birth. Afflicted infants are irritable and listless and present with diarrhea, failure to thrive, and skin lesions in the previously mentioned distribution featuring erythematous bullous and pustular lesions as well as dry, red, scaly patches. Candidal and *S aureus* superinfection can occur. Treatment consists of oral zinc supplementation. Biotin deficiency, as well as several other nutritional deficiencies, can present with identical skin findings, and treatment is with supplementation of the deficient nutrient.

Langerhans cell histiocytosis refers to a group of disorders characterized by proliferation of histiocytes, a progenitor cell in the bone marrow. Members of this group include Letterer-Siwe disease and Hand-Schüller-Christian disease, eosinophilic granuloma, and congenital self-healing reticulohistiocytosis. Skin lesions may involve the scalp and flexural areas of the perineum, axilla, and neck. The lesions appear as small, pink to tan scaling papules and pustules that can coalesce; ulceration may be apparent in the inguinal crease with secondary impetiginization (honey-colored crusting caused by *S aureus* superinfection). The rash is most often confused with that of seborrheic dermatitis. Diagnosis can be confirmed by skin biopsy.

Evaluation

History

A thorough history should be obtained (Questions Box). Candidal diaper dermatitis should be suspected if oral antibiotic therapy has recently been used.

Questions

Diaper Dermatitis

- When did the rash begin?
- Does the rash resolve and then recur?
- Is the rash pruritic?
- Is the infant feeding, sleeping? Is he/she irritable?
- Have any home remedies or previous treatments been used? Which ones?
- Does the child have a family history of atopic dermatitis or psoriasis?
- Is the child taking antibiotics now or has the child used them recently?
- What type of diapers is used?
- How frequently are the diapers changed?

Physical Examination

On physical examination, the presence of skin lesions elsewhere on the body should be noted. This is particularly important in the case of a persistent, resistant, or recurrent diaper rash, where systemic

diseases such as psoriasis must be considered. The distribution of the rash within the diaper area itself may provide clues to the diagnosis. Candidal and seborrheic dermatitis occur primarily in the creases, whereas irritant contact dermatitis usually affects the convex areas of the skin with relative sparing of the intertriginous areas. Streptococcal disease manifests primarily as marked perianal erythema.

Laboratory Tests

Although the diagnosis of candidal diaper dermatitis is usually evident clinically, microscopic examination of skin scrapings with KOH may be performed to establish the diagnosis. Typically, budding yeast with hyphae and/or pseudohyphae is seen. The diagnosis of perianal streptococcal disease or bullous impetigo may be confirmed by bacterial cultures from the perianal area or bullous lesions, respectively. Biopsies may be warranted for recalcitrant diaper dermatitis. Other laboratory studies may be carried out to investigate for suspected nutritional deficiencies.

Management

The mainstay of therapy for irritant diaper dermatitis is prevention, requiring **good hygiene**, which involves keeping the diaper area clean and dry. Gentle but thorough cleansing of the diaper area is necessary when stool is present and can be done with water alone or water and mild soap. The area should then be patted dry and allowed to air-dry completely if possible or dry with the use of cotton balls. Cleansing frequently with harsh soaps or scrubbing too vigorously can further irritate skin that is already damaged and inflamed.

In addition, the diaper should be **changed frequently**. The diaper area should be exposed to as much air as reasonably possible (eg, by allowing the infant to sleep without a diaper). Cloth and regular disposable diapers are not as effective as superabsorbent gel diapers in decreasing moisture. Although **dusting powders** such as cornstarch or talc minimize friction and talc does not enhance the growth of yeast on skin, concern about pulmonary effects from inhalation precludes their routine use even in the absence of any skin inflammation. **Moisture-resistant barrier ointments or creams** such as zinc oxide or petrolatum are very helpful in reducing irritation. The role of hygiene in all forms of diaper dermatitis cannot be overemphasized. Topical application of medicated creams and ointments is not effective in the presence of poor hygiene.

Irritant contact dermatitis usually responds to the above-described hygienic measures and the application of barrier ointments and low-potency **topical corticosteroids** such as 0.5% or 1% hydrocortisone ointment or cream. Seborrheic dermatitis usually resolves spontaneously but can also be treated with low-potency topical corticosteroids. Candidal diaper dermatitis responds to **topical antifungal creams** such as nystatin, miconazole, or clotrimazole. In addition, a low-potency corticosteroid may be required if inflammation is severe. Oral antifungal therapy is usually not indicated,

though may be needed in cases of recurrent candidiasis. Oral antibiotic therapy usually clears perianal streptococcal or staphylococcal disease, but the relapse rate is high. The topical antibiotic mupirocin may be used to treat bullous impetigo only if the lesions are superficial, few, and isolated. Oral antibiotics (eg, cephalexin or clindamycin) may be required for more extensive bacterial infections. Combination topical medications containing both a corticosteroid and an antifungal should not be recommended routinely because they usually contain high-potency corticosteroids. When topical steroids and antifungals are used in conjunction with barrier ointment, the medication should be applied before the barrier ointment.

When the more common causes of diaper dermatitis, such as irritant contact dermatitis, *Candida*, or seborrheic dermatitis, do not respond to conventional therapy, further workup must be initiated because there may be an underlying systemic disease manifesting as diaper dermatitis; some of these can be life-threatening.

Prognosis

Although recurrence of diaper dermatitis is common, the usual varieties respond well to measures aimed at keeping the diaper area clean and dry and to medicated creams.

CASE RESOLUTION

The infant presented in the case scenario has irritant contact dermatitis. He has a recent history of gastroenteritis, and stool is known to be particularly irritating to the skin. Treatment includes keeping the diaper area clean and dry with frequent diaper changes, use of superabsorbent diapers, and fastidious toilet, as well as topical application of a low-potency corticosteroid ointment or cream and a barrier ointment such as zinc oxide after bathing.

Papulosquamous Eruptions

Ki-Young Suh, MD; Kathy K. Langevin, MD, MPH; and Noah Craft, MD, PhD

CASE STUDY

A 6-month-old female infant presents with an erythematous, confluent, slightly raised and scaly rash on the cheeks. The extremities are also covered with a fine papular rash. The infant has had some scaling behind the ears and on the scalp since early infancy, but the symptoms have recently increased. The mother has been applying baby oil to the scalp to relieve the scaliness. Except for some intermittent rhinorrhea, the infant has otherwise been well. Immunizations are deficient; she received only the first set when she was 2 months old. The family history is positive for bronchitis. The infant's weight is at the 75th percentile, and the height is at the 50th percentile. Vital signs

are normal. The physical examination is normal except for the presence of the rash.

Questions

1. What are the characteristics of papulosquamous eruptions?
2. What are the common conditions associated with papulosquamous eruptions in children?
3. What are the appropriate treatments for the common papulosquamous eruptions?
4. When should children with papulosquamous eruptions be referred to a dermatologist?

Rashes, a common problem in children, can be classified in ways that help to establish a diagnostic approach. First, rashes are assessed in terms of appearance, whether macular (flat), papular (raised), squamous (scaly), vesicular (fluid-filled), or bullous (large, fluid-filled). Next, the extent of the rash is determined. Rashes may be described as generalized or localized. Location is also important. The site of a localized rash may be consistent with certain diagnoses, for instance, diaper dermatitis. Pruritus is an important distinguishing feature. Other systemic symptoms must also be taken into consideration. Rashes may be a primary skin condition or may be a manifestation of an underlying infection or reaction to a precipitating agent.

Papulosquamous eruptions, the subject of this chapter, are rashes characterized by scaly papules and plaques. Eczema is a poorly defined group of skin disorders characterized clinically by scale, and histologically by spongiosis, and makes up a large component of the papulosquamous disorders. The etiology of many papulosquamous eruptions is unknown, and the clinical appearance of lesions is the reason they are classified together.

Epidemiology

Although a large number of conditions may cause papulosquamous eruptions in children, a select number of diagnoses account for most problems. One of the most common causes of papulosquamous eruptions in children is atopic dermatitis. Atopic dermatitis has become increasingly more common, and the prevalence in school-aged children in the United States is estimated to be between 10% to 20%. Positive family history is often elicited. Though the severity of atopic dermatitis generally improves with age, lifelong dry, itchy skin, in varying degrees of severity, is not uncommon. Seborrheic

dermatitis is another common eczematous skin rash seen in the pediatric population. Though most commonly described in infants younger than 3 or 4 months, it can occur in all pediatric age groups. It is estimated to have a prevalence of up to 5%, encompassing both the pediatric and adult populations, though higher in adults with males more commonly affected. It is generally more severe during the winter months.

Scabies is likely the most common cause of worldwide papulosquamous eruptions and is frequently encountered in both general pediatric and dermatology settings. The prevalence is much greater in developing countries and in situations where populations are forced into close proximity (eg, during wars or incarcerated individuals). Family members and close contacts are at greatest risk of infection.

Clinical Presentation

Papulosquamous eruptions consist of skin-colored to erythematous raised, scaly papules and plaques that may involve the face, trunk, or extremities. The lesions can be pruritic, and scratching may lead to crusting or secondary infection. Sometimes multiple family members are affected (Dx Box). Chronicity and repeated manipulation, may lead to thickening or lichenification of involved skin.

Pathophysiology

The pathophysiology of atopic dermatitis has not been definitively established. Recent evidence suggests that mutations in the filaggrin gene, which is responsible for much of the skin barrier function, may play a large role in atopic dermatitis. However, it seems to

Dx Papulosquamous Eruptions

- Raised, scaly papules and plaques
- Pruritus
- Afebrile, unless secondary infection is present
- Personal or family history of allergies
- Intertriginous rash

be a multifactorial disease with variable expression, influenced by environmental factors. Inheritance of this disease is associated with atopy, made up of the triad of atopic dermatitis, allergic rhinitis, and asthma. The disorder is attributed largely to skin barrier function; however, immune dysfunction and reactivity of nerves and blood vessels may also be involved. Initially, the disease is characterized by Th1 cytokine predominance, but later in chronic disease, there is activation of the Th2 immune pathway with a resultant synthesis of cytokines, including IL-4 and IL-5, causing elevated immunoglobulin (Ig) E levels, eosinophilia, and diminished cell-mediated immunity. Elevated IgE is reported in 43% to 82% of patients with atopic dermatitis.

Like atopic dermatitis, the etiology of seborrheic dermatitis remains unclear. There is believed to be an association with the yeast *Malassezia furfur*, though whether this organism is causative has not been established. It is widely accepted that this yeast has some role in seborrheic dermatitis, which is further substantiated by the improvement of this skin condition with antifungal agents. Individuals with seborrheic dermatitis that is severe or extensive may have some sort of immune dysfunction, as in uncontrolled HIV and AIDS.

The inflammatory response in scabies is triggered by an infestation with a mite, *Sarcoptes scabiei*. The adult female burrows under the skin and lays 60 to 90 eggs. After 2 weeks, the eggs become adults. Affected individuals may be asymptomatic on first exposure. Up to 2

to 6 weeks after infestation, the host's immune system becomes sensitized to mites or scybala (mite feces), resulting in systemic pruritus and rash. In most individuals the rash associated with scabies is an allergic phenomenon and does not represent mites at each eruptive papule on the body.

Differential Diagnosis

While many papulosquamous eruptions are easily distinguishable clinically, the differential diagnosis can be challenging at times. Familiarity with the appearance of these conditions and their differentiating features is critical. The Internet can be valuable by providing access to images of many dermatologic conditions. Some sites such as VisualDx (accessible at www.visualdx.com) display pictorial representations and allow for searching by features such as rash morphologies, symptoms, exposures, skin color, body location, age, immune status, and many other factors.

Most conditions that are associated with papulosquamous eruptions in children include atopic dermatitis, seborrheic dermatitis, contact dermatitis, psoriasis, pityriasis rosea, lichen planus, lichen striatus, scabies, and fungal infections of the skin.

Eczema is a general term that is used to denote a type of papulosquamous eruption. The most common eczematous conditions seen in children are atopic eczema or dermatitis, seborrheic dermatitis, and contact dermatitis. **Atopic dermatitis** is a disorder of infancy and childhood and may persist into adulthood. More than half of affected individuals are symptomatic by 1 year, and 90% of cases have their onset by 5 years of age. The area of involvement changes with age. In infancy, the face, scalp, and extensor surfaces are involved, often in areas where the infant can relieve itching by rubbing, and the diaper area is often spared (Figure 121-1A). By childhood, the more typical pattern seen in adulthood becomes prominent with involvement of the neck and antecubital and popliteal fossae. Adults

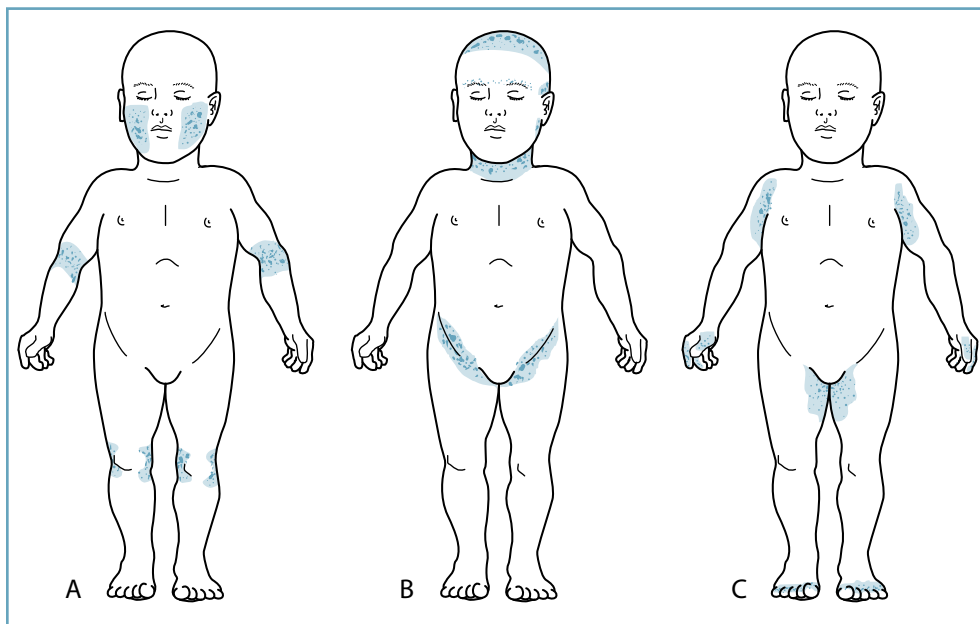

Figure 121-1. Typical distribution of papulosquamous eruptions in children. **A.** Atopic dermatitis: usually located on cheeks, creases of elbows, and knees. **B.** Seborrheic dermatitis: usually located on scalp, behind ears, thigh creases, and eyebrows. **C.** Scabies: usually located on axillae, webs of fingers and toes, and intragluteal area.

tend to have greater extremity involvement, along with the head and neck. Clinically, xerosis (dry skin), erythema, and a pruritic papular eruption are apparent. Scratching and rubbing lead to crusting, weeping, and eventually lichenification. Changes in color, including hypopigmentation and hyperpigmentation, may also occur. Hypopigmented areas with fine scale that are usually noted on the face are called pityriasis alba (considered to be the mildest form of atopic dermatitis). Xeroderma, or dry skin, is a frequent coexisting condition. Ichthyosis vulgaris, characterized by dirty-appearing excessive scaling and hyperlinear palms, is seen in half of patients affected with atopic dermatitis. Lesions around mucosa (Dennie-Morgan lines in the infraorbital fold under the eye and cheilitis around the mouth) may also be seen. Symptoms of other atopic conditions, such as allergic rhinitis, asthma, or food-related allergies, will occur in many of these patients.

Seborrheic dermatitis, which frequently develops during the first 3 months of life, is characterized by scaly papules or confluent scaly plaques, particularly of the scalp. Scalp eruptions in infancy are referred to as cradle cap. Seborrheic dermatitis has a predilection for areas with a high density of sebaceous glands, such as the scalp, face, ears, presternal chest, penis, and intertriginous areas, including the folds of the diaper region (Figure 121-1B). The red or pink papules and plaques may have a greasy quality. Secondary infections may occur with *Candida*, particularly in the intertriginous areas. Seborrheic dermatitis is usually not exceedingly pruritic, and this feature can be used to distinguish between it and atopic dermatitis. The intertriginous involvement and the onset shortly after birth also differentiate these 2 types of dermatitis. Severe seborrheic dermatitis can be associated with an immune deficiency, most commonly in HIV-infected patients.

Irritant or allergic contact dermatitis occurs when individuals come into physical contact with an irritant or a specific allergen, respectively. Irritant dermatitis is caused by direct cytotoxic effect, while allergic contact dermatitis is a delayed type IV hypersensitivity response to an allergen. Though their etiologies are different, they typically have a similar clinical appearance. Individuals usually develop well-defined erythematous vesicles, papules, or plaques, often with scale, and can have oozing and subsequent lichenification. Diaper dermatitis is one of the most common types of irritant dermatitis in the pediatric population (see Chapter 120). Rhus dermatitis (poison ivy/oak) and nickel allergy are 2 common types of allergic contact dermatitis seen in this population. It remains controversial whether atopic dermatitis is a risk factor for allergic contact dermatitis. However, children with atopic dermatitis may have more exposure to sensitizers, in conjunction with a damaged epithelial barrier, putting them at risk.

Plaque-type psoriasis, a chronic papulosquamous skin condition manifested most commonly as well-defined erythematous papules and plaques with silvery scale, is a not uncommon disease of childhood, with females more frequently affected. About 40% of adult patients with psoriasis report having the disease in childhood. It

most commonly affects the scalp in the pediatric population as well as the face and intertriginous areas. Infrequently, a young infant may develop psoriasis in the diaper area. Guttate psoriasis features smaller scaly papules and is usually precipitated by group A streptococci infection in the pharynx or perianal area. Pruritus is variable, but not prominent. Classically, psoriatic lesions can develop at sites of trauma (scratches and cuts), known as the Koebner phenomenon.

Pityriasis rosea is a self-limited papulosquamous eruption that is frequently seen in adolescents. The lesions tend to be round or ovoid and classically have a symmetrical distribution on the trunk extending downward from the midline at a 45-degree angle. Classically, there is a larger “herald patch” preceding the eruption by a few days to weeks. It should be duly noted that the classic presentation is not always present—many patients cannot recall a herald patch and the pattern over the trunk is commonly haphazard. It is generally self-limited and resolves in 1 to 2 months. It is pruritic in about one-quarter of those affected. Though the etiology is unknown, recent evidence suggests that human herpesvirus 7 infection is associated with most cases, and some patients may have a viral prodrome preceding the rash.

Lichen planus is an uncommon papulosquamous eruption in the pediatric population. It is characterized by pruritic, polygonal, pink to purplish flat-topped papules overlying Wickham striae; white scale can be seen. Etiology is also unknown, though hepatitis C, as well as other viruses, as a causative factor has been proposed. Flexor surfaces are usually affected and these lesions can Koebnerize.

Lichen striatus is an asymptomatic lichenoid eruption consisting of flat-topped papules that are skin color to slightly hyperpigmented. The lesions develop along the lines of Blaschko and may be arranged in a curvilinear distribution. This eruption spontaneously resolves over months to years. It is mostly commonly seen between 9 months to 9 years of age. The etiology is unknown.

Scabies may resemble atopic or seborrheic dermatitis in infants and young children. The lesions may be papules, pustules, or vesicles. The characteristic burrow, which is only 3- to 10-mm long, is often difficult to appreciate unless certain diagnostic maneuvers are undertaken. The lesions are most often noted on the skin of the hands and feet, including the palms and soles in infants and young children. Intertriginous areas such as the intragluteal region, groin, and finger webs are commonly infected (Figure 121-1C). In infants, the face and head may be involved. Scratching and secondary infection may alter the appearance of the rash. Reddish-brown nodules may be characteristic of more chronic infection. In institutionalized or immunosuppressed individuals, extensive mite infection can occur, resulting in thick, greasy-appearing, yellowish scale and crusts over the extremities and trunk, a condition referred to as *crusted scabies*.

Fungal infections (eg, tinea corporis and tinea pedis) commonly appear as papulosquamous eruptions. Commonly, the lesions assume a characteristic morphology, with scaly papules grouped in a circle or coalesced into a plaque with central clearing.

Evaluation

History

A thorough history should be obtained (Questions Box). The presence of a rash in other family members suggests a contagious condition such as scabies or a familial disorder such as atopic dermatitis. An onset in the first few weeks of life is consistent with seborrheic dermatitis. It is important to determine if any medications have been used because these may modify the appearance of the rash. In addition, certain medications can cause a rash themselves, though these tend to be more morbilliform in appearance (see Chapter 122). Pruritus should be noted. Asking about lesions developing at sites of previous trauma can aid in diagnosing eruptions that Koebnerize, such as psoriasis and lichen planus.

Questions

Papulosquamous Eruptions

- How long has the child had the rash?
- What did the rash look like when it first appeared?
- Are other family members affected?
- Have any medications been used to treat the rash or any been given prior to the onset of the rash?
- Is pruritus present?
- Does the child have any other symptoms such as wheezing or rhinorrhea?
- Does the child have a history of any contact between the affected skin and any irritating substance?
- Has the child been febrile?

Physical Examination

The physical examination helps define the exact nature of the eruption and its distribution, which is often the clue to its etiology. The entire body should be examined, and particular attention should be paid to the intragluteal region and web spaces between fingers and toes. Certain rashes have characteristic appearances. For example, a circular cluster of scaly papules with central clearing signifies tinea corporis or the herald patch of pityriasis rosea. The presence of burrows characterizes scabies. Burrows appear as a 3- to 10-mm grayish-white line (only about 1 mm wide). Vesicles, pustules, and nodules may also be present in scabies.

It is also important to distinguish if any secondary lesions, such as linear excoriations, are present. Secondary infections are also important to diagnose and treat because they can complicate many of the papulosquamous eruptions.

Associated cutaneous features can also aid in diagnosis. Hyperlinear palms, keratosis pilaris (erythematous 1- to 2-mm folliculocentric papules often on lateral upper arms, anterior thighs, and cheeks), and perioral/periocular lichenified papules are often seen in children with atopic dermatitis.

Overall health, including height, and weight should be assessed. Failure to thrive in conjunction with eczematous skin changes should raise the suspicion for an immunodeficiency.

Laboratory Tests

Certain diagnostic tests may help clarify the etiology of certain papulosquamous eruptions. In children with atopic dermatitis, approximately 30% may have coexisting food allergies and 70% may have coexisting respiratory allergies. Food allergies tend to develop during early infancy whereas respiratory allergies may develop during childhood. While it is important to identify food (and later on, environmental) allergies via skin or radioallergen sorbent/immunoCAP testing, which measures allergen-specific IgE (Chapter 80), parents must understand that food allergies **infrequently** cause or exacerbate atopic dermatitis. Based on misperceptions on the role of food allergies in atopic dermatitis, parents may on their own institute dietary restrictions for their child, which often results in gross undertreatment of the skin itself and may even lead to dangerous levels of malnutrition. Therefore, proper referral and counseling are especially important in infants who have both atopic dermatitis and food allergies. Patch testing may identify allergens causing contact dermatitis. Serologic IgE may or may not be elevated in children with atopic dermatitis.

The burrow of the mite that causes scabies may not be readily apparent. Scrapings with mineral oil are most commonly done today to help identify the mite, eggs, or feces (scybala)—any of these are diagnostic. Multiple burrows or web spaces are scraped. Scrapings of skin also assist in diagnosing candidal or tinea infections. These scrapings should be mixed with 10% to 20% KOH, which facilitates the dissolution of epithelial debris and allows for identification of the spores or hyphae.

If a secondary bacterial infection is suspected, cultures of the skin are indicated. Most of the papulosquamous eruptions are diagnosed clinically and no other specific diagnostic tests, short of a skin biopsy, assist in the diagnosis.

Management

The management is determined by the diagnosis.

Management of atopic dermatitis hinges on skin barrier function and the reduction of dryness and irritation with **vigilant skin care**. There has been debate whether frequent short baths daily versus bathing infrequently is more beneficial. It is most crucial that these patients bathe for short times only, applying cleansers only to the face, groin, and other soiled areas. The cleanser should be soap-free or the soap should be nonirritating, nondrying, and perfume- and dye-free. Children should pat dry after bathing with immediate application of either emollient or medication. Thick emollients such as petroleum jelly or other greasier ointments are preferable. In general, moisturizer from a jar tends to be more hydrating than that from a pump. For school-aged children, using greasier emollients at night under pajamas and then thinner emollients during the day may increase compliance. Sunflower seed oil is an inexpensive emollient

that can be used after morning bathing for daytime use. Avoiding scratchy clothing such as wool can be helpful, as can humidifiers in the winter to prevent excessive environmental dryness. The humidifiers should be cleaned regularly to prevent mold buildup, and a cool mist is considered safer to prevent burns.

Topical steroids are used to treat various papulosquamous eruptions, especially during flares. These drugs are the mainstay of therapy designed to minimize inflammation. The agents usually prescribed in cases of atopic as well as seborrheic dermatitis are triamcinolone 0.025%, 0.1%, and hydrocortisone 1% creams or ointments. Though ointments allow for better penetration and, often, less irritation, they are often disliked for their greasy texture, minimizing its usefulness because they are not applied regularly. The weaker hydrocortisone should be used for the face and groin and the higher strengths in areas of thicker skin. Chronic use should be discouraged to avoid skin atrophy. Parents can be educated on applying the medication to the appropriate areas for 1 to 2 weeks for flares, with maintenance use on weekends or 2 days per week. Sometimes brief courses of systemic steroids may be needed during more severe exacerbations, but if a patient is requiring oral steroids regularly, a referral to a dermatologist may be needed to consider other treatments such as systemic immunomodulators or ultraviolet (UV) therapy, both used for atopic dermatitis and psoriasis. Oral steroids may be required for rhus contact dermatitis, one of the more common forms of allergic contact dermatitis, and should be given for 2 to 3 weeks to prevent flaring.

For scaly scalp psoriasis, seborrheic dermatitis, and atopic dermatitis, several treatments can be used. For pruritus and inflammation, a topical steroid in gel, liquid, or foam vehicle can be applied. Mineral oil can help loosen scale, but needs to be washed out using an anti-seborrheic shampoo to prevent buildup. It should be massaged gently onto the scalp and allowed to sit for several minutes before rinsing. Fluocinolone oil or steroid shampoos can be used effectively for scalp psoriasis as well.

Tacrolimus and pimecrolimus are topical calcineurin inhibitors, which can be used as **steroid-sparing agents**, most often in mild cases of atopic dermatitis, seborrheic dermatitis, and inverse psoriasis (intertriginous). As of January 2006, a black box warning was placed on these 2 medications because there have been rare cases of skin cancer and lymphoma among patients using these drugs. The causal relationship for this warning was not well defined and, thus, many dermatologists still prescribe these medications in conjunction with topical steroids for their patients. As stand-alone agents, they are not as effective as steroids for more severe cases and are substantially more expensive.

In psoriasis, topical steroids are often used in conjunction with **calcipotriene** ointment or cream. **Tar** and **anthralin** are still used today as adjunctive topical treatments, though are falling out of favor due to their messy quality and more favorable alternatives.

Antihistamines may play a role in reducing the pruritus, especially at bedtime due to their sedating effect. Hydroxyzine and diphenhydramine work well in the evenings. For daytime,

fenofenadine, cetirizine, or loratadine are less-sedating choices. Regular use of antihistamines during a flare can help to break the itch-scratch cycle often observed in children with atopic dermatitis. The other conditions can have variable degrees of pruritus for which antihistamines can be useful. Clipping fingernails decreases the risk of skin trauma after scratching.

Antibiotics are indicated if secondary infection is present. The most common pathogen involved is *Staphylococcus aureus*. Staphylococcal antigens also exacerbate the inflammation of atopic dermatitis. Treatment with antistaphylococcal systemic antibiotics such as cephalosporins may be needed for more widespread secondary infections. Topical antibiotics such as mupirocin may be used in localized secondary infections. Streptococcal-associated guttate psoriasis should also be treated with appropriate antibiotics.

Seborrheic dermatitis is generally treated with a combination of products including topical keratolytics, corticosteroids, and antifungals (see also Chapter 119). The seborrheic dermatitis of infancy can be treated with topical shampoos containing selenium sulfide and gentle sloughing of the scaly lesions using a soft brush or cloth. Topical calcineurin inhibitors have anti-inflammatory properties without skin atrophy side effects, but are generally reserved for peri-orbital or recalcitrant cases due to the cost of the medications.

If children with atopic dermatitis develop infection with herpes simplex (eczema herpeticum), they should be treated with **acyclovir**. Involvement of the nasal tip is concerning for eye involvement and warrants an ophthalmology consult. If involvement is severe, the patient may need to be hospitalized for intravenous antiviral therapy. Children with atopic dermatitis are also prone to viral infections resulting in warts and molluscum contagiosum, and these should be managed accordingly.

Coinfection with *Candida*, which occurs with seborrheic dermatitis and psoriasis, requires the use of topical medications such as **nystatin**, **clotrimazole**, or **miconazole**. Antifungal shampoos may also help in reducing the scaling due to fungal agents such as *Pityrosporum*. Tinea corporis also responds to topical antifungal agents. Tinea capitis will require systemic antifungals (see Chapter 119).

The treatment for pityriasis rosea remains controversial, especially because it is a self-resolving condition. There are several studies demonstrating effectiveness of **acyclovir**, **erythromycin**, or **UV therapy** to speed recovery.

There are several medications used to treat scabies. The current preferred product is 5% **permethrin** cream. It is approved for infants 2 months or older, although its safety and efficacy has been reported in a 23-day-old infant. It should be applied from head to toe in infants and from neck to toe in small children and adults, left on for 8 to 12 hours, then rinsed off. **Lindane**, which has been used for more than 50 years and previously used worldwide, is a 1% cream. Because of concern about the percutaneous absorption of lindane and its potential neurotoxicity, it is no longer widely used and is not available in some areas. Oral **ivermectin** is also a successful scabicide. A single dose of 200 µg/kg, then repeated in 1 week, can be

used in children weighing more than 15 kg and women who are not pregnant or breastfeeding. All scabicides should be re-administered 7 days after initial treatment. The effective elimination of scabies necessitates that all affected household members be treated simultaneously and that bed linens and clothing be washed in hot water. Patients should be warned that the pruritus of scabies often takes several weeks to subside and can be treated supportively with steroids and antihistamines.

Prognosis

In general, the prognosis for children with papulosquamous eruptions is excellent with appropriate management, which is contingent on accurate diagnosis. Both atopic dermatitis and seborrheic dermatitis tend to improve as children get older. However, chronic problems such as hand dermatitis, which can be exacerbated by occupational exposures, can become a significant problem in patients with atopic dermatitis. Children with significant atopic dermatitis should be counseled against careers with frequent wet work, such as hairdressers, hospital workers, or food service. It is also critical to counsel families that maintaining atopic dermatitis with the prevention of flares is the primary goal and is more important than having perfect skin. Families of children with severe atopic dermatitis can have difficulty in maintaining a good quality of life for these patients, and the entire family structure can suffer as chronic care can be challenging. Children with atopic dermatitis frequently face remissions and exacerbations, particularly associated with seasonal changes. Prevention and maintenance must be stressed. It is advisable that patients with recalcitrant eczema have further workup with an allergist to eliminate triggers.

Many of these eruptions, such as lichen striatus and pityriasis rosea, are self-limited and only need symptomatic treatment. Psoriasis has a more chronic course, and early diagnosis and treatment can help to reduce the disease severity and progression. Chronic disease such as atopic dermatitis and psoriasis can be psychologically challenging for children because they can often be ridiculed at school and excluded from activities for unfounded fears of contagiousness. The teachers may need to be educated as well and emotional and psychological support provided for these children.

Scabies and tinea will improve with appropriate management and education to prevent recurrence.

CASE RESOLUTION

The infant's presentation in the case history is characteristic of atopic dermatitis. The baby experienced the onset of symptoms as a young infant (most atopic patients develop symptoms after 2 months of age). Atopic dermatitis can often affect the head and face of young patients. Xerosis is also apparent.

The most important discussion with the mother should be on good skin care. The mother should be advised that although she may use the baby oil to loosen the scale on the scalp, she should shampoo afterward with a mild antiseborrheic shampoo to prevent buildup. A mild topical steroid, such as hydrocortisone 1% ointment, may also be recommended though chronic use should be dissuaded. If skin scrapings reveal secondary infection with *Candida*, an antifungal cream should be added to the regimen; if a secondary bacterial infection is suspected, a culture should be taken and treatment with either topical or systemic antibiotics initiated. Short baths with a mild cleanser and regular application of emollients is critical.

The mother should also be educated on potential flares with vaccinations and infections, as well as with climate changes. It is important that the infant catch up on her vaccinations, but cautioning the mother about a potential flare can prevent distress.

Morbilliform Rashes

Kathy K. Langevin, MD, MPH, and Noah Craft, MD, PhD

CASE STUDY

A 10-month-old infant girl is brought to the office with a history of rhinorrhea, cough, and fever for 3 days prior to the onset of a confluent, erythematous rash. The rash started on her face. She has been irritable, and her eyes are red and teary. Her immunizations include 3 sets of diphtheria, tetanus, and acellular pertussis, polio, rotavirus, *Haemophilus influenzae* type b, conjugated pneumococcal, and hepatitis B vaccines. No one at home is ill. The girl was seen in the emergency department 2 weeks before because she caught her finger in a car door. On physical examination, the girl's temperature is 102.2°F (39°C). A confluent eruption of erythematous macules and papules

is evident on the face, trunk, and extremities. Rhinorrhea and conjunctivitis are also present.

Questions

1. What are the common causes of febrile macular/papular or morbilliform rashes in children?
2. What features distinguish one disease from another?
3. How does a child's nutritional status affect their reaction to certain exanthem-inducing viruses?
4. What are the public health considerations concerning viral exanthems in children?

Exanthems are skin findings resulting from an underlying disease. More than 50 different viruses, in addition to bacteria and *Rickettsia*, have been identified, though viruses tend to be the leading cause. In children, these exanthems are most commonly macular, papular, or mixed. The rash of measles is described as morbilliform, and this adjective is used to describe similar-appearing eruptions of macules and papules. Frequently these rashes are seen in conjunction with fever, and additional symptoms include myalgias, rhinorrhea, conjunctivitis, headache, gastrointestinal (GI) complaints, and lymphadenopathy. The exanthems of various underlying viruses can also be seasonal. Although many of the common childhood illnesses of the past are now prevented by immunizations, not all segments of the population are adequately immunized. In addition, some children are not eligible for immunization because of their young age. Allergic reactions to medications, particularly antibiotics, may also result in similar eruptions and can be accompanied by symptoms of low-grade fever and pruritus. Differentiating viral exanthems from allergic reactions may be difficult in febrile children who have been empirically started on antimicrobial agents.

Epidemiology

In most children, the viruses that cause exanthems produce mild disease without significant morbidity or long-term sequelae. Of greater concern to the public health is the risk of potential spread through the population. Morbilliform eruptions are a common presenting complaint, particularly in certain age groups and at certain times of the year.

Measles, also known as rubeola, is caused by an RNA virus, and has markedly decreased in the United States since the live vaccine

was introduced in 1963. It is transmitted by direct contact with infectious droplets or by airborne spread. In temperate climates, it is most frequently seen in the winter and spring. In the pre-vaccine era, measles was a significant cause of morbidity and mortality. Periodic resurgences have occurred, particularly among unimmunized preschoolers, older adolescents, and young adults. In addition, young infants are also at risk because of decreased levels of passively transferred maternal immunity related to lack of maternal natural infection or immunization. Vaccine-related immunity apparently wanes more rapidly in mothers than does naturally acquired immunity. Because of the increased number of cases in preschoolers and in children with primary vaccine failure who received the vaccine appropriately, the 2-dose recommendation by the American Academy of Pediatrics was implemented in 1989, though there continue to be cases each year. Measles is no longer endemic in the United States but continues to be imported. The incubation period of measles is about 10 days. Individuals are infectious from about 3 to 5 days before the onset of rash until 4 days following its appearance.

Rubella is also caused by an RNA virus and is no longer considered endemic in the United States, with less than 15 cases annually. Sporadic outbreaks are reported, generally in foreign-born or under-immunized persons, but about 10% of US-born individuals older than 5 years are considered to be susceptible. The peak incidence is in the late winter to spring, and it is likely transmitted via direct or droplet contact from nasopharyngeal secretions. Though generally a mild disease, its most serious manifestation is congenital rubella syndrome, which may develop in the offspring of infected pregnant women, with the greatest risk of congenital defects during the first trimester. The incubation period is 14 to 23 days.

Erythema infectiosum, also called fifth disease, is most commonly seen in children 4 to 10 years of age during late winter to early spring. Most adults have antibodies indicating previous infection. The disease is caused by an acute infection with parvovirus B19, a DNA virus, and spread through respiratory secretions, percutaneous exposure to blood or blood products, and vertical transmission from mother to fetus. The incubation period is generally 4 to 14 days but may be up to 21 days.

Roseola infantum, also known as exanthem subitum, generally affects children from 6 months to 2 years of age, as maternal antibodies are protective until the age of 6 months. The illness is due to infection with human herpesvirus (HHV) 6 or 7, though HHV-6b, a DNA virus, is most commonly the etiologic agent. The virus is shed in the saliva, even among healthy, previously infected infants. Almost all children are seropositive by the age of 4. Reactivation is possible though not common, and there is no seasonal pattern. The incubation period for HHV-6 is likely 5 to 15 days and is unknown for HHV-7.

Enteroviruses are the most common cause of exanthems in the summer and fall. They are all RNA viruses of the picornavirus group and include coxsackieviruses (groups A and B), echoviruses, and enteroviruses. Infection is spread through fecal-oral and respiratory routes as well as via fomites. There is also vertical transmission. Infection is more common in young children and in those with poor hygiene. The incubation period is usually 3 to 6 days.

Kawasaki disease, an acute self-limited vasculitis, is of uncertain etiology, although an infectious cause is suspected due to epidemics occurring usually in the winter and spring. Most patients are between 6 months and 5 years of age. Males outnumber females by a ratio of 1.5:1. The incidence of the disorder among Asians is higher than in other populations, suggesting genetic factors play a role. The incubation period is unknown.

Gianotti-Crosti syndrome, also known as papular acrodermatitis of childhood, has historically been associated with hepatitis B infection. In the United States, it is believed to be a host response to multiple viral infections including, but not limited to, hepatitis A and B, Epstein-Barr virus (EBV), measles, and the enteroviruses. It is seen most frequently in children 1 to 6 years of age.

Scarlet fever is a cutaneous reaction to several erythrogenic exotoxins produced by group A streptococcus (GAS) via delayed-type hypersensitivity. It is transmitted through respiratory secretions. Scarlet fever is usually seen in young children between 1 to 10 years with pharyngitis. It occurs most commonly in cooler climates during the late fall, winter, and early spring. The incubation period is 2 to 5 days.

Rocky Mountain spotted fever (RMSF) is caused by *Rickettsia rickettsii*, an intracellular organism. Infection is transmitted by the bite of *Ixodes* ticks, which are both reservoirs and vectors of the organism. It can be seen throughout the United States, with most cases seen in the southern states. Children younger than 15 years are most commonly infected. Highest incidence of infection is seen between April and September. The incubation period lasts from 2 to 14 days.

Clinical Presentation

Morbilliform eruptions may involve the face, trunk, or extremities. The eruption is usually erythematous, and the lesions are flat or slightly raised. Occasionally, lesions within the mouth, referred to as enanthems, are evident. Most children are febrile (Dx Box) and may have other symptomatic complaints.

Dx Morbilliform Rashes

- Macular, papular, or combined rash
- Fever
- Enanthems (lesions in the mouth)
- Lymphadenopathy
- Respiratory symptoms
- Gastrointestinal symptoms

Pathophysiology

The mechanism for development of a rash is variable. In some cases, the rash is the reaction of the body to infection or to the presence of a toxin. In general, the sequence involves exposure to an infectious agent and then acquisition of the agent most commonly through droplet infection or fecal-oral contamination. The agent, usually a virus, then replicates, perhaps in the reticuloendothelial system. Lymph nodes enlarge, reflecting the involvement of the reticuloendothelial system. Associated viremia may be present.

In Kawasaki disease, vasculitis affects multiple organ systems. Various cytokines and autoantibodies play a role in the inflammatory response. In a toxin-mediated rash (eg, scarlet fever), previous exposure to the toxin is believed to sensitize the individual.

Differential Diagnosis

While many exanthems can be easily recognized clinically, the decreased frequency of many of these usual childhood diseases means that physicians encounter these conditions less frequently than in the past. Familiarity with the appearance of these conditions is critical to diagnosis. The Internet can be valuable by providing access to images of many dermatologic conditions. Some sites such as VisualDx (accessible at www.visualdx.com) display pictorial representations and allow for searching by features such as rash morphologies, symptoms, exposures, skin color, body location, age, immune status, and many other factors.

Morbilliform exanthems are associated with several infectious diseases, such as measles, rubella, erythema infectiosum, roseola, enterovirus infections, Gianotti-Crosti syndrome, Kawasaki disease, scarlet fever, and RMSF. Drugs can also cause eruptions similar to those caused by the aforementioned diseases.

The rash associated with **measles** is preceded by the 3 “Cs” of cough, coryza, and conjunctivitis in addition to fever, which last for several days before the eruption of the exanthem. Lesions on the buccal mucosa, called Koplik spots, are well-circumscribed white-gray papules (Figure 122-1) that appear during the prodrome and resolve

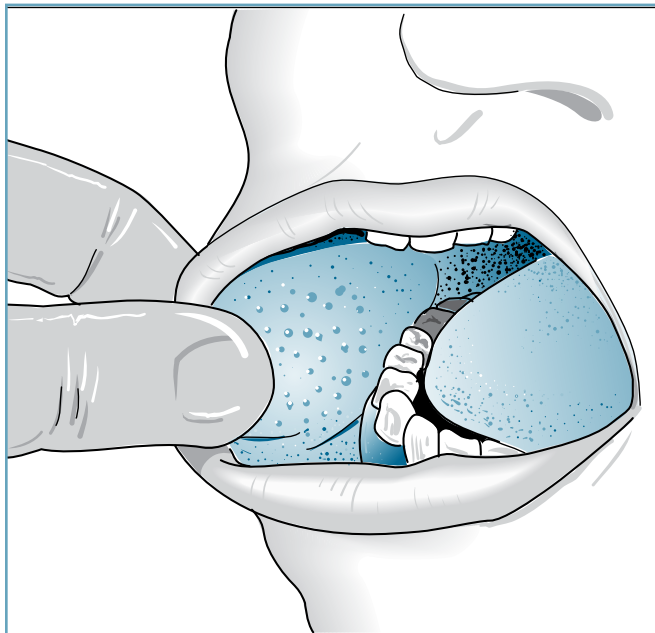

Figure 122-1. Koplik spots.

after 3 to 4 days. This enanthem, though rare, is pathognomonic for measles. The measles rash itself usually begins on the head, particularly behind the ears and around the margin of the scalp, and then spreads cephalocaudally. After 2 to 3 days, the eruption becomes confluent and copper-colored, fades in the order it appeared, and then may desquamate.

Measles is not generally associated with systemic lymphadenopathy. The major complications of measles in children in developed nations are pneumonia, encephalitis, and secondary bacterial infections. In developing nations, death usually results from respiratory and neurologic complications, often in those with marginal nutritional status especially vitamin A deficiency. In individuals who were initially immunized with killed measles vaccine (1963–1968), acquisition of measles results in atypical measles, generally more severe than regular measles, and characterized by acute high fever, myalgias, and cough. A papular, vesicular, or hemorrhagic eruption that begins peripherally follows a few days later. Lobar pneumonia is usually present, and associated findings include hepatosplenomegaly and weakness.

Rubella produces a relatively minor illness in children, although adults, particularly women, may experience a painful arthritis. Up to half of infections are asymptomatic. There can be a prodrome of fever, headache, conjunctivitis, and upper respiratory symptoms. The eruption consists of fine erythematous macules and papules that become near confluent, starting on the face and progressing caudally to the trunk, resolving after 3 days. Lymphadenopathy, particularly of the postauricular or suboccipital nodes, is characteristic of the disease. Forschheimer spots are pinpoint rose-colored macules that can develop on the soft palate in patients with this infection. Congenital rubella syndrome results in multisystem anomalies that can follow maternal infection and is part of the TORCH congenital infections (toxoplasmosis, other agents [hepatitis B, coxsackievirus,

siphilis, varicella-zoster virus, HIV, parvovirus B19], rubella, cytomegalovirus, herpes simplex).

Erythema infectiosum (EI) is characterized by a distinctive eruption that may be preceded by mild prodromal symptoms including low-grade fever, headache, myalgias, and malaise. The eruption generally occurs 7 to 10 days after the prodrome. The facial rash consists of erythematous patches on the cheeks with sparing of the nasal bridge and periorbital areas. This “slapped-cheek” appearance generally fades after several days and is considered the first stage of the illness. In the second stage the extremities may develop a lacy reticulated rash of macules and papules 1 to 4 days later that can be pruritic. Palm and sole involvement is rare. This usually lasts about a week but may have recurrences over several weeks in the third stage, with triggers such as activity, sunlight, emotional stress, and hot baths. Most children are only mildly ill and may attend school, but children with underlying hematologic disorders may experience aplastic crises because of the affinity of parvovirus B19 for developing red blood cells. Immunocompromised children are also at risk for chronic anemia. Pregnant females may transmit this infection to their fetuses, which can result in fetal hydrops, growth retardation, isolated pleural and pericardial effusions, and fetal loss. Adults with parvovirus infection frequently develop arthritis, though only 10% of children experience this symptom. Neurologic disturbances including encephalitis and neuropathies may follow parvovirus infection, though this is rare. **Papular-purpuric gloves and socks syndrome (PPGSS)** is a self-limited acute eruption linked to parvovirus B19 infection. It occurs usually in the spring and summer, characterized by often-painful edema and erythema and progressing to purpuric macules and papules with a sharp line of demarcation at the wrists and ankles. A nonspecific enanthem of petechiae and erosions can occur. Symptoms of myalgias, lymphadenopathy, anorexia, and fatigue may follow the rash. The exanthem generally resolves after 1 to 2 weeks with no residual sequelae.

Roseola infantum usually causes a fairly mild illness in children, though there can be associated complications. Defervescence usually accompanies the rash, which consists of fine, non-pruritic, blanchable, pink macules or papules with a surrounding halo that generally appear first on the trunk, and then spread centrifugally. Some may develop an enanthem consisting of erythematous papules on the soft palate and uvula called Nagayama spots. Periorbital edema can also be seen. On average, the rash evolves over 12 hours and usually resolves by 2 days. Infants may appear sickest during the prodromal phase, when the fever is high (temperature: often $\geq 103^{\circ}\text{F}$ [39.5°C]), and infants are irritable as a result. Fever generally lasts 3 to 5 days and can be accompanied by upper respiratory symptoms and lymphadenopathy. Seizures during the febrile period can occur in up to 15% of primary infections. Workup to rule out sepsis is often warranted.

The skin eruptions associated with **enterovirus infections** are highly variable. They may be distinct and characteristic, such as hand-foot-and-mouth disease (HFMD), most commonly associated with coxsackievirus A16 and enterovirus 71 (see Chapter 123). However, many of the enteroviral exanthems are less distinctive and have a generalized morbilliform appearance. Neurologic

complications associated with enteroviral infections include aseptic meningitis and encephalitis and have been reported in infections with coxsackievirus B and enterovirus 71. Other systems affected by enteroviral infections include respiratory, GI, ophthalmic, and cardiac.

The rash of **Kawasaki disease** is also highly variable; it may be morbilliform, urticarial, scarlatiniform, or resemble erythema multiforme. During the first week of illness, there may be desquamation of the perineum. The diagnosis of Kawasaki disease requires fever (generally $>39^{\circ}\text{C}$ [lasting at least 5 days]) and 4 out of the 5 following findings: (1) bilateral non-purulent conjunctivitis; (2) changes in the oropharyngeal mucosa including fissured lips, oral erythema, and strawberry tongue; (3) changes in the extremities such as erythema/edema or desquamation; (4) cervical lymphadenopathy with one node measuring at least 1.5 cm in diameter; and (5) the exanthem described previously. Irritability, abdominal pain, and diarrhea are not uncommon. Incomplete Kawasaki disease can be diagnosed when only 2 of the additional criteria are met, thus the practitioner should consider this diagnosis when persistent high fever and only 2 or 3 of the above symptoms are present. The major complication of Kawasaki disease is coronary artery abnormalities, and males and those younger than 12 months are at increased risk.

The exanthem of **Gianotti-Crosti** syndrome consists of monomorphic, pink- to skin-colored, usually non-pruritic papules on the face, buttocks, and extremities, with sparing of the trunk. There is often a prodrome of fever and upper respiratory symptoms with associated generalized lymphadenopathy and hepatosplenomegaly. The exanthem fades after 2 to 3 weeks but can last up to 2 months.

Scarlet fever is primarily a disease of childhood. The onset is marked by sudden high fever, headache, vomiting, malaise, and sore throat. Within 12 to 48 hours, erythema develops on the neck, chest, and axillae. The rash quickly becomes generalized to a sandpaper-like rash of fine red papules on an erythematous background. Linear accentuation in the axillary, antecubital, and inguinal folds is known as Pastia lines. The face is flushed, except around the mouth (circumoral pallor). There is pharyngeal injection with exudate developing after a few days. The tongue is initially white with prominent red papillae (Figure 122-2), known as strawberry tongue. As the scarlet fever rash resolves, desquamation begins in 7 to 10 days, lasting up to 6 weeks.

The rash of **RMSF** begins as blanchable pink macules or papules that evolve into petechial or purpuric non-blanching lesions. They begin on the wrists and spread centripetally. The palms and soles are almost always involved. The exanthem is preceded by symptoms of fever, headache, and malaise. Gastrointestinal symptoms such as nausea, vomiting, and diarrhea can be present. The rash generally develops 2 to 3 days after the prodrome.

Morbiliiform rashes are the most common type of cutaneous **drug eruption**. They generally begin as erythematous macules and papules on the trunk that then spread to the extremities symmetrically. There is usually concurrent eosinophilia. Pruritus and low-grade fever can also be present, often confounding the diagnosis. Though most drug rashes begin 1 to 2 weeks after starting the drug,

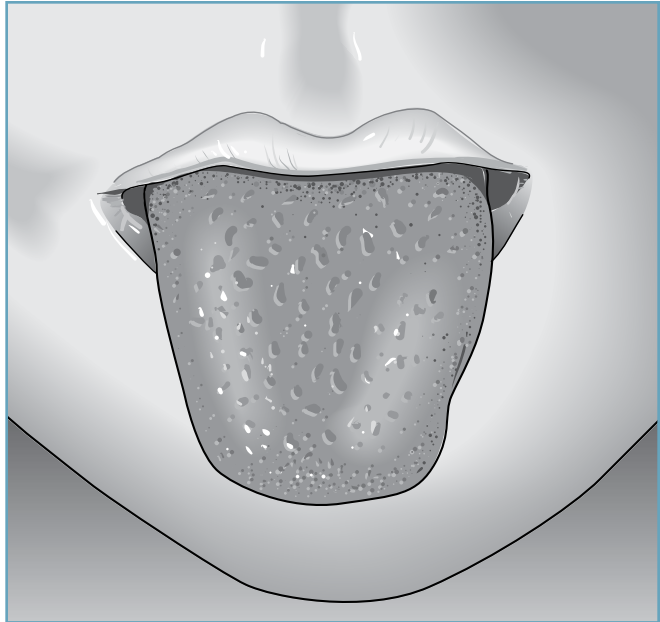

Figure 122-2. Strawberry tongue.

an eruption may develop after a drug has been discontinued. After stopping the offending medication, the rash usually resolves over 1 to 2 weeks, but there can be progression to Stevens-Johnson syndrome or toxic epidermal necrolysis. The underlying pathogenesis of many of these drug rashes continues to be unknown; however, current studies indicate a cell-mediated pathogenic mechanism.

Infection with **EBV** is associated with rash in young children and in adolescents on antibiotics, usually ampicillin or amoxicillin. The eruption is morbilliform, and the lesions may be erythematous or copper-colored. Fever, upper respiratory symptoms, lymphadenopathy, hepatosplenomegaly, and facial and peripheral edema, including unilateral periorbital edema, may be noted. The rash is likely due to an immunological interaction between the infectious agent and the drug.

Evaluation

History

A thorough history should be obtained (Questions Box).

Physical Examination

The focus of the physical examination is to help define the characteristics of the eruption such as location, extent, and degree of coalescence. The presence of any associated physical findings such as fever, lymphadenopathy, enanthem, desquamation, rhinorrhea, conjunctivitis, organomegaly, or central nervous system (CNS) symptomatology should be determined.

Laboratory Tests

Laboratory assessment may be helpful in certain conditions, though most of these diagnoses are made clinically. Serologic testing is most valuable for defining a community outbreak of a specific disease such

Questions

Morbilliform Rashes

- What does the rash look like? Has a similar rash occurred before?
- What symptoms, if any, are associated with the rash or occurred before the onset of rash?
- How long has the child had these symptoms?
- Is the child taking any medications (antibiotics)?
- Does the child have any ill contacts?
- What is the child's immunization status?

as measles. In most viral exanthems, the results of serologic studies are not available until the condition has resolved and the patient has recovered. Tests may include acute and convalescent titers for specific viruses. Alternatively, immunoglobulin (Ig) M levels of antibodies against certain infections may be used to document that the infection was recent. Polymerase chain reaction may also be useful. Isolating the virus can confirm the diagnosis, but is often difficult to obtain. Because neutropenia and lymphocytosis characterize many viral illnesses, such findings are not helpful in differentiating specific causal agents. Lymphocytosis, with characteristically atypical lymphocytes, distinguishes EBV infection. Although a heterophile antibody test is usually positive in older children and adolescents, it may be nonreactive in young children, where infection is documented by specific EBV serology.

Pregnant women with suspected parvovirus B19 infection should have IgM and IgG levels drawn. If infection is confirmed, serial ultrasounds should be performed to monitor for symptoms of hydrops fetalis. Confirming diagnosis of rubella in a pregnant woman is also important because of the potential risk of congenital rubella syndrome.

Kawasaki disease is associated with elevation in markers of inflammation, including leukocytosis, thrombocytosis, elevated erythrocyte sedimentation rate, and C-reactive protein, though no test is diagnostic. Sterile pyuria is noted in 70% of the cases. Scarlet fever is characterized by leukocytosis. Eosinophilia can also be seen after a few weeks in up to 20% of patients. Laboratory confirmation, either via rapid streptococcal test or throat culture, should be done to confirm that the pharyngitis is due to GAS, not a virus. If the pharyngitis has resolved, serologic studies such as antistreptolysin O provide evidence of the recent infection.

A 4-fold or greater change in titer between acute and convalescent serum as determined by indirect immunofluorescent antibody assay is diagnostic for RMSF. Many patients will have thrombocytopenia, leukopenia, anemia, and hyponatremia. In general, any child presenting with headache, fever, and possible exposure to tick bite should be evaluated for this disease.

Imaging Studies

An echocardiogram to check for evidence of coronary artery aneurysm is a mandated part of the evaluation in Kawasaki disease, both during the acute phase and with serial repeat examinations,

more frequently and earlier in those at high risk. Long-term cardiac management is required for those with identified coronary artery abnormalities. Ultrasound, if performed in children with suspected Kawasaki disease who present with symptoms of an acute surgical abdomen, may reveal hydrops of the gallbladder.

Management

The management of most viral exanthems is supportive and symptomatic. Hydration is critical because GI complaints of diarrhea are often associated. Antihistamines should be used for symptoms of pruritus in addition to regular use of emollients. Painful oral lesions can be treated with topical analgesics. In cases where complications such as encephalitis or pneumonia develop, hospitalization is indicated. Spread of infection such as measles to susceptible contacts can be reduced through the use of vaccine within 72 hours of exposure, or immunoglobulin within 6 days. Measles vaccine should be administered after the Ig in children who have been exposed. The measles, mumps, rubella vaccine is administered for the 2-dose vaccine series in children at about 12 months of age and again at 4 years. Measles, mumps, rubella, varicella is no longer available in the United States. HIV infection is not a contraindication to measles vaccination. In developing nations, administration of vitamin A is recommended to all children with measles if vitamin A deficiency is present in the community and mortality from measles is 1% or greater. Antibiotic therapy should be initiated if bacterial coinfection is suspected but should not be started empirically. The management of Kawasaki disease includes the administration of intravenous IG (IVIG) and aspirin, which should be started within 10 days of onset of fever. The current recommendation is to administer a single dose at 2 g/kg given as an infusion over 10 to 12 hours. Periodic echocardiograms are also required in these patients with close monitoring by a cardiologist. Measles and varicella vaccinations should be deferred for 11 months in any patient receiving IVIG.

If there is a concern for hepatitis in patients with Gianotti-Crosti syndrome, workup should be initiated.

Control measures are important because most morbilliform exanthems are due to infectious agents. Children with postnatal rubella should be kept from school or child care facilities for 1 week after onset of rash. Those with congenital rubella syndrome are considered contagious for 1 year, and caregivers must be educated. Females receiving rubella vaccine should not become pregnant for 28 days following vaccination. Hand hygiene is an important control measure that should be used to minimize spread of many of these viruses.

Vigilant education about the importance of immunizations is vital to reducing the impact of diseases such as measles and rubella. Though the number of cases in the United States is low, importation of these viruses from other countries mandates continued widespread vaccination.

Pregnant women infected with parvovirus B19 with ultrasound suggestive of hydrops fetalis should be referred to a tertiary care facility because intrauterine blood transfusions have proven successful. Routine exclusion of pregnant women from the workplace

where erythema infectiosum has been identified is not recommended because the virus is transmitted before the onset of rash and is, thus, unlikely to be effective. Patients with aplastic crisis and chronic parvovirus infection may be contagious for extended periods and require longer periods of precautions. In addition, patients with PPGSS are considered infectious when clinical symptoms of their eruption are present. Patients with aplastic crises may need transfusions, and IVIG has been used successfully in immunocompromised patients with chronic infection. However, most cases of EI do not require absence from school or treatment beyond supportive care.

Treatment with doxycycline is the drug of choice for infection with *Rickettsia*. Penicillin within 10 days of onset of symptoms is used to treat scarlet fever as a result of GAS pharyngitis to prevent the development of rheumatic fever. Erythromycin can be used in patients allergic to penicillin.

Prognosis

The prognosis for most morbilliform rashes of childhood is generally good, with full resolution of symptoms unless children are very young, have congenital disease, have an underlying condition, or develop long-term complications. In some young infants, viruses that cause exanthems may produce severe complications such as pneumonia and encephalitis. Subacute sclerosing panencephalitis is a late-onset, rare, and serious degenerative CNS disease that occurs as a complication of measles infection. Some patients with roseola may develop chronic neurologic sequelae, but most cases are benign. The prognosis for Kawasaki disease is usually favorable with appropriate management. Up to 25% of untreated children and a fraction of those who have been treated may develop coronary artery aneurysms, sometimes with symptoms remaining silent for years. Kawasaki disease is the leading cause of acquired heart disease in children in the United States. In patients with severe infection with RMSF, long-term neurologic complications can be seen.

CASE RESOLUTION

The infant in the case scenario has the classic symptoms of measles. Normally such a young infant would not yet have received immunization against measles because the first dose is administered at 12 to 15 months of age with the second dose at 4 to 6 years of age. Immunoglobulin will likely not modify the disease in this patient because her rash is near confluent, suggesting exposure more than 6 days ago. She should be evaluated for evidence of complications, including pneumonia. Unimmunized household contacts, as well as pregnant women and other contacts younger than 1 year, should receive IG. Treatment is supportive.

Vesicular Exanthems

Kathy K. Langevin, MD, MPH, and Noah Craft, MD, PhD

CASE STUDY

A 2-year-old toddler is evaluated for a 2-day history of fever (temperature: 103.1°F [39.5°C]), runny nose, decreased appetite, and a rash over the abdomen. The boy has had no previous known exposures to chickenpox (varicella) and no history of varicella vaccination. He attends child care daily. No one at home is ill. The boy is currently taking no medications except for acetaminophen for fever, and he has no history of dermatologic problems. On physical examination, the heart rate is 120 beats/min, the respiratory rate is 20 breaths/min, and the temperature is 100.4°F (38.0°C). The toddler's overall appearance is nontoxic. The skin examination is significant for a few scattered erythematous vesicular lesions over the abdomen

and one erythematous papule on the back. The rest of the examination is normal.

Questions

1. What are the most likely causes of vesicular exanthems in febrile children?
2. How can types of vesicular rashes be differentiated on the basis of patient history?
3. What are the key historical questions to ask?
4. What is the natural course of varicella?
5. What treatment options are available for children with varicella? What options are available for other vesicular exanthems?

Exanthems are generalized, erythematous rashes that are due to an underlying disease. They are most frequently caused by viral or bacterial infections, though they can also be due to noninfectious etiologies. Infectious eruptions are most commonly morbilliform in the pediatric population, but they can have variable manifestations, including vesicular, bullous, petechial, and purpuric eruptions. Vesicles are elevated, fluid-filled lesions that measure 1 cm or less in diameter. Bullae are quite similar, only larger in size. Vesicles often lose their initial morphology quickly because they can break spontaneously or coalesce into bullae. They can arise *de novo* or from macules or papules. Vesicles may be discrete, grouped, generalized, or linear, depending on their etiology, and their specific distribution is often helpful in formulating a differential diagnosis.

Epidemiology

Epidemiological factors can help differentiate infectious from noninfectious etiologies. Patient age, season of the year, presence or absence of similar cases in the community, regular attendance at child care or school, and lower socioeconomic class, which may contribute to exposure, should all be considered. Gender and ethnicity are usually less informative but can help distinguish certain diseases causing exanthems.

Primary varicella-zoster virus (VZV), or chickenpox, is a herpesvirus and one of the most common vesicular exanthems seen in childhood. In the pre-vaccine era, 90% of children in the United States were infected before the age of 10, with 3 to 4 million cases annually. Males and females are equally affected. Most reported cases are in children younger than 10 years, although the percentage of

infections in adolescents and young adults has increased since the routine administration of the varicella vaccine. It is primarily transmitted person to person by airborne spread of aerosolized viral particles from vesicles of infected persons. It may also be transmitted through respiratory secretions, from contact with zoster lesions, and vertically from mother to fetus. It is extremely infectious and transmission to susceptible household contacts approaches 80%. The incubation period ranges from 10 to 21 days, but varicella can develop between 1 to 16 days of life in newborns delivered to mothers with active disease around the time of delivery.

Herpes simplex virus (HSV) is a DNA virus, with HSV-1 and HSV-2 affecting most adults worldwide. Herpes simplex virus 1 infections generally occur outside the genital area while HSV-2 infects the anogenital area. However, there has been an increase in the prevalence of extragenital HSV-2. Neonatal infection is generally acquired at delivery from an infected mother who is often unaware of her infection. Herpes simplex virus 1 is typically transmitted by direct contact with oral secretions or lesions and HSV-2 from direct contact with infected genital secretions. Shedding of viral particles can occur in the absence of active infection. The incubation for HSV infections is 2 days to 2 weeks.

Hand-foot-and-mouth disease (HFMD), as well as herpangina, are due to enteroviral infections. Hand-foot-and-mouth disease is most commonly due to infection with coxsackievirus. Coxsackievirus groups A and B have been implicated in herpangina. Enteroviral infections occur most commonly in summer and early fall. The incubation period for most enteroviruses is between 3 to 6 days.

Bullous impetigo is a less common form of impetigo than the non-bullous forms. Bullous impetigo is most frequently seen in

the summer and is transmitted by direct person-to-person contact, possibly via fomites as well. It is caused by coagulase-positive *Staphylococcus aureus*, mostly due to phage group 2, and is a localized reaction to exfoliative toxin released by the bacteria. It affects mostly neonates, infants, and younger children.

Infections caused by scabies or fungi can cause vesicular eruptions as well. Scabies is transmitted during prolonged close contact with an infested individual. Scabies has an incubation period of 4 to 6 weeks in patients without previous exposure. Reexposed patients develop symptoms a few days after repeat exposure. Tinea pedis is a common infection worldwide, though less so in children. It is acquired via contact with infected skin scales and in damp areas where the fungi reside. Tinea capitis, a common fungal infection in children (see Chapter 119), does not result in a vesicular rash, but like tinea pedis, can result in a dermatophytid or id reaction that is vesicular. The incubation period of fungal infections is unknown.

Dyshidrotic eczema is a disease that can occur in children with chronic eczematous dermatitis or atopic dermatitis, but can occur in non-atopic children as well. Rhus dermatitis is the prototypical allergic contact dermatitis, which develops about 1 to 3 days after exposure to plants such as poison ivy, poison oak, and poison sumac. Linear papules and vesicles are seen at points of contact between the plant antigen and the skin.

Clinical Presentation

Vesicular exanthems are eruptions of distinctive lesions that are raised and fluid-filled (Dx Box). They may be located anywhere on the child's body and, depending on the etiology, may or may not be pruritic. Other symptoms that may accompany such rashes include fever, upper respiratory symptoms, and gastrointestinal and central nervous system (CNS) involvement.

Dx

Vesicular Exanthems

- Raised, fluid-filled vesicles on the skin
- Lesions may be pruritic
- Possible associated fever, upper respiratory infection symptoms, myalgias
- History of affected contacts
- Lesions on mucous membranes

Pathophysiology

Vesicles and bullae arise from a cleavage at various levels of the skin either within the epidermis (intraepidermal) or at the epidermal-dermal junction (subepidermal). Sometimes the 2 types of lesions can be differentiated based on the amount of pressure required to collapse the lesion, especially if the lesion is a large bulla. In addition, the thickness of the wall of a bulla can be estimated by its translucency or flaccidity. A biopsy of the lesion, however, is the only way to reliably differentiate between the 2 areas of separation, though this will not necessarily provide the diagnosis. Specific changes occur in

the epidermis depending on the etiology of the vesicular exanthem. For example, with certain viral infections such as herpes simplex, varicella, and herpes zoster, a “ballooning degeneration” of epidermal cells occurs.

In bullous impetigo, the vesicles and bullae are caused by staphylococcal exfoliative toxin, which cause the keratinocytes in the granular layer of the epidermis to split apart. There are no bacteria seen within the blister cavity and a few inflammatory cells can be present.

The rash due to scabies infestation is the result of a hypersensitivity reaction to the proteins of the parasite. In vesicular lesions, there is spongiosis, or intercellular edema, in the epidermis caused by the mite, which can result in a vesicle. Spongiosis also leads to vesicle formation in dyshidrotic eczema, though the pathogenesis of this disease is not known. Dyshidrotic is a misnomer because this disease is not related to sweat gland dysfunction or occlusion. Spongiosis is also present in id reactions and allergic contact dermatitis.

Differential Diagnosis

While many vesicular eruptions are easily distinguishable clinically, the differential diagnosis can be challenging at times. Familiarity with the appearance of these conditions and their differentiating features is critical. The Internet can be valuable by providing access to images of many dermatologic conditions. Some sites such as VisualDx (accessible at www.visualdx.com) display pictorial representations and allow for searching by features such as rash morphology, symptoms, exposures, skin color, body location, age, immune status, and many other factors.

Primary VZV infection (chickenpox) consists of an average of 300 vesicles with the greatest concentration of lesions on the head and trunk, though it can be generalized. Lesions exist in various stages of resolution, progressing from erythematous macules and papules that then evolve into vesicles and, eventually, pustules that then crust and heal normally without scarring. Characteristically, the vesicle has been described as a “dewdrop on a rose petal.” Associated prodrome includes malaise and mild fever, and is usually present. Symptoms tend to be more severe in older patients. Fetal infection during the first or early second trimester can result in fetal demise or in congenital varicella syndrome, consisting of limb hypoplasia, cutaneous scarring, ophthalmic abnormalities, and CNS defects. Infection acquired from 5 days pre-partum to 2 days postpartum can also be fatal because of the absence of protective maternal antibodies. Bullous varicella can result when *Staphylococcus aureus* infects the vesicles of chickenpox, with greater chance for scarring.

Herpes zoster, a reactivation of a latent infection with the VZV, can also cause a vesicular rash. The virus, which rests dormant in neuronal cells, travels along the nerves when reactivated and becomes released into the skin. It is generally a disease of older people, though children can be affected. In zoster, the lesions are grouped unilaterally in the distribution of 1 to 3 sensory dermatomes. It can be quite painful, and postherpetic neuralgia can last for months. In immunocompromised patients, the rash of zoster can become disseminated.

Disseminated HSV in an infant is usually due to HSV-2, is very severe, and is often accompanied by skin findings. In children and adolescents, HSV-1 gingivostomatitis and perioral vesicles are the most common clinical findings. A prodrome of parasthesia with recurrent infection is not uncommon. There can also be an ulcerative enanthem. Herpes simplex virus persists for life in the sensory ganglia and, when reactivated, results in single or grouped vesicles, often on the vermilion border with an erythematous base. Triggers include stress, ultraviolet exposure, and fever. Genital lesions are more frequently due to HSV-2, but the prevalence of genital infection due to HSV-1 is increasing.

Hand-foot-and-mouth disease is associated with a brief, mild prodrome of fever, malaise, and mouth pain. The exanthem consists of erythematous macules and papules with a central gray vesicle. Generally, the volar surfaces of the hands and feet, as well as the buttocks, tend to be involved. The concomitant enanthem is seen on the tongue, buccal mucosa, palate, uvula, and anterior tonsillar pillars. In herpangina, patients acutely develop fever, malaise, headache, and neck pain. There is a painful enanthem of small grayish-white vesicles on the soft palate, uvula, buccal mucosa, pharynx, and tonsils. These ulcerate with a surrounding red halo.

Impetigo is the most common bacterial skin infection in children. In bullous impetigo, there can be associated fever, weakness, and diarrhea, though there are often no systemic symptoms. Small vesicles enlarge rapidly into flaccid bullae that easily rupture. These lesions can be generalized and can arise from normal-appearing skin.

Parasites such as the tiny mite *Sarcoptes scabiei* can cause an intensely pruritic, generally papular eruption, though vesicular lesions can occur. Commonly, secondary excoriations are seen (see Chapter 121). In older children and adults, interdigital folds, flexor wrists, waistline, trunk, and genital area are more commonly affected. A linear burrow is pathognomonic but often difficult to identify clinically. Patients younger than 2 years have involvement predominantly of the head, neck, palms, and soles. In this age group, the eruption is more likely to be vesicular (Box 123-1). Arthropod bites can also result in isolated and scattered vesicles.

Fungal pathogens that cause tinea pedis include *Trichophyton rubrum*, *Trichophyton mentagrophytes*, *Trichophyton tonsurans*, and *Epidermophyton floccosum*. Infection can directly cause a scaly or vesicular rash or can result in a hypersensitivity reaction to the fungi, presenting as vesicles on the palms, soles, sides of the fingers, and occasionally on the extremities and trunk. *Trichophyton mentagrophytes* can cause vesicles and bullae on the medial foot. It can be associated with an id reaction, in which deep-seated pruritic vesicles develop secondary to tinea infection elsewhere. An id reaction, most commonly on the hands, face, and trunk, can also result from tinea capitis, usually caused by *T tonsurans* and *Microsporum canis*, though it does not cause a vesicular exanthem on its own.

The clinical appearance of dyshidrotic eczema can be identical to that of an id reaction or fungal infection and consists of “tapioca,” pearl-like, deep-seated vesicles frequently on the palms and soles, as well as the lateral sides of the fingers that are extremely pruritic.

Box 123-1. Common Causes of Acute Vesicular Exanthems

Infectious

Viral

- Varicella-zoster virus
- Herpes simplex virus
- Enterovirus

Bacterial

- *Staphylococcus aureus*

Fungal

- *Trichophyton rubrum*
- *Trichophyton mentagrophytes*
- *Trichophyton tonsurans*
- *Microsporum canis*
- *Epidermophyton floccosum*

Infestations

- *Sarcoptes scabiei*
- Arthropod bites

Noninfectious

- Allergic contact dermatitis
- Dyshidrotic eczema
- Id reaction

Secondary impetiginization (bacterial superinfection) is common. Cases can be acute and recurrent, as well as chronic.

A delayed type 4 hypersensitivity reaction secondary to contact with plants of the genus *Toxicodendron* is a common cause of allergic contact dermatitis. The main allergen in these plants is a catechol. Rhus dermatitis causes a classic linear vesicular rash (see Chapter 121). Contact with other allergenic substances may also produce a vesicular rash and such substances include nickel, rubber compounds, fragrances, and preservatives in cosmetics.

The differential diagnosis of acute vesicular exanthems can also be organized according to the distribution of the lesions. Distinctive locations as well as specific patterns are important to consider in each individual case. The presence or absence of fever can assist in developing the appropriate differential (Figure 123-1). Epidemiological, as well as historic, information may suggest the diagnosis. For example, known exposure to VZV (chickenpox) 10 to 21 days prior to a vesicular eruption facilitates diagnosis of this disease. A history of hiking, camping, or other outdoor activities suggests possible contact with poison ivy or poison oak.

In addition, the presence of a specific prodrome can often be elicited with primary or recurrent herpes simplex. Pain on swallowing often occurs with enteroviral infection. A history of similar lesions lessens the likelihood of acute primary infection and suggests a chronic condition such as the recurrent disorder pompholyx (dyshidrotic eczema).

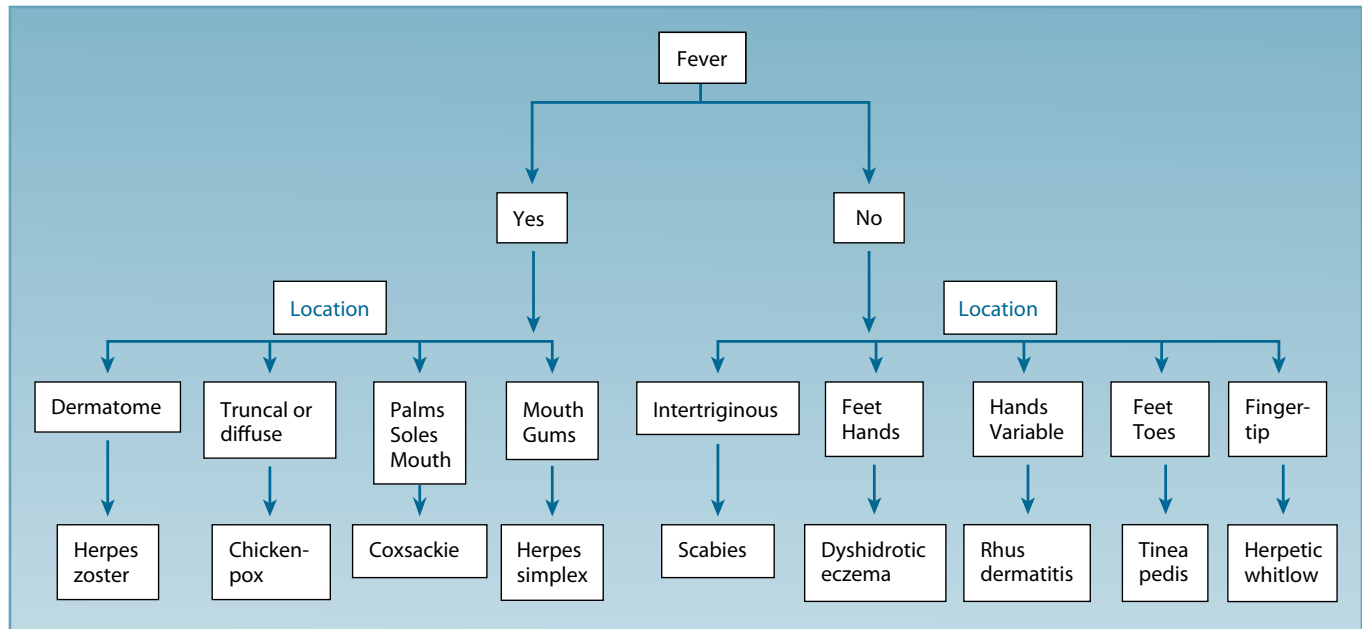

Figure 123-1. Approach to the evaluation of vesicular eruptions.

Evaluation

History

A thorough history should be obtained (Questions Box). Practitioners must inquire about the current state of general health, as well as the specific details about the eruption.

Questions

Vesicular Exanthems

- How long has the child had the rash? Where is it located?
- Does the child have associated symptoms such as fever, runny nose, cough, or sore throat?
- Does the child have nonspecific symptoms such as decreased appetite?
- If the child has any symptoms accompanying the rash, did these develop at the same time as the rash?
- Is there any reason to suspect that the patient is relatively immunocompromised from chronic steroid use, chemotherapy, or an acquired immunodeficiency?
- Does the child have a history of similar lesions?
- Does anyone else in the family have a similar rash?
- Has the child been camping or hiking in the woods?
- Are there pregnant contacts?

Physical Examination

Although the physical examination focuses on the skin, other aspects of the examination are helpful diagnostically. Vital signs should be taken to verify the presence or absence of fever. The oropharynx should be examined closely for any lesions on the tongue, gingiva, buccal mucosa, palate, anterior tonsillar pillars, and posterior

pharynx. The lips should also be examined for any evidence of vesicular lesions that may occur with a primary or recurrent herpes simplex infection.

Patients should be completely unclothed to permit a thorough examination of the skin. The distribution of the lesions should be noted. Physicians should determine whether the vesicles are grouped in a particular dermatomal distribution, as with zoster (shingles), or more generally distributed and in various stages of development, as with varicella. A linear distribution may suggest contact with poison ivy or poison oak. Physicians should also note the following: Do the lesions include or exclude the palms and soles? Are the buttocks involved? Are the lesions concentrated on one specific part of the body, such as the feet and toes or the hands? Are the sizes of the lesions uniform? If not, are other larger bullous-like lesions present in addition to vesicles?

It is also helpful, if at all possible, to examine the skin of family members for similar lesions.

Laboratory Tests

Few, if any, laboratory studies are usually needed in healthy children with vesicular eruptions because the diagnosis is often made clinically. A Tzanck smear showing multinucleated giant cells that contain intranuclear viral inclusions may be useful in making a preliminary diagnosis of HSV or VZV. Direct fluorescent antibody and polymerase chain reaction are rapid and sensitive methods to diagnose VZV and HSV.

Definitive confirmation of scabies can be made by microscopic examination of skin scrapings from suspicious lesions. The presence of the adult mite or ova, larvae, nymphs, or feces (scybala) is diagnostic. For children with suspected tinea pedis, a skin scraping mixed with potassium hydroxide can be performed and examined under the microscope. Fungal cultures can also be taken.

Management

The mainstay of treatment for most vesicular eruptions is parent and child education as well as reassurance. For example, most varicella, HSV, gingivostomatitis, HFMD, and herpangina infections are self-limited and no treatment except parental reassurance and education regarding adequate hydration is necessary. These diseases can, however, be quite serious, as the recent epidemic of enterovirus-71 in Asia did result in death in severe cases. Depending on the etiology of the vesicular rash, immunocompromised children such as those with HIV or AIDS and patients who are receiving chemotherapeutic agents or systemic corticosteroids may require specific intervention.

Topical agents such as calamine lotion, oatmeal soaks, or Aveeno baths should be used in children with intense pruritus or multiple lesions. Topical products, which are potentially sensitizing (eg, diphenhydramine-containing agents) should be used cautiously and discontinued if the condition is not improving. Cool, wet compresses with plain water or aluminum acetate (Burow solution) can be quite soothing in cases of rhus dermatitis, scabies, or tinea pedis.

Antipyretics (acetaminophen) may be used to treat otherwise healthy children with varicella. Aspirin-containing medications should be avoided in children with varicella because of the association with Reye syndrome. Oral analgesics may also be indicated for symptomatic relief of pain associated with herpetic gingivostomatitis or enterovirus mouth lesions.

Oral antihistamines (diphenhydramine or hydroxyzine) may be used in children with varicella or scabies for treatment of pruritus. These drugs are also helpful in allergic contact dermatitis (rhus dermatitis) and dyshidrotic eczema. Though the sedating antihistamines are generally more effective, non-sedating antihistamines can also be used in the daytime, particularly for the more chronic dyshidrotic eczema.

Steroids may be effective in the control of some vesicular rashes; however, the practitioner must first be certain the lesions are not secondary to varicella or herpes simplex. In certain cases, steroids may be used in infectious diseases, such as eczema herpeticum, but in conjunction with antiviral therapy, and under close monitoring. Topical steroids can be used for outbreaks of vesicles of dyshidrotic eczema, reserving oral steroids for severe outbreaks. In severe cases of rhus dermatitis, a course of systemic steroids, such as prednisone, 1 to 2 mg/kg/d, may be warranted and generally requires at least 2 to 3 weeks of therapy. Use of an oral histamine-2 blocker such as ranitidine or famotidine can help prevent gastritis as a complication of oral prednisone.

Oral acyclovir is not recommended routinely for the treatment of uncomplicated varicella in otherwise healthy children, but should be considered when the risk of developing moderate to severe disease is increased. According to the American Academy of Pediatrics (AAP) Committee on Infectious Diseases, acyclovir should be considered in patients older than 12 years; those with chronic cutaneous or pulmonary disorders; those receiving chronic or short, intermittent courses of corticosteroids (systemic or aerosolized); or those

receiving salicylates long term. Oral or intravenous (IV) acyclovir may also be warranted in pregnant women infected with varicella. Acyclovir is most effective if initiated within the first 24 hours of the exanthem though the impacts on symptoms may be minimal. (See the AAP 2009 *Red Book* for further details and specific recommendations regarding immunocompromised children and the role of VariZIG.)

Additional recommendations for children with varicella include keeping fingernails short in young children to prevent superinfection of lesions from scratching. Children should drink plenty of fluids to avoid dehydration. Patients are considered contagious from 1 to 2 days prior to the onset of the rash until the lesions are all dried and crusted (usually 5–7 days after the rash develops), at which time they may return to school. In children with persistent or recurrent fever, secondary complications should be considered. A significant association between primary varicella infection and invasive group A beta-hemolytic streptococcal infection has been recognized and should be considered in the child with fever on or beyond the fourth day of the illness. There is a possible association between ibuprofen treatment and increased severity of GAS superinfection, thus ibuprofen should be avoided for the treatment of fever due to varicella. In infants greater than 28 weeks' gestational age born to mothers with varicella infection 5 days pre-partum, disease severity can be mitigated by placentally transmitted maternal antibody to the virus.

Treatment with acyclovir for zoster, or shingles, can heal lesions more rapidly and provide pain relief. It is possible that the varicella vaccine may reduce the risk of developing zoster. Since 2006, the recommendation is for 2 doses of varicella vaccine as immunity appears to wane and sporadic outbreaks occur. Incidence of varicella zoster infection has decreased by 80% since universal use of the live attenuated vaccine in healthy children.

Persons with frequent, generally more than 6 per year, outbreaks of HSV, may benefit from suppressive therapy with acyclovir. Herpetic whitlow is an HSV infection on the fingertip as a result of direct autoinoculation from oral or genital lesions. Treatment is not usually indicated. Herpes gladiatorum and herpes rugbiaforum are cutaneous HSV infections on the skin of wrestlers and rugby players, respectively. While it does not require treatment with antiviral agents such as acyclovir, athletes should not be engaged in person-to-person contact when herpes lesions are present. Eczema herpeticum is HSV infection in children with underlying atopic dermatitis or other underlying skin disease that results in rapidly progressive widespread vesicles that then erode and crust. There can be significant fever and irritability, and severe infection may warrant hospitalization for treatment with IV acyclovir. Treatment with topical calcineurin inhibitors (eg, tacrolimus) is contraindicated.

Localized bullous impetigo in otherwise healthy patients can be treated with topical mupirocin 2% or retapamulin 1% ointments. More widespread or complicated infections require **oral antistaphylococcal therapy** with agents such as amoxicillin and clavulanate (Augmentin), erythromycin, or cephalexin (Keflex). Recurrent disease should warrant workup for carriage and treatment

if needed. Local knowledge of methicillin-resistant *S aureus* rates and bacterial cultures should be considered. For the treatment of tinea pedis, topical **antifungal agents**, in powder, cream, or ointment formulations, can be effective when applied twice daily until clear. Discomfort can be alleviated with cool water or Burow solution soaks. Tinea pedis can be difficult to control. Its treatment is centered on meticulous foot hygiene. Because careful foot care is often not a priority for most patients, complete eradication is not realistic. Patients should be instructed to wash their feet and change their socks when they return from school, dry their feet completely, avoid occlusive shoes, and wear open-air shoes or sandals whenever possible. Topical antiperspirants may be needed (aluminum chloride). Cotton socks are recommended. In severe or refractory cases, an oral antifungal preparation such as griseofulvin, terbinafine, or itraconazole may be prescribed for an extended period. Tinea capitis also requires oral antifungal therapy (see Chapter 119). For the treatment of scabies, see Chapter 121.

Prognosis

Overall, the prognosis for vesicular exanthems is good, with most children recovering in 1 to 2 weeks, depending on the etiology. Secondary infections can occur with varicella, however, and should be suspected in children with persistent or recurrent fever. Additional complications in non-immunosuppressed patients include bacterial superinfection of the skin, pneumonia, CNS involvement, Reye syndrome, glomerulonephritis, and arthritis. Complications from HSV infections include conjunctivitis, keratitis, and encephalitis.

Secondary infections with skin flora can be a complication of any of these skin conditions because denuded lesions allow for superinfection. In addition, many of these rashes can be pruritic, resulting in open, excoriated skin.

CASE RESOLUTION

In the case presented at the beginning of this chapter, the toddler has a classic presentation of primary varicella (chickenpox). Management should include symptomatic treatment with acetaminophen and antihistamines, along with topical preparations such as calamine lotion and oatmeal baths. The parent should be instructed regarding the natural course of this infection and be informed that the infection is highly contagious. In addition, symptoms indicating possible complications, such as persistent or recurrent fever, circumferential redness or swelling of the lesions, and shortness of breath, should be reviewed with the parents.

Autism Spectrum Disorders

Robin Steinberg-Epstein, MD

CASE STUDY

The mother of 18-month-old twin boys is concerned because one twin is not talking as much as his twin sibling. They are both very active. She feels that even though the child is quiet, he is very smart. He likes to figure out how things work. He seems very sensitive to sounds and covers his ears around loud noises. He loves music and even knows which CD his favorite song is on. He will play with his sibling, but doesn't seem interested in other children.

In your office both boys are very active. It is difficult to get an adequate examination, because this child is screaming the whole time. While both children have stranger anxiety, the twin about whom the mother is

concerned seems to have extreme stranger anxiety. He otherwise appears well.

Questions

1. What are autism spectrum disorders (ASDs)?
2. How do ASDs differ from language delay?
3. How do you evaluate a child for ASDs?
4. Where can a clinician refer a patient with an ASD?
5. What types of treatment are available?
6. Should a child suspected of having an ASD receive further immunizations?

Autism spectrum disorders are characterized by impairment in communication, social interaction, and odd behaviors/interests. According to the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition text revision), a person with autistic disorder must meet 6 of 12 possible criteria across 3 primary domains: social

interaction, communication, and restrictive or repetitive behaviors. These disturbances must originate prior to age 3 and cause significant degrees of impairment (Box 124-1).

Autism spectrum disorders include autistic disorder, Asperger syndrome, Rett syndrome, and pervasive developmental disorder not

Box 124-1. Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) Diagnostic Criteria for Autistic Disorder^a

A. A total of six (or more) items from (1), (2), and (3), with at least two from (1) and one or more from (2) and (3):

- (1) qualitative impairment in social interaction, as manifested by at least two of the following:
 - (a) marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction
 - (b) failure to develop peer relationships appropriate to developmental level
 - (c) a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people
 - (d) lack of social or emotional reciprocity
- (2) qualitative impairment in communication as manifested by at least one of the following:
 - (a) delay in, or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gesture or mime)
 - (b) in individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others
 - (c) stereotyped and repetitive use of language or idiosyncratic language
 - (d) lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level
- (3) restrictive repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following:
 - (a) encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus
 - (b) apparently inflexible adherence to specific, nonfunctional routines or rituals
 - (c) stereotyped and repetitive motor mannerisms (hand or finger flapping or whole body movements)
 - (d) persistent preoccupation with parts of objects (wheels, doors, lights)

These symptoms result in significant or abnormal functioning in at least one area (social interaction, social language, or symbolic/imaginative play) with onset prior to age 3.

^a Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed. Text rev. Washington, DC: American Psychiatric Association; 2000.

otherwise specified. While the criteria differ somewhat, all of these disorders have in common an impairment in social communication and repetitive or unusual interests of varying degrees. Because these disorders require similar management and treatment, and there is some subjectivity in assessing the level of impairment, many choose to use the term *autism spectrum disorder* to incorporate all those who are significantly affected by its symptomatology.

Epidemiology

As recently as 1999 the prevalence of this disorder was thought to be 1 in 2,500. More recent numbers from the Centers for Disease Control and Prevention (2009) cite 1 in 110 children. This amounts to 1.5 million Americans. The incidence is rising by almost 15% a year. Boys are affected approximately 4 times as often as girls, which equates to 1 in every 70 boys. However, affected girls are often more impaired. Autism is considered the fastest-growing developmental disability. This increase is, in part, the result of an understanding of a broader phenotype.

Clinical Presentation

Autism spectrum disorders are truly a spectrum of social communication deficits. While there is a certain set of behaviors that defines the disorder, any child may have any combination of the symptoms that lead to the same result—severe and incapacitating social deficits. Furthermore, the challenges that face this population are more than just developmental delays. Their behaviors are aberrant and odd.

Many children with autism have difficulty with eye contact and body posture. Even those who have some eye contact often do not use their eyes to convey a social message. They may look out of the corner of their eyes, focus only on the lips of the speaker, or only look infrequently. In other words, they may make eye contact, but at the wrong time. They may talk to you with their bodies facing away from you. They may not gesture to help clarify intention.

While some children have limited communication, some offer too much information. They may be quick to talk to you about things they are interested in, but are not able to talk to you about your interests. They seem socially insensitive. As younger children they are often entertained by their own interests for long periods. Some have limited need for relationships, yet others desire interaction but do not understand how to initiate or maintain interactions. While many of these children are nonverbal, some repeat or echo what they hear from movies, television, or nearby conversation. Others seem able to converse, but have trouble with social banter. It is important not to be deceived by a child who interacts or hugs, but only on his own terms.

Autistic children often have a fascination with patterns. The pattern may be in the form of household routines, or patterns within a particular subject area. This may manifest in an obsession for sameness and resistance to change or in an obsessive need to know everything about a particular topic. Many know all there is to know about such favorite topics as Thomas the Tank Engine or dinosaurs from the Jurassic period, but cannot answer a question such as, “How are

you?” or “What is your name?” They may be upset by a road detour or a furniture rearrangement. Some of these children, out of an incredible ability to recognize patterns, will be able to read as early as 2, even though they are unable to speak functionally and cannot comprehend what they read.

A significant portion of children have difficulty with sensory processing. This takes the form of problems with smells, tastes, sounds, sights, and touch. This symptom may be manifest in the need to taste everything including nonfood items, covering ears in loud situations, or an inability to tolerate tags in clothing.

There is a huge variation in cognitive ability. The severity of autism is independent of cognitive ability. While a significant portion of those with autism are mentally retarded, many are of normal intelligence and even gifted.

Parents often raise behavioral concerns. It is important to recognize red flags and behaviors that demand further evaluation (Boxes 124-2 and 124-3). In other words, there are certain classic symptoms, but be mindful of the child that is just unable to connect with others. Clinicians should rely on their own instinct. Inconsistent symptoms are the hallmark of this disorder. Some parents of children with autism describe a phenomenon whereby the children are developing normally until 12 to 15 months of age and then suddenly lose skills or stop progressing. This is particularly concerning.

Pathophysiology

There are numerous proposed etiologic possibilities for the origins of autism, from the inbreeding of computer “whizzes” to exposure to microwaves. However, no consistent explanation or pattern has emerged. We do know that the structure of the brain is different, but why?

Box 124-2. Red Flags (Common Aberrant Behaviors Associated With Autism)

- Decreased eye contact (common, but NOT universal)
- Only wants to be cuddled on his terms
- Areas of unusual knowledge—recognizes entire alphabet by 2, all types of dinosaurs by 4, names of all Thomas trains, interest in fans or spinning items
- More interested in how things work than with playing
- Unusual sensitivities—oversensitive to hearing, bright lights, shirt tags, new foods, new places
- Smelling or licking nonfood items
- Repeating words instead of answering questions or answering off topic
- Difficulty interacting with other children
- Plays amongst children, not with them
- Resistance to change, “very independent”
- “In his own world”
- Lines things up
- Unusual hand movements or jumping when emotional
- Things have to be a certain way
- Odd tone of voice (prosody)
- Increased pain tolerance

Box 124-3. Absolute Indications for Referrals

- Not babbling or gesturing (pointing, waving) by 12 months
- No single words by 16 months
- Absence of 2-word non-echolalic phrases by 24 months
- ANY loss of ANY language or social skills at ANY age requires immediate evaluation.

^a Filipek PA, Accardo PJ, Baranek GT, et al. The screening and diagnosis of autism spectrum disorders. *J Autism Dev Disord.* 1999;29:439–484.

Up to 10% of those with autism have another medical condition (Box 124-4) that might have led to this disorder. However, this leaves 90% without an etiology.

Genetics seems to play a role in the development of autism. There is a risk of the disorder among siblings of up to 8%, which is more than 10 times the risk in the normal population. Family members are more likely to exhibit social deficits, anxiety, or depression than are family members who do not have a relative with the disorder. Several candidate chromosomes have been suggested as being associated with this disorder, but no one loci is responsible for this disorder.

It is also important to realize that up to 30% of children with autism have abnormalities on electroencephalogram (EEG). This may point to the structural abnormalities in the autistic brain but does not seem to account for the disease itself. The epileptiform changes should be evaluated by a neurologist to determine if medication is indicated.

Several environmental markers have also been suggested as being linked to autism, but none has proved credible. Major epidemiological studies both within the United States and internationally have examined the roles of vaccinations, diet, and thimerosal preservative in the development of this disorder. None of these studies has found proof to support these theories. Children with ASD should receive routine health maintenance including all recommended immunizations. There are noted associations such as older paternal age, prematurity, and jaundice.

Differential Diagnosis

Very few entities present with impairment in the same 3 domains as those that are affected by autism. There are a limited number of disorders that mimic autism (Box 124-5). On the other hand, there are several disorders that commonly occur with autism (Box 124-6) and, if not identified, will make treatment more difficult.

Evaluation

There is not one diagnostic test, blood or otherwise, that will confirm the diagnosis of autism. The diagnosis is based on history and the interaction with the child.

History

Regular developmental surveillance and screening should be part of every well-child evaluation, especially between ages 9 and 30 months. The American Academy of Pediatrics recently suggested adding a 30-month visit for developmental screening in an attempt to

Box 124-4. Medical Conditions Associated With Autism

- Epilepsy
- Fragile X
- Tuberous sclerosis
- Prader-Willi syndrome
- Visual or auditory impairment syndrome
- Down syndrome
- Cerebral palsy
- Neurofibromatosis
- Congenital rubella

Box 124-5. Disorders That May Mimic Autism

- Hearing impairment
- Global developmental delay
- Tourette disorder and comorbidities
- Selective mutism
- Reactive attachment disorder
- Lead ingestion
- Sensorimotor integration dysfunction
- Severe auditory processing/language deficit
- Severe anxiety
- Severe attention-deficit/hyperactivity disorder
- Brain trauma
- Childhood onset schizophrenia

Box 124-6. Disorders That Can Occur With Autism

- Tuberous sclerosis
- Congenital blindness
- Global developmental delay
- Chromosomal abnormalities (Down syndrome, fragile X syndrome, Prader-Willi syndrome, etc)
- Phenylketonuria
- Epilepsy
- Elevated lead level
- Congenital infections
- Brain trauma
- Bipolar disorder
- Neurofibromatosis
- Congenital profound hearing loss
- Tourette disorder
- Landau-Kleffner syndrome
- Inborn errors of metabolism
- Anemia
- In utero exposure to drugs/alcohol
- Depression/anxiety
- Attention-deficit/hyperactivity disorder

capture atypical development to target for early intervention. Special attention should be given to a child who has a sibling with autism or a child whose parent or caregiver has expressed concern. Several screening tools can be used, including the Parents' Evaluation of Developmental Status (PEDS), Ages and Stages Questionnaire (ASQ), or the Brigance. The Modified Checklist for Autism in Toddlers (M-CHAT) is another excellent screening tool (moderate sensitivity and high specificity) to identify both developmental and social competency skills which, when deficient, may be associated with autism. These screening tools are quick and easy and can be filled out by the parent in the waiting area or with minor assistance from office personnel.

Once you suspect that a child has a developmental difference, it is important to gather as much information as possible. Thorough birth and medical histories are important in helping to understand if early experiences may predispose this child to any deficits.

Family history is also important because this disorder is presumed to be genetic. Furthermore, it may help to consider other etiologies. Family structure will help to determine if abuse, neglect, or maternal depression play any role in the child's delay. However, autism is NOT due to poor parenting.

Developmental history is the most important part of the history. It is important to probe all 4 areas of developmental milestones: fine motor, gross motor, language, and social development (see Chapter 27). Again, we expect more significant delays in language and social interaction, but you may see delays in all components of development. Additionally, probing for abnormal behaviors specific to autism helps distinguish this disorder from others. See the Questions Box for some suggestions that may help elicit information relevant to a diagnosis of autism in a toddler, but you must adjust the history depending on the age of the child. Always include early language milestones. Be aware that children with autism tend to have splinter skills. These are skills that may be normal or above developmental level for age. Don't let these skills distract you from probing areas of suspected delay.

Finally, parents and physicians often fall victim to common myths and excuses regarding development (Box 124-7) because it is not easy for many parents to discuss or admit delays. These myths, while they sound plausible, are not substantiated and only serve to further delay onset of intervention.

Physical Examination

A thorough physical examination with special attention directed to the growth parameters, neurologic examination, dysmorphic features, and neurocutaneous stigmata are essential to a complete evaluation. Height, weight, and head circumference should be plotted. Keep in mind that 25% of children with autism have a head circumference greater than the 97th percentile. That is not to say that everyone with a large head has autism, only that it is an associated feature. Those with Rett syndrome have a head circumference that may arrest by 5 months of age. Of course, in utero infections may predispose to a small occipitofrontal circumference and developmental concerns.

Questions

Autism

Questions to Ask Parents

- Does he seem to hear you? Did he have a hearing test in the neonatal period?
- Does he make noises? If so, what kind?
- When did he say his first word after "mama" and "dada"? Does he have 2-word phrases?
- Are there any other behaviors that concern you?
- Can he scribble? Has he lost any skills? Does he line things up?
- When did he first walk? What does he like to play with?
- Do tags on the back of clothes bother him?
- Is he interested in other children? What does he do if he sees another child in a park?
- When do you first remember him pointing with one finger?
- Does he play peek-a-boo? Will he try to engage you?
- Does he talk into a play phone?
- Does he eat a variety of foods?
- Does he turn when you call him?

Questions to Ask Yourself as the Clinician

- Are there any complicating historical factors that may predispose this child to a developmental problem?
- Is this merely personality variation, or does this represent delays and aberrant behavior?
- Is this a language delay or are you concerned about more social or odd behaviors?
- What should be done to evaluate?
- What types of intervention would be helpful?

Box 124-7. Common Excuses for Unusual Behaviors

1. We speak 2 languages at home. (By age 3 in a bilingual home, language should follow a normal progression. Social and unusual behaviors should always follow a normal trajectory.)
2. He is a boy. (This is accounted for in the range of normal.)
3. He is a twin. (If one twin is autistic, the other twin has a great risk of being autistic or delayed.)
4. He is the first child. (No evidence that firstborns speak late.)
5. He is the baby. (No evidence that last borns speak late.)
6. He is having a bad day.
7. He watches too much television. (Neglect can lead to delays, but these children still need intervention.)

These are NOT reasons to delay evaluation!

Detecting subtle physical signs such as clinodactyly, simian crease, or a high-arched palate, while not diagnostic, are somewhat helpful in raising suspicion for neurodevelopmental delays. A Wood light evaluation may be helpful in uncovering neurocutaneous stigmata.

A series of dysmorphic features like a thin upper lip, flat philtrum, and upturned nose might suggest a syndrome such as fetal alcohol syndrome. Hypotonia is a common finding amongst children with

autism, but might suggest an inborn error of metabolism. One must also check reflexes because degenerative disorders, such as muscular dystrophy, can present with language delay.

One of the most useful examinations in the office is to simply have a conversation with an older child or to play with a younger child. Bring out bubbles and engage in a popping game. Watch the child's eyes and his interaction with you and with his parent. Pretend the otoscope is a phone that rings, pick it up, talk briefly, and pass it to the child. Watch his response. Does he play with you or just with the bubbles or neither? Does he display repetitive flapping when excited?

Laboratory Tests

No single laboratory or radiologic evaluation will make the diagnosis. However, some tests are helpful to rule out comorbid conditions. If the child has not had an audiological evaluation, then this is step one. However, do not wait for the audiology results before referring the patient for help. From a medical perspective, a tiered approach to the workup is often helpful. The first tier would include laboratory studies such as a high-resolution karyotype and a DNA test for fragile X. In those with global developmental delay or regression (or when indicated), consider a lead level, carnitine profile, plasma homocysteine levels, serum amino acids, urine organic acids, thyroid evaluation, and vision evaluation. Consider ammonia, lactate, and pyruvate on those with a severe presentation. An EEG would be appropriate if concerns of seizures are present. Check the results of the newborn screen. The yield of this evaluation is anticipated to be low (approximately 4%), but if positive, may aid in the diagnosis of a specific comorbidity.

A relatively new test, chromosomal microarray (comparative genomic hybridization), has been found to yield 3 times the detection rate of chromosomal alterations as compared to the high resolution karyotype. Replacing the high resolution karyotype with this test would improve detection to over 7%. It is expected that this test will become part of the new standard.

Tier 2 would include an evaluation aimed toward specific rare diseases. Some consideration might be given to chromosomal 15 methylation, MECP2 (methyl CpG binding protein 2 [in females]), PTEN (phosphatase and tensin homolog deleted on chromosome 10), fibroblast karyotype if pigmentary abnormalities are noted, steroid profile, guanidinoacetate urine analysis (only in males), or other associated genetic evaluations. Current literature would suggest that evaluations for autism yield an etiology 15% of the time.

Imaging Studies

If there is a history of regression, microcephaly, or the presence of focal findings suggestive of central nervous system malformations, consider a magnetic resonance imaging (MRI) test. Otherwise, obtaining an MRI is considered low yield. Children with regression, more significant involvement, or behavior suspicious of a seizure should receive an EEG. While positron emission tomography and single-photon emission computed tomography scans will show abnormalities, they are not considered specific enough for either diagnosis or to direct care. There are no present indications for their

use in an individual child with autism. They are used primarily in the research setting.

Management

Making the diagnosis is sometimes challenging, but early diagnosis is critical in changing ultimate outcomes. Early diagnosis and intervention can reduce cost of lifelong care by two-thirds.

For children younger than 3 years, refer to the local governmental agency in addition to speech/language and occupational therapy, which is covered by their health insurance. In most states there exists a government-sponsored early intervention program for children 0 to 3. This agency is responsible for the evaluation and behavioral/educational/therapeutic interventions for children with suspected delays. This should lead to a comprehensive diagnostic evaluation and placement in an intensive intervention program. Therefore, once a hearing test has been completed, a referral to such an agency is the next step. It takes on average 6 months from the time a child is seen in a physician's office to when those services are obtained. Therefore, it is important to identify children before age 2 ½ years. Make that referral!

For children older than 3 years, the responsibility belongs to the local school system. So even though a child is not yet school-aged, their local school district is responsible for both the evaluation and interventions necessary to appropriately remediate this child. However, the clinician should check with local resources to ensure that such a system exists in the respective state. Be aware that between ages 3 and 21 years, each child is entitled to a free and appropriate education guaranteed under the federal mandate known as the Individuals with Disabilities Education Act. This program should be comprehensive and individualized to each child's needs. After a thorough assessment, the school will meet with the parents to develop an Individualized Education Plan.

Most children with autism require at least speech and language services, occupational therapy, and social skills training. Many require a one-on-one aide in a mainstream class, and others benefit from special education services in the form of pullout or a special day class. Augmentation can be created privately. Some states have mandated that medical insurance support these additional, yet necessary, services, but in others it is the sole responsibility of the parent.

Interventions

Autism is a neurologic condition that can improve with intensive **multimodality interventions**. This improvement is slow. There are no quick solutions, magic medications, or diets to "cure" autism. Behaviors like impulsive aggression, repetitive behaviors, resistance to change, and obsessive behaviors are frequently targeted by systematic interventions. Furthermore, some basic social learning behaviors can be shaped with different types of intervention. There are a number of different techniques (Box 124-8) based on different psychological principles that may be used to help improve the difficulties associated with autism.

Box 124-8. Techniques Used for Treatment**Floor Time**

This intervention uses personal relationships and play in the child's area of interest to draw the child through increasingly complex developmental tasks.

Applied Behavioral Analysis

Applied behavioral analysis strives to achieve pre-learning skills such as eye contact, imitation, sitting, and following simple directions using the principles of conditioning and behavioral psychology. In a 1:1 fashion a child is trained to respond in a predetermined way using a specific curriculum and reinforcers.

Behavioral Analysis

This method uses close study of behaviors, determining antecedent triggers and consequences, such as a tantrum. The goal is to substitute acceptable responses, such as using words, and increases rewards for substituted behaviors.

Pivotal Response Training

This strategy uses principles of behavior analysis but also uses the child's interests and internal drives to motivate. The hope is to generalize the skills from a therapy room to a variety of environments. Children with autism often have difficulty performing the same previously mastered skill in a new setting.

Picture Exchange Communication System

This system uses pictures that the nonverbal child can use to show a caregiver what they want.

Treatment/Education of Autism and Communication Handicapped Program

This is a complete program that incorporates the child into a large autism community. The goal is toward autonomy and uses many methods based on cognitive therapeutic principles.

Social Stories

These are often used as a complementary strategy. These stories describe in detail basic social skills in different scenarios.

Speech and language services are a vital component of intervention. The initial goal is to help establish communication. In higher-functioning children who already have established language, this service is vital for the establishment and development of prosocial language—eye contact, inferences, understanding jokes, and the more subtle aspects of language. Social skills groups are often used to teach appropriate social responses in a semi-naturalistic environment.

Occupational therapy is often necessary to help with both fine motor skills and the processing of sensory information. This can be helpful in easing transitions. There is not a great deal of research to support its use for sensory concerns, but it is a widely accepted premise that sensory exposure helps children who have either an oversensitive or an undersensitive sensory system.

Special education in the form of an aide, classroom pullout, or special day class is often necessary to help with commonly associated learning disabilities. Children with autism can have a full array of learning difficulties. Commonly associated learning difficulties

are in reading comprehension, written expression, specific math disability, and auditory comprehension.

Under the law, these services should occur in the least restrictive and most appropriate environment.

Pharmacotherapy

The mainstay for treatment of autism remains behavioral. Medications do not seem to help the core symptoms of autism. However, almost 2 of 3 of these children receive medications for behaviors that, despite intensive behavioral intervention, continue to obstruct progress or become dangerous.

Only 2 drugs are US Food and Drug Administration–approved for use in this population; risperidone and aripiprazole are approved for the agitation associated with this disorder. On the other hand, there are many other targeted behaviors for which medications are used. The choice to use medication is not a simple one. It should be directed toward the emotion or psychological function causing the symptom. The most common medications include selective serotonin reuptake inhibitors and stimulants. However, research and clinical experience tells us that children with autism are more sensitive to side effects and at lower doses. Therefore, the choice and direction of medication management in this population is often best guided by a developmental-behavioral pediatrician, neurologist, or child psychiatrist (see Chapter 126).

Alternative Treatments

A variety of alternative treatments have been suggested. Secretin injections, dietary restrictions, chelation, high-dose vitamins, anti-fungals, and neuron injections are just some of the interventions considered in this realm. Some of these methods reported anecdotal improvement; others are dangerous and have resulted in death. None of these methods is considered traditional or the standard of care because there are minimal empiric data to support their use.

Prognosis

Many children show dramatic improvements with early intervention. Unfortunately, others show minimal improvement. Therefore, all children need intensive interventions. Some prognostic indicators such as IQ, early and intensive interventions, and a supportive family bode well. Obtaining an accurate IQ is often challenging. The major determinant of ultimate outcome seems to be progress in a comprehensive, early intervention program for 2 years, prior to age 5. Having little or no language by age 6 is a poor prognostic indicator. Therefore, the goal remains focused on early identification, intensive treatment, and advocacy for children to receive such interventions with ongoing support.

The intensive early intervention programs have only been available since about 1995. Autistic children have now moved into the mainstream. In spite of receiving early intervention, these children continue to have problems with transitions, more complex social

interactions, and higher-level organization tasks. Therefore, physicians must continue to advocate for and support these families through the years.

Many adults with autism also continue to require significant support. They may require sheltered living and work environments, safety monitoring, ongoing medical support and, depending on severity, institutionalization.

Another significant portion of autistic children attend college, get married, and have children. This portion is difficult to quantify because these numbers are changing very rapidly and the true number of children with this disorder has yet to be realized.

CASE RESOLUTION

The child described in the vignette was evaluated by a developmental pediatrician and the local governmental agency where he received a comprehensive assessment by a multidisciplinary team. The diagnosis was confirmed and his brother was also noted to have a language delay. They were both placed into an early intervention program. The primary patient was placed in a one-on-one structured teaching environment for 4 months. After significant improvement, he was moved to a therapeutic preschool setting that emphasized generalization of his newly acquired skills, speech therapy, occupational therapy, and social skills. His brother received speech therapy 2 times a week. Both are due to start a regular kindergarten class in the fall with ongoing speech and social support. The primary patient has been placed on a stimulant medication to control hyperactivity and problems with attention.

Attention-Deficit/ Hyperactivity Disorder

Andrew J. Barnes, MD, MPH, and Iris Wagman Borowsky, MD, PhD

CASE STUDY

Cody, a 10-year-old boy, has visited a primary care clinic annually for well-child care, seeing different pediatricians each time. After failing all subjects during the first half of fourth grade, his teacher asks his mother to see if Cody's doctor can do anything to help him at school. When the appointment is made, the clinic obtains standardized attention-deficit/hyperactivity disorder (ADHD)-specific behavioral rating scales from Cody's parents and teachers. Prior to the visit, the pediatrician reviews these rating scales and Cody's medical history. She discovers that at Cody's 6-year well-child visit, a colleague documented, "likely has ADHD, medication is indicated." The medical records indicate that the family deferred starting stimulant medication and were told to follow up as needed. There is no further mention of ADHD. Cody also has a history of several urgent care and emergency department visits for minor unintentional injuries.

Questions

1. What are the primary symptoms of ADHD? What other conditions should be considered in the differential diagnosis of ADHD?
2. What other psychiatric disorders or neurodevelopmental disabilities commonly coexist with or mimic ADHD?
3. What is the appropriate evaluation of children with suspected ADHD?
4. What treatment modalities are useful in the management of ADHD?
5. What is the role of primary care in the long-term management of ADHD?

The core symptoms of ADHD are inattention, impulsivity, and hyperactivity. The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* diagnostic subtypes of ADHD are (1) predominantly inattentive type, (2) predominantly hyperactive/impulsive type, and (3) combined type. Most children and adolescents with the disorder have the combined type, exhibiting symptoms of both inattention and hyperactivity/impulsivity. Growing evidence suggests that differentiating such subtypes has little bearing on prognosis or treatment; with *DSM-5*, ADHD diagnostic criteria and categorical nosology are likely to change.

The diagnosis of ADHD is based solely on clinical judgment, requiring documentation of at least 6 of 9 behaviors from the inattentive and/or hyperactive/impulsive *DSM-IV* domains (Box 125-1). Some symptoms of ADHD must be present before 7 years of age, and present symptoms must persist in at least 2 major contexts of the child's life (eg, home and school) for at least 6 months. These symptoms must be more frequent and severe than those typically seen in children of the same developmental age and must impair the child's developmental competence, learning, and/or social interactions. The symptoms should not be better explained by another condition (such as anxiety or autism). If impairing symptoms occur at

sub-diagnostic levels and/or are associated with a *DSM-IV* exclusionary condition such as autism, a diagnosis of ADHD-Not Otherwise Specified should be made. Treatment, however, is symptomatic and not specific to subtype.

Transient behavioral variations and problem-level ADHD-like symptoms that are not frankly disordered are best classified using the framework of *DSM-Primary Care (DSM-PC)* instead of *DSM-IV* (eg, "Hyperactive/Impulsive Developmental Variation—Middle Childhood: The child plays active games for long periods. The child may occasionally do things impulsively, particularly when excited.").

Epidemiology

Attention-deficit/hyperactivity disorder is the most common neurobehavioral disorder in children. An estimated 4% to 12% of school-aged children have ADHD, and there is a 3:1 predominance of boys in community samples. Over the past 2 decades, ADHD diagnoses have increased; it remains unclear whether this represents a true increase in incidence, secular changes in diagnostic criteria and practices, sociocultural bias, and/or effects of unspecified environmental factors.

Box 125-1. *DSM-IV-TR* Criteria for Attention-Deficit/Hyperactivity Disorder^a**Diagnostic Criteria for ADHD**

A. Either 1 or 2

- 1) Six (or more) of the following symptoms of **inattention** have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

Inattention

- a) Often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities
 - b) Often has difficulty sustaining attention in tasks or play activities
 - c) Often does not seem to listen when spoken to directly
 - d) Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions)
 - e) Often has difficulty organizing tasks and activities
 - f) Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as schoolwork or homework)
 - g) Often loses things necessary for tasks or activities (eg, toys, school assignments, pencils, books, or tools)
 - h) Is often easily distracted by extraneous stimuli
 - i) Is often forgetful in daily activities
- 2) Six (or more) of the following symptoms of **hyperactivity-impulsivity** have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

Hyperactivity

- a) Often fidgets with hands or feet or squirms in seat
- b) Often leaves seat in classroom or in other situations in which remaining seated is expected
- c) Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
- d) Often has difficulty playing or engaging in leisure activities quietly
- e) Is often "on the go" or often acts as if "driven by a motor"
- f) Often talks excessively

Impulsivity

- g) Often blurts out answers before questions have been completed
- h) Often has difficulty awaiting turn
- i) Often interrupts or intrudes on others (eg, butts into conversations or games)

- B. Some hyperactive-impulsive or inattentive symptoms that caused impairment were present before 7 years of age.
- C. Some impairment from the symptoms is present in 2 or more settings (eg, at school [or work] or at home).
- D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.
- E. The symptoms do not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder and are not better accounted for by another mental disorder (eg, mood disorder, anxiety disorder, dissociative disorder, or personality disorder).

Code Based on Type**314.01 Attention-Deficit/Hyperactivity Disorder, Combined Type:**

if both criteria A1 and A2 are met for the past 6 months

314.00 Attention-Deficit/Hyperactivity Disorder, Predominantly

Inattentive Type: if criterion A1 is met but criterion A2 is not met for the past 6 months

314.01 Attention-Deficit/Hyperactivity Disorder, Predominantly

Hyperactive, Impulsive Type: if criterion A2 is met but criterion A1 is not met for the past 6 months

314.9 Attention-Deficit/Hyperactivity Disorder Not Otherwise Specified

^a Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed. Text rev. Washington, DC: American Psychiatric Association; 2000.

Clinical Presentation

Children with ADHD have problems with selective attention and mental stamina for non-rewarding or non-preferred activities. They often make careless mistakes or fail to pay attention to details. They may be easily distracted and have difficulty starting tasks and concentrating on tasks long enough to complete them. Stopping a preferred activity can also be problematic, and caregivers often note that their children with ADHD over-focus or "get lost" in their favorite activities, such as videogames, drawing, or reading. Difficulties following instructions and organizing tasks and activities are also characteristic of ADHD. Poor impulse control manifests as difficulty waiting one's turn, frequently blurting out responses at inappropriate times, and interrupting or intruding on others. Symptoms of hyperactivity include fidgetiness, excessive talking at inappropriate times, difficulty remaining seated or playing quietly, and subjective

feelings of restlessness in adolescents. Difficulties with social relationships and low frustration tolerance are also commonly seen in children with ADHD.

Pathophysiology

The etiology of ADHD is unknown. Genetic, prenatal/perinatal, and neurologic factors may play a role. Family studies indicate that first-degree relatives of children with ADHD have a risk of ADHD that is 5 times greater than normal controls. In addition, measures of behavior and attention are more alike in monozygotic twins than in same-gender dizygotic twins. The most widely confirmed gene association with ADHD is the 7-repeat allele of the D₄ dopamine receptor gene that, while found in about 30% of the general population, is found in 50% to 60% of those with ADHD. Prenatal and perinatal risk factors that have been associated with ADHD include in utero

exposure to alcohol or cigarettes; extreme prematurity; brain injury or stroke; and severe early deprivation, neglect, and maltreatment.

Attention-deficit/hyperactivity disorder is currently conceptualized as a neurodevelopmental-behavioral disorder. Patients with frontal lobe lesions have long been known to exhibit severe and intractable inattention, hyperactivity, disinhibition, and impulsivity. Recent neurodevelopmental research suggests that frontal and prefrontal regions of the brain are involved in executive functions, including organizing, planning, sequencing, selective attention, impulse inhibition, the ability to stick to a plan yet change it as needed (set maintenance), the ability to self-talk through internal rules, and working memory. A number of recent studies, some longitudinal, show delayed maturation (myelination) and abnormal activation/inactivation of critical prefrontal circuits and fronto-striatal reward-motivation circuits in children and adolescents with ADHD compared to controls. Dopamine and norepinephrine are involved in neurotransmission within these brain pathways, and the prefrontal cortex is rich in catecholamine receptors. Psychostimulants that target ADHD symptoms increase the availability of these neurotransmitters in the brain. Stimulants seem to primarily increase activity in key areas of the striatum, such as the ventral tegmental area, in turn activating the prefrontal cortex and executive functions.

Differential Diagnosis

The symptoms of ADHD can be seen in a variety of other conditions (Box 125-2). Sensory deficits, especially hearing impairment, can imitate attention deficits. Attention-deficit/hyperactivity disorder symptoms are often a component of autism spectrum disorders and other neurodevelopmental conditions, such as neurofibromatosis, co-occurring with typical features of the respective diagnoses, such as impaired social communication in autistic children. Lead and other heavy metals have dose-related detrimental effects on behavior and development; likewise, chronic iron deficiency can result in or mimic ADHD. Seizure disorders, such as petit mal (absence) or partial complex seizures, may be misdiagnosed as predominantly inattentive-type ADHD. Other neurologic disorders that can present with symptoms of ADHD include Wilson disease and adrenoleukodystrophy; however, focal, sometimes progressive neurologic deficits of acute-to-subacute onset are the hallmarks of these rare conditions. Certain medications, such as high-dose corticosteroids, phenobarbital, and theophylline, may cause ADHD-like mental status effects, as can recreational drugs of abuse, including inhalants and marijuana. Hyperthyroidism can cause the hyperactive symptoms of ADHD, but other signs of increased metabolism, such as elevated heart rate, tremors, or weight loss, should be apparent. Exposure to alcohol or drugs in utero has been associated with subtle difficulties with learning and attention as the child develops. Congenital infections, central nervous system infections in early childhood, and traumatic brain injuries may produce behaviors similar to those seen in ADHD. Severe and/or chronic psychosocial-environmental problems, such as family stresses, marital discord, unemployment,

Box 125-2. Differential Diagnosis of Attention-Deficit/Hyperactivity Disorder

- Developmental delay
- Learning disability
- Language disorder
- Sensory deficiencies (eg, hearing or vision impairment)
- Autism spectrum disorders
- Seizure disorder
- Neurogenetic syndromes (eg, Neurofibromatosis type I)
- White matter disorders
- Iron deficiency
- Environmental toxins (lead)
- Side effects of medication (eg, phenobarbital)
- Hyperthyroidism
- Congenital infection
- In utero exposure to drugs or alcohol
- Previous brain insult (eg stroke, trauma, infection)
- Family stresses
- Ineffective parenting
- Psychiatric disorders
 - Conduct disorder
 - Oppositional disorder
 - Anxiety disorders
 - Affective disorders (depression, bipolar illness)
 - Personality disorders (aggression, antisocial behavior)
 - Substance abuse

poverty, homelessness, trauma/maltreatment, substance abuse, and ineffective parenting (eg, overly-permissive or overly-authoritarian) can also masquerade as, co-occur with, and/or exacerbate ADHD.

Children with ADHD have an increased prevalence of co-occurring psychological pathology, which can magnify the core symptoms of the disorder. These include oppositional defiant disorder (35%), conduct disorder (26%), depressive disorders (18%), anxiety disorders (26%), Tourette disorder and tics, speech and language disorders, and specific learning disabilities, such as dyslexia and dyscalculia. In adolescents and young adults, aggression, delinquency, and other antisocial behaviors, as well as substance abuse, are often seen together with untreated or undertreated ADHD.

Evaluation

Children and adolescents with symptoms of inattention, hyperactivity, academic or social underachievement, or impulsivity should be evaluated first by a primary care clinician, ideally one with whom the child has enjoyed continuity of care. A complete evaluation of this nature is best accomplished with plenty of time for face-to-face review of records and a comprehensive history and examination; 90 to 120 minutes is a suggested minimum amount of time to do this effectively and correctly, usually necessitating several appointments spaced apart by days or weeks.

History

The diagnostic evaluation of ADHD should begin with multiple informants (caregiver[s], child, sibling[s]) giving a comprehensive medical history that includes details of the child's problem behaviors, their antecedents, and their outcomes and consequences (Questions Box). The clinician should find out how these informants perceive and handle the child's behavioral problems and, in turn, how the child responds. Social/family stresses and the home-school environment should be described and evaluated, and school reports and report cards reviewed. Interviewing the child alone provides an opportunity to better understand his or her thoughts, feelings, insight, judgment, self-image, and developmental status; however, children generally have poor insight into their ADHD symptoms and are generally not considered reliable informants for DSM ADHD symptoms. Interviewing caregivers alone and talking with teachers over the phone before or after the visit can be very helpful and alleviate some of the burden on the child of what is often initially a problem-oriented discussion about him or her. The clinician should inquire about the child's difficulties, developmental strengths and competencies, adaptive strategies, stress management, self-regulation, protective factors, and adjustment.

Historical information should cover all DSM criteria (see Box 125-1). Parents and teachers may report the child's behaviors using an ADHD-specific questionnaire or rating scale that includes these (eg, Vanderbilt scales), which can be found in the American

Academy of Pediatrics (AAP) toolkit *Caring for Children With ADHD: A Resource Toolkit for Clinicians*. Non-ADHD-specific developmental screening tools do not replace this type of comprehensive ADHD assessment because their sensitivity and specificity for ADHD are diagnostically inadequate.

The clinician should evaluate for coexisting conditions that would warrant further investigation. This is where broad screening tools, such as the Child Behavior Checklist and Behavior Assessment Scales for Children, can be useful. For example, frequent sadness or isolation would suggest depression, and persistent negative, hostile, and defiant behavior toward authority would suggest oppositional-defiant disorder. The AAP toolkit for clinicians includes both a scale specific to ADHD behaviors and a broader scale for possible coexisting conditions.

Physical Examination

The child's weight, height, and head circumference should be plotted on a growth curve and the pattern of growth evaluated; pubertal status should be recorded. Children should be examined for congenital anomalies, syndromic stigmata, or dysmorphic features, such as fetal alcohol facies or café-au-lait skin macules. A musculoskeletal evaluation should be done to document bulk, strength, tone, gait, station, and fine and gross motor coordination; a neurologic examination should include assessment of the cranial nerves, sensation including hearing and vision, balance and proprioception, and repetitive movements, tics, or tremors. The psychiatric and behavioral status examination should include an assessment of the child's mental status, affect, mood, insight, judgment, social-emotional reciprocity, joint attention, speech/language and communication, memory, fund of knowledge, and thought content and processes.

Observing the child's behavior during the office visit is crucial, with the caveat that many children with ADHD do not appear grossly hyperactive or inattentive in the office. Interaction between the child and his or her parents should be observed and documented nevertheless. The clinician should note how the child does with complex parental and examiner instructions, directives, and questions, and how parents deal with any "misbehavior." Does the child cooperate and comply with the examination, and does he or she seem motivated to change? How well does the child relate to adults? The clinician should watch the child play (eg, draw, play with toys) and note the child's organization of activities, attention span, distractibility, and motor activity.

Laboratory Tests

Diagnostic tests, such as specific neuropsychological or psychiatric metrics (eg, IQ tests), are not indicated for initial ADHD evaluations and should be guided by selected findings on the history and physical examination. Psychometric testing or standardized school district tests may show that a discrepancy exists between the child's raw abilities (IQ) and academic progress in one or more areas (achievement scores or grades); in this case, a referral for psycho-educational testing to rule out specific learning disabilities is indicated. Referral for further evaluation of speech, hearing, and vision should also be

Questions

Screening for Attention-Deficit/Hyperactivity Disorder

- History of Presenting Complaint (from multiple informants)
 - What concerns do you have about his/her development, behavior, or learning?
 - How is he/she doing in school academically and socially?
 - Is he/she happy in school?
 - Has your child been held back in any grade, suspended, dropped out, or considered dropping out?
 - How often does he/she have problems completing home chores, class work, or homework?
 - How often does he/she have major problems controlling his or her behavior at home, in school, or with friends?
 - How often is behavior management, self-regulation, and/or discipline difficult at home or school?
 - What are the antecedents and consequences for problem behaviors at home and/or school? What discipline techniques have been tried and what effects did each have?
- Perinatal, Developmental, Academic, and Medical History
- Psychological History and Previous Treatments
- Social and Environmental History
- Family History (focused especially on immediate family ADHD, school problems, developmental delays, conduct problems; cardiac, musculoskeletal, neurological, or psychiatric conditions)

done as indicated. Blood tests, such as hematocrit, lead level, and thyroid hormone, likewise, are only indicated if there are relevant signs or symptoms. Additionally, computerized continuous performance tasks designed to measure vigilance or distractibility have low sensitivity and specificity and fail to adequately differentiate children with ADHD from controls.

Brain imaging (eg, magnetic resonance imaging or positron-emission tomography) currently has no role in the evaluation of ADHD. Despite their utility in population-level studies, such measures cannot yet accurately differentiate between the brains of individuals with and without ADHD. An electroencephalogram or neurologic consultation is indicated only if absence or partial complex seizures are suspected by history or physical examination.

Management

Treatment of ADHD must be multimodal, continuous, and longitudinal, recognizing that ADHD is a chronic condition. Family education should emphasize the strengths of children and families, and address parental concerns. Families should be aware that children with ADHD often experience functional impairments in academic achievement, self-esteem, social skills, peer status, unintentional injuries, and family functioning. The clinician can ease parents' guilt by explaining the neurodevelopmental basis of ADHD and assuring that ADHD is not the result of insufficient parenting. Children who discover that their problems are not their fault may feel that a heavy burden has been lifted from their shoulders. However, both parents and children may find it difficult to accept that the child has a chronic disorder. Support groups such as Children and Adults with ADHD (CHADD) (www.chadd.org) may be helpful for families. Clinicians should work together with the child, family, and school personnel to specify appropriate target outcomes. They should then monitor the child for target behaviors and adverse effects. If target outcomes are not met, the clinician should reevaluate the initial diagnosis, use of available treatments, adherence to the plan, and potential for coexisting conditions.

Behavior Management

The goals of behavior management are to modify the child's physical and social environment at home and school in order to influence positive behavioral change. Behavioral modification techniques include rewards for the target outcome behaviors (eg, verbal praise hugs; points or stars on a chart that can be traded for material objects or a desired activity, such as a game or special time with a parent) and punishments for unacceptable behaviors (eg, time out, loss of a privilege, extra chores, or reduction in allowance). Acceptable and unacceptable behaviors should be clearly defined and measurable, and rewards and punishments should be spelled out in a contract drawn up with the child. The strongest behavioral interventions follow immediately after a behavior (eg, immediate praise when a child follows a command after the first time it was given). If rewards or punishments are used over time, parents and teachers must be creative in periodically varying the rewards and penalties. Management of overactive children who have difficulty focusing attention, following

rules, and controlling impulses can be challenging for both parents and teachers. The best results come from praising and reinforcing positive behaviors and ignoring negative behaviors unless they are dangerous or intolerable. Using praising and ignoring in combination can be very successful. Parent commands should be clear and countable (eg, "You need to go upstairs to brush your teeth before the egg timer goes off in 3 minutes."). Because children with ADHD can have difficulty carrying out multistep commands, it is best to set them up for success by giving clear, doable, single-step commands. Behavior management in combination with medication management can be extremely effective. Potential benefits of behavioral therapy when used concurrently with medication include improved scores on some academic measures, improved behavior, and decreased anxiety symptoms. Interventions such as play therapy, psychotherapy, and cognitive therapy have no documented efficacy in managing core ADHD symptoms, but may be indicated for common co-occurring conditions such as anxiety, conduct disorder, and depression. Approaches that target executive function training and cognitive-emotional self-regulation may be useful adjuncts as well.

Educational Interventions

The pediatrician can improve the child's educational experience by contacting the child's teachers and even attending school conferences and special education meetings. While most children with ADHD can be managed in the regular classroom, special education in a smaller, more focused setting may be indicated for behavioral or academic difficulties. Teachers can use specific strategies to help children with ADHD focus their attention and follow directions in the classroom (Box 125-3). Behavioral therapy should be integrated into the classroom, focusing on a child's strengths and minimizing stigma. Teachers and caregivers who are most successful in working with children with ADHD are able to set firm limits and discipline children without anger or frustration, while at the same time remaining flexible enough to recognize when a change in tactics or even "rolling with it" is necessary. Caregivers of children with ADHD can request needed classroom accommodations through Section 504 of the Americans with Disabilities Act, and children whose ADHD symptoms lead to significant learning deficits may qualify for an Individualized Education Plan through the Individuals with Disabilities Educational Act. A letter from a primary

Box 125-3. Strategies for Managing Children With Attention-Deficit/Hyperactivity Disorder in the Classroom

- Seat children where distractions are minimized and teachers can see how and when children are paying attention.
- Cue children discretely or nonverbally to remind them to refocus their attention.
- Give clear, succinct, 1- to 2-step directions, and repeat them frequently and patiently.
- Break up work periods by allowing children to get up and move around (eg, handing out papers, cleaning chalkboard).

care clinician documenting a child's health impairments, developmental risks, and academic limitations attributable to ADHD can go a long way in helping to ease this process for families and schools.

Because children with ADHD are easily provoked into misbehavior and are prone to clashes with peers, they can also benefit from closer supervision in unstructured school areas such as the playground, cafeteria, halls, and bus. Programs designed to improve social competence and peer relationships (eg, group social skills training, therapeutic recreational activities) may also be helpful.

Pharmacotherapy

Research has shown that psychostimulant medication with and without behavioral therapy is efficacious in reducing the core symptoms of ADHD. Furthermore, there is some evidence that these effects translate into an increased ability to follow rules, improved classroom behavior, and improved relationships with peers and parents; impacts on higher-order executive functions are less predictably attained. Effects of stimulant medication on learning are not well studied. Caution should be used when treating children younger than 5 years or weighing less than 20 kg with stimulant medication because many pharmaceutical stimulant preparations have narrower therapeutic windows on a per-kilogram basis for children of smaller stature.

Psychostimulants are the most commonly used agents for ADHD and, by far, the most evidence-based. Currently available stimulants include short-acting (3–6 hours), intermediate-acting (6–8 hours), and long-acting (10–12+ hours) formulations of methylphenidate and amphetamines (Box 125-4). Studies have found few, if any, differences between the efficacy of methylphenidate and dextroamphetamine, but some children will respond better to one or the other.

Box 125-4. Stimulant Medications

Methylphenidate

- Short (Ritalin, Metadate, Methylin)
- Intermediate (Ritalin SR, Metadate ER, Methylin ER)
- Extended release (Concerta, Metadate CD, Ritalin LA, Focalin XR, and transdermal [Daytrana])

Amphetamine

- Short (Dexedrine, Dextrostat)
- Intermediate (Adderall, Dexedrine)
- Extended release (Adderall-XR, Vyvanse)

Stimulants affect behaviors within 30 minutes and affect attention (eg, for a school subject like math) within 1.5 hours after administration. There is little evidence of tolerance to stimulants over time, but short-term tolerance occurs so that blood levels must increase during the day to maintain efficacy. Long-acting stimulants, such as Concerta, produce increasing plasma concentrations throughout the day, eliminate the need to take medication at school, and may persist during after-school homework time. A transdermal delivery system (Daytrana) is now available for children aged 6 to 12 years.

The most common side effects of stimulant medications are decreased appetite, stomachaches, headaches, delayed sleep onset, and jitteriness, occurring in 4% to 10% of children. Transient motor tics may occur while on the medication (or an existing chronic tic disorder or Tourette disorder exacerbated or unmasked). At higher doses, stimulants may negatively influence height velocity and may slightly decrease predicted adult height. While dosing of stimulant medication is based on individual variation in response, researchers have found that children generally do better on a maximized tolerable dose of stimulant medications, which is body-weight dependent, rather than the lowest dose that shows a clinical effect. The best stimulant dose for an individual child is thus the dose that produces near-complete symptom remission while producing acceptable side effects (eg, appetite suppression is usually tolerable whereas growth suppression is not). For this reason, it is recommended that clinicians do a controlled open-label titration trial of multiple dosages of a single agent using a systematic method. For example, one might use either long-acting methylphenidate in 18, 36, and 54 mg dosages, or long-acting amphetamine in 10, 20, and 30 mg dosages in 1-week blocks, with teacher- and parent-completed DSM-based scales (such as the Vanderbilt or Conners) at the end of each week. The clinician can then use these scales to develop a medication management plan with the family. Published guidelines, such as the Texas Medication Algorithm Project, can aid the clinician in this regard.

Once the medication dosage is stable and helpful, often after 2 to 4 visits over 1 to 2 months, follow-up should occur at least every 3 to 4 months, with particular attention to emerging developmental competencies, self-mastery, and improvement in targeted goal behaviors. Such visits should minimally include an interim history, weight, height, blood pressure, and scales of clinical response from caregivers and teachers.

If a particular stimulant does *not* produce symptom remission at all or only does so with severe or intolerable adverse effects, the clinician should systematically try 1 or 2 other stimulants because 70% to 80% of children can achieve complete remission of symptoms in this manner. If 2 or 3 psychostimulants are not effective or produce unacceptable side effects, other medications can be used. Atomoxetine (Strattera) is a non-stimulant medication that selectively inhibits the norepinephrine transporter. Atomoxetine is approved for children older than 6 years, has once-daily dosing, should be titrated to an effective weight-based dose, and often takes 1 to 6 weeks to produce effects; adverse effects can include gastrointestinal upset and mood irritability. α_2 -agonists such as clonidine (Catapres) and guanfacine (Tenex, Intuniv) are often useful as adjuncts for children with poorly controlled hyperactivity/impulsivity or comorbid tics, although few children with ADHD achieve adequate symptom remission on α_2 -agonist monotherapy. Tricyclic antidepressants and bupropion can have positive effects on ADHD symptoms for some children, although again are rarely used as monotherapy. Pemoline (Cylert) is generally not used because of the potential for fatal hepatotoxicity. Modafinil, mood stabilizers, antiepileptics, and atypical antipsychotics are generally not indicated in the treatment of ADHD in the primary care setting.

Complementary and alternative medicines, such as vitamins, dietary restrictions, and occupational therapy/sensory integration, are used by 54% of parents, but only 11% discuss these with their child's clinician. Primary care practitioners are challenged to help families safely navigate the limited evidence available on such therapies' risks and benefits. For example, melatonin is often helpful for comorbid sleep disorders prevalent in children with ADHD, and the Feingold Diet is said to alleviate hyperactivity by eliminating artificial flavors, colors, and preservatives in the diets of children sensitive to these putative effects. There is no evidence, or negative evidence, for some popular holistic approaches, such as Behavioral Optometry. Finally, while there may be neurobehavioral toxicity associated with low doses of various environmental toxins, particularly in young children, pediatricians are encouraged to emphasize primary prevention; there is no role for chelation in this context.

Prognosis

Attention-deficit/hyperactivity disorder is a chronic condition, persisting into adolescence and adulthood in about two-thirds of affected children. Overall, adults who had un- or under-treated childhood ADHD complete less schooling, hold lower-ranking occupations, have lower self-esteem and more social-skill deficits, and exhibit more antisocial behavior and alcohol and drug abuse. However, ADHD does not preclude attaining high educational and vocational goals, and more than half of adults with childhood ADHD no longer meet full *DSM-IV* criteria. Hyperactivity usually greatly diminishes or resolves in high school or early adulthood; some young adults experience a bothersome sense of inner restlessness. Attention problems and impulsivity may continue to varying degrees. Adults with ADHD may choose occupations that match their strengths and minimize limitations (eg, on-the-road salesperson vs desk job accountant). While some adults with ADHD choose to continue medication, others may function well without medication.

CASE RESOLUTION

Cody's primary care clinic reorganized their system of care to leverage the core concepts of the **medical home** to improve the care for children with chronic conditions, including ADHD. One of the clinic's nurses, Karen, has been trained to coordinate referrals to behavioral health and other specialists as indicated, communicate and coordinate care with schools and community services, and monitor adherence and response to treatments.

During Cody's visit, the pediatrician confirms the diagnosis of ADHD and probable comorbid anxiety using AAP practice guidelines and standardized criteria. She educates Cody and his family about multimodal evidence-based interventions for these conditions and introduces the family to Karen and the medical home model of care. Karen follows up with the family by phone 1 week later as planned and learns that they are reluctant to start Cody on any medicine. She guides Cody's parents to voice their preferences and cultural perspectives on possible interventions and then assists them in making another appointment with the same pediatrician, ensuring continuity of care. At the next visit, the pediatrician uses motivational interviewing to help the family find agreement on a watchful waiting approach with close, continuous school and home follow-up by Karen and at least quarterly visits with the same pediatrician. One month later, following a behavioral crisis at school, Cody's parents request an urgent appointment with same-day access. The pediatrician reviews recent parent and teacher behavioral rating scales at the point of care (gathered by Karen the prior week) and reiterates the available first-line treatment options. The family agrees to pursue an open titration trial of stimulant medication for ADHD symptoms and referral to a therapist for evaluation and possible treatment of the anxiety symptoms. Another clinic visit is scheduled in 1 month, while Karen follows up weekly with parents, teachers, and therapists.

Psychopharmacology in Children

Robin Steinberg-Epstein, MD, and Kenneth W. Steinhoff, MD

CASE STUDY

An 8-year-old girl has been diagnosed with high-functioning autism. The local developmental-behavioral pediatrician has recommended treating her anxiety and inattention with atomoxetine. The girl's mom is very hesitant. She trusts you and wants your opinion.

Questions

1. How does one assess the safety and appropriateness of psychotropic medications?
2. What kind of blood tests are used to maximize safe administration and how often are they performed?
3. What is the evidence that psychotropic medications are overprescribed?
4. What are the usual side effects of commonly used psychotropic medications?

Psychopharmacologic agents are now used with greater frequency in the pediatric population. Approximately 50% of children and adolescents will, at some point before age 18, meet criteria for a psychiatric diagnosis. Almost a quarter of children will have substantial impairment as a result of those symptoms. Unlike antibiotics or other medications used in children, psychopharmacologic agents are used daily and for extended periods. Furthermore, it is important to recognize that there is a dearth of evidence-based information supporting the use of many medications in children, including psychotropics. Therefore, most of these medications are used in an **off-label** fashion. The medical community must then rely on published data (often in adult subjects), clinical experience, and expert consensus to guide medication choice, dose, and management. This often provokes parental anxiety and sparks numerous concerns from families who don't understand that the US Food and Drug Administration (FDA) label limits the claims a manufacturer can make but does not limit a clinician's use of medications. Furthermore, families are often anxious because clinicians rely almost exclusively on history and structured behavioral observation, which is the most important "test" for most of these disorders. Unfortunately, there is a national shortage of pediatric subspecialists trained to choose, monitor, and manage these medications for children. It is, therefore, necessary for pediatricians to be familiar with the various medication classes and the controversies facing families of affected children.

Pediatricians need to understand the principles guiding the use of these medications and to become familiar with some of the more frequently used psychopharmacologic agents. The most used classes

of medication in children include **stimulants**, **selective norepinephrine reuptake inhibitors (SNRIs)**, **selective serotonin reuptake inhibitors (SSRIs)**, and **atypical neuroleptics**, also known as **serotonin-dopamine antagonists (SDAs)**. This information can also be useful in helping families navigate this confusing maze.

The decision to use psychopharmacologic agents should not be made without considerable thought. Medication should be an integral part of a comprehensive treatment program that addresses the academic, behavioral, medical, and developmental needs of the child. The decision to place a child on any agent should be based on significant dysfunction as well as discussion and full disclosure of potential risks and benefits with both parents and child. Rating scales should be employed and target symptoms identified as a means of monitoring medication benefit. A medication trial, once undertaken, should be carefully monitored, methodically addressing both adverse events and effectiveness. It is generally best to change one agent or dose at a time, followed by structured observation (eg, rating scale[s]) to determine the effect of the change. Therefore, one usually begins with **monotherapy**, optimizes the dose, and assesses risks and benefits before developing a more complex regimen. Such a trial necessitates frequent visits and discussion with the administering physician. Given current scientific information and clinical experience, the use of psychopharmacologic agents in young children (<5 years) should be reserved for extraordinary circumstances.

It should come as no surprise that children are not little adults. Pharmacokinetics in children is affected by increased rates of metabolism in their relatively larger livers, a faster glomerular filtration, and variable fatty tissues. Some children, therefore, require

a larger dose than those used for adults. Conversely, perhaps due to size, fat distribution, and other explanations, a much smaller, and seemingly ineffective, dose may be enough. There is little correlation between blood level and treatment response for most agents. Furthermore, some medications have a duration of effects that will exceed their **half-life** (atomoxetine), but for others (such as stimulants) their effect diminishes despite having a significant blood level. Additionally, for most agents (such as stimulants and SDAs) there is no correlation with milligrams per kilogram. Frequent clinical monitoring and communication with parent and family are vital to understanding medication benefit and adherence.

Psychostimulants

Psychostimulants (see Chapter 125) are the most studied psychotropics used in pediatrics. These medications are used to treat the hyperactivity, inattention, and impulsivity seen with **attention-deficit/hyperactivity disorder (ADHD)** and disturbances of attention seen in other disorders (**autism, traumatic brain injury, depression**, etc). Stimulants are also used in the treatment of **narcolepsy**. Over the past decade many new delivery systems have been developed with differing durations of action, which help to cater to the specific lifestyle needs of the patient. Much work has been done to determine optimal blood level delivery leading to the most consistent effect. Overall, the duration of action and clinical efficacy are more relevant than the blood level in this class of medication.

The mechanism of action of these agents is to increase **dopamine** and **norepinephrine** in the synapse. Overall, this enhances activity in the **prefrontal cortex** of the brain responsible for attention, focus, and **executive function** (organization and planning).

There is substantial evidence in multisite, double-blind, placebo-controlled studies (eg, Multimodal Treatment Study of Children With Attention-Deficit/Hyperactivity Disorder) to support the first-line use of these medications in the treatment of school-aged children and adolescents with ADHD. There is evolving evidence (Preschool ADHD Treatment Study) to support the use of these drugs in preschoolers. There is a growing body of evidence to support their use in autism, albeit at lower doses and with a lower threshold for side effects.

Parents have a variety of concerns related to stimulants, much of which is propagated by the media; however, NOT treating ADHD results in significant comorbidities and risks for negative outcomes. Nonetheless, several areas of controversy exist, and often become a primary focus for hesitant parents. Understanding the facts can help to demystify these medications for parents. For example, a risk of substance abuse has long been linked with stimulant medication. There is a substantial body of evidence to show that the use of stimulant medication does **not** lead to an increased risk of later substance abuse. In fact it is the untreated ADHD, linked with the development of maladaptive behaviors, which places adolescents at a higher risk of substance abuse. The hypothesis is that treatment of ADHD with stimulant medication will actually reduce substance abuse and a whole host of other potential negative outcomes such as early tobacco use, undesired pregnancy, motor vehicle crashes, etc. More long-term studies will be needed to clarify this issue.

Another frequently raised concern includes the association between stimulants and an increase in sudden unexpected deaths. This would obviously raise discomfort for any parent. However, scrutiny over these statistics by the FDA actually revealed a lower incidence of sudden unexpected deaths in those on stimulants compared with the unmedicated population. Those who died tended to have an underlying cardiac defect. This led to the FDA recommendation (2006) that those persons with **preexisting cardiac conditions** not use stimulants and those families with a history of cardiac structural defects or sudden unexpected death receive an echocardiogram and cardiac clearance prior to starting medication.

Height suppression has also historically been raised as a concern with these medications. Numerous studies have tried to answer this question. A recent longitudinal study (over 10 years) supports an initial growth suppression emphasized in the first 3 years, which appears to resolve over the remaining 7. Parents can be further reassured that if there is height suppression it seems to be minimal, in the range of 1.5 cm. It is better to have a high school graduate who is slightly shorter than a taller dropout. Finally, parents believe that their children will be “zombies” on medication. Children who are overmedicated can appear glassy-eyed and overly passive, but good communication and interaction between families and doctors will quickly alleviate this problem. Additional information regarding these medications may be found in Chapter 125.

Selective Norepinephrine Reuptake Inhibitors

The SNRIs presently include one medication that is frequently used in children: **atomoxetine** (Strattera). Atomoxetine is used in both the treatment of ADHD and for the **inattention** and **anxiety** associated with autism.

The mechanism of action for atomoxetine is to block the reuptake of norepinephrine in the synapse. This may have a direct effect on enhancing the signal-to-noise ratio in the brain and may also ultimately lead to an increase in dopamine in the prefrontal cortex of the brain. Unlike stimulant medications, atomoxetine avoids the nucleus accumbens so that it has no abuse liability.

Atomoxetine was originally studied as an antidepressant, but early investigation did not yield robust antidepressant effects. Marketed as providing “continuous symptom relief,” a careful duration of action study shows little effect on core ADHD symptoms after 9 hours, but some possible other small effects (compliance) may last slightly longer. Its attractiveness stems from its identity as an FDA-approved **non-stimulant**. Although usually less effective than stimulants, it has a different side-effect profile and may show slight mood benefits.

Research shows that this medication, which is FDA approved for ADHD, is effective in treating symptoms of this disorder for a given individual, but in groups of people is not as effective as the stimulant medications. Atomoxetine generally has a 60% response rate (measured by 25% reduction in ADHD ratings) compared with a 70% to 80% response (measured by 30% reduction in ADHD ratings) found in stimulant medications. Furthermore, 3 different head-to-head studies with stimulants have demonstrated atomoxetine as less

effective on average; however, some individual patients do well with this medication. It should especially be considered in cases of stimulant failure (poor tolerance and/or poor effect of a trial on a methylphenidate preparation and a trial on an amphetamine preparation), worries about substance use and diversion, exacerbation of tic disorder with stimulants, and the presence of comorbid anxiety or autism.

This medication is not without **side effects**. The side effects are very similar to the traditional stimulants with the added concerns of drowsiness, dizziness, and cough. Furthermore, atomoxetine carries a warning citing a slightly increased risk of suicidal thought similar to the SSRIs. It is not associated with tic exacerbation. Response to this medicine is more like that of an antidepressant, in that it may take 4 to 6 weeks to see the full impact of a particular dose. The dosage range is 0.5 mg/kg to 1.8 mg/kg. Those on the autistic spectrum tend to respond at lower doses and with a lower threshold for adverse side effects.

There have been a few reports of a serious **idiosyncratic reaction** suggesting liver failure. These patients were on FDA-approved doses of atomoxetine for several months. They had vomiting, jaundice, and elevated liver enzymes. These findings resolved off medication and returned with reexposure to the drug. This led to an FDA warning to consider potential liver failure in a vomiting patient on atomoxetine.

In consideration of both the stimulants and SNRIs, the American Academy of Pediatrics and the American Academy of Child and Adolescent Psychiatry recommend stimulants and SNRIs as first-line treatments for ADHD. There is no indication that blood or urine tests need to be monitored for either class of medication. Improvement, adverse event, and adherence monitoring using rating scales should occur regularly—at least every 3 months (once dose and agent have been optimized).

Parents often want to know if these medications can be used intermittently and stopped as soon as possible. Stimulants and SNRIs have their best results when administered 7 days a week and without large breaks. Longitudinal studies suggest that while some symptoms may resolve over time, significant impairment from even a small number of symptoms persists into adulthood for 60% to 70% of those diagnosed with ADHD. Therefore, many people may continue on medication for a number of years. To assess for continued benefit, a break from medication should be attempted annually. It is beneficial to reoptimize doses and agents throughout treatment. As children grow larger they often need higher doses. However, as compensatory mechanisms develop and some symptoms subside, some patients may

require less medication. “Holidays” from medications has no established intrinsic value on their own and should only be recommended for children with significant medication side effects such as substantial weight loss. If a parent is requesting a **drug holiday** it is a signal that the parent may need to review the value of the medication. A discussion should ensue as to whether the parent and child continue to see benefit, the patient is having troubling side effects, or the medication at any dose is not helpful with concerning symptoms. Consider that atomoxetine, once stopped, needs time to rebuild in the system.

Selective Serotonin Reuptake Inhibitors

The SSRIs (Table 126-1) are frequently used in children and adolescents to treat a variety of depression- and anxiety-based symptoms (Box 126-1). Similar to the SNRIs, the SSRIs block presynaptic reuptake of serotonin after it is released into the synapse, thereby enhancing serotonin activity in the synapse. Empirical evidence has established their benefit in the treatment of depressive disorders and anxiety disorders.

Medication is NOT a substitute for therapeutic support. As a matter of fact, most clinical guidelines recommend psychotherapy as first-line treatment for most anxiety and depressive disorders in children. Biologic intervention should only be undertaken if psychotherapy progress is minimal or impairment severe. **Obsessive-compulsive disorder** (OCD) is a unique anxiety disorder that typically requires higher doses of SSRIs but is also responsive to a specific form of cognitive-behavioral therapy that includes exposure response prevention.

Medications are chosen based on side-effect profile and half-life. Due to a significant placebo effect and a lack of multiple, large, highly powered studies in children, only a few have any FDA approval in children (Table 126-1). There are numerous studies that may not meet strict scientific criteria, but taken together with vast clinical experience and consensus imply reasonably well-tolerated and

Box 126-1. Disorders Treated by Selective Serotonin Reuptake Inhibitors

- Depression

<i>Generic</i>	<i>Product</i>	<i>FDA Pediatric Approval</i>	<i>Suggested Pediatric Dose, mg</i>	<i>Half-life</i>	<i>Time Steady State, days</i>
Fluoxetine	Prozac	Depression/OCD	2.5–60	4–6 d	28–35
Sertraline	Zoloft	OCD	12.5–200	26 h	5–7
Fluvoxamine	Luvox	OCD	12.5–100 bid	15 h	5–7
Paroxetine	Paxil	None	5–30	21 h	5–10
Citalopram	Celexa	None	5–40	36 h	7
Escitalopram	Lexapro	Depression	2.5–20	27–32 h	7

Abbreviations: bid, twice a day; FDA, US Food and Drug Administration; OCD, obsessive-compulsive disorder.

beneficial effects of these medications. Studies have consistently found SSRIs to be more effective and safer than the tricyclic antidepressants as a treatment for depression.

These drugs are metabolized via the liver through the **cytochrome P450 system**. There are individual enzyme variations that lead to variable metabolism of any of the many medications that travel through these pathways. Overwhelming this system may lead to inhibition and buildup of medications or facilitated rapid metabolism of others. Thus monitoring of all medications metabolized via this pathway is necessary. Reduced metabolism of the SSRIs may lead to **serotonin syndrome**—a relatively rare response to a flood of serotonin—presenting with confusion, hypomania, restlessness, diaphoresis, shivering, tremor, hyperreflexia, and diarrhea. This syndrome often goes unrecognized and these patients may find their way to a pediatrician's office or emergency department (ED). Occasionally, the combination of an SSRI with an atypical antipsychotic or stimulant may precipitate such a response.

Many children with anxiety or depression go on to experience intermittent exacerbations throughout life. This does not mean that they should stay on these medications forever. Present recommendations support an initial 6- to 12-month treatment period with the SSRI that provided response. If the symptoms return after discontinuation, the next trial should last 2 years. Finally, if the symptoms again return, then this suggests longer-term treatment. Occasionally, symptoms will not respond the next time the same agent is used.

Selective serotonin reuptake inhibitors are generally well tolerated with mild transient side effects such as gastrointestinal symptoms, headache, increased motor activity, or insomnia. One needs to monitor for less common side effects like disinhibition, a phenomenon of increased impulsive behaviors in association with SSRIs that is usually dose related. Those with autism are particularly susceptible to this response.

There are no specific recommendations on dose other than to start low and go slow. Typically effects may be seen between 1 and 4 weeks. The value of increasing the dose (except in the case of OCD) versus continuing on at the same dose versus changing agents is not clear until a patient has been treated for at least a month. See suggested dosage ranges in Table 126-1.

Some have suggested that these medications are **addictive**. This relates to the appearance of withdrawal symptoms on sudden cessation. Abruptly stopping medications that have a shorter half-life such as paroxetine and sertraline may lead to flu-like symptoms including body aches and vomiting. A child may present to their primary care provider with flu-like symptoms, not recognizing a connection between the symptoms and having skipped their medications for several days. The onset and severity of symptoms is proportional to the dose and duration of use and inversely proportional to the half-life. Occasionally, these children end up hospitalized for vomiting and dehydration. Simply readministering their skipped dose alleviates the symptoms. A planned taper should take 4 to 6 weeks.

Again, controversy follows these medications. In 2004 the FDA created a black box warning advising that children and adolescents on SSRIs should be monitored for worsening depression, agitation, and suicidality, particularly in the early stages of treatment. This warning came out of an FDA meta-analysis showing an increased risk of suicidal ideation in depressed teens soon after starting the medications. No completed suicides occurred. This prompted an FDA recommendation to see children placed on SSRIs weekly for a month, then bimonthly for a month, then monthly and, ultimately, at longer regular intervals. This expectation was felt to be impractical for clinicians in practice. Therefore, these recommendations have recently been relaxed to incorporate physician judgment. It is advised to monitor each individual patient carefully, but the potential for benefit usually outweighs the risks. These concerns should NOT detract from the importance of these medications.

The FDA warning led to a decrease in prescriptions of SSRIs, which resulted in the first increase in the suicide rate since the FDA SSRI approval. The FDA warnings should serve only to increase awareness, not be a contraindication. An increase in suicidality has not been noted in adolescents with isolated anxiety or autism. Selective serotonin reuptake inhibitors serve a vital role in helping children paralyzed by anxiety, obsession, and depression to lead more normal lives.

Atypical Antipsychotics (Serotonergic Dopamine Antagonists)

The **atypical antipsychotics** or **second-generation antipsychotics** (Table 126-2), also known as **SDAs**, are medications with dopamine D2 and serotonin 5-hydroxytryptamine type 2 antagonism. These newer medications offer a lower risk of both **extrapyramidal side effects** like **dystonia**; **akathisia**, a feeling of restlessness; tremor; tardive dyskinesia; and hyperprolactinemia compared with the conventional antipsychotics. However, these medications carry significant cardiometabolic risks. Although initially billed as a safer alternative to traditional antipsychotics, some have suggested that these newer medications merely substitute one set of severe side effects

Table 126-2. Serotonin-Dopamine Antagonists (Atypical Antipsychotics)

Generic	Product	FDA Pediatric Approval	Dose
Risperidone	Risperdol	Agitation with autism, schizophrenia, mania, and bipolar disorder	.25–10 mg/day
Olanzapine	Zyprexa	None	2.5–20 mg/day
Quetiapine	Seroquel	None	12.5–250 mg bid
Ziprasodone	Geodon	None	20–120 mg/day
Aripiprazole	Abilify	Agitation with autism, schizophrenia, mania, and bipolar disorder	.5–30 mg/day

Abbreviations: bid, twice a day; FDA, US Food and Drug Administration.

for another. These medications offer benefits for severe behaviors that are not responsive to other intervention.

While often used off-label, these medications are incorporated into best practice clinical guidelines for psychotic depression, schizophrenia, bipolar disorder, oppositional defiant disorder, conduct disorder, agitation in mental retardation, Tourette disorder, stuttering, and autism. The only diagnoses for which an atypical antipsychotic has pediatric approval are schizophrenia, bipolar disorder, mania, and agitation associated with autism. Therefore, while these medications often lack enough empiric evidence to be validated for all the indications mentioned, clinical consensus by experts recommend judicious use in treating children with serious mental illness after other forms of intervention have failed or in cases of severe psychosis or aggression. These medications should NOT be used to promote weight gain, as a sedative or sleep aid, or as a treatment for ADHD.

Medications are chosen based on clinical experience and side-effect profile. These medications are not innocuous. They must be used with full disclosure to parents. The most common side effects are listed in Box 126-2. The severity of some of the side effects deserve discussion. The SDAs, with possibly the exception of aripiprazole, have caused significant increases in weight, glucose, and lipids, and decreases in sensitivity to insulin, otherwise known as *metabolic syndrome*.

Box 126-2. Serotonin-Dopamine Antagonists: Potential Side Effects

<ul style="list-style-type: none"> • Weight gain • Sedation • Dizziness • Hypotension • Prolongation of QT interval • Metabolic syndrome (hyperglycemia and increased lipids) • Constipation 	<ul style="list-style-type: none"> • Dry mouth • Headache • Cataracts (in dogs) • Increased liver function tests • Decreased triiodothyronine, thyroxine • Extrapyramidal side effects • Akathisia (sense of restlessness)
---	---

There have been transient elevations of **prolactin** among recipients of these medications. The clinical significance of this increase is unclear. Weight gain frequently accompanies these medications and must be monitored. A prolonged QT interval on electrocardiogram (ECG) is rarely noted and has not been associated with death, but remains a clinical concern.

Risperidone is the best studied medication of its class for children. However, the studies on which its FDA approvals hinged exposed side effects, most notably weight gain. Therefore, anticipatory counseling regarding diet management is routinely recommended. Another important finding indicated that a small but significant number of children with agitation and autism were successfully able to stop treatment after 6 months, suggesting that a trial off medication may be warranted in those patients with agitation and autism successfully treated for 6 months.

Neuroleptic malignant syndrome is a rare, potentially life-threatening complication of neuroleptics that is extremely unlikely with the newer generation of medication. However, due to its lethality and its potential presentation to a pediatric office or ED this entity should be mentioned. Neuroleptic malignant syndrome is characterized by hyperthermia, autonomic instability, diaphoresis, “lead pipe” rigidity, increased creatine phosphokinase due to rhabdomyolysis, and delirium. It may occur at any point during treatment with these medications.

There is no set agreement on appropriate monitoring of these medications in children. Most conservative suggestions include following body mass index (BMI) at each visit, after 6 weeks, and again each 9 to 12 months checking complete blood cell count, a comprehensive chemistry including liver function tests, triiodothyronine, thyroxine, HbA1c, prolactin, fasting glucose, and lipid levels, especially in overweight children or in families with a history of diabetes mellitus. An ECG prior to starting medications, 1 month after baseline, and biannually are only necessary for children on ziprasidone to monitor the QT interval. Children are often sent to the primary care provider to obtain these tests and to monitor BMI.

As with any medication, psychotropic agents are sometimes misprescribed. By and large, however, psychopharmacologic agents are still underused in the treatment of many disorders. Hopefully, new and ongoing research will help physicians recognize mental illness in children and substantiate and refine the use of such medications in their care.

Careful thought and discussion of target symptoms as well as side effects will help physicians choose the best medication and treatment plan. It will also prepare parents to observe both the positive and negative response to medication.

While this chapter goes into significant detail on side effects, it is critical to understand that the diseases being treated are often incapacitating. Informed consent and parent/child involvement are vital in medication choice. Pediatricians have an extremely influential voice in supporting compliance. Therefore, knowledgeable guidance is crucial in helping parents make an uncomfortable and difficult decision that may ultimately lead to dramatic improvements in quality of life.

CASE RESOLUTION

You empathize with the parents over this decision but are able to explain that this medication is a reasonable and safe one to try. The patient starts the medication and experiences some nausea in the first few days. With your reassurance, this resolves. Her mom calls a few weeks later to thank you for your advice and to let you know that while her daughter still has difficulties from the autism, she seems to be somewhat less anxious and is functioning better at school.

Physical Abuse

Melissa K. Egge, MD, and Sara T. Stewart, MD

CASE STUDY

A 6-month-old male infant arrives at the emergency department after becoming limp and nonresponsive at home. The mother states that her son was fine when she left him in the care of her boyfriend before going to the store for cigarettes. When she returned 1 hour later, he was asleep, but then he seized and stopped breathing. The infant is being ventilated by bag-valve-mask ventilation. On examination, the infant is pale and limp. The heart rate is 50 beats/min and the blood pressure is 130/80 mm Hg. There are no external signs of injury.

Questions

1. What are the major lethal injuries associated with physical abuse of children?
2. What are the types of injuries seen in physically abused children?
3. What are the presenting signs in children with head injuries?
4. What are the legal obligations of physicians in the area of child abuse?

Physical child abuse was first described in the pediatric literature in 1962 by Kempe et al in their classic paper on the **battered child syndrome**. Child abuse or maltreatment takes many forms, including physical abuse; **failure to thrive** (Chapter 129); **sexual abuse** (Chapter 128); **emotional abuse**; **prenatal exposure to substances** such as drugs and alcohol (Chapter 131); and **pediatric condition falsification (also referred to as medical child abuse)**, a complex disorder previously known as Munchausen syndrome by proxy in which parents confabulate or create a medical condition in their children.

The nature and extent of inflicted injuries are variable and may include **bruises, burns, fractures, lacerations, internal hemorrhage, and ruptures**. Physicians must be aware of the legal obligations related to the suspicion of child abuse. They must assess the nature of the injuries, initiate appropriate medical therapy, and determine if the history offered is consistent with the medical findings.

Epidemiology

It is estimated that the rate of childhood victimization in the United States is 10 per 1,000, and that approximately 15% to 20% of these children suffer some form of physical abuse. Certain factors are associated with physical abuse. Most victims are young children; two-thirds are younger than 3 years and one-third are younger than 6 months. Caring for young children is frequently demanding, so crying infants and toilet-training toddlers are particularly at risk for abuse. Factors such as **lower socioeconomic class, substance abuse, poor parenting skills, and domestic violence** place children at increased risk for abuse.

Clinical Presentation

Children who have been physically abused present with injuries that range from non-severe to lethal (Dx Box). Visible bruises, **bites**, and burns may be noted. Children may also have symptoms related to fractures, such as crying or refusal to walk or move an extremity. More severely injured children may present with seizures, apnea, shock, or cardiopulmonary arrest.

Dx

Physical Abuse

- Bruises
- Bites
- Burns
- Fractures
- Intracranial hemorrhage
- Intra-abdominal hemorrhage
- Apparent life-threatening event
- Retinal hemorrhage
- History that changes
- Injuries not explained by history

Pathophysiology

Injuries in children who experience physical abuse are the result of direct trauma inflicted on the children. Abusive parents often have unrealistic expectations of their children, leading to frustration and abuse when the child does not meet the expectations. Parents who have often been victims of abuse themselves know only corporal punishment as a disciplinary modality. These parents often exhibit poor impulse control; they do not intend to harm their children but desire to alter their children's behavior. As a result, sometimes the outcome is unexpected.

Head injuries, the most deadly form of abuse, may result from either a direct blow to the head or from rotational head movement (eg, shaking). Classically, a crying infant is vigorously shaken and suffers **diffuse axonal injury** or **intracranial hemorrhage**. In particular, subdural hemorrhage may occur from rupture of the bridging veins. The infant may also become apneic either during or after the trauma. Seizures, cerebral edema, hypoxic brain injury, and retinal hemorrhages may also occur. Such injuries are frequently associated with a fatal outcome or long-term damage to the central nervous system.

Abdominal trauma is the second most common cause of fatal child abuse and is typically due to a direct blow to the abdomen. Skeletal fractures result from multiple different types of traumatic forces to the bones. Rib fractures are most classically associated with the head trauma of shaking and are due to compression of the ribs by the hands that are holding the infant or child.

Differential Diagnosis

When evaluating children with physical injuries, the major differentiation is the distinguishing of injuries that are **intentional** or **abuse-related** from those that are **unintentional**. Practitioners should be suspicious of changing histories, histories that are inconsistent with the injuries sustained, and histories that do not match the developmental capabilities of the child. Unwitnessed injuries in young children, particularly pre-ambulatory infants, should also be suspect.

Bruises, burns, and fractures may be intentional or unintentional. Normal ambulatory children sustain bruises over bony prominences such as the forehead, elbows, and shins with unintentional, accidental trauma. Bruises over soft areas such as the cheeks or the pinnae of the ear, as well as bruises on protected areas such as the inner thighs or neck, are more suggestive of inflicted trauma. Injuries to the oral mucosa may result from efforts at forced feeding or occlusion of the mouth in an effort to silence crying. **Retinal hemorrhages** in infants most often result from intentional head trauma, such as shaking. They may also be due to other medical conditions that can usually be discerned from the history and physical examination and by consultation with an ophthalmologist. Ideally, a pediatric ophthalmologist performs indirect retinal examination of dilated eyes within 24 hours of the patient's admission (Box 127-1).

Children may be intentionally burned by being immersed in hot water or having hot objects such as irons or cigarettes held against them. Children who are immersed in hot water develop circumferential burns that may envelop an entire extremity. Such a burn is usually in a glove or stocking pattern, or in a doughnut pattern on the buttocks. These burns are distinct from splash or spill burns, which take on an irregular drip pattern. In distinguishing inflicted from accidental burns, a scene investigation is often helpful to measure the water temperature in the home water heater and determine the length of time required to reach that temperature in the location of the alleged incident. Families should be advised that their water heaters be set to 120°F to prevent accidental scald injuries.

Box 127-1. Causes of Retinal Hemorrhages

- | | |
|--|-----------------------------|
| • Inflicted head trauma | • Hypo- or hypernatremia |
| • Unintentional head trauma (rare) | • Vasculitis |
| • Birth trauma | • Papilledema |
| • Retinopathy of prematurity | • Hypertension |
| • Blood dyscrasias | • Cytomegalovirus retinitis |
| • Leukemia/lymphoma | • High-altitude illness |
| • Meningitis/sepsis | • Carbon monoxide toxicity |
| • Extracorporeal membrane oxygenation (ECMO) | • Osteogenesis imperfecta |
| | • Glutaric aciduria |

Long bone fractures (especially humerus and femur) should be suspect, particularly in preverbal or pre-ambulatory children. Certain fractures, such as **classic metaphyseal lesions**, **rib**, **sternum**, and **scapula fractures**, are highly suggestive of inflicted trauma.

Numerous medical conditions may mimic abuse. Bullous impetigo may resemble burns. A coagulopathy may lead to multiple bruises. Leukemia, thrombocytopenia, and aplastic anemia are also associated with bruising. Osteogenesis imperfecta or rickets may result in multiple fractures. Bone cysts and osteoporosis due to inactivity from multiple causes (eg, cerebral palsy, paralysis, and meningomyelocele) may predispose to the development of pathologic fractures.

Evaluation

Children who present with injuries need to be evaluated with a careful history and complete physical examination. Infants with altered mental status, apnea, or seizures should be evaluated in a similar manner because their symptoms may be secondary to intracranial injury.

History

The history should focus on an explanation for the medical findings (Questions Box) and, in infants and toddlers, a thorough developmental history should be included. Children should be interviewed alone if they are of an appropriate age. Physicians should determine if other risk factors, such as domestic violence or substance abuse, are present.

Questions

Physical Abuse

- What caused the injury?
- Was the child healthy until the injury occurred?
- Has the child sustained similar injuries in the past?
- Is there a family history of any conditions that would account for easy bruisability or fragility of the bones (eg, von Willebrand disease, osteogenesis imperfecta)?
- Is the child developmentally normal? What are the child's motor skills?
- Who was with the child when the injury occurred?
- What was done immediately after the injury? Was medical care sought?

Physical Examination

A child's state of hygiene and growth parameters should be noted, and the physical examination should be comprehensive. The location, color, and size of bruises, abrasions, lacerations, or other skin trauma should be recorded. Dating of bruises is imprecise because the degradation rate of hemoglobin, and therefore the rate of color change, is influenced by the depth and extent of the bruise and by the child's health and nutritional status. Large blue-brown spots, which occur commonly on the back and buttocks in darker-skinned children, are termed *mongolian spots* or *congenital dermal melanocytosis*. These should not be mistaken for bruises.

Medical providers should also note any skin findings that resemble characteristic patterns of inflicted skin trauma, such as slap marks to the face or gag marks around the mouth. Pinch marks can also be seen on the genitalia of a toilet-training toddler. Belts, cords, and blunt objects may leave patterned marks on the skin after a child is hit with the object. Bite marks are composed of indentations, bruises, or breaks in the skin that reflect the configuration of teeth that is unique to the perpetrator (Figure 127-1). Inflicted burns may also assume a characteristic pattern depending on the mechanism of injury (Figure 127-2).

The extremities, skull, and ribcage should be carefully examined to detect the presence of skeletal trauma. Findings such as decreased range of movement, tenderness, swelling, redness, or bruising may be associated with an underlying bone fracture. These findings are not always present, however, particularly if the fracture is in its healing stages.

Practitioners should be aware that infants with head or abdominal injuries may also present with no external signs of trauma. Those with head injury may have seizures, apnea, vomiting, increased crying, or altered mental status, often with no explanation as to the etiology. The retina should be evaluated for hemorrhages in these children. Children with abdominal injuries may present in shock or with symptoms such as vomiting, abdominal pain, or distention. They may have a rigid abdomen with guarding and decreased bowel sounds. Inflicted abdominal injuries may include hematomas of the bowel wall, bowel perforations; or trauma to the liver, spleen, pancreas, or kidneys.

Laboratory Tests

Children who present with bruises should have a hematologic assessment with a complete blood cell count (CBC) and differential (including a platelet count), a prothrombin time, and a partial thromboplastin time. Cultures from lesions may help differentiate infection from burn injury.

Children with fractures should be assessed with a chemistry panel (including blood urea nitrogen and creatinine), calcium, phosphorus, and alkaline phosphatase levels.

Children with suspected abdominal trauma should be evaluated with a CBC, urinalysis, liver function studies, amylase, and lipase. These studies may demonstrate anemia secondary to hemorrhage, hematuria from renal injury, or elevated liver or pancreatic enzymes due to solid or hollow viscus organ trauma (see Chapter 63).

Figure 127-1. Patterned bruises associated with inflicted trauma.

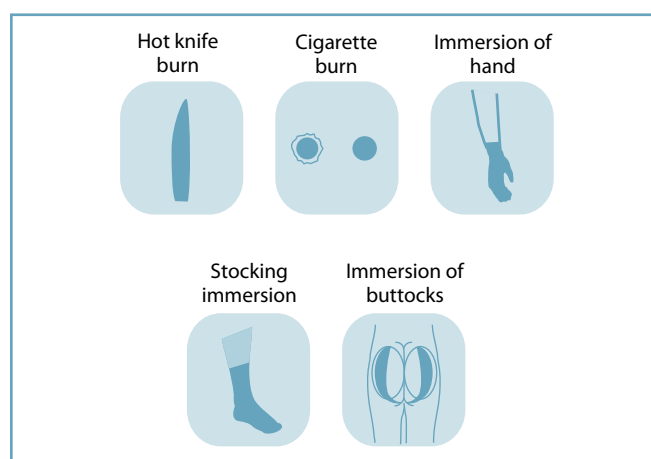

Figure 127-2. Patterned burns associated with inflicted trauma.

Imaging Studies

Children younger than 2 years who are suspected victims of physical abuse are at the highest risk of having an inflicted skeletal fracture. For this reason, this group of patients should be evaluated with a radiographic skeletal survey to identify any acute or healing fractures that may be present. Bone scintigraphy is also useful in detecting occult fractures and may be useful in conjunction with the skeletal survey. Follow-up skeletal survey in 2 weeks can also be useful to assess for fractures that were not noted at the time of the initial films.

If there is concern that children have suffered non-accidental head trauma, they should be evaluated with a computed tomography (CT) scan and magnetic resonance imaging. The combination of these modalities is particularly helpful in dating intracranial bleeding (see Chapter 64).

Abdominal radiographs may demonstrate air-fluid levels from dysmotility, distended loops of bowel, or free air under the diaphragm. Abdominal and pelvic CT scans may show bowel or solid organ disruption or hemorrhage.

Management

The management of children who are suspected victims of abuse focuses on medical stabilization and psychosocial investigation. Injuries should be treated in the appropriate manner. Children with extensive internal injuries frequently require admission to an intensive care unit. Consultation with appropriate surgical specialists in neurosurgery, orthopedics, or general surgery should be obtained.

The psychosocial assessment of the family often requires the expertise of a social worker. Further assessment may require an in-home evaluation such as that conducted by law enforcement or child protective services. All 50 states require that physicians who suspect child abuse report these suspicions to appropriate agencies. Physicians do not have to be certain of the abuse.

These mandated agencies pursue the investigation and provide supportive family services as needed. Children may be removed from their homes and placed in foster homes to ensure their safety. Cases of suspected abuse are usually evaluated in court to determine the safety of the children's environment, the ability of parents to care for their children, and the criminal culpability of suspected perpetrators. Physicians may be expected to offer testimony in such hearings.

Prognosis

The prognosis is variable. Some children succumb to inflicted injuries before coming to medical attention, and others sustain permanent neurologic damage. Even in cases in which the physical well-being of children is ensured, their mental and emotional well-being is often significantly impacted, requiring intensive and ongoing mental health care.

Recent longitudinal studies in adults have shown a link between adverse childhood experiences and health problems in adulthood.

Prevention

Practitioners should preemptively discuss with families those developmental stages that are at higher risk for parental frustration and subsequent child abuse, including infant colic, toddler potty training, and tantrums. Infant crying is the most common trigger for abusive head injury. A pediatric provider may offer guidance in handling these difficult situations and should assess the parents' coping skills with such behaviors when they arise. Pediatricians should also inquire about stressors particular to each family, such as unemployment, mental health issues, social isolation, and intimate partner violence. Support systems for the family should be identified and positive attributes praised.

CASE RESOLUTION

The case study describes a classic case of non-accidental trauma. The infant was left alone with an individual with limited parenting skills. The infant has evidence of increased intracranial pressure, and may have traumatic axonal injury or intracranial hemorrhage. The infant is intubated, given anticonvulsants, and admitted to a pediatric intensive care unit. Consultation with neurosurgery, ophthalmology, and social services is obtained. Appropriate imaging studies and skeletal surveys are performed when the infant is sufficiently stabilized, and the child is ultimately diagnosed with subdural hemorrhage, retinal hemorrhages, and rib fractures.

Sexual Abuse

Sara T. Stewart, MD

CASE STUDY

A 4-year-old girl is brought to the emergency department with the complaint of vaginal itching and discharge. Her past health has been good, and she has no medical problems. She lives with her biological parents and her 2-year-old brother.

On physical examination, the vital signs are normal and the child is well except that the genital area is swollen and erythematous and a green vaginal discharge is present. The girl is interviewed briefly but denies that anyone has touched her. The mother states that she has never left her daughter unattended and is angered by the questions.

Questions

1. What are the anogenital findings in prepubescent and postpubescent children who may have experienced sexual abuse?
2. What behavioral problems are common in children who have been sexually abused?
3. What are the pitfalls in disclosure interviews of children who have been sexually abused?
4. What is the significance of sexually transmitted infections (STIs) in children who have been sexually abused?

Child sexual abuse is the involvement of children and adolescents in sexual activity that they cannot consent to because of their age and developmental level. An age disparity exists between the victims, who are younger, and the perpetrators, who are older. The intent of the abuse is the **sexual gratification** of the older individuals, and the abusive incident(s) may or may not include physical contact. Sexual abuse may include acts of **oral, genital, or anal** contact by or to a child and may involve acts such as **exhibitionism** or involvement in **pornography**. It is differentiated from “sexual play” by the difference in the developmental levels of the participants and the coerciveness of the behavior.

Sexual abuse has been recognized with increasing frequency since the 1980s, in part because medical knowledge about the anogenital anatomy in both molested and non-molested prepubescent children has expanded. Technical advances have altered the manner in which these children are evaluated. In particular, the colposcope, with its potential for magnification and photographic or videotape documentation, has been valuable. Parental awareness and school-based programs have led to increased disclosures about abuse as well as a greater willingness on the part of adults to believe these disclosures.

Patient interviews are another key component of the assessment process that has been shaped by continued research in the field. Non-leading, open-ended questions are asked by interviewers as few times as possible and, when available, these questions are asked by specialized forensic interviewers.

Epidemiology

Approximately 17 in 1,000 children are thought to be victims of child maltreatment per year in the United States, and 10% of these are victims of sexual abuse. Exact figures on the prevalence of child sexual abuse are not readily available because they depend on reports of a condition that may not come to medical attention for many years. Anonymous surveys indicate that about 20% to 25% of women and 10% to 15% of men have been sexually abused before reaching adulthood.

Victims of sexual abuse come from all socioeconomic and ethnic groups. Girls experience sexual abuse at a rate 5 times that of boys. Some investigators believe that the statistics for boys are falsely low because boys are generally reluctant to disclose their abuse. Men are more commonly the perpetrators than women, and at least 20% of perpetrators are adolescents. Frequently, the sexual abuse has been occurring for several years. Perpetrators are usually known by the victims, and recent national data showed that 37% of perpetrators were biological parents, 23% were nonbiological parents, and 40% were other individuals. The mean time from onset of abuse to disclosure is 3 years. Sometimes children are not ready to disclose but the abuse is discovered accidentally because the victims develop symptoms, such as vaginal discharge or functional complaints.

Clinical Presentation

Most cases of child sexual abuse come to the attention of authorities after the child **discloses** the abuse. There may or may not be associated physical or behavioral complaints. Physical symptoms in the anogenital area may include **bleeding, pain, swelling, dysuria, vaginal discharge, or difficulty stooling**. More often, however, children

have no specific anogenital symptoms. Instead, they have nonspecific complaints such as headache, abdominal pain, or vague systemic symptoms such as fatigue (Dx Box).

Dx Child Sexual Abuse

- Anogenital erythema
- Anogenital bleeding
- Genital discharge
- Anogenital scarring
- Behavioral symptoms (eg, encopresis, enuresis)
- Disclosure of abuse
- Somatic complaints (eg, abdominal pain, headache)
- Sexually transmitted infections
- Sexualized behavior
- Pregnancy (adolescents)
- Delinquency, promiscuity (adolescents)

Behavioral changes may also be noted as these children respond to the stress of their victimization and their environments. These changes may include **sleep disturbances, hyperactivity, enuresis, encopresis, decreased appetite, and depression.** Sexually abused adolescents may manifest **school failure, delinquency, and suicide attempts.** Children may also respond with sexual behavior or sexual knowledge that is considered to be inappropriate or excessive for age.

Psychophysiology

Children suffer sexual abuse after becoming **entrapped.** They may be enticed with promises of rewards or presents, or may be made to feel special or grown up by being allowed to engage in adult behavior. Some children do not regard the sexual experiences as threatening but rather as a means by which they can obtain the love they crave. Only when they grow older do they realize that these sexual relationships were not normal or appropriate.

Other children are **coerced** into sexual activity with threats of physical harm. Once they have acquiesced, they are maintained in the relationship with threats of reprisal if they disclose the abuse. Children feel both guilty and responsible for what has happened. This sense of responsibility for family disruption is often perpetuated by the legal system, which may remove the children from their families or may place the offending family member in custody.

Lastly, some children enter into sexual relationships out of **curiosity.** They too become entrapped, particularly because they were initially willing to participate.

As a child reacts to an abusive experience, it is common to feel a need for secrecy. As a result, disclosures of abuse are often delayed, and when they do occur, the child often provides the information incrementally over time. Children may also recant their disclosures about abuse; such recantations are not considered to reliably indicate that the abuse did not occur.

Differential Diagnosis

A number of medical conditions that involve the anogenital area may be mistaken for acute or chronic changes due to sexual abuse (Box 128-1).

Box 128-1. Conditions Mistaken for Sexual Abuse

<i>Genital</i>	<i>Anal</i>
• Accidental trauma	• Inflammatory bowel disease
• Lichen sclerosus et atrophicus	• Hemorrhoids
• Urethral prolapse	• Anal abscess associated with neutropenia
• Labial adhesions	• Perirectal abscess
• Congenital malformations	• Perianal streptococcal infection
• Hemangioma	

Children may sustain accidental blunt or **penetrating** injuries to the genital area. The most common of these are **straddle injuries** that occur from falls. Pain and bleeding are the most common symptoms with these injuries, and the labia majora, labia minora, or periurethral areas are typically affected. The hymen is unaffected.

Genital bleeding is also a frequent complaint in girls with **urethral prolapse**, a condition that is reported most often in prepubescent African American girls between 4 and 8 years of age. These girls have a protuberant mass extruding from the urethra. The condition is of uncertain etiology but it is not related to abuse.

Lichen sclerosus et atrophicus is a less common dermatologic condition that can also be confused with the sequelae of sexual abuse. In this condition, there is typically atrophic, hypopigmented skin in a figure eight configuration in the anogenital area with associated macules, papules, and hemorrhagic blisters. The skin changes may be misinterpreted as scarring from prior abuse and because the atrophic skin is easily traumatized, findings may also be confused with recent abuse. One factor that may differentiate this condition from injuries related to sexual abuse is that the hymen is unaffected in lichen sclerosus et atrophicus.

Labial adhesions occur most commonly in toddlers and may be confused with scarring from prior sexual abuse. The adhesions develop as the result of inflammation in the genital area of a prepubertal (hypoestrogenic) female. There can be multiple causes of the inflammation, including poor hygiene, recurrent vulvovaginitis, and trauma. The presence of labial adhesions is not a specific indicator of past sexual abuse.

Congenital malformations may also affect the anogenital area. **Failure of midline fusion** along the median raphe can have the appearance of denuded skin and may be confused with an abrasion or superficial laceration of the area. This failure of fusion is a congenital finding, however, and there is no bleeding as with a traumatic injury. Other congenital malformations include hemangiomas that may bleed and be mistaken for traumatized tissue. These hemangiomas are most often noted in infants younger than 2 to 3 years, and they usually regress with time.

Medical conditions may also affect the perianal area and may be mistaken for abuse. **Crohn disease** may lead to fissures, fistulas, perirectal abscesses, or tags. In general, Crohn disease affects older children and produces other symptoms such as fever, weight loss, and stooling problems, or extraintestinal symptomatology. Perirectal abscesses may occur in patients with neutropenia, sometimes as the presenting complaint of leukemia. Hemorrhoids occur rarely in children, and their presence should raise concern about intra-abdominal venous congestion.

Conditions causing **vaginal discharge** (Box 128-2) may be related to sexual abuse, particularly if they are secondary to STIs such as **gonorrhea** or **Chlamydia** infection. Other agents, including **Candida**, **Shigella**, and **group A beta-hemolytic streptococci**, may produce similar symptoms, yet not be sexually acquired. The streptococci may produce a painful erythematous rash in the perianal area, which is frequently misdiagnosed as secondary to trauma or sexual abuse.

| • Candidiasis | |

Evaluation

The extent and urgency of the evaluation is in part dependent on whether the allegations involve an acute abusive episode or one that occurred in the past. An acute abusive episode (one that has occurred within the previous 72 hours) warrants an immediate assessment for evidence that may otherwise be lost within hours.

History

When a child presents with a physical finding, statement, or behavior that raises the concern of possible sexual abuse, it is important for the examiner to ask carefully thought out, non-leading questions to determine whether the level of suspicion has been reached such that the examiner is mandated to report the concern to a child protective services agency. Beyond that, an attempt should be made to minimize the number of times that the child is questioned about the abuse-related incidents. It is also important to establish sufficient medical history to address any pressing clinical issues. Such a history should include a review of systems, menstrual history, sexual activity history, past incidents of abuse, and any prior genital trauma or medical procedures of the anogenital area. A psychosocial history should also be obtained, as behavioral problems, depression, anxiety, suicidality, homicidality, and other issues requiring mental health expertise are common in sexually abused children (Box 128-3).

Because most victims of sexual abuse have a normal physical examination, the history is often of primary importance in the case. As a result, the child must also be interviewed by someone with

professional expertise in the areas of interviewing and child sexual abuse. This individual may be a physician, or it may be a social worker, psychologist, rape counselor, or specialized detective or district attorney. The interview should be structured to include open-ended questions such as, “Tell me what happened” (Questions Box). Interview tools such as drawings or anatomically detailed dolls may be used but are best left to experts with experience in these controversial modalities. Statements that children make should be recorded in the medical record as close to verbatim as possible.

Questions

Child Sexual Abuse

- Can you tell me what happened?
- Has anything like this happened before? If so, what happened the first time?
- Who did this to you?
- Has anyone else done this to you?
- How often has this happened?
- Where were other people (eg, your mother) when this happened?
- Did you tell anyone? Who? What did they do?

Physical Examination

It is helpful for the examiner to be familiar with the normal **anogenital** anatomy of prepubescent children. The anatomy of boys remains constant throughout childhood, except for the increase in size of the penis and testes and the appearance of pubic hair during adolescence. Figure 128-1 shows the normal anogenital anatomy of girls, which changes from infancy through adolescence. All girls are born with a hymen, which is thick and full and covers the hymenal orifice in newborns. As maternal hormones regress, the hymen becomes thinner and more translucent, frequently taking on an annular or crescentic configuration. When puberty begins, the hymen once again becomes thickened, scalloped, and full. Careful examination of the hymen may involve positioning a child in not only the supine frog-leg position, but also the prone knee-chest position (Figure 128-2). For a variety of reasons there are frequently no genital abnormalities noted on examination in victims of sexual abuse. Penetration of the hymen in postpubertal adolescents may result in stretching without tearing of the tissue, and in prepubescent children, hymenal transections may heal with little residual evidence of the trauma. Many types of abuse (eg, orogenital contact, fondling) commonly leave no

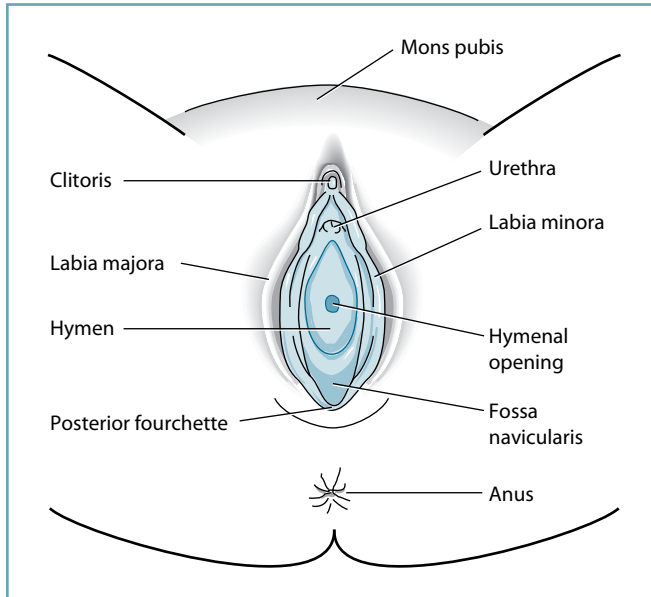

Figure 128-1. Normal anogenital anatomy of prepubescent girls.

visible findings. The medical examiner must therefore realize that a normal anogenital examination does not preclude sexual abuse.

In cases of acute molestation, evidence of injury may be readily apparent, particularly if the examination is performed with the assistance of magnification such as **colposcopy**, or enhancing agents such as toluidine blue, which is preferentially taken up by exposed endothelium. Injuries that may be noted include **ecchymoses**, **petechiae**, **active bleeding**, **abrasions**, and **lacerations**. Those due to penile penetration commonly involve the hymen in the 6 o'clock position and the area of the posterior fourchette (see Figure 128-1).

The evaluation of children who have been molested in the past or on a chronic basis is more problematic. Many injuries heal with little residual scarring. Scarring that does occur may appear as a notch or concavity in the contour of the hymenal edge. The pattern of blood

vessels may also be interrupted, and areas of increased or decreased vascularity may be apparent. Sometimes a marked reduction in the amount of hymenal tissue is present in an area of prior trauma.

Male genitalia are less often injured by sexual abuse. More often the injuries seen in prepubescent boys, as well as in some girls, involve changes in the perianal area. The incidence of these changes in all children who have been sodomized is unknown but is believed to be low. When changes do occur, they may appear as scars, tags, or irregularities in perianal rugae and anal tone.

Laboratory Tests

When the molestation has occurred within 72 hours of the examination and the mechanism of injury could have resulted in deposition of body fluids on the child, **forensic evidence** should be collected as required by law enforcement. This evidence usually involves samples of vaginal washings and dried secretions, which are evaluated for the presence of DNA in an effort to identify the perpetrator. Clothing that was worn at the time of the assault should also be submitted since it is frequently positive for DNA evidence. **Forensic packages**, which are referred to as **rape kits** and are distributed by law enforcement agencies, have specific instructions concerning the appropriate collection of samples.

Approximately 5% to 10% of sexually abused children acquire an **STI** as a result of the abuse. Because of this, any child with a history of genital, oral, or anal penetration; a sibling with an STI; an assailant with a history of an infection; or a child, sibling, or assailant with signs or symptoms of an STI must undergo a laboratory evaluation for possible infection. If testing is indicated, cultures should be obtained from the involved body areas (vagina or urethra, rectum, throat). At a minimum, a child with genital discharge should be evaluated for *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Trichomonas vaginalis*. The presence of these infections in a prepubertal child, in the absence of perinatal transmission, is indicative

Figure 128-2. Various positions for an anogenital examination in a prepubescent girl. A. Seated on the mother's lap. B. Supine, frog-leg position. C. Prone, knee-chest position.

of prior close genital contact. Most frequently this is due to sexual abuse. It is impossible to determine the etiology of vaginal discharge based only on its clinical characteristics.

All tests for STIs in prepubertal children should be evaluated in a reliable laboratory because of the legal implications of venereal infections in young children. Culture is considered to be the gold standard for diagnosing gonorrhea and *Chlamydia* in this setting because of its specificity. While newer nucleic acid amplification tests (NAATs) may have higher sensitivity in some settings, there are limited data on their use in prepubertal children so they should not be used as the sole method of evaluation. A positive NAAT should be confirmed by culture or by a second nucleic acid test targeting a different DNA sequence.

Testing for HIV, syphilis, hepatitis B, and hepatitis C should be performed if signs or symptoms of the diagnosis are present, if another STI is detected, if the perpetrator is known to be infected, or if the patient/family wishes to undergo the testing. Genital warts can be diagnosed clinically, and any lesions suspicious for herpes simplex virus types (HSV) 1 or 2 should be cultured and typed. While culture remains the gold standard for diagnosing HSV infection, serologies for HSV type-specific glycoprotein G antigens may be helpful if culture is not available. Lastly, pregnancy testing should be considered in any postpubertal girl.

Management

The management of children who have been sexually abused has 3 major components.

1. Any medical problem sustained as a result of the abuse, such as traumatic injuries, must be addressed. In addition, STIs should be managed (Table 128-1). See Chapter 97 for a more extensive discussion of STIs in adolescents. Adolescents who have been the victims of an acute assault should be offered pregnancy counseling, STI prophylaxis, and emergency contraception as medically indicated.
2. The emotional well-being of patients must be ensured. In cases of acute assault, crisis intervention is mandatory. If children have been the victims of chronic or prior sexual abuse, referral to appropriate counseling services should be done.
3. The physician must report the incident of sexual assault or abuse to the appropriate agencies, as mandated by the laws of the locality in which the physician practices. The physician may be required to testify in court about particular findings and whether abuse occurred. Testifying may be intimidating. It is helpful for the physician to review the medical records ahead of time and to discuss this information with the attorney who issues the subpoena to the physician.

Prognosis

Several factors influence the prognosis in cases of child sexual abuse, including the relationship of the perpetrator to the child, chronicity of the abuse, support following the disclosure, and preexisting psychosocial conditions. Physical injuries are usually nonexistent

Table 128-1. Management of Sexually Transmitted Infections in Children

Infection	Medication	Dose
<i>Neisseria gonorrhoeae</i>	Ceftriaxone	250 mg IM × 1 dose
	Cefixime (age >8 y, weight ≥45 kg)	400 mg PO × 1 dose
<i>Chlamydia</i>	Azithromycin	20 mg/kg PO × 1 dose (max: 1 g)
	Erythromycin (weight <45 kg)	50 mg/kg/d divided QID × 14 days
	Doxycycline (age >8 y, weight ≥45 kg)	100 mg PO BID × 7 days
Herpes genitalis	Acyclovir	1,200 mg/d divided TID × 7–10 days (max: 80 mg/kg/d)
<i>Trichomonas</i>	Metronidazole	15 mg/kg/d divided TID × 7 days OR 2 g PO × 1 dose (weight ≥45 kg)
Bacterial vaginosis	Metronidazole	15 mg/kg/d divided TID × 7 days OR 2 g PO × 1 dose (weight ≥45 kg)
Syphilis	Benzathine penicillin	50,000 U/kg, single IM dose (max: 2.4 million U)

Abbreviations: BID, twice a day; IM, intramuscularly; PO, orally; QID, 4 times a day; TID, 3 times a day.

or minor, and healing occurs with minimal residual evidence. In most cases, psychological counseling is indicated. Such counseling is beneficial, and emotional recovery is not only possible but likely to occur in a supportive environment.

Studies of **adverse childhood experiences** have shown that child sexual abuse is associated with an increased risk of medical, psychological, and social problems in adulthood.

CASE RESOLUTION

In the case history presented at the beginning of this chapter, the mother claims that no one has access to her child, but the girl's symptoms strongly suggest an infection with *Neisseria gonorrhoeae*. Secrecy about abuse is very common. Both the child and the mother should be interviewed by a skilled person. Cultures for gonorrhea should be carefully collected and sent to the most reliable laboratory. Antibiotic therapy may be initiated if the child is symptomatic. The case may be referred immediately to social services and law enforcement agencies if there is a disclosure. Alternatively, if the child denies the abuse, the referral may be deferred pending laboratory confirmation of the diagnosis.

Failure to Thrive

Carol D. Berkowitz, MD

CASE STUDY

A 2-year-old girl is brought to the office because of her small size. She was born at term but weighed only 2,200 g (less than fifth percentile) and measured 43 cm (less than fifth percentile). The mother is a 30-year-old gravida V para IV aborta I who smoked during pregnancy but denies using alcohol or drugs. She received prenatal care for only 2 weeks prior to delivery, and she claims to have felt well.

The child's physical health has been good. She is reported to be normal developmentally but speaks only 4 to 5 single words. She has not yet started toilet training.

The family history for medical problems, including allergies, diabetes, and cardiac and renal disease, is negative. The mother is 5 feet (152 cm) tall, and the father is 5 feet, 4 inches (163 cm) tall. The girl has 3 siblings, aged 5 years, 4 years, and 3 years, who are all normal. The father is no longer in the household. The mother is not employed outside of the home, and she receives public assistance.

She states that frequently there is not enough food in the home, although she receives food stamps.

On physical examination, the girl is less than the fifth percentile in height and weight. Although she is very active, she does not use any understandable words. The rest of the examination is normal.

Questions

1. What are the key prenatal factors that affect the growth of children?
2. How can caloric adequacy of a diet be assessed?
3. How do parental measurements affect their children's stature?
4. What are the behavioral characteristics of infants with environmental failure to thrive (FTT)?
5. What are some strategies to increase caloric intake of infants and children?

Failure to thrive can be defined as the failure of children to grow and develop at an appropriate rate. The term is most often applied to infants and toddlers younger than 3 years. Failure to thrive is not a disease or even a diagnosis but represents a sign that a child's size or rate of growth is below expected. The term FTT first appeared in the pediatric literature in 1933 and was used for children whose growth impairment related to a suboptimal environment. Prior to 1933 the condition was referred to as **cease to thrive**. The terms **growth deficiency**, **growth impairment**, **undernutrition**, and **inadequate growth** are sometimes used interchangeably. Historically, FTT has been divided into 2 distinct categories, **organic** and **nonorganic**. In organic FTT, an underlying **medical problem**, such as cystic fibrosis or congenital heart disease (CHD), is believed to contribute to the failure to grow at an appropriate rate. In nonorganic FTT, also referred to as **environmental deprivation**, inadequate growth is attributed to lack of nourishment and a non-nurturing home environment. Some clinicians use the term FTT exclusively to mean environmentally related growth impairment. It is important to recognize that many children with growth problems have both organic and environmental components, a condition sometimes referred to as *multifactorial* or *mixed* FTT.

The diagnosis of FTT is entertained when the growth parameters of children as plotted on a standardized curve are below the fifth percentile in height or weight. Children who are above the fifth percentile may also be diagnosed with FTT if the rate of growth has decelerated

and 2 major percentiles (eg, decreased from the 75th percentile down to the 10th percentile) have been crossed within 6 months (Dx Box). Studies have shown, however, that between birth and 6 months of age approximately 39% of healthy infants cross 2 major percentiles on the weight for age curve (either up or down) as did up to 15% of children between 6 and 24 months of age. Similar trends were noted for length. Physicians should, however, carefully track these infants to be certain that such changes are related to the child's genetic disposition and not an environmental or medical problem.

Dx Failure to Thrive

- Weight below fifth percentile
- Height below fifth percentile
- Weight for height below fifth percentile
- Rate of growth lower than expected
- Delayed developmental milestones
- Disturbed interactional skills

The challenge for the physician caring for the child with FTT is to determine the etiology of the problem, which may not be readily apparent. Nonspecific, nondirected laboratory tests are not helpful because their yield is low and their cost is high. The evaluation of small, underweight children requires a careful history and physical

examination as well as an assessment of mother–infant interactions. A home visit helps because it permits evaluation of the mother–infant relationship in a more natural setting and an assessment of the family’s economic and food resources.

Epidemiology

The prevalence of FTT varies in different segments of the population. **Poverty** puts children at risk for **undernutrition**, and 12% of Medicaid recipients are less than the third percentile in weight. **Child neglect** can lead to FTT but is not a necessary component; approximately 60% of cases of child abuse are reported for child neglect. Several other factors may contribute to variations in growth. All of these are not the result of a pathologic process but may reflect variations in individual genetic potential.

Environmentally related FTT may occur in different family settings. In some families, an **acute depressive episode** in the mother is the key component (see Chapter 19). Family living conditions are good, and the educational background of the mother is adequate. The depressive episode may be related to a loss that occurred during the pregnancy or shortly after delivery or to peripartum depression, a distinct entity. The mother is too depressed to interact effectively with her children. In other families **financial resources** are marginal. The mother may be **chronically depressed** and the father involved in alcohol or substance abuse. Domestic violence frequently occurs (see Chapter 138). Spacing between children is less than 18 months, and the number of children is often the same as the age of the oldest child. The mother is too overwhelmed to meet the needs of the children. A third type of family also involves a mother who is depressed and has experienced losses, usually of a chronic nature. Her financial and educational backgrounds are adequate, but she views one of her children (the one who now presents with FTT) as bad or evil and the source of all her problems. As a result, an individual child is singled out, and the neglect is intentional.

Clinical Presentation

Children with FTT present with **low weight, short stature, poor appetite, or failure to gain weight or grow taller**. Sometimes parents may express concern, and at other times teachers may detect children’s growth problems. Some children with FTT are diagnosed during a health maintenance visit or when they are being evaluated for another medical problem, such as a febrile illness. Following a child longitudinally will give the physician a better sense of the child’s growth pattern and a clue to the etiology of observed growth impairments. When nutrition is suboptimal, weight tends to decrease first, followed by length and ultimately head circumference.

Pathophysiology

The common pathway for the development of FTT in both organic and nonorganic cases is **insufficient calories** to sustain growth (Box 129-2). Caloric intake may be inadequate for several reasons. Some factors are societal, specifically poverty and inadequate access

Box 129-2. Factors Affecting Calories Available for Growth

Insufficient Intake

- Poverty
- Inadequate access to food
- Improper formula preparation
- Eating difficulties
- Vomiting

Increased Loss

- Malabsorption

Increased Needs

- Congenital heart disease
- Chronic lung disease

to food. Other factors may involve increased caloric needs. Certain chronic conditions are characterized by increased caloric expenditure (eg, some forms of chronic lung disease) or increased loss of ingested food (eg, diarrhea or malabsorption syndromes).

In environmentally related FTT, a disturbed mother–infant interaction is believed to contribute to reduced caloric intake and any associated gastrointestinal symptoms (ie, vomiting). Although various disturbances in mother–FTT infant dyads have been described, maternal depression is the most common maternal feature noted in environmentally related FTT. Infants withdraw after unsuccessful attempts to interact with nonresponsive mothers, and infants become apathetic and disinterested in food. Alternatively, overactive mothers, some of whom have a bipolar (manic-depressive) disorder, are out of synchrony with their infants. The infants become agitated, especially during feedings, and cannot feed and frequently vomit. These infants, who may interact with persons other than their mothers, usually do well in other environments.

Older children with long-standing environmental deprivation have **disturbed hypothalamic-pituitary functioning**. The etiology of this dysfunction is uncertain but has been attributed to sleep disturbances with an effect on levels of growth hormone.

Differential Diagnosis

The growth of children with FTT may be impaired with regard to weight, height, head circumference, or any combination of growth parameters. If weight is the only abnormal parameter, inadequate caloric intake is probably the major problem. If height is reduced and the weight is appropriate or high for height, the diagnosis may be short stature rather than FTT. Small head circumference in the face of low growth parameters suggests a central nervous system (CNS) basis for the growth delay. It is important to determine if children’s skills are developmentally appropriate when determining the etiology of FTT. Affect and interactional skills should also be noted. Environmentally deprived infants are apathetic and noninteractive. They appear hypertonic and may be diagnosed with cerebral palsy or have features suggestive of infantile autism, but their symptoms resolve with a change in surroundings.

The most common causes of short stature include **familial short stature** and **constitutional delay**. Children with familial short stature are small because the parents are short. Except for a deceleration in growth, which usually occurs between the ages of 6 and 18 months, children with constitutional delay appear healthy. They have

a delayed bone age that is comparable to their height age (the age when their height is at the 50th percentile), however. In children with either familial short stature or constitutional delay, growth parameters at birth are usually normal.

Children with low growth parameters at birth may have been premature or have suffered from **intrauterine growth restriction (IUGR)**. Most studies support the notion that well premature infants exhibit catch-up growth (head circumference by 18 months, weight by 24 months, and height by 40 months). Ill preterm infants may not demonstrate such **catch-up growth**, either because of increased caloric needs related to residual medical problems (eg, bronchopulmonary dysplasia) or impaired nutritional intake resulting from certain conditions (eg, cerebral palsy). Overall, 15% of infants who are classified as IUGR or **small for gestational age (SGA)** do not exhibit catch-up growth. There is significant evidence now that IUGR may be associated with insulin resistance and subsequent propensity to obesity and metabolic syndrome. Disturbances in leptin, gherlin, and adiponectin have also been described. This recent finding has significant implications for the management of these infants vis a vis their nutritional intake. It is postulated that some individuals are “programmed” to be slighter and smaller, and nutritional interventions to achieve a more average weight have deleterious effects down the line.

Children who are **SGA** may have suffered any of several in utero insults that affect postnatal growth, including exposure to cigarettes, alcohol, and illicit drugs. In addition, maternal infection with such diseases as rubella may result in a congenital infection in infants with subsequent growth impairment.

A number of other conditions may lead to disturbed growth, including endocrine disorders, skeletal dysplasias, food allergies, and malabsorption. These conditions occur less frequently and are usually more readily apparent as children undergo the evaluation for the growth problem.

Evaluation

History

Careful questioning about certain topics provides clues to diagnosis in about 95% of cases. The physician should learn about the pregnancy and delivery, children’s medical and dietary history, and the family history.

It is important to obtain a history of the pregnancy and delivery (Questions Box: Pregnancy and Delivery). The infant’s birth weight and gestational age are key pieces of information. Low birth weight is said to account for 20% to 40% of short children from low-income families. It is helpful to confirm that the neonatal screen for genetic and metabolic diseases was normal. Recurrent spontaneous abortions suggest that mothers may have an underlying problem such as a balanced chromosomal translocation that leads to fetal wastage. Mothers who have experienced repeated losses may have difficulty bonding with subsequent infants. The physician should determine whether mothers used cigarettes, alcohol, or drugs during the pregnancy by asking mothers questions beginning with the phrase “How

Questions

Pregnancy and Delivery

- Was the pregnancy planned?
- How did the mother feel when she learned that she was pregnant?
- Was the infant wanted?
- Was prenatal care obtained?
- How many times has the mother been pregnant?
- Is there a history of abortions, either spontaneous or therapeutic?
- How much did the mother drink during the pregnancy, if at all?
- How much did the mother smoke during the pregnancy, if at all?
- How much did the mother use drugs (either prescribed or illicit) during the pregnancy, if at all? Which drugs did she use?
- Did the mother take any medications during the pregnancy?
- Did the mother have any rashes or illnesses during the pregnancy?
- Has the mother felt depressed, sad, or hopeless?
- Has the mother felt little interest or pleasure in doing things?
- Was the infant term or premature?
- How much did the infant weigh at birth?

much?” Any medications taken by the mother may affect the subsequent growth of the infant.

A review of children’s medical history may also provide a clue to the etiology of FTT (Questions Box: Medical and Family History). It is essential that the physician obtain as many of the previous growth parameters as possible to determine whether children are small but growing at a normal rate or if their rate of growth is too slow. Previous illnesses should be assessed because these events may interrupt growth temporarily. Certain complaints may indicate underlying organic disorders, and recurrent infections raise the possibility of a congenital or acquired immune disorder including infection with HIV. A history of easy fatigability may be a clue to CHD. Although most children with CHD grow normally, growth problems may occur with congestive heart failure, some forms of cyanotic heart disease, and complex atrial septal defects, especially if associated with pulmonary hypertension. Children with urinary incontinence may have renal disease that interferes with their growth. The presence of seizures may be a sign of a CNS problem that makes it difficult to obtain adequate nutrition. Some children with seizures are heavily medicated and are too sleepy to eat.

Questions

Medical and Family History

- Is the child’s growth rate normal or slow?
- Has the child had any previous illnesses (eg, gastroenteritis, recurrent pneumonia)?
- Does the child tire easily?
- How tall are the parents?
- Are there any medical problems that run in the family?

A family history as well as a **social history** is important to obtain. Determination of parental heights, which is best accomplished by measuring the parents, is critical. This is particularly important in children with short stature. Specific **mid-parental height curves** allow the physician to determine if a child's height is appropriate given the parental stature.

A nutritional assessment is an essential part of the history. The physician or another member of the health care team, such as a dietician, can perform this assessment. The dietary history can be determined either by using a **24-hour recall** of children's intake during the previous day or a prospective **3-day diary**, in which parents record the kinds and quantities of foods their children eat. This nutritional information can be used to find ways to alter children's diet to ensure adequate and balanced meals.

Physical Examination

The essential component of the physical examination is determination of growth parameters. Calculation of the **body mass index** ($BMI = \text{weight [kg]} \div \text{height [m]}^2$) is useful in children older than 2 years. Children with a low BMI are suffering from undernutrition. Short children with a normal BMI are not. Infants younger than 2 years should be plotted on a weight-for-length curve to determine their degree of undernutrition or overnutrition. The World Health Organization has developed and distributed growth curves for children up to 24 months of age. These curves are felt to reflect optimal rather than average growth having been developed from a longitudinal study of healthy breastfed infants. These curves can be accessed at www.cdc.gov/mmwr/preview/mmwrhtml/rr5909a1.htm. Measuring arm circumference and triceps skinfold thickness is also useful and provides information about body composition that is not obtained by height and weight. Children should also be evaluated for dysmorphic features (eg, limb length discrepancies in Russell-Silver syndrome). It is important to remember that children with Down syndrome grow at different rates than other children, and separate standardized curves for assessing these children are available (see Chapter 37). Separate curves are also available for children with Turner and Williams syndrome. The presence of one major congenital anomaly or 2 minor anomalies suggests the existence of other anomalies. The incidence of growth hormone deficiency is reportedly higher in children with cleft lip and palate. Children with heart murmurs may have FTT related to CHD or to a syndrome such as Williams syndrome, in which the heart disease is but one feature.

Infants with environmentally related FTT exhibit certain **behavioral characteristics** that are easy to recognize. They refrain from making eye contact and exhibit **gaze avoidance**. Infants are not cuddly and do not like being held. When held, they may arch their backs in an effort to avoid the holder. Their muscles seem tense, and they are often considered to be hypertonic. These children may also exhibit specific disabilities including oromotor dyspraxia and sensory-motor disorder, and they may demonstrate food texture aversion or difficulty with chewing and swallowing (**sensory food aversion**). Children with neurologic disabilities often exhibit difficulties with

oral skills. Children who have negative early experience with eating may have what has been termed *posttraumatic feeding disorder*.

Psychosocial Assessment

The evaluation of children with FTT and their families entails a detailed psychosocial assessment to determine what environmental factors may be affecting children's growth. Such an assessment is helpful even if the FTT has an organic basis, because chronic disease affects family functioning. This evaluation can be carried out by a primary care physician, social worker, or psychologist. The key is to query the caretaker about living conditions, adequacy of food supply, and economic resources.

Laboratory Tests

Routine laboratory tests appropriate for any pediatric health maintenance visit should be obtained in children with FTT if these studies have not been performed recently. Such tests include hemoglobin, lead level (screening as determined by risk factors and geographic area), and urinalysis. Other laboratory tests should be determined by the findings on history and physical examination. There is no recommended uniform diagnostic evaluation for FTT. Evaluation for endocrinopathies, such as hypothyroidism or growth hormone deficiency, should be carried out in children whose bone age is less than their height age or who have symptoms of these disorders. Genetic consultation or chromosomal assessment should be performed in children with dysmorphic features or in families with a history of fetal wastage.

Imaging Studies

Radiographs to determine bone age are useful in children with short stature that is not related to parental heights. Children with constitutional delay have a bone age that is consistent with their height age.

Management

Any recognized underlying medical problem, for instance nephrogenic diabetes insipidus, should be managed appropriately. Children with IUGR who are not demonstrating catch-up growth may be candidates for growth hormone therapy. Consultation with pediatric endocrinology is warranted.

Adequate Caloric Intake

Ensuring that children receive appropriate caloric intake is essential. The caloric intake, which averages 120 to 150 cal/kg/d for most infants, should be based on children's ideal rather than actual weight (see Chapter 23). For infants on formula, the physician should review the exact preparation of formula with the mother. Overly diluted formula results in an unusually large intake volume with a lack of weight gain. For infants who are breastfed, the physician should observe a feeding session to be certain that mothers have an adequate milk supply and infants are able to suck and swallow appropriately (see Chapter 24). Infants should be weighed before and after feeding. Some infants with FTT have neurologic problems that prevent them from sucking and swallowing consistently without becoming fatigued.

Children who are slow feeders may require **formula concentration** (Table 129-1). These infants may also receive added calories in the form of Polyose (glucose polymer) or oil such as medium-chain triglycerides mixed in the milk. Older children may be placed on supplemental feedings such as PediaSure or instant breakfast drinks, prepared with whole milk. These drinks are a less expensive form of nutritional supplementation than PediaSure and are well tolerated. Up to 24 oz/d of the breakfast drinks can be consumed, and are given in addition to, not in place of, a balanced diet.

Table 129-1. Concentration of Infant Formula to Increase Caloric Intake

<i>Concentrated Infant Formula (13-oz can)</i>		
<i>Formula (oz)</i>	<i>Water (oz)</i>	<i>Calories (cal/oz)</i>
13	13	20
13	10	23
13	8	25
<i>Powdered Formula</i>		
<i>Formula (scoops)</i>	<i>Water (oz)</i>	<i>Calories (cal/oz)</i>
1	2	20
5	8	25

Mothers should be advised that many children preferentially tolerate 6 small meals a day rather than 3 large ones. In addition, parents should be told that access to non-nutritional foods such as cookies adversely affects children's appetites. Excess consumption of fruit juices should also be limited because it decreases the intake of other foods and may induce diarrhea. The physician should inform parents regarding foods that can be added to children's diets to increase caloric intake. These foods include powdered milk, cheese, sour cream, avocado, and peanut butter. Often children have a few favorite foods. Though food variety is appealing to adults, many children prefer a small number of nutritious foods. They should be allowed to consume these foods freely.

Children with neurologic disorders and associated problems with chewing and swallowing may need chronic gavage feeding or be fed through a gastric feeding tube.

Parenting Issues

Some parents need more help about appropriate child-rearing practices than the physician can provide. They should enroll in parenting programs that address multiple aspects of the parenting process. Mothers with substance abuse problems may need to participate in drug treatment programs. Other caregivers may need individual counseling for depression or emotional problems. A nurturing father has an important role in caring for an infant, particularly if a mother is experiencing postpartum depression.

In some middle-class families, mealtime has evolved into a battle of control. Some children find that food is supplied in a manner more conducive to its consumption at school rather than at

home. Parents should be counseled about avoiding conflicts about meals with children because the children win simply by closing their mouths. Parents should be encouraged to allow toddlers independence around mealtime.

Families may also require supplementary services to ensure that food supplies are adequate and financial resources are sufficient. Such services include Supplemental Nutrition Assistance Program (SNAP, formerly food stamps); Supplemental Food Program for Women, Infants, and Children (WIC); and Temporary Assistance for Needy Families (TANF).

Regardless of the individual needs of the family, it is critical that the physician craft a therapeutic alliance with the child's caregivers.

Home Visitation

Home visitation services provide useful diagnostic information and help parents implement advice. Such information may include lack of access to running water, overcrowding, and inadequate food resources. Home visitation may be available in the community through the use of public health nurses or private visiting nurse agencies. These nurses should interact with the primary care physician so that families' compliance with treatment recommendations can be determined.

Child Protective Services

Involvement by **child protective services** (CPS) may be necessary if parents are unable to comply with medical recommendations, if children do not grow, or if there is intentional neglect on the part of families. In some families with children with FTT, the home environment is not safe for the children and they require placement elsewhere. Families in which one child is singled out as "bad" and is intentionally neglected need immediate referral to CPS, and some families overwhelmed by multiple problems including parental substance abuse also need such a referral (see Epidemiology).

Hospitalization

Hospitalization is occasionally necessary if infants with FTT are severely malnourished and food must be given in a controlled environment. Concern about refeeding syndrome can be addressed in the inpatient setting. In addition, these infants may have intercurrent illnesses that require inpatient care. In addition, health care professionals may determine that the home environment is unsafe and that no other placement, such as foster care, is available.

Children with either organic and environmentally related FTT usually gain weight in the hospital. Thus the hospitalization of children with FTT simply to demonstrate appropriate weight gain in a different environment is considered neither appropriate nor cost-effective. Some insurance companies will not reimburse hospitals for inpatient management of children with FTT. Additionally, some children with environmentally related FTT do not gain weight in the hospital because they are subjected to many diagnostic tests that interfere with nutritional intake (eg, receiving nothing orally), and they acquire nosocomial infections.

Prognosis

Many children with FTT respond dramatically to change in diet or in environment. Improvement in affect and cognitive functioning frequently follows nutritional improvement. These children grow and achieve and maintain normal stature. With early intervention, cognitive abilities also can be fully realized. Even when intervention has been delayed, catch-up growth and development are expected, although 25% to 30% may have weight and occasionally height below the fifth percentile. Continued monitoring for residual psychosocial or neurodevelopmental disabilities is appropriate even after growth has normalized. School performance and cognitive outcome in children who have experienced FTT is poorer than in children who have not experienced FTT. It is unclear if this association is related to early iron deficiency anemia, lack of calories or other micronutrient deficiencies, or psycho-environmental deficits.

CASE RESOLUTION

In the case scenario presented, the full-term infant had a low birth weight, which suggests IUGR. Although the mother reports using no alcohol or drugs, such denial is not uncommon. The child's growth pattern should be determined to see if the rate of growth has changed recently, and the BMI should be calculated to check for both undernutrition and short stature. A mid-parental height curve should be used to determine if the child's short stature is related to the parents' short stature. Intervention should involve mobilizing resources for the child and family to ensure adequate food and financial and emotional support.

Fetal Alcohol Syndrome

Melissa K. Egge, MD

CASE STUDY

A 6-year-old male is brought into the clinic by his maternal aunt who expresses concerns about her nephew's behavior that are echoed by his kindergarten teacher. The teacher has reported that the child has a limited attention span and is often disruptive in class. The child's growth parameters have remained at the third percentile since birth. He has a smooth philtrum, thin upper lip, and short palpebral fissures.

Questions

1. What are the diagnostic criteria outlined by the Centers for Disease Control and Prevention (CDC) for fetal alcohol syndrome (FAS)?
2. What is the differential diagnosis of the facial characteristics of FAS?
3. What typical behavioral and learning problems do children with FAS experience?
4. What therapeutic interventions are appropriate to recommend for children with FAS?

Fetal alcohol syndrome refers to a clinical diagnosis that requires careful evaluation by an experienced clinician to recognize the physical, behavioral, and cognitive abnormalities in an affected child. Diagnosis may be made at birth, but the condition is often not diagnosed until school age. Fetal alcohol syndrome has been recognized in the medical literature for decades and in historical literature for centuries; however, fine-tuning the criteria for diagnosis has been an ongoing process. Although several groups have created guidelines to help analyze children with FAS, the CDC in 2004 published broad-based criteria (Box 130-1) that are helpful for a number of reasons. First, they educate clinicians and caregivers about the wide spectrum of phenotypes that manifest after prenatal alcohol exposure. Second, using the most recent CDC criteria for FAS, the greatest number of potentially affected children is captured in the hopes that earlier intervention with a wider scope of services may be provided. Criteria must be met in all 3 categories of facial features, growth problems, and central nervous system abnormalities. For cases in which FAS is suspected but diagnostic criteria are incompletely met, the term fetal alcohol spectrum disorders (FASD) may be used to couch the findings, especially when maternal alcohol exposure is confirmed. The next step will be establishing criteria for FASD. However, at this time the term is not intended for diagnostic purposes but rather a descriptor of recognized phenotypes along a spectrum leading up to FAS.

Part of the difficulty in delineating a phenotype for alcohol exposure is that the degree of exposure is variable during embryogenesis (and organogenesis): quantity ingested, concomitant drug exposures, malnutrition, and individual genetic responses to exposure. This wide variability in degree of exposure and individual response leads to a multitude of clinical presentations.

Box 130-1. Centers for Disease Control and Prevention Diagnostic Criteria for Fetal Alcohol Syndrome

Requires all 3 of the following:

1. Facial features—all 3 required
 - a. Palpebral fissure length \leq 10th percentile for age/race
 - b. Smooth philtrum rank 4–5
 - c. Thin upper lip rank 4–5
2. Growth parameters—at least 1 required at any age (not height for weight)
 - a. Height \leq 10th percentile
 - b. Weight \leq 10th percentile
3. Central nervous system abnormalities—at least 1 of the following
 - a. Structural—1 required
 - i. Head circumference (OFC) \leq 10th for age, sex
 - ii. Brain abnormality by imaging
 - b. Neurologic
 - i. Seizures
 - ii. Measured delay in motor skills
 - iii. Abnormal neuro exam not attributed to another condition
 - c. Functional—1 required
 - i. Cognitive delay or global developmental delay ($<$ 3rd percentile)
 - ii. Deficits in \geq 3 functional domains ($<$ 16th percentile)
 1. Cognitive
 2. Executive function
 3. Motor function (fine and/or gross)
 4. Attention-deficit/hyperactivity disorder symptoms
 5. Deficits in social skills
 6. Other (sensory, memory, language, etc)

Adapted from: Bertrand J, Floyd RL, Weber MD, et al. *National Task Force on FAS/FAE: Guidelines for Referral and Diagnosis*. Atlanta, GA: Centers for Disease and Prevention: 2004:11–50

Epidemiology

Prenatal alcohol exposure is much more common than the number of diagnosed cases of FAS. It has been estimated by surveys of women of childbearing age that approximately 15% engage in regular consumption of alcohol and 2% are binge drinkers. Although estimates of children affected by FAS vary by region and population, an estimated 1 in 1,000 live births would meet criteria for diagnosis. The estimate jumps 10-fold when certain high-risk groups are the focus. Approximately 1 in 100 children in foster care and nearly that many (3–9/1,000) Native American children meet criteria for diagnosis of FAS. If one includes children who meet some but not all FAS criteria, the prevalence is 1 in 100 or greater.

Pathophysiology

Alcohol is a teratogen, and like other teratogens its effect on the developing fetus depends on several factors, many of which are difficult to record. While it is important to ask about the timing, quantity, and pattern of prenatal alcohol exposure, it is often difficult to obtain an accurate history. In addition, due to genetic differences in women's abilities to metabolize ethanol by alcohol dehydrogenase, each baby receives a unique "dose" during gestation. Also individualized is each woman's nutritional intake and use of other drugs or medications. Alcohol acts as a toxin to cause damage and apoptosis to neurons in the fetal brain. Alcohol also inhibits proper migration, development, and functioning of cells during embryogenesis, contributing to structural anomalies in multiple organ systems, such as the kidney, heart, and brain.

Clinical Presentation

Signs and symptoms of FAS may be recognized at birth or not until later in childhood. At birth, an infant may present with asymmetrical intrauterine growth restriction, small for gestational age, head circumference disproportionately smaller than the body, or appropriate for gestational age. A variety of birth defects have been associated with fetal alcohol exposure, and many of these have been demonstrated in animal models. Newborns may exhibit signs of withdrawal either from alcohol or concomitant drug exposure. With time, the infant may demonstrate failure to thrive or poor weight gain due to poor nipping. In toddlerhood, developmental delays may be recognized by a caregiver or during developmental screening questions by a primary care provider. As children approach school age, teachers may report behavioral concerns and poor school performance. Concerns such as distractibility, hyperactivity, and difficulty processing multistep directions may be raised in school. In addition, children may exhibit signs of fine motor delay, such as difficulty tying shoes or fastening buttons. Age-appropriate social skills are lacking in affected children, who often fail to develop "street smarts." They take the blame, succumb to peer pressure, and are oblivious to social norms. Approaching the teen years, the classic facies may become less distinctive.

Diagnosis

Facial Dysmorphism

There are 3 classic facial features required for the diagnosis of FAS. The characteristics are typical of midface hypoplasia and include short palpebral fissures, smooth philtrum, and thin upper lip. Other facial characteristics, such as epicanthal folds and flat nasal bridge, may be present but are not required for diagnosis. In order to accurately measure the palpebral fissures, the child should look directly up while the distance between the endocanthion and the exocanthion is measured. Palpebral fissure length (PFL) must be less than 2 standard deviations below the mean for a diagnosis of FAS.

There are lip-philtrum guides created by the University of Washington for Caucasians and for African Americans accounting for ethnic differences in contour of lips (Figure 130-1). The images are ranked 1 through 5, with 5 representing the most affected phenotype: thinnest lip and smoothest philtrum. When the child is neither Caucasian nor African American a best approximate is used. In order to properly use the lip-philtrum guides, the child's face should be relaxed, or the lip and philtrum will appear thinner and smoother. The clinician should evaluate the child's face within a specific horizontal planar view to avoid the illusion of a thinner lip. There are guidelines on how to use the images published on the University of Washington's FAS Web site at <http://depts.washington.edu/fasdpn/>.

Growth Problems

The criteria for deficiencies in growth may involve the child's weight or length or both at any time. With the CDC criteria, one may qualify to meet criteria for growth problems based on birth or postnatal measurements. The child's weight or length must be less than or equal to the 10th percentile for age and sex. It is important, however, to evaluate other organic and environmental etiologies of short stature or poor weight gain, such as poor nutrition. Considerations for small head circumference are accounted for in the central nervous system (CNS) abnormalities.

CNS Abnormalities

The criteria for neurologic problems may be met several ways as children manifest an array of cognitive, behavioral, and developmental deficits. Criteria for structural abnormalities are met by a head circumference at the 10th percentile or lower at any age or 3% or less when the child's weight and height are less than 10%. An experienced neuroradiologist may detect an abnormally small cranial structure, such as the cerebellum or corpus callosum, on magnetic resonance imaging. Manifestations of structural abnormalities include seizure activity not attributed to another cause or other focal deficits. Other functional CNS abnormalities may not be recognized until the child enters school and is compared to peers.

Figure 130-1. Lip philtrum guidelines for Caucasians and African Americans. Reproduced with permission from Susan Astley.

Differential Diagnosis

The hazards of using a “gestalt approach” to diagnosing FAS can lead to inappropriate stigmatizing labels and missed opportunity to diagnose another genetic disorder, which may carry a different prognosis. Several syndromes share facial features of FAS (Table 130-2). Fetal alcohol syndrome should be considered a diagnosis of exclusion when in utero alcohol exposure cannot be confirmed.

Evaluation

It is important that appropriately trained professionals assess the child for each component of diagnosis, but initial data should be gathered prior to referral.

Table 130-2. Syndromes With Facies Resembling Fetal Alcohol Syndrome

<i>Syndrome</i>	<i>Long or Smooth Philtrum</i>	<i>Thin Upper Lip</i>	<i>Small Palpebral Fissures</i>
Cornelia de Lange	X	X

Noonan			
Fetal valproate	X	X	
Maternal phenylketonuria effects	X	X	X
Floating-Harbor	X		
Opitz	X		X

History

A confirmed history of maternal alcohol consumption is not required for diagnosis, according to the CDC guidelines, but should be documented if available. A detailed developmental history is important to document, including feedback from teachers or child care providers.

Physical Examination

As detailed previously, measurement of the PFL and ranking of the child’s philtrum and upper lip should be documented. Both current and previous height, weight, and head circumferences should be plotted on an appropriate growth chart. Also, any additional physical features may be recorded to support diagnosis.

Diagnostic Studies

Imaging studies to screen for cranial malformations are not currently recommended unless the child is experiencing some focal neurologic deficits or seizure activity. Similarly, targeted imaging of other organ systems is warranted when there are signs of an abnormality (ie, murmur would warrant an echocardiogram).

Consultation with a geneticist may be appropriate to rule out other disorders with similar phenotype (Box 130-2).

Management

Once a diagnosis related to alcohol exposure is suspected by a clinician, the referral process should begin. A dysmorphologist or experienced clinician may do the detailed measurements of the PFL and rank the facial features. Depending on local resources, a multidisciplinary team evaluation is ideal. A child psychologist or developmentalist can assess age-appropriate skills and need for therapeutic

Box 130-2. Physical Findings and Malformations Associated With Prenatal Alcohol Exposure

Cardiac

- atrial or ventricular septal defects, aberrant great vessels, and tetralogy of Fallot

Skeletal/Extremity

- shortened 5th digits, clinodactyly (curved 5th digit), radioulnar synostosis, Klippel-Feil syndrome, flexion contractures, hemivertebrae, camptodactyly (flexion contracture of digit), scoliosis, short metacarpals, short/webbed neck, hockey stick palmar crease

Renal

- aplastic, dysplastic, hypoplastic kidneys
- Ureteral duplications hydronephrosis horseshoe kidneys

Ocular

- strabismus refractive problems secondary to small globes ptosis
- retinal vascular anomalies

Auditory

- conductive hearing loss neurosensory hearing loss

Skin

- Hemangiomas, Hypoplastic nails

GU

- Hypoplastic labia majora

Facial features that are common but not required for diagnosis

- “Railroad track” ears
- Epicanthal folds
- Flat nasal bridge
- Cleft lip

intervention. Only validated instruments should be used to test developmental capabilities. When delays are detected, referral to appropriate therapies should be initiated through early intervention services. An individualized education plan (IEP) may be requested of the school by a caregiver who retains the child’s educational rights. Public schools may provide occupational, physical, and speech therapies and social skills training. A psychiatrist may select therapies and medications particular to a child’s unique mental health needs (see Chapters 125 and 126). Social workers are integral to providing support and additional resources to the family. As teens approach adulthood, referrals to vocational training and programs to transition young adults to independent living are important.

Prognosis

Unfortunately, many of the neurotoxic effects of alcohol on the developing fetus have lasting sequelae. Early interventions may improve but not correct cognitive deficits and associated mental health issues of aging children and adults with FAS. The mental health disorders are thought to be due to adverse childhood experiences (ridicule, harassment, failures) related to their behavioral and cognitive deficits. Some of the mental health disorders include oppositional defiant disorder, conduct disorder, depression, adjustment disorders, anxiety disorders, substance abuse, and sleep disorders. Unfortunately, many adults with FAS have failed to finish high school, and become unemployed or incarcerated. A fraction of adults with FAS will require assisted living arrangements.

CASE RESOLUTION

This child meets diagnostic criteria for FAS. It is recommended to the caregiver that she initiate obtaining “educational rights” over her nephew so she can request an IEP from his school’s administration. An assessment for attention-deficit/hyperactivity disorder (ADHD), such as the Connor’s Rating Scale, Vanderbilt, or another standardized measure for ADHD, should be given to the caregiver and teacher to each evaluate the child. Prescription for stimulant medications may be warranted in conjunction with behavioral therapy. Depending on local resources, the caregiver and child may be referred for psychotherapy, including parent–child interactive therapy where his aunt may be coached on how to deal with his behaviors in the most positive, effective manner.

Infants of Substance-Abusing Mothers

Sara T. Stewart, MD

CASE STUDY

An infant is born by emergency cesarean section because of abruptio placentae. The mother is a 29-year-old gravida VI para IV aborta II with a history of crack cocaine and heroin abuse during pregnancy. The infant is 36 weeks' gestation. The birth weight is 2,400 g, and the length is 43 cm. The physical examination is normal. The infant does well for the first 10 hours but then develops jitteriness, with irritability, diarrhea, sweating, and poor feeding. A urine toxicology test on the infant and mother are positive for cocaine.

Questions

1. What complications affect infants secondary to maternal substance abuse during pregnancy?
2. What withdrawal symptoms do newborn infants experience as a result of maternal substance abuse during pregnancy?
3. What typical behavioral and learning problems are found in infants and children whose mothers abused illicit substances during pregnancy?
4. What are the appropriate management strategies for infants who have experienced in utero drug exposure?

Maternal substance abuse during pregnancy places infants at risk for a number of medical, psychosocial, and developmental problems. The particular problems experienced by infants depend on the drug (or drugs) to which they have been exposed; many infants have been exposed to multiple drugs in addition to cigarettes and alcohol. The long-lasting effects of alcohol exposure are well established, but the effect of newer drugs is less well defined. Illicit drugs change in their popularity, form of use, and availability at different points in time.

The environment into which children are born also affects their health and development. Environments where substance abuse is common are frequently suboptimal for normal growth and development due to (1) the impact of substance abuse on parenting; (2) fragmentation of families; (3) domestic violence; (4) incarceration of significant family members; (5) illnesses, including HIV infection; (6) limited financial resources; (7) homelessness or substandard housing; (8) unemployment; (9) child abuse and neglect; and (10) limited access to health care. Because of these environmental issues, many drug-exposed infants are cared for by foster parents or nonparental family members. These factors also make it difficult to determine, in a given child, which problems are due to the drug exposure versus the accompanying environmental conditions. This differentiation is of less significance to the practitioner than to the researcher or epidemiologist because the practitioner will care for the problems that drug-exposed children manifest regardless of etiology.

Epidemiology

Approximately 10% of women between the ages of 15 and 44 years report having used illicit substances in the past month. While data collected via maternal self-report are typically an underestimate of prevalence, one national survey reported that 5.2% of women used illicit substances while pregnant. The highest rate of use was among pregnant adolescents aged 15 to 17 years, as 22% reported illicit drug use in the past month. The same survey also found that 12% of women reported drinking alcohol and 16% reported smoking cigarettes while pregnant. Meconium analysis has demonstrated not only extensive differences in the prevalence of in utero drug exposure among hospitals, but has also shown differences in the substances of choice in different geographic areas. While polysubstance abuse is the most common clinical scenario in all communities, national data on the primary drug of choice for pregnant teens admitted for substance abuse treatment has shown changes over the past 15 years. Primary alcohol abuse has decreased by 50%, primary cocaine abuse has decreased by 66%, primary methamphetamine abuse has increased by 4.4%, and primary marijuana abuse has increased by 2.4%.

Clinical Presentation

Many of the different substances that women use while pregnant can result in similar sequelae in the infant or child. In utero growth restriction, irritability, disordered eating or sleeping, and

hypertonicity may be seen in newborns and infants. Older children may have developmental delays, symptoms of attention-deficit/hyperactivity disorder (ADHD), learning disabilities, or behavioral difficulties such as oppositional or impulsive behavior. Newborns that have been prenatally exposed to opiates such as heroin or methadone may manifest symptoms of neonatal abstinence syndrome (drug withdrawal). These symptoms may include respiratory, gastrointestinal (GI), or nervous system effects such as apnea, tachypnea, emesis, diarrhea, irritability, hypertonicity, tremors, seizures, temperature instability, and sneezing. Symptoms often occur within 72 hours of birth, but due to the long half-life of methadone, symptoms of methadone withdrawal may take up to 5 days to develop.

Alcohol and cocaine have been associated with birth defects as well. Abnormalities such as absent limbs, cardiac defects, genitourinary anomalies, ocular anomalies, and microcephaly have been reported with cocaine exposure. Alcohol has been associated with a spectrum of effects, termed *fetal alcohol spectrum disorders (FASD)*. Within this spectrum, a subset of patients fit the well-defined criteria for a diagnosis of fetal alcohol syndrome (FAS). These criteria include facial dysmorphism, growth deficiency, and neurodevelopmental abnormality. The presence of 3 sentinel features in the facial dysmorphism is the most sensitive and specific diagnostic finding for FAS. These features include a flat philtrum, thin upper lip, and short palpebral fissures. The spectrum of neurodevelopmental problems includes diagnoses such as microcephaly and seizures, as well as many types of developmental, cognitive, and behavioral difficulties. Also included within FASD is a category for alcohol-related birth defects. This category includes anomalies such as congenital heart defects, skeletal deformities, renal anomalies, hearing loss, ophthalmologic abnormalities, and cleft lip and palate.

Pathophysiology

Drugs used by pregnant women may affect infants in 3 different ways: (1) the drugs may be addictive and result in symptoms of withdrawal during the neonatal period, (2) they may be toxic and lead to impaired functioning and neurodevelopmental problems, and (3) they may be teratogenic and cause congenital anomalies and a dysmorphic appearance. The ultimate effects of the drugs are due to a complex interaction of environmental and genetic influences that have variable effects depending on the timing of the prenatal exposure. Differences in the maternal metabolism of drugs lead to differences in fetal exposure to toxins, and genetically determined differences in fetal susceptibility to the toxins lead to a spectrum of effects in exposed children. During gestation, the effects of drug exposure also vary depending on the timing of exposure. Each organ has a unique period of susceptibility as it forms during the first trimester. Prenatal substance exposure during this time period is more likely to result in organ malformation. The second and third trimesters primarily involve organ growth, cell differentiation, and functional maturation of organs, so exposure during this time period is

more likely to result in growth abnormalities or functional difficulties. The specific effects of the different substances on the developing fetus can be understood in terms of their biochemical properties.

In utero exposure to opiates such as heroin and methadone results in physiological addiction. These drugs bind to opiate receptor sites in the brain and GI tract. When the drugs are no longer present after birth, the newborn experiences withdrawal. Animal models have also found that prenatal exposure to opiates can lead to decreased density of cortical neurons and decreased development of neurons.

Cocaine and its metabolites cross the placenta and concentrate in amniotic fluid. Cocaine is toxic and teratogenic, and it interferes with 3 neurotransmitter pathways in the brain. (1) Cocaine blocks the reuptake of norepinephrine. This is associated with tachycardia, hypertension, diaphoresis, and an increased incidence of preterm labor. Diffuse vasoconstriction may affect the placenta and lead to anomalies such as placental infarcts or abruptio placentae. The fetus may also be affected by the vasoconstriction and its resultant hypoperfusion and ischemia, and may develop anomalies such as atresia of the GI tract, stroke, or absent limbs.

(2) Cocaine decreases the reuptake of dopamine. This effect is apparent in cocaine-using mothers who have decreased appetite and subsequent poor nutrition during pregnancy. Stereotypical behavior, hyperactivity, euphoria, confidence, and heightened sexuality may be associated with sexual promiscuity and increased risk of acquiring HIV and sexually transmitted infections (STIs). (3) Cocaine decreases serotonin reuptake, leading to decreased sleep. The sleep cycle of cocaine-exposed infants is often disrupted.

Methamphetamine is commonly manufactured from ephedrine or pseudoephedrine, and has greater central nervous system (CNS) penetration than its metabolite, amphetamine. It has direct toxic effects on the CNS and causes increased release and decreased reuptake of dopamine, norepinephrine, and serotonin. These neurotransmitter alterations result in symptoms that are similar to those described for cocaine. There is limited published data on the incidence of teratogenesis as a result of in utero methamphetamine exposure, but recent data show that exposed newborns are at risk of being born small for gestational age.

Direct effects of methamphetamine use are dose- and frequency-dependent in the adult user. It has been shown to have cardiovascular, pulmonary, renal, and hepatic toxicity. Higher dose and increased frequency have also been associated with psychosis and with toxicity to subcortical structures. More recent data have also noted subcortical white matter and gray matter changes in prenatally exposed children.

Reports have documented the occurrence of withdrawal symptoms within days after birth in alcohol-exposed neonates, but the more common effects of prenatal alcohol exposure are direct cellular toxicity and teratogenesis. The specific mechanism by which alcohol and its metabolites damage fetal tissues is unknown, but it has been shown to affect CNS neuronal migration and synaptogenesis. For a given level of alcohol intake, the precise level of fetal exposure to the metabolites is likely to vary among women, depending

on maternal genetic makeup and the resulting variability in alcohol metabolism. The timing of the exposure during different periods of development can also lead to different teratogenic effects on the fetus. Exposure during the first trimester may affect organogenesis or craniofacial development, and exposure in the second and third trimesters can cause poor growth and neurotoxicity. Maternal alcohol use may also be associated with poor nutrition, resulting in poor delivery of nutrients to the fetus.

Phencyclidine (PCP) has sympathomimetic effects, including increases in blood pressure, heart rate, respiratory rate, deep tendon reflexes, and tone. In addition, PCP has cholinergic effects, causing sweating, flushing, drooling, and pupillary constriction. Infants exposed to PCP in utero do not exhibit these symptoms, however, but display neurologic and developmental disorganization.

Differential Diagnosis

The major differential diagnoses relate to the symptomatology produced by the abused substance or substances (Dx Box). Neonates exposed to addictive substances, most commonly opiates such as methadone and heroin, may present with symptoms of withdrawal (Box 131-1). Irritability and jitteriness may be symptoms of drug withdrawal or direct drug neurotoxicity, but may also be due to hypoglycemia, hypocalcemia, hypomagnesemia, and sepsis. Seizures occur in 1% to 3% of heroin-exposed infants, and the differential diagnosis for neonatal seizures includes intracranial hemorrhage, hypoxic-ischemic encephalopathy, CNS infection, CNS malformation, and metabolic disorders. Gastrointestinal symptoms such as vomiting or diarrhea may be confused with reflux, formula intolerance, obstruction, or infectious gastroenteritis.

Dx

Infants of Substance-Abusing Mothers

- Symptoms of withdrawal (see Box 131-1)
- Congenital anomalies
- Developmental delay and behavioral disorders
- Growth retardation
- Sexually transmitted infections

Dysmorphic appearance may also be the result of alcohol or drug exposure. Fetal alcohol syndrome is the most clearly defined dysmorphic syndrome related to maternal substance abuse during pregnancy. In making such a diagnosis, other genetic disorders that may have overlapping findings should be considered as well.

Failure to thrive (FTT) may also be a presenting complaint in infants or children with a history of in utero drug or alcohol exposure. (See Chapter 129 for a discussion of the differential diagnosis of FTT.) It is important to consider maternal substance abuse in all patients who have been diagnosed with FTT, particularly if they were born small for gestational age.

Older children may present with a wide range of neurodevelopmental and behavioral problems. Common behavioral complaints

Box 131-1. Symptoms of Neonatal Abstinence Syndrome

- | | |
|---------------------------|-------------------------|
| • Irritability | • Vomiting |
| • Jitteriness | • Diarrhea |
| • Tremors | • Apnea |
| • Hypertonicity | • Tachypnea |
| • Seizures | • Sweating |
| • Mottling | • Poor feeding |
| • Temperature instability | • Sleeping difficulties |

include impulsivity, inattention, hyperactivity, and antisocial behavior. While many of these symptoms have been correlated with prenatal drug exposure, postnatal environmental factors such as continued parental substance abuse, violence, inconsistent or poor parenting, and foster care placement are also significant contributors. As a result, it may be difficult to clearly determine the precise etiology of developmental and behavioral problems in a drug- or alcohol-exposed child.

Maternal substance abuse should be considered in all infants who present with STIs such as syphilis, hepatitis B, hepatitis C, and HIV.

Evaluation

History

The possibility of maternal substance abuse should be considered in the face of certain maternal risk factors. These factors include the absence of prenatal care, evidence of poor maternal nutrition, poor maternal weight gain, presence of STIs, symptoms of acute intoxication, abruptio placentae, precipitous delivery, and a history of domestic violence.

Infants who manifest symptoms of withdrawal should be evaluated for the possibility of maternal substance abuse. This assessment involves an appropriate history as well as a toxicological evaluation. Mothers disclose their drug history to varying extents, depending on the circumstances of the interview. If mothers are concerned about the health and well-being of their infants and do not fear legal repercussions, they are more likely to discuss their drug use. An appropriate drug history should be obtained in a nonjudgmental manner (Questions Box). Studies have shown that the use of a structured questionnaire rather than a cursory interview increases the incidence of reported substance abuse by 3- to 5-fold.

Physical Examination

Infants should be assessed for common complications related to maternal substance abuse. They should undergo a full physical examination to check for the presence of any malformations. Growth measurements should be noted, and physicians should determine if evidence of growth impairment or microcephaly is present. Premature infants should be monitored for problems related to prematurity, such as intraventricular hemorrhage and necrotizing enterocolitis. Assessment for signs of neonatal abstinence syndrome should be done in the days after birth (see Box 131-1). Neurologic

Questions

Infants of Substance-Abusing Mothers

- Did the mother use any substances such as alcohol, cigarettes, marijuana, or prescription and illicit drugs during the pregnancy?
- Has she ever used these substances? Is she currently using these substances?
- If so, how much? How frequently? By what route? To what extent is she trying to abstain?
- Is the mother at risk for sexually transmitted infections? Has she ever been tested?
- Did the mother have prenatal care? When did the care start?
- What is the status of other children in the family?
- Does the father abuse alcohol or drugs?

and developmental status should be assessed and monitored at each visit. Abnormalities such as hypertonicity, coarse tremors, and extensor leg posture are frequently noted in the newborn period, and disturbances in both fine and gross motor coordination may persist through the toddler years.

Laboratory Tests

In addition to obtaining a toxicological history, screening for drugs should also be performed. The legal guidelines for screening mothers for drugs vary in different localities. In general, if clinical symptoms indicate a need, infants can be screened on medical grounds without specific parental consent because the information obtained is important in the care of the infant. Screening of the mother's urine without her consent is more problematic, however, because of the potential legal implications of a positive test.

Testing is most commonly performed on urine samples, which are typically able to detect an exposure within the prior 3 days. It is important to realize that a negative screening test does not rule out the possibility of exposure within this window of time, however, as a drug's metabolite may be present but not to the level of the test's detection threshold. Newer tests include meconium analysis, which is more sensitive and specific than urine, and is able to detect exposures in the second and third trimesters. Recent data indicate, however, that its greatest sensitivity lies with exposures beyond 24 weeks' gestation. Analysis of newborn hair samples can also detect exposures occurring during the third trimester. At present, there is limited ability to determine precisely when an exposure occurred during gestation, other than according to the broad detection windows discussed here in conjunction with maternal self-report on the timing of drug use.

Most screening tests of urine, meconium, and hair samples use immunoassay techniques, which are inexpensive and sensitive, but not very specific. False-positive results may be obtained for multiple illicit substances. Common scenarios include a positive amphetamine

screen in a patient who has taken over-the-counter medication containing ephedrine or pseudoephedrine, or a positive opiate screen in a patient who is using cough medicine with dextromethorphan. For this reason, and because of the potential legal implications of a positive result in this setting, it is strongly recommended that positive immunoassay results be confirmed with further testing of the sample via gas chromatography/mass spectrometry.

Further evaluation in the neonatal period should include an evaluation for the presence of STIs, particularly HIV, hepatitis B, hepatitis C, and syphilis.

Imaging Studies

There is no routine imaging recommended based solely on a history of in utero substance exposure. Instead, imaging should be directed by symptomatology. For example, infants with a heart murmur and a history of prenatal alcohol exposure warrant a cardiac evaluation and possible echocardiography. Also, infants with prenatal drug exposure and abnormal neurologic examinations should have a thorough neurologic evaluation, which may include neuroimaging.

Management

In the neonatal period, the management of drug-exposed infants requires attention to associated conditions such as prematurity, in utero growth restriction, and in utero infection with STIs.

Irritability and crying may occur either from withdrawal or as the result of drug toxicity on the CNS. These infants may respond to swaddling, a soothing voice, or a quiet environment as a means to reduce the symptoms. Some exposed infants may have slow or disordered feeding and may require evaluation by an occupational therapist or nutritionist as well.

The assessment of a newborn's withdrawal symptoms is typically done using a standardized scoring tool to assist in the documentation of symptom severity. Once scores reach a threshold level, pharmacologic treatment may be required. For opiate-exposed infants, treatment with an opiate such as methadone, diluted tincture of opium, or paregoric is particularly helpful. Paregoric, once commonly used to treat symptoms of withdrawal, is now used less frequently because of the presence of alcohol and benzoic acid in the preparation. Phenobarbital is also commonly used in cases of poly-drug exposure. Diazepam is useful for symptoms related to alcohol withdrawal or to rapidly reverse symptoms of opioid withdrawal. Problems with using diazepam relate to the presence of sodium benzoate in the preparation, which can displace bilirubin from albumin. Medications should be tapered over time, allowing infants to out-grow the dosage.

Social service is also a key component of management. In many jurisdictions, child protective services must be notified of positive toxicological tests on newborn infants or their mothers. Likewise, infants who display symptoms of neonatal drug withdrawal may also have to be reported to these agencies. These agencies are generally responsible for performing a home assessment and determining the

adequacy of the home environment. In some cases, infants may be assigned to foster homes. Parents may be ordered to participate in drug treatment programs and parenting classes.

After the newborn period the focus of management is on the provision of **well-child care and developmental monitoring**. Attention should be paid to physical growth and administration of immunizations. If a sensory impairment or neurodevelopmental delay is apparent, children should be referred to appropriate community agencies. Federal programs that operate under the Individuals with Disabilities Education Act provide interventional services for disabled and at-risk children 6 years of age and younger.

Symptoms of ADHD or other behavioral problems in older children may require intervention, with recommendation for specific school programs as well as pharmacologic treatment. Regular assessments of school performance should be obtained from children's teachers. Standardized neurodevelopmental tests should be administered at periodic intervals to ensure appropriate progress.

Prognosis

Many infants, particularly those exposed to alcohol in utero, suffer long-term sequelae and disability. Most commonly, these effects are subtle but can have far-reaching impact for the child. Remedial educational programs help, but do not cure, the problems. Recent studies have shown that for drug-exposed children, the environment in which they are raised is a significant factor affecting their ultimate outcome. A stable, nurturing environment minimizes the many adverse effects of prenatal drug exposure and promotes normal neurodevelopment by enforcing the acquisition of skills and knowledge.

CASE RESOLUTION

The case history presented highlights the typical features of the drug-exposed infant. Management includes testing for hepatitis B, hepatitis C, syphilis, and HIV and administering medication such as phenobarbital if the irritability does not respond to swaddling or other measures. The situation should be reported to child protective services to ensure an assessment of the infant's home environment.

Substance Abuse

Monica Sifuentes, MD

CASE STUDY

A 17-year-old adolescent male is brought to your office by his father with a chief complaint of chronic cough. You have followed this patient and his siblings for several years and know the family quite well. The father appears very concerned about “this cough that just won’t go away.” The adolescent is not concerned about the cough, however, and reports no associated symptoms such as fever, sore throat, chest pain, or sinus pain. You ask the father to step out of the room for the rest of the interview and the physical examination.

On further questioning, the patient reports that he smokes a few cigarettes a day and has tried marijuana as well as cocaine. He denies regular use of these substances, but reports exposure to these drugs at parties and when he hangs out with “certain friends.” The adolescent is now in the 11th grade, attends school regularly, and thinks school is “OK.” His grades are average to above average, but he thinks he might fail history this semester. Although he used to play baseball, he dropped out last year. He hopes to get a part-time job at a local fast-food restaurant this summer if his parents let him. Currently he is sexually active and uses condoms occasionally. He denies suicidal ideation and exposure to any firearms.

On physical examination, he appears well developed and well nourished with an occasional dry cough. He is afebrile, and his respiratory rate, heart rate, and blood pressure are normal. Pertinent findings on examination include slight conjunctival injection bilaterally and mild erythema of the posterior pharynx. No tonsillar hypertrophy is apparent. The rest of the examination is within normal limits.

Questions

1. What are the most common manifestations of substance use and abuse in adolescents?
2. What are the risk factors associated with substance abuse in adolescents?
3. What other conditions must be considered when evaluating adolescents with a history of chronic substance abuse?
4. What laboratory evaluation, if any, should be considered in adolescents with suspected substance use or abuse?
5. What are the specific consequences, if any, of short-term and long-term use or abuse of substances such as alcohol, marijuana, cocaine, opiates, and hallucinogens?

Primary care practitioners are in a unique position to educate patients, particularly young teenagers, about substance use and abuse through primary prevention and anticipatory guidance. Opportunities for education include health maintenance visits, the preparticipation sports physical, and during the encounter for an acute injury or illness. More importantly, given their long-standing relationship with families, primary care providers can identify and treat a substance abuse problem as it develops and assist patients and their families with the appropriate referrals and local resources.

Ideally, all preadolescent and adolescent patients should be questioned and counseled about the use of illicit drugs, alcohol, and tobacco at each health maintenance visit (see Chapters 6 and 33). Unfortunately, this occurs inconsistently because most health care professionals often feel uncomfortable opening Pandora’s box, or simply do not have the resources to intervene. Time constraints, unfamiliar billing codes, and difficulty maintaining confidentiality for sensitive services in a busy office or clinic make screening for substance use a major challenge. Primary care practitioners thus lose a valuable opportunity to adequately assess adolescents for substance

abuse and provide them with the necessary guidance to ensure their future health and well-being.

Substance use can be defined as the use of or experimentation with illicit drugs, alcohol, or tobacco. Illicit drugs include marijuana; cocaine; amphetamines; hallucinogens such as lysergic acid diethylamide (LSD), mescaline, and psilocybin, which is found in *Psilocybe mexicana* mushrooms; opiates; and phencyclidine (PCP). **Substance abuse** refers to the chronic use of mind-altering drugs in spite of adverse affects. **Addiction** is the term applied to compulsive and continued use of a substance in the face of these adverse consequences. The substance may produce physical dependence or symptoms of withdrawal when it is discontinued.

Epidemiology

Current Trends and Prevalence Rates

A wide range of substances are currently being used by adolescents in the United States. Alcohol, tobacco, and marijuana are clearly the more common and most popular substances and serve as “gateway

drugs” to more serious drug use. Several surveys tracking adolescent substance use and abuse are conducted annually in the United States to identify high-risk behavior among 8th to 12th graders. The 3 most well-known of these surveys are Monitoring the Future administered annually by the University of Michigan for the National Institute on Drug Abuse of 8th, 10th and 12th grade students; the Youth Risk Behavior Surveillance (YRBS) survey conducted biannually by the Centers for Disease Control and Prevention (CDC) of students in grades 9 through 12; and the National Household Survey on Drug Abuse and Health, a computer-assisted interview of residents 12 years and older conducted in the home. It is important to remember that most statistics do not include the estimated 15% to 20% of students who drop out of high school before their senior year.

In a recent survey of graduating high school seniors (2009 YRBS), approximately 80% admitted to **alcohol** use at some time during their life. Just over half (51%) of students reported drinking alcohol during the month preceding the survey, and 3% to 5% admitted that they used alcohol daily. Binge drinking has probably contributed most to the overall morbidity and mortality associated with alcohol use in adolescents and young adults. Among high school seniors in the class of 2009, one-third reported having 5 or more drinks in a row at least once during the previous 2 weeks. Although **tobacco** use among adolescents decreased from 1975 to 1993, 2009 data from the CDC reveal that approximately 20% of teenagers nationwide still report current cigarette use. Eight percent of adolescents smoked a half a pack or more cigarettes per day in 2009 compared with 11% in 2005 and 19% in 1977. Among students nationwide who smoked cigarettes and are younger than 18 years, 14% report buying them themselves in a store or gas station. Nationwide current smokeless tobacco use (eg, chewing tobacco, snuff, or dip) and cigar or cigarillo use is 9% and 14%, respectively. As expected, its use is much higher among males than females.

Marijuana is the most commonly used illicit psychoactive substance. In 1993, 35% of high school seniors reported ever having used marijuana, and in 1997, this figure increased to more than 50%. Current estimates from the 2009 Youth Risk Behavior Surveillance System (YRBSS) report this figure to be approximately the same at 46%, with nearly 25% reporting marijuana use one or more times during the month preceding the survey. Daily use of marijuana has been reported in 5% of high school seniors.

The use of other substances among adolescents had generally taken a downward trend in the late 1980s and early 1990s; however, figures are increasing again. This is known in the substance abuse literature as “generational forgetting” as adverse effects of specific drugs fade over the years. Reportedly, approximately 9% of high school graduates in 1997 tried cocaine, with approximately 4% having used it in the previous month. These figures remain unchanged more than 20 years later in 2009. The 1991 prevalence rate for LSD usage was 5%, and its use has shown no appreciable decline in the past 10 years. In fact, LSD use among teens has increased significantly and may be more widespread than cocaine use among high school students. According to the latest YRBS 2009 survey, 10% of

high school seniors nationwide had tried LSD or another hallucinogenic drug. Lifetime amphetamine use among 12th graders was 4% in 2009 and ranged from 2.3% to almost 8% across state surveys. In addition, nationwide ecstasy use was reported as approximately 7%.

Concurrently, the reported use of over-the-counter (OTC) nonprescription stimulants that contain caffeine or phenylpropanolamine has increased. Other substances used to “get high,” such as inhalants, are often used by younger students (preteens). Nineteen percent of ninth graders surveyed by the CDC in 1997 reported having sniffed or inhaled substances to become intoxicated compared with 13% in 2009. Dextromethorphan is one of the most recent OTC products to be abused by adolescents secondary to its hallucinogenic effects and easy accessibility. Recent studies report an increasing trend in its abuse, particularly in teens younger than 18 years. Additionally, prescription drugs such as Oxycontin, Percocet, Vicodin, Adderall, Ritalin, and Xanax are reported to have been taken by 20% of teenagers in 2009 without a doctor’s prescription one or more times during their life.

Although not considered an illicit substance by some, anabolic steroids are abused by some adolescents, mostly males, to increase muscle size and strength. In 1997 approximately 3% admitted to using them at some time in their lives. More recently, studies indicate as many as 5.5% of high school students participating in sports use anabolic steroids (6.6% males, 3.9% females). The 2009 nationwide figure per the CDC is 3.3%, however these figures vary across state and local surveys from 2% to 7%.

Demographics

In general, adolescent males use illicit drugs more than females do, with a few exceptions. Males are more likely to use anabolic steroids, but females reportedly use amphetamines, barbiturates, tranquilizers, and OTC diet pills more than their male counterparts. In addition, although annual prevalence rates for overall alcohol use show little gender difference, adolescent males have a higher rate of heavy or binge drinking. Tobacco usage is essentially the same for both genders, except for smokeless tobacco and cigars where males predominate.

Non-college-bound adolescents are more likely to use illicit substances than their college-bound counterparts, and these adolescents are also more likely to use drugs more frequently. There is no difference, however, between the 2 groups in the rates of ever having tried illicit substances. Binge drinking also continues to escalate among older adolescents and young adults attending college. The specific influence of parental education, socioeconomic status, and race, or ethnicity on the use and abuse of illicit substances is difficult to determine since many other factors such as genetics and the environment contribute to drug use and addiction.

Risk Factors and Risk Behaviors

Although alcohol and tobacco are considered licit or lawful drugs, it is illegal for minors to purchase and use alcohol and tobacco in the United States. Alcohol and tobacco use, however, often begins during adolescence, and sometimes during the preteen years. The strongest predictor of drug use by youth is having friends who use

drugs (alcohol, tobacco, or other substances) regularly. In addition, it has been shown that the more risk factors identified, the greater the risk of substance abuse in the teenager.

Several factors are important precursors (risk factors) to drug use during adolescence. These include association with drug-using peers; attitudinal factors, such as favorable attitudes regarding drug use in the family and low religiosity; poor school performance or academic failure, often beginning in the late elementary years; young age of initiation of alcohol or drug use; presence of a conduct disorder; environmental factors, such as the prevalence of drug use in a given community; a family history of alcoholism or drug use; poor parenting practices; high levels of conflict within the family; minimal bonding between parents and children; and early and persistent problem behaviors during childhood such as untreated attention-deficit/hyperactivity disorder (ADHD).

It has been well documented in the literature that early age of onset of alcohol and tobacco use is predictive for the use of other drugs, the use of a greater variety of drugs, and the use of more potent agents. Additionally, the use of alcohol at an early age is associated with future alcohol-related problems such as lifetime alcohol dependence and abuse. The early initiation of alcohol also results in greater sexual risk-taking behavior during adolescence (unprotected sexual intercourse, exposure to multiple sexual partners, being drunk or high during sexual intercourse, and increased risk of pregnancy) as well as academic problems and delinquent behavior later in adolescence. Long-term effects during young adulthood include employment problems, criminal and aggressive behavior, and continued substance abuse.

The role of the media and technology in adolescent alcohol and tobacco use has been the subject of much discussion over the last 10 years. A number of studies have confirmed that exposure to television and movie smoking is one of the key factors that prompt teens to smoke, and that preteens whose parents forbid them from viewing R-rated movies are less likely to begin smoking or drinking. One prospective study revealed that exposure to R-rated movies or having a television in the bedroom significantly increased the risk of initiating smoking for white teenagers. Additionally, watching more movie depictions of alcohol use is strongly predictive of drinking onset and binge drinking in adolescents in the United States. Advertising also contributes to the depiction of alcohol and tobacco use as normative activities. In fact, it has been reported that advertising may be responsible for up to 30% of adolescent alcohol and tobacco use.

Clinical Presentation

Adolescents who are involved in substance abuse may present to the physician in several different ways. Illicit substance use might be uncovered during the routine interview for an annual health maintenance visit or preparticipation sports physical. Alternatively, the adolescent might have physical complaints including chronic cough, persistent allergies, chest pain, and fatigue. Chronic conditions such as asthma may be worsening despite appropriate therapy in the adolescent smoking tobacco or marijuana.

Abdominal tenderness may be noted on physical examination and found to be associated with gastritis, hepatitis, or pancreatitis. The adolescent also recently may have been in a motor vehicle crash, involved in other trauma, or their parents may complain of the teen's frequent mood swings, irritability, or erratic sleep patterns.

Pathophysiology

Although several theories have been proposed to explain why casual substance use develops into abuse and addiction in some adolescents, the most critical factor seems to be the presence of underlying psychopathology. Adolescents who have untreated major depressive disorders, ADHD, or schizophrenia, for example, may use mood-altering substances to treat unpleasant feelings of dysphoria and low self-esteem. Although initially used as a temporary measure, this method of self-medication makes chronic use with some substances more likely.

It is well known that genetic influences play a role in adult use and abuse of alcohol; however, less evidence exists regarding adolescents. What is known is that families and parental attitudes play a significant role in the development of alcohol and other drug use in teens. Permissive attitudes toward alcohol and drug use by parents or guardians and parental or older sibling drug use predict greater drug and alcohol use in the adolescent.

Differential Diagnosis

The differential diagnosis for symptoms and behaviors associated with substance abuse includes underlying psychiatric disorders. Affective, antisocial, and conduct disorders as well as ADHD can be the primary or secondary condition in adolescents who are abusing drugs. Like adults, adolescents may be using illicit drugs to self-medicate. The pharmacology and toxicity of the illicit substances most commonly used by adolescents are summarized in Table 132-1.

Evaluation

History

The interview should be conducted in a private, quiet area to minimize interruptions. If parents have accompanied adolescents, they should be politely asked to leave the room after they have had an opportunity to express their concerns and after issues of confidentiality are addressed in the presence of both parties. This avoids further awkward moments when parents may ask what was disclosed during the interview with their teenager. After parents have left the room, issues regarding confidentiality and privacy should be reviewed once again with the patient. Special circumstances, such as a disclosure of sexual or physical abuse and/or possible suicide ideation or homicidal intent, that dictate that confidentiality be broken also should be discussed (see Chapter 6).

The interview should then proceed in a casual, non-pressured fashion. Initial inquiries should cover less-threatening general topics such as school, home life, and outside activities, including activities

Table 132-1. Pharmacology and Toxicity of Substances Commonly Used by Adolescents^a

Substance	Pharmacology	Effects	Toxicity
Nicotine	Potent psychoactive drug, acting on receptors in CNS to produce effects: stimulation, relaxation, focuses attention		Non-tolerant individuals Weakness, nausea, vomiting Feeling unwell
Marijuana	Active ingredient (Δ^9 -tetrahydrocannabinol) rapidly absorbed into bloodstream from inhaled smoke	Low dose Euphoria, relaxation, time distortion, auditory and visual enhancement High dose/toxic Mood fluctuations, hallucinations, paranoia, psychosis	Acute Panic attacks, psychosis (rare) Chronic Short-term memory impairment, amotivational syndrome, reduced sperm counts
Alcohol	Causes nerve cell membranes to expand and become more “fluid”—interfering with neuronal conduction Interference of neurotransmitters	Mild Disinhibition, euphoria, mild impaired coordination, mild sedation Moderate Increased sedation, slurred speech, ataxia	Severe Confusion, stupor, coma, respiratory depression
Cocaine	Increased release and decreased reuptake of biogenic amines causing CNS and peripheral nervous system stimulation Local anesthesia Vasoconstriction	Produces a sense of well-being and heightened awareness, decrease in social inhibition, intense euphoria	Delirium, confusion, paranoia, hypertension, tachycardia, hyperpyrexia, mydriasis
Stimulants Amphetamines Crystal methamphetamine Ecstasy	CNS stimulation (sympathomimetic)	Heightened awareness Restlessness and agitation, decreased appetite Low doses increase ability to concentrate	Hypertension, hyperthermia, seizures, stroke, coma, arrhythmias
Hallucinogens LSD Mescaline Mushrooms	Inhibits release of serotonin	Distortions of reality—perceptual alterations, “synesthesias” common (eg, “hearing” smells)	Paranoia, flashbacks, psychosis, depression
Phencyclidine	Dissociative anesthetic with analgesic, stimulant, depressant, and hallucinogenic properties	Dissociative anesthetic Dose-dependent euphoria, dysphoria, perceptual distortion	Psychoses; aggressive, violent behavior; depression; seizures, rhabdomyolysis
Opiates Opium Heroin Methadone	Binds to opioid receptors in CNS, causing CNS depression	Sedative analgesics Euphoria followed by sedation, somnolence	Respiratory depression, CNS depression, miosis, bradycardia, hypotension, arrhythmia, seizures, rhabdomyolysis
Sedatives Benzodiazepines Barbiturates	CNS depression, binds to specific receptor that potentiates GABA	Sedation Anxiety reduction	Similar to opioid intoxication
Anabolic steroids	Bind to androgen receptors at cellular level, stimulate production of RNA and protein synthesis	Euphoria Increased irritability and aggressiveness Induction of mental changes at high doses	Psychosis
Inhalants	CNS stimulation and excitement, progressing to depression	Euphoria, hallucinations, psychosis	Respiratory depression, arrhythmia, seizures, sudden sniffing death syndrome (sudden death secondary to arrhythmia)

Abbreviations: CNS, central nervous system; GABA, γ -aminobutyric acid; LSD, lysergic acid diethylamide.

^a Data from Schwartz B, Alderman EM. Substances of abuse. *Pediatr Rev.* 1997;18:206–214, and Joffe A, Blythe MJ, eds. Mental health, psychotropic medications, and substance abuse. *Adolesc Med.* 2003;14:455–466.

with friends. **HEADSSS** (*home environment, employment and education, activities, diet, drugs, sexual activity/sexuality* [including a history of sexual abuse or assault], *suicide/depression, and safety*) allows for a thorough review of the essential components of the psychosocial history (see Chapter 6).

Some practitioners prefer to use questionnaires to obtain this background information. A questionnaire is given to patients to fill out while they are waiting to be seen, and the responses are reviewed privately during the actual visit (Box 132-1). Controversy exists regarding the role of such questionnaires, primarily concerning the truthfulness of answers, because parents may be with the teenager as he or she is attempting to complete the form.

More specific questions related to the use of alcohol and tobacco as well as illicit substances should be asked after general subjects have been discussed (Questions Box). If adolescents seem wary of answering these questions, it may be helpful to initially inquire about their friends. Questions should be phrased with the assumption that the responses will be affirmative (eg, How many beers do your friends drink in a week? And you, do you drink the same amount?). It is hoped that this less-threatening approach invites more honest answers. An assessment of the risk of suicidal behavior is also indicated. Further questions relevant to substance abuse are given in Box 132-2.

Because many clinicians do not have unlimited time to interview adolescents and obtain all of the details at one visit, another approach has been developed to efficiently screen for drug and alcohol problems using 3 questions: (1) Have you *ever* smoked a cigarette? (2) Have you *ever* had an alcoholic drink? and (3) Have you *ever* used marijuana or any other drug to get high? The thinking is that by using the word “*ever*” the clinician is asking a clearer question. Additional screening is recommended for any teenager who answers “*yes*” to any of these 3 initial questions. Six questions, known as the CRAFFT questions, are then reviewed to further screen the adolescent for drug and alcohol problems (Box 132-3). The teen receives 1 point for each “*yes*” answer; a total score of 2 or more indicates a high risk for a substance abuse problem and the need for additional follow-up as well as a referral to a mental health professional. The validity of this tool with adolescents has been reported in the literature and is well supported.

Physical Examination

Positive findings on physical examination are rare, especially in adolescents who use alcohol or other substances only occasionally. In adolescents with a history of chronic substance abuse, however, certain physical findings may be present.

All vital signs should be reviewed. Tachycardia and hypertension occur primarily with acute intoxication with cocaine or stimulants such as amphetamines. The current weight also should be recorded and compared with previous values, and any significant weight loss should be noted. The skin should be examined closely for track marks, skin abscesses, or cellulitis, especially if patients admit to using drugs intravenously. Findings consistent with hepatitis (hepatomegaly and jaundice) may be present in these individuals. The presence of diffuse adenopathy, thrush, leukoplakia, seborrheic dermatitis, or parotitis should raise the suspicion of HIV infection.

Questions

Adolescent Substance Abuse

- Do any of the adolescent’s friends drink alcohol, smoke marijuana or tobacco, or use any other drugs?
- What drugs, including alcohol and tobacco, are currently being used by the adolescent? For how long and how frequently?
- In what environments does the adolescent use these substances?
- Has the adolescent ever blacked out or been arrested while under the influence of drugs or alcohol?
- Has drug or alcohol use ever interfered with school, work, or other social activities?
- Has drug or alcohol use adversely affected relationships with family, friends, or romantic partners?
- Has the patient ever had sexual encounters while under the influence of drugs or alcohol?
- Does the adolescent ever use drugs or alcohol to feel better or to forget why he or she feels sad?
- Do the adolescent’s parents use alcohol, tobacco, or illicit drugs?

Upper respiratory symptoms such as chronic nasal congestion, long-lasting “colds” and “allergies,” and epistaxis can occur with chronic inhalation of cocaine. Signs of nasal congestion, septal perforation, and wheezing may be noted on examination. In addition, smoking crack cocaine can cause chronic cough, hemoptysis, and chest pain.

Box 132-2. Open-Ended Questions Intended to Provide a Basis for Further Exploration of Advanced Substance Abuse^a

1. What do your friends do at parties? Do you go to the parties? Do you drink? Get drunk? Get high?
2. Do you drive drunk? Stoned? Have you ridden with a driver who was drunk or stoned? Could you call home and ask for help? What would your parents say? Do?
3. Do you go to concerts? Do you drink there? Do you get high? Who drives after the concert?
4. After drinking, have you ever forgotten where you had been or what you had done?
5. Have you recently dropped some of your old friends and started going with a new group?
6. Do you feel that lately you are irritable, “bitchy,” or moody?
7. Do you find yourself getting into more frequent arguments with your friends? Brothers and sisters? Parents?
8. Do you have a girlfriend/boyfriend? How is that going? Are you having more fights/arguments with him/her lately? Have you recently broken up?
9. Do you find yourself being physically abusive to others? Your brothers/sisters? Your mother/father?
10. Do you think your drinking/drug use is a problem? Why?

^a Reproduced with permission from American Academy of Pediatrics. *Substance Abuse: A Guide for Professionals*. Schonberg SK, ed. Elk Grove, IL: American Academy of Pediatrics; 1988.

Smoking marijuana over long periods can result in similar findings. Gynecomastia can be seen with use of anabolic steroids, marijuana, amphetamine, and heroin. In the adolescent female using anabolic steroids, there may be signs of virilization, such as a deep voice, hirsutism, and male pattern baldness. The detailed neurologic evaluation is probably the most important part of the examination. Any abnormalities in memory, cognitive functioning, or affect should be noted. Chronic marijuana use is sometimes accompanied by an amotivational syndrome.

Acute intoxication with some drugs such as cocaine may lead to delirium, confusion, paranoia, seizures, hypertension, tachycardia, arrhythmias, mydriasis, and hyperpyrexia. Acute PCP intoxication produces abnormal neurologic signs, tachycardia, and hypertension. Findings such as central nervous system and respiratory depression, miosis, and cardiovascular effects (eg, pulmonary edema, orthostatic hypotension) are consistent with opiate overdose. However, signs and symptoms of acute intoxication are generally seen in the emergency department setting rather than in the primary care provider's office or clinic.

Laboratory Tests

Routine drug screening in the evaluation of possible substance abuse is not recommended and generally not indicated. Specific laboratory studies should be performed only in those patients who are known substance abusers and enrolled in a drug treatment program

Box 132-3. The CRAFT Questions: A Brief Screening Test for Adolescent Substance Abuse^{a,b}

- | | |
|----------|--|
| C | Have you ever ridden in a CAR driven by someone who was “high” or had been using alcohol or drugs? |
| R | Do you ever use alcohol or drugs to RELAX, feel better about yourself, or fit in? |
| A | Do you ever use alcohol or drugs while you are by yourself (ALONE)? |
| F | Do you ever FORGET things you did while using alcohol or drugs? |
| F | Do your FAMILY or FRIENDS ever tell you that you should cut down on your drinking or drug use? |
| T | Have you ever gotten into TROUBLE while you were using alcohol or drugs? |

^a Reprinted with permission from Knight JR, Sherritt L, Shrier LA, Harris SK, Chang G. Validity of the CRAFT substance abuse screening test among adolescent clinic patients. *Arch Pediatr Adolesc Med.* 2002;156:607–614. © Children's Hospital Boston, 2009.

^b Two or more “yes” answers suggest that the adolescent may have a significant problem with abuse or dependence, and warrants an additional assessment.

to monitor for abstinence; required by court order; or in patients with an acute presentation of altered mental status, intoxication, or abnormal neurologic findings, such as may be seen in an emergency department setting. In the office setting, these symptoms are frequently absent, and urine or serum studies to “check” for drug use are not warranted nor useful.

If these tests are performed, they require the adolescent's consent. The results should not be shared with anyone other than the patient, unless the patient gives permission or the substance found is the cause of an acute medical condition. According to the American Academy of Pediatrics and the Society for Adolescent Medicine, obtaining a urine drug test without the consent of the adolescent undermines the physician–adolescent relationship and the development of a meaningful, trusting relationship at this critical time in the patient's life. Drug testing should not be performed simply to allay parental anxiety or confirm suspicions regarding possible substance abuse for a parent, teacher, or athletic coach.

If urine is obtained for drug testing, it is critical that it is not contaminated or diluted and that the provider be familiar with the particular laboratory performing the drug test as well as the reported sensitivity and specificity of each test. Urine testing is available to detect marijuana and its metabolites, cocaine, amphetamines, PCP, opiates, barbiturates, and benzodiazepines. Blood levels can be obtained for alcohol, marijuana, cocaine, amphetamines, barbiturates, and benzodiazepines. Although salivary or urinary concentrations of cotinine and nicotine concentrations can also be performed, these measurements are primarily used in research studies.

Testing for specific inhalants is not routinely done. The deleterious effects of these substances on the hematologic, liver, and renal systems can be evaluated by performing a complete blood cell count, liver function tests, prothrombin time and partial thromboplastin time, and blood urea nitrogen and creatinine.

Management

One of several approaches to the problem of substance use and abuse can be chosen depending on the adolescent's degree of risk-taking behavior and drug involvement, the provider's relationship with the adolescent and their family, the adolescent's desire to change their behavior, and the family's awareness of the problem.

Anticipatory Guidance

If preadolescents or adolescents and their peers are not participating in any high-risk behaviors including tobacco, alcohol, or drug use, pediatricians should provide patients with age-appropriate anticipatory guidance. This should include information regarding safety issues, consequences of alcohol and tobacco use, and exposures to illicit drugs. Adolescents should be praised and encouraged to continue their current behavior but should be invited to return to the office if they have any questions or problems. This may be particularly helpful for patients whose daily environment exposes them to high-risk situations for drug use.

Early Intervention

Primary care practitioners should provide early intervention guidance to preadolescents or adolescents who are engaging in occasional high-risk behavior but whose substance use does not interfere with or disrupt their daily lives. Such use implies only occasional or casual use of illicit substances by patients or peers. This scenario is the most challenging since many adolescents as well as their parents perceive occasional alcohol or drug use as "experimental" or a phase of "normal teen behavior" and therefore may trivialize any advice given by the pediatrician. Interventional guidance involves discussing potential risks created by the adolescent's current behavior. For example, individuals who drink alcohol or smoke marijuana at parties have an increased risk of involvement in a motor vehicle crash afterward either as the driver or passenger. Another common scenario involves alcohol intoxication and poor judgment with regard to sexual behavior. All teens should be made aware of the possible consequences of their unsafe behavior especially if their occasional drug use has progressed to more regular use in risky situations.

Specialized Programs

Preadolescents or adolescents who are routinely using drugs but are clearly motivated to stop can often be managed by primary care physicians. Many of these teenagers began using illicit substances at an older age, have a fairly good relationship with their families, have supportive relationships with friends who do not use drugs, and have continued to do well in school and participate in other outside activities. Practitioners initially should identify the problem and establish whether the adolescent desires to change their behavior. Then practitioners should meet with families, develop an appropriate strategy for treatment intervention, and follow the adolescents periodically in the office. Timely and consistent reinforcement by the primary care physician is necessary, especially in the beginning of treatment. Referral to outpatient programs, such as Alcoholics Anonymous or

Narcotics Anonymous, also may be indicated. Appropriate community resources for the teenager as well as family should be reviewed.

Mental Health or Treatment Programs

Referral to a mental health or specialized treatment program (drug detoxification center) is indicated for adolescents who continue to use drugs despite office treatment by the primary care practitioner and adverse effects on their daily lives and relationships. In addition, those teenagers who are suspected to have a concomitant psychological or psychiatric condition should be referred immediately for psychiatric evaluation. Other criteria for specialty treatment programs include a long history of drug abuse, a serious life-threatening event in conjunction with substance abuse (eg, attempted suicide or motor vehicle crash), familial strife, or persistent involvement with a drug-dependent crowd. Primary care practitioners should become familiar with local inpatient programs and residential substance abuse treatment facilities in their community. Although the selection of a program is often dictated by financial resources, it is very important to select an appropriate one for both the adolescent as well as the family. Guidelines exist to aid practitioners in the selection process for both public and private facilities. These guidelines include total abstinence, appropriate professionals with expertise in drug abuse, familial involvement in the program, family therapy, and appropriate outpatient follow-up.

Prevention Programs

Prevention programs have been developed to assist and influence the decisions young people make about the use of illicit substances. Current programs focus on multiple aspects of the lives of children and adolescents. Programs may involve individual decision-making, self-esteem, and basic education regarding drugs. They frequently emphasize communication skills, family values and dynamics, parenting skills, and positive peer associations. Structured curricula also have been created for use in the schools, and community outreach programs have been organized by groups such as local police departments. The actual effectiveness of each type of program is a subject of controversy, but they are all aimed at somehow preventing the initial or continued use of illicit substances in children and preteens.

Prognosis

It is difficult to assess the outcome for adolescents who undergo treatment for substance abuse because definitions of success vary. For some teenagers, success implies periods of sobriety, for others it means complete abstinence, and for still others it is abstinence in addition to recovery from other contributing problems. Specific outcome data that are available, however, reveal that abstinence rates are positively correlated with regular attendance in a support group and parental participation in these groups. In addition, general success rates range from 15% to 45%, depending on short- or long-term assessments. As expected, there is a lifetime potential for relapse among all substance abusers.

CASE RESOLUTION

In the case presented, the adolescent is at high risk for substance abuse given his drug-using friends, tobacco use, possible school failure, and recent change in extracurricular activities (ie, dropping out of baseball). The findings on physical examination also are consistent with his smoking history. The physician should review these risk factors with the teenager and acknowledge the difficulty in removing one's self from such an environment. The adolescent's motivation to change his behavior should be assessed, and referrals to special intervention programs can be discussed. Regardless of the outcome, the physician should continue to see the teenager at an agreed-on interval to monitor his ability to quit smoking and high-risk behavior.

Eating Disorders

Monica Sifuentes, MD

CASE STUDY

A 16-year-old adolescent female is brought to the office by her mother because she feels that her daughter is too thin. The mother complains that her daughter does not eat much at dinner and always says she is not hungry. Recently the girl bought diet pills that were advertised in a teen magazine. She claims that the pills are supposed to help her gain weight, so she doesn't understand why her mother is so upset. She says she feels fine and considers herself healthy.

The girl is a 10th-grade student at a local public school and attends classes regularly, although her friends are occasionally truant. She is involved in the drill team, the swim team, and the student council. She has many friends who have "nicer" figures than she does. Neither she nor her friends smoke tobacco or use drugs, but they occasionally drink beer at parties. The girl is not sexually active and denies a history of abuse. Her menstrual periods are irregular; the last one was approximately 6 weeks ago.

She currently lives with her mother, father, and 2 younger siblings. Although things are "OK" at home, she thinks her parents are too strict and don't trust her. They have just begun to allow her to date.

Her physical examination is significant for a thin physique and normal vital signs. On the growth chart, her weight is at the 15th percentile and her height at the 75th percentile, giving her a body mass index of 17 (10th percentile). The remainder of her physical examination is unremarkable.

Questions

1. What are the common characteristics of disordered eating in adolescents?
2. What are the important historical points to include when interviewing patients with suspected eating disorders? And which teens are considered at risk?
3. How is the diagnosis of anorexia nervosa (AN) and bulimia nervosa (BN) made?
4. What is the treatment plan for adolescents with eating disorders?
5. What are the medical complications of AN and BN?
6. What is the prognosis for these conditions? How can primary care practitioners help improve the outcome?

Eating disorders are complex problems that are sometimes difficult to diagnose based on strict *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* criteria (Box 133-1). Adolescents may have partial or atypical forms, a combination of both AN and BN, or an underlying affective component that confuses the issue. They may not display a blatant refusal to eat, but may instead exhibit subtle characteristics of disordered eating: constant dieting, obsession with a certain physical exercise, or irregular menstruation. In addition, preoccupation with physical appearance and weight is not uncommon or necessarily pathologic in today's Western society. Both the fashion industry and media promote the idea that thinness and beauty are interrelated. Thus typical adolescents who long to be accepted by peers and who are learning to develop a sense of independence and control are prime targets for the development of eating disorders. The primary care physician is in a unique position to recognize individuals at risk, appropriately screen those teenagers with specific behaviors, and provide early intervention to prevent the development of a full-blown eating disorder (Box 133-2). The overall goal is to decrease the life-long medical and psychological morbidity and mortality associated with this condition in adolescents.

Epidemiology

In general, eating disorders are most common among white females and in more affluent communities. Although they occur in many other settings, in previous years they were nearly unheard of in lower socioeconomic groups, among ethnic minorities, or in children younger than 12 years. Today they can be seen in all ethnic, cultural, and social backgrounds in the United States as well as in other developed countries. In addition, males make up an estimated 5% to 10% of all patients with eating disorders.

Although dieting behavior among adolescents and young adults is not uncommon, true AN has a prevalence of approximately 0.5% to 1% in these individuals. Estimates have ranged from 1% to 10% in high-risk groups such as upper- and middle-class white females. Less than 5% of these cases are males, with a female-male ratio of 9:1. The age of onset is usually during early or middle adolescence (age 12–16 years). However, AN has been reported to have a second peak later in adolescence, and it has become increasingly more common for children and younger teens to be dissatisfied with their weight and concerned with body image. Studies have been reported in middle-income elementary school girls where significant body and

Box 133-1. Diagnostic Criteria for Anorexia and Bulimia Nervosa^a

Anorexia Nervosa

- A. Refusal to maintain body weight at or above a minimally normal weight for age and height
- B. Intense fear of gaining weight or becoming fat, even though underweight
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight
- D. In post-menarcheal females, amenorrhea (ie, the absence of at least 3 consecutive cycles)

Bulimia Nervosa

- A. Recurrent episodes of binge eating, characterized by the following:
 - (1) Eating, in a discrete period, an amount of food that is definitely larger than most people would consume under similar circumstances and in the same period
 - (2) A sense of lack of control over eating during the episode
- B. Recurrent inappropriate compensatory behavior to prevent weight gain (self-induced vomiting, laxative or diuretic use); fasting; or excessive exercise.
- C. Criteria A and B both occur on average at least twice a week for 3 months
- D. Self-evaluation is unduly influenced by body shape and weight
- E. The disturbance does not occur exclusively during episodes of anorexia nervosa

^a Adapted and reproduced with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*. 4th ed. Text rev. Washington, DC: American Psychiatric Association; 2000.

weight dissatisfaction were noted with increasing grade. Skipping meals and desserts, fasting, and vomiting were all reported specifically to lose weight. Unfortunately, the goal for many of these young girls is not to be of normal weight, but to be underweight.

The prevalence of BN is approximately 1% to 4%, although some studies report that as many as 8% of adolescents and college women and 0.4% of men are bulimic. The age of onset tends to be later than for AN, with symptoms beginning during late adolescence (age 17–20 years) and young adulthood. Females outnumber males by a factor of 5.

Several other behavioral and affective disorders have been associated with AN and BN. These include major depression and other mood disorders in patients as well as first-degree relatives, alcoholism and substance abuse, other addictive behaviors (eg, laxative abuse), poor impulse control and anxiety disorders, and obsessive-compulsive personality. In addition, suicidal behavior (attempts) is more likely in individuals with BN as are reports of an increased incidence of family members with substance abuse and dependence disorders.

Mild variants of eating disorders, which do not meet full diagnostic criteria, occur in approximately 5% to 10% of postpubertal females. Additionally, more than half of junior high and high school girls have dieted at some time, many repeatedly.

Box 133-2. Diagnostic and Statistical Manual for Primary Care (DSM-PC) Child and Adolescent Version Diagnostic Criteria: Dieting/Body Image Problem^a

- Dieting and voluntary food restrictions that result in weight loss or failure to gain weight as expected during growth, but behaviors not intense enough to qualify for diagnosis of anorexia nervosa
- Individual becomes obsessed with the pursuit of thinness and develops fears of gaining weight
- Consistent disturbance in body perception, denies dieting or weight loss is a problem

^a Adapted from Wolraich ML, ed. *The Classification of Child and Adolescent Mental Diagnoses in Primary Care: Diagnostic and Statistical Manual for Primary Care (DSM-PC) Child and Adolescent Version*. Elk Grove Village, IL: American Academy of Pediatrics; 1996.

Box 133-3. Risk Factors for the Development of an Eating Disorder^a

- Family history of an eating disorder or obesity
- Affective illness or alcoholism in a first-degree relative
- Specific activities/sports: ballet, gymnastics, modeling, running, wrestling
- Personality characteristics (eg, perfectionism)
- Parental eating behavior and weight
- Low self-esteem
- Physical or sexual abuse
- Body image dissatisfaction
- History of excessive dieting, frequently skipped meals, compulsive exercise

^a Adapted from Rome ES, Ammerman S, Rosen DS, et al. Children and adolescents with eating disorders: the state of the art. *Pediatrics*. 2003;111:e100.

Clinical Presentation

Patients with eating disorders usually present with complaints related to weight loss or failure to gain weight and often are referred to the primary care provider by concerned parents, well-intentioned friends, informed coaches, or school personnel. Many adolescents also present with secondary amenorrhea noted during an annual examination. Sometimes an underlying psychiatric condition such as obsessive-compulsive disorder (OCD) is the grounds for the medical referral. Occasionally patients with eating disorders are hospitalized because of complications such as electrolyte disturbances related to diuretic use, hematemesis from induced vomiting, or syncope from hypovolemia.

Pathophysiology

Anorexia Nervosa

Although several factors predispose individuals to the development of AN, this condition has no single cause (Box 133-3). Longitudinal studies clearly point to a significant role of inappropriate dieting behavior in the pathogenesis of an eating disorder. However, because not all dieters develop an eating disorder, other significant

risk factors must be involved. Current theory suggests that a complex relationship exists among multiple factors, and that genetic-environmental interactions along with the adolescent's personal experiences (epigenetics) contribute to the etiology of AN.

Biological Factors

It has been postulated that the normal increase in adipose tissue with the onset of puberty creates a special problem for some females. An eating disorder may develop as an attempt to control or combat this normal pubertal weight gain with the initiation of dieting behavior. Preexisting hypothalamic dysfunction also has been implicated as a contributing factor to AN. In addition, changes in neurotransmitter levels have been shown to occur with initial vomiting or dieting. These changes may then lead to specific psychiatric symptoms that may perpetuate disordered eating. However, recent data with neuroimaging studies have shown that most of the physiological disturbances resolve with normalization of the patient's body weight. In addition, a pre-morbid disturbance in the neurotransmitter serotonin has been speculated to be a risk factor for the development of both AN and BN. Serotonin controls appetite by creating a sensation of fullness or satiety. In addition, it is known to have an effect on sexual and social behavior, mood, and stress responses. Although further studies are needed to confirm the exact role of this hormone in the development of an eating disorder, it has been shown that decreases in this brain neurotransmitter have been associated with impulsivity, aggression, and depression.

Leptin, a circulating hormone produced in adipose tissue, also seems to have a significant role in mediating the neuroendocrine effects of AN. Decreased concentrations of leptin are seen with reduced body fat stores as a result of decreased caloric intake and energy deficits. Paradoxically, leptin levels also appear to contribute to physical hyperactivity (compulsive exercise, restlessness), which is often seen in patients with AN despite their inadequate metabolic intake.

Genetic Factors

A genetic predisposition to anorexia has been shown in studies of monozygotic twins. The incidence of the disorder is increased in sisters and other female relatives of patients with AN.

Personal Characteristics

In general, patients with anorexia are described as obsessive-compulsive personality types, perfectionists, and overachievers. They also display low self-esteem and high anxiety levels despite their successes. They are the "model daughters" who have never caused any previous problems given their compliant, self-sacrificing, non-assertive nature.

There is an increased association between AN and major depression as well, and many studies of women have shown that first-degree relatives of patients with AN have higher rates of depression than the general population. However, many depressive symptoms in patients with AN improve with the restoration of body weight. Therefore, some of these clinical features of depression also may be secondary to the adolescent's state of malnutrition or starvation.

Familial Influences

Researchers have noted that certain family dynamics may serve to initiate and perpetuate AN, although it is no longer believed that family dysfunction is the main cause of disordered eating. Typically, however, the family is overprotective and rigid, with the mother often enmeshed in her daughter's life. Conflict resolution tends to be poor, and an inability to express feelings within the family is often evident. Multiple case-control studies have shown there is a higher rate of both AN and BN in relatives of patients with eating disorders. This may be due to inheritance patterns of personality traits as well as comorbid mood and anxiety disorders.

Social/Environmental Pressures

Both the media and Western industrialized societal standards are believed to play a role in "setting the stage" for the development of an eating disorder. Affluent communities are especially at risk for this. Within these social circles, thinness, food, eating, and obsessive exercise can become the prime focus of daily activity.

In addition, young women become caught in what has been labeled a "slender trap" in which thinness is equivalent to attractiveness and success. Food restriction or purging is a means of attaining thinness. An inability to maintain thinness equals failure. Role models in the media, such as fashion models and actresses, also serve as ideals by which young people create their standards.

Other Influences

Involvement in particular extracurricular activities, such as ballet and gymnastics, may contribute to the development of AN in females. For male athletes, such influences include participation in sports such as wrestling, in which maintaining a given weight is important and dieting is used to achieve that weight. Chronic medical conditions, such as diabetes mellitus or inflammatory bowel disease (IBD), also may contribute to the development of an eating disorder.

Bulimia Nervosa

Several theories have been proposed to explain the etiology of BN but, similar to AN, no single etiology has been confirmed. Most likely multiple factors contribute to the development of this eating disorder, and it is the complex interaction between these factors at a particular developmental point in an older adolescent's life that leads to this condition.

Biological, psychological, familial, and societal influences are thought to contribute to the development of BN in older teenagers and young adults. Among other issues, adolescent and parental obesity are both risk factors for BN as are early menarche, early sexual experiences, and a history of childhood sexual or physical abuse that occurs in conjunction with a comorbid psychiatric condition. More importantly, dieting has been documented as an important risk factor in this age group.

Familial dysfunction and high levels of conflict also have been associated with BN. Unlike with AN, conflict might be discussed openly but negatively within the family, and there may be an inadequate expression of emotions that may lead to a lack of parental

warmth and concern. Thus the relationship between the parent and teenager is distant rather than enmeshed. The adolescent generally has a low level of self-esteem, high impulsivity, and body image dissatisfaction. Additionally, parents and relatives have a high rate of affective and eating disorders as well as alcoholism.

Differential Diagnosis

It is important to differentiate AN from BN, although occasionally this distinction may be difficult to make if patients display behavior consistent with both conditions. In addition, approximately 50% to 60% of patients with eating disorders have associated comorbid psychiatric disorders. Major affective disorders to consider include depression, bipolar disorder, and OCD. Anxiety disorders and substance abuse also are commonly seen, although the latter is more strongly associated with BN.

Other diagnoses to consider when evaluating patients for AN include IBD, malabsorption, celiac disease, diabetes mellitus, malignancies, Addison disease, hyperthyroidism or hypothyroidism, hypopituitarism, tumors of the central nervous system (CNS), and substance abuse, particularly with amphetamines and crack cocaine. Superior mesenteric artery syndrome is another important condition to consider in the differential diagnosis; however, it also can be a consequence of an eating disorder.

Evaluation

History

A complete medical history including a detailed review of systems should be obtained from all adolescents with suspected eating disorders to rule out the multiple other conditions in the differential diagnosis of weight loss. The primary care provider then should interview the patient alone and focus on establishing the diagnosis of disordered eating by addressing more specific issues related to food, eating behaviors, dieting, exercise, and body image (Questions Box). (See Steinegger in Selected References for a detailed discussion of interviewing techniques to use in patients with a suspected eating disorder.) The severity of both the medical and nutritional aspects of the condition should be determined initially, followed by a psychosocial evaluation. Inquiries should focus on symptoms associated with complications such as dysphagia secondary to esophagitis from recurrent vomiting, constipation from fluid restriction, or muscle weakness associated with emetine toxicity from chronic ipecac use. Although rarely seen by the primary care provider at the initial visit when the diagnosis of an eating disorder is made, recognition of serious medical complications is paramount to determining the urgency of further care.

Interviewing an adolescent with an eating disorder can be quite challenging; however, a thorough psychosocial assessment should be performed after a discussion about confidentiality has occurred with the adolescent and her parents. The **HEADDSSS** format (*home environment, employment and education, activities, diet, drugs, sexual*

Questions

Eating Disorders

- Have there been any changes in the adolescent's weight? What is the most, and least, the adolescent has ever weighed? When did these weights occur, and for how long?
- How does the adolescent feel about how he or she looks? Is there anything he or she would like to change? How long has he or she been feeling this way?
- How much does the adolescent want to weigh?
- How often does the adolescent weigh himself or herself?
- What is a typical day of eating like, including eating times, types of foods, beverages, amount consumed, and portion size?
- What did he or she eat yesterday (24-hour dietary recall)?
- Does the adolescent have any food restrictions? Is the teenager a vegetarian? Does he or she count calories? Binge eat?
- Does the adolescent hide or throw away food?
- How does the adolescent and his or her friends handle weight control?
- What does the adolescent do when he or she feels "fat"? Does the adolescent vomit to lose weight? How often does this occur? Triggers?
- Has the adolescent or any of his or her friends ever used diuretics, diet pills, ipecac, enemas, or laxatives to lose weight or compensate for overeating?
- Does the adolescent exercise? If so, what type and how often? Is he or she stressed if they miss a workout?
- In what sports or dance activities, if any, does the adolescent participate?
- For females, are menstrual periods regular? Last menstrual period? Age at menarche?
- Does the adolescent have any other symptoms associated with complications of eating disorders?
- Does the adolescent have any depressive symptoms, such as sleeping problems or fatigue that can accompany eating disorders?

For Patients With Bulimia Nervosa

- When do binges occur?
- What are the precipitating factors?
- What happens specifically during a typical episode?
- Does the adolescent use drugs or alcohol?
- Is there a history of depression or attempted suicide?

activity/sexuality, suicide/depression, safety) is useful to direct the psychosocial interview from general topics to more sensitive ones (see Chapter 6). Particular attention should be paid to the adolescent's overall functioning at home, with friends, and at school; the presence of other comorbid psychiatric disorders such as depression or anxiety; and a history of suicidal ideation or sexual/physical abuse. Out-of-control behavior as a result of substance abuse also should be assessed. The use of psychological testing/questionnaires to assess cognition and depression may be beneficial, depending on the comfort level of the primary care practitioner with these tools. Otherwise, consultation with a mental health professional is warranted.

A detailed menstrual history also must be obtained from females because secondary amenorrhea is frequently present in patients as

an early sign of AN secondary to decreased body fat. Menses may be irregular or absent with BN as well. A family history of eating disorders, substance abuse, or psychiatric disease should be reviewed with the teenager and confirmed by the parent.

A dietary history should be obtained from the adolescent as well as the parents independently and should focus on any dietary restrictions or aversions. This may be difficult initially since the patient often does not believe he or she has a problem with food. A 24-hour dietary recall can be an important place to begin the assessment.

Physical Examination

In both conditions, the patient should undress, wearing only underwear, for the physical examination. This prevents any bulky clothes from hiding the true body habitus. The height and weight should be plotted on a growth chart, and the body mass index (BMI) should be calculated ($BMI = \text{weight [kg]} / \text{height [m]}^2$). Delayed growth or short stature also should be noted because it can occur with severe malnutrition as well as other systemic conditions. Vital signs, including blood pressure, should be recorded. Evidence of cardiovascular instability can be manifested by tachycardia, bradycardia, or orthostatic hypotension. The patient also may be hypothermic as a result of her overall malnutrition. The general appearance and affect of the patient must be noted. Adolescents with full-blown AN are often emaciated with an obvious loss of subcutaneous tissue, and they may appear apathetic, anxious, or have a flat affect. Patients with BN may be mildly obese or of normal weight with a full-appearing facies secondary to parotid and submaxillary swelling, a complication of frequent purging. In most cases, however, the teen appears “normal” at the initial visit.

Physical findings in patients with **anorexia nervosa** are consistent with a “state of hibernation.” Hypothermia, orthostatic hypotension, bradycardia, and lanugo (downy hair) on the arms and back are seen. The palms and soles may be yellow secondary to hypercarotenemia, and pigmentation of the chest and abdomen may be increased as a result of malnutrition. Thinning or loss of pubic and scalp hair as well as dry skin also may be seen. The breasts should be examined carefully for sexual maturity rating (SMR) (Tanner Staging) as well as galactorrhea. The presence of galactorrhea, along with a history of amenorrhea, warrants further investigation for a prolactinoma. Of note, patients with AN may have interrupted or delayed pubertal development. A cardiac murmur must be noted and further evaluated because one-third of patients with anorexia have mitral valve prolapse. The abdomen should be palpated for tenderness or masses, and may be scaphoid in appearance. Bowel sounds are often decreased in patients with anorexia, and stool may be palpated secondary to constipation. The presence of pubic hair (genital SMR) also should be noted. A rectal examination should be performed for any evidence of bloody stool, which is a finding consistent with IBD. The extremities should be evaluated for coldness, mottling, or edema. Finally, a complete neurologic examination, including a mental status

evaluation, should be performed to exclude any signs of a CNS lesion or endocrine disorder.

In patients with **bulimia nervosa**, specific physical findings, if any, are often associated with dehydration and electrolyte imbalances that occur as a result of chronic vomiting or laxative abuse. Vital signs should be reviewed for tachycardia, sinus bradycardia, and orthostatic hypotension; their presence indicates hemodynamic instability. The patient also may be hypothermic. The skin should be inspected on the dorsum of the hand over the knuckles for scratches, scars, or calluses from self-induced vomiting (Russell sign). Petechiae and subconjunctival hemorrhages also may be seen as a result of severe retching. The oropharynx should be inspected for dental caries, enamel erosion, or discoloration as well as for parotid hypertrophy. In addition, palatal scratches or mouth sores can be seen. The abdomen should be palpated for epigastric tenderness or mid-abdominal pain. Positive findings may be due to esophagitis, gastritis, or pancreatitis.

From a musculoskeletal standpoint, any muscle weakness or cramping should be appreciated and may indicate an electrolyte abnormality. Edema of the extremities may be seen in laxative abusers and should be noted.

Laboratory Tests

Box 133-4 lists the laboratory studies necessary in the evaluation of patients with AN. A complete blood cell count may be helpful because leukopenia, anemia and, rarely, thrombocytopenia can be found with this disorder. Electrolytes (sodium, potassium, chloride, and carbon dioxide) and blood urea nitrogen are important especially if patients use diuretics, laxatives, or ipecac. Serum calcium and phosphorous must be monitored, especially in the “refeeding” phase of treatment. The erythrocyte sedimentation rate may be low with anorexia and high with IBD or some other inflammatory process. Normal liver function tests aid in excluding other causes of weight loss. Some endocrine tests help differentiate a hormonal problem from AN, especially in patients with primary or secondary amenorrhea (see Box 133-4). An electrocardiogram (ECG) allows practitioners to diagnose QTc prolongation, heart block, and arrhythmias. In addition, an ECG is indicated in patients with electrolyte abnormalities, or with a history of significant purging or weight loss.

Laboratory abnormalities in BN reflect the type and extent of purging behavior of adolescents. Box 133-4 summarizes the necessary laboratory studies for patients with BN.

Radiographic studies, such as computed tomography of the head or magnetic resonance imaging of the brain, are indicated if the diagnosis of an eating disorder is uncertain. Bone density studies such as a DEXA (dual-energy x-ray absorptiometry) scan are not performed routinely except in adolescents with amenorrhea of greater than 6 to 12 months. An upper and lower gastrointestinal series may be warranted in patients with esophageal complaints or if IBD is a strong consideration. The performance of other procedures, however, should be based on the individual case.

Box 133-4. Initial Laboratory Assessment for a Patient with an Eating Disorder

Anorexia Nervosa

- Complete blood cell count, erythrocyte sedimentation rate
- Serum electrolytes (Na, K, Cl, CO₂)
- Blood urea nitrogen/creatinine
- Serum glucose
- Serum calcium, phosphorous, magnesium, zinc
- Serum protein, albumin, cholesterol
- Liver function tests
- Endocrine labs (perform in patients with amenorrhea)
 - Urine pregnancy test
 - Follicle-stimulating hormone
 - Luteinizing hormone
 - Estradiol
 - Thyroid function tests: thyroid-stimulating hormone/T₄/T₃
 - Prolactin
- Urine pH and urinalysis
- Electrocardiogram

Bulimia Nervosa

- Serum electrolytes (Na, K, Cl, CO₂)
- Serum glucose
- Serum calcium, phosphorous, magnesium, zinc
- Blood urea nitrogen/creatinine
- Serum amylase
- Urine pH and urinalysis
- Electrocardiogram

Management

It is the role of primary care practitioners to recognize when inappropriate dieting and weight loss become an obsession for adolescents and when abnormal behaviors develop for maintenance of obvious malnutrition. When treating patients with eating disorders, physicians must first establish trust and, in doing so, patients should be reassured that practitioners are not attempting to remove all control by trying to make the adolescent “fat.” The goal is to create a therapeutic alliance between the clinician, adolescent, and family to restore and maintain the patient’s health and well-being. Depending on the severity of symptoms and the comfort level of the physician in monitoring the early medical, nutritional, and psychological issues, the adolescent may be followed by the primary care practitioner in conjunction with a registered dietitian, family therapist, and mental health professional (psychologist or psychiatrist). Early in the treatment course, the primary physician must be willing to follow the patient frequently (as often as once or twice a week if necessary). If the practitioner wishes to refer the patient to an experienced multidisciplinary team of specialists, it is important that the primary provider remain involved in the care of the teenager.

A consensus must be reached between the adolescent and pediatrician regarding the minimum acceptable weight given the patient’s age, height, pubertal stage, premorbid weight, and previous growth.

This should be done with the assistance of a registered dietitian who is experienced in working with children and teenagers with eating disorders. Unlike with adults, weight restoration in the adolescent also must take into account normal growth needs. An agreement that describes goals of treatment and maintenance of health should then be established between the adolescent and all members of the treatment team. Weight gain must be the initial priority, especially in adolescents with AN as long as the patient is otherwise medically stable and does not require inpatient hospitalization. Details regarding this nutritional regimen, which includes a stepwise increase in daily caloric intake, amounts of protein to be ingested, daily fat intake, and treatment goal weights, should be developed by the dietitian and reviewed with the adolescent and his or her family in conjunction with mental health support and close medical follow-up. Early nutritional rehabilitation and timely medical stabilization are essential to correct the cognitive deficits associated with disordered eating.

Family and individual counseling is an important part of the overall therapeutic plan. Patients with disordered eating often try to hide their illness and generally are in denial regarding their abnormal eating patterns and the degree of weight loss. Parents, too, may be in denial or simply unaware of the extent of their teenager’s condition. The primary care provider must work cooperatively with mental health colleagues to provide the necessary psychological and psychiatric services for their patient. Although extremely difficult, patients must begin to acknowledge their behaviors and accept the need for assistance before effective mental health intervention can occur. This also allows the adolescent to assert himself or herself and remain in control. Support groups also may be beneficial and frequently are an important component of a day-treatment program (day hospitalization, partial hospitalization) for those adolescents with eating disorders who require more intensive outpatient care but not an inpatient hospitalization or residential program. Day-treatment programs are generally less costly and may be more accessible than traditional hospital-based programs.

Pharmacotherapy with agents such as the selective serotonin-reuptake inhibitors (SSRIs) are generally not prescribed in adolescents with AN, except to treat comorbid conditions like depression and anxiety. Several studies have shown, however, that these same medications can be effective in patients with BN by decreasing binge-eating and purging behaviors. Serotonin/norepinephrine-reuptake inhibitors and tricyclic antidepressants are also an option.

Numerous studies have shown that eating disorders are best treated by an interdisciplinary professional team experienced in the care of children and adolescents with eating disorders. This team generally consists of the primary care provider, an adolescent medicine specialist with expertise in caring for patients with eating disorders, a psychologist or psychiatrist, a nutritionist, and a social worker. Ideally, the team is available to offer both inpatient as well as outpatient services, although most cases are managed in an outpatient setting. Criteria for inpatient admission should be established by the team and reviewed with patients and their families.

Medical complications of eating disorders are well established and listed in Box 133-5. Inpatient treatment is required for less than 75%

Box 133-5. Medical Complications of Eating Disorders^a

Associated With Purging Behavior

- Fluid and electrolyte imbalances (from laxative abuse and vomiting)
- Irreversible cardiac muscle damage (from ipecac toxicity)
- Esophagitis, dental erosions, Mallory-Weiss tears (from chronic vomiting)
- Renal stones (from dehydration)
- Amenorrhea, hypoenestrogenemia, osteopenia (from decreased body mass index [BMI])

Associated With Caloric Restrictive Behavior and Weight Loss

- Electrocardiogram abnormalities: low voltage, sinus bradycardia, sinus tachycardia segment depression (from electrolyte abnormalities), prolonged QTc
- Cardiac arrhythmias, including supraventricular beats and ventricular tachycardia, with or without exercise
- Mitral valve prolapse
- Pericardial effusion
- Delayed gastric emptying, slow gastrointestinal motility, constipation, bloating, fullness, abnormal liver function tests (from fatty infiltration of the liver)
- Increased blood urea nitrogen, increased risk of renal stones, total body depletion of sodium and potassium
- Refeeding syndrome (from extracellular shifts of phosphorous)
- Leukopenia, anemia, thrombocytopenia
- Amenorrhea, hypoenestrogenism, osteopenia (from decreased BMI)
- Growth retardation, pubertal delay
- Cognitive deficits
- Cortical atrophy, seizures

^a Modified from American Academy of Pediatrics Committee on Adolescence. Identifying and treating eating disorders. *Pediatrics*. 2003;111:204–211.

ideal body weight, continued weight loss despite intensive outpatient treatment, or a history of rapid weight loss. Refusal to eat or body fat less than 10% also are criteria for hospital admission. Other indications include cardiovascular compromise, such as bradycardia (<50 beats/min during the day or <45 beats/min at nighttime), orthostatic hypotension, or altered mental status; evidence of persistent hypothermia (<35.6 °C [96.08 °F]); suicidal or out-of-control behavior; intractable vomiting; electrolyte disturbances or uncompensated acid-base abnormalities; hematemesis; and significant dehydration as evidenced by systolic blood pressure lower than 90 mm Hg. Cardiac arrhythmias, including prolonged QTc, also require inpatient monitoring. Rarely does confirmation of the diagnosis warrant an inpatient stay. The goal of hospitalization is to correct medical complications, document appropriate weight gain, and establish healthy and safe eating habits. Hospital admission also has been shown to improve the long-term prognosis of children and adolescents with eating disorders.

Prognosis

Overall, the outcome for patients with eating disorders is variable, with the recovery of some patients after minimal intervention and the development of more chronic problems in others. Binge eating, for example, may replace food restriction. Most studies report the prognosis as more favorable if the patient's condition is identified early and treated rapidly and aggressively. Predictors of poor outcome for AN include very low body weight at the time of initial treatment, long duration of illness, a concomitant personality disorder, a dysfunctional parent-child relationship, and a compulsion to exercise. For BN, factors found to be predictive of poor outcome include longer duration of illness at presentation, severity of eating pathology and frequency of vomiting, pre-morbid obesity, associated comorbid disorders such as personality disorder or substance abuse, and suicidal behavior. A family history of alcoholism also has been reported as a poor prognostic factor for BN.

The mortality rate for adolescents with AN is approximately 2%. Higher numbers were reported in the past when adult and adolescent data were combined. Exact figures for BN have not been determined, although it has been quoted as being similar to that of AN. The most common cause of death in both disorders is suicide. Medical causes are often due to cardiac arrhythmias from electrolyte abnormalities.

CASE RESOLUTION

In the case history presented at the beginning of this chapter, the girl does not meet the strict criteria for the diagnosis of AN, but her preoccupation with dieting and weight is worrisome. Concerns about her eating and dieting behaviors should be discussed with the teenager alone and then together with her family. Both the patient and her family should be strongly encouraged to seek treatment. She should be referred to a mental health professional and nutritionist for further evaluation, with the emphasis on healthy eating and the continued support and involvement of the primary care physician. She should be followed frequently until her weight and eating behaviors have reached the mutually agreed upon goal among all professionals involved in her care, after which she should continue to be seen at regular intervals.

Body Modification: Tattooing and Body Piercing

Monica Sifuentes, MD

CASE STUDY

A 16-year-old girl comes to your office for her annual physical examination. Although previously healthy, the mother is concerned that her daughter seems irritable and unwilling to participate in recent family events. The adolescent is currently in 10th grade at a local public school, gets As and Bs in most subjects, is a member of the volleyball team, and has just begun working at a movie theater part-time. Both of her parents are employed and the adolescent gets along well with her 19-year-old sister, who is currently in college, and her 14-year-old brother. She has many friends in the neighborhood as well as at school.

You interview the adolescent alone and learn that she occasionally smokes marijuana, has tried cocaine on one occasion, and attends parties where many people are drinking alcohol. She has been sexually active in the past but is not currently. She denies depression and describes her mood as generally happy, except when she is forced to spend what she believes is excessive time with her family instead of friends.

On physical examination the adolescent's height and weight are in the 50th percentile for age. Her body mass index is 21. Vital signs are normal. You note a small tattoo at her right hip area. The girl's mother is unaware of its presence according to the teen. She obtained it a few months prior while visiting her sister in college.

Questions

1. What is the epidemiology of body modification in adolescents and young adults?
2. What is the motivation for obtaining tattoos and body piercing in this age group, and is there an association with high-risk behavior?
3. What techniques are used to place tattoos and perform body piercing?
4. What adverse consequences can be seen following body modification, and what should be done to treat them?
5. How can the primary care provider assist an adolescent to make a safe and healthy decision regarding body modification?

Body modification is the practice of permanently altering one's appearance and historically has been practiced in many cultures for thousands of years. This includes tattooing, body piercing, scarification, and branding. Although much less common than tattooing and body piercing, scarification is the use of various techniques to produce scars on the skin. It is described as a more "intense" form of body modification and has been reported to be more appealing to darker pigmented individuals or those seeking a more dramatic result. The practice of body modification should be differentiated from "cutting," which is a disorder of self-mutilation that can be seen in adolescents suffering from anxiety, depression, or abuse and is beyond the scope of this discussion (see Chapter 50).

Although in the past body modification has been associated primarily with the disenfranchised such as criminals, gang members, or psychiatric patients, it is now a common occurrence in mainstream society. **Body art** is seen in most clinical settings serving youth and young adults as well as in middle schools, high schools, and on college campuses. Additionally, it is not uncommon to encounter a

teenager with multiple tattoos and body piercings or to evaluate an adolescent for a possible complication of the procedure. Whether described as a rite of passage, expression of their own individuality, or desire to join a particular peer group, obtaining a tattoo or body piercing has become a widespread experience during adolescence and young adulthood and therefore should be added to the primary care provider's list of issues to review during the routine health maintenance visit.

Epidemiology

It is currently estimated that 13% to 25% of the general population has a tattoo in the United States. However, because tattooing was reportedly the sixth fastest-growing retail business in 1996, these figures are probably a gross underestimation. Surveys conducted in outpatient clinics and on school and college campuses confirm that approximately 10% to 13% of teens ages 12 to 18 years have a tattoo. In one particular study of more than 2,000 US high school students, 55% expressed interest in obtaining a tattoo regardless of its

permanence or the students' academic success in school. In addition, it has been reported in the literature that half of new tattoos are in women and that many are obtained while in college.

Body piercings are more common in adolescents and young adults, and some experts speculate that this may be because the procedure is not permanent, allowing the individual to remove the jewelry at any time. In one study among college students, 45% had undergone body piercing and 22% had tattoos both with and without piercings. Other studies that include younger adolescents attending an outpatient adolescent clinic report approximately 27% of teens with body piercing and 13% with a tattoo.

The motivation for obtaining body art also has been reviewed in the literature, with most studies confirming the adolescent's search for uniqueness and desire to enhance their independence and self-identity. For some teenagers, it is seen as a form of decoration or it fulfills a desire for peer acceptance and can solidify group membership. Tattoos in particular can be seen as a quest to permanently document a relationship with an individual or group. Despite popular belief, studies do not confirm that most adolescents obtain a tattoo or body piercing impulsively while under the influence of illicit drugs or alcohol. In fact, many older teens and young adults report taking quite a while to decide whether to obtain a tattoo or piercing.

Parental involvement and permission to have a tattoo placed or body piercing performed is variable for many teenagers. In most cases, parents are not consulted prior to the procedure, although in many states parental consent is required by law, and tattooing of minors is prohibited. However, current legislation is not consistently enforced and, in many states, tattooing and body piercing have different regulations.

Clinical Presentation

Tattoos can be found on any area of the body and, depending on the talent of the artist and the desire of the client, can be simple and one color or very elaborate with many colors. In general, amateur tattoos are less intricate and are considered more risky because they are often not performed under ideal circumstances, following antiseptic techniques or with conventional pigments and applicators. Unconventional pigments include charcoal, India ink, and mascara. Pencils, pens, sewing needles, and other sharp objects, including guitar strings, may be used to apply the dye for a self-administered tattoo.

The most common site for piercing is high on the pinna of the ear. Regular lobular ear piercings are not generally included in the context of body modification because they occur commonly at any age. Other body sites that are pierced include the tragus of the ear, eyebrows, tongue, nose, nasal septum, lip, navel, and nipples. Intimate or genital piercings also can be seen in both males and females. The foreskin, penis, scrotum, clitoris, perineum, and labia are all common areas for intimate piercings. Although specific data by gender are not available, it is reported that more men than women tend to obtain genital piercings.

Technique, Application, and Safety Standards

Tattoos

The process for applying a professional or commercial tattoo is fairly standardized, although different tattoo parlors may have their own individual practices. In general, the client selects a design and the tattoo is stenciled or drawn on the skin. The skin is then cleansed with an antiseptic solution, and petroleum jelly is placed on the site. Most professionals use an electric tattoo gun, which is similar to a dental drill, that holds one or several needles in a needle bar that punctures the skin a few millimeters deep and up to several thousand times a minute. The pigment reaches the level of the dermis via the solid bore needle(s), and blood and serosanguineous fluid are wiped away as tattoo placement continues. When the tattoo is completed or the session is finished, an antiseptic ointment is applied, and a bandage is placed over the site.

The client is instructed to remove the dressing in 24 hours and to keep the area moist with an antibiotic ointment. Additionally, clients may place Keri lotion or vitamin E oil over the healing tattoo several times a day. The area should be cleansed with a mild soap and patted dry (not rubbed). If aftercare instructions are followed carefully, most tattoos heal in approximately 1 to 2 weeks.

Ideally the application process uses inks that are poured into one-time use disposable containers and needles that are disposed of after each client. However, although the pigments are subject to US Food and Drug Administration regulation, the tattooing process itself and the use of the inks are not regulated. In addition, certain pigments may not be approved for intradermal use and have been known to contain lead, mercury, and arsenic.

The practice of universal precautions is required by state and local regulatory agencies and advocated by specific educational groups such as the Alliance of Professional Tattooists (APT), a nonprofit organization established in 1992 to promote standards for professional and associate tattooists and develop guidelines for consumers to evaluate the safety of a tattooist. Membership in APT is voluntary and requires that the professional tattooist participate in a health and safety seminar and have at least 3 years of full-time experience at a consistent location. Despite these efforts and standards, however, specific areas of concern regarding the tattoo industry remain and include unlicensed tattoo artists and establishments, the presence of unregulated ingredients in the pigments, inconsistent cleaning of equipment between clients, an inability to reliably sterilize all parts of the equipment despite good efforts, and infrequent inspections of tattoo parlors by regulatory agencies.

Body Piercing

The process for body piercing is generally less complicated than tattooing and depends, in part, on the site to be pierced. The client chooses the jewelry and body part to be pierced, the area is cleaned with a topical antiseptic, and a large hollow needle is brought through

the skin. The jewelry is then brought through the hole following the needle and sealed with a bead, bar, or metal disc. Because the procedure is relatively quick, topical anesthetics are usually not required.

While earlobe piercings are relatively straightforward, they are commonly performed using a “piercing gun” at a local mall, cosmetic shop, or kiosk. Because the stud is driven through the earlobe via the gun rather than through a hollow tube manually, the tissue ends up torn rather than pierced. Additional concerns regarding the piercing gun include inconsistent and informal training of personnel, an inability to sterilize all parts of the gun, and embedded earrings and ear backs. The gun cannot be adjusted for the thickness of other tissues, so although it is a popular method for earring placement, this tool is not recommended for sites other than the earlobe.

The immediate aftercare of piercing varies by the site pierced. For example, local skin discoloration and a non-malodorous serous exudate can occur with piercings of the nares or navel. Tongue or lip piercings have been associated with significant swelling for several days following the procedure. In addition, a yellow-white fluid secretion can occur that can mimic an infection to the unfamiliar examiner. Clients with oral piercings are generally instructed to dissolve ice in their mouths immediately post-piercing to help with pain and swelling, treat further discomfort with a nonsteroidal anti-inflammatory agent, and elevate the head when sleeping.

Healing times greatly vary depending on the body site. In general, sites with greater vascularity and exposure, such as the face and tongue, tend to heal faster than those through cartilage, which is poorly vascularized. Areas of the body that are subject to movement also have slower healing times. For example, the tongue may take 1 to 2 months to heal, the nasal septum 2 to 3 months, and the tragus of the ear 3 to 4 months. High-ear piercings through the cartilage also can take 3 to 4 months to heal. Navel piercings have the longest healing time (up to 12 months) because of friction and moisture from clothing and often are associated with the most complications.

As with tattooing, not all states have regulations and safety standards in place for body piercing and, if they do exist, local governing bodies do not consistently enforce them. Universal precautions should be strictly practiced, and adolescents need to be familiar with these guidelines as well as know how to find a reputable piercer prior to obtaining body art.

Because no formal training programs exist for piercers, many learn by video or apprenticeship. In general, practitioners in studios have completed an apprenticeship and have more training than those in cosmetic shops, malls, or ear-piercing kiosks. They also are more experienced in piercing sites other than the ears and may be a member of the Association of Professional Piercers (APP). The APP is a nonprofit organization dedicated to the education, health, and safety of body piercing for the public. It has developed self-regulatory policies for the industry, standards for membership in their organization, and annual conferences on health and safety issues. Membership includes at least 1 year of piercing experience, documented training in blood-borne pathogens and cardiopulmonary resuscitation, and certification in first aid. Members also must show

photographic proof of a medical-grade autoclave in the piercing studio and send in spore test results from the autoclave. To help document this, a detailed video of the studio is required along with copies of all aftercare education given to clients. Once this process is completed, the member receives a certificate to mount in the studio.

Current legislation regarding minors and piercing is regulated by individual states, and in some states, such as California, there is an exclusion of ear piercing performed with “piercing guns” from the definition of body piercing. With regard to minors, the APP requires that the parent or legal guardian as well as the minor show proof of identification prior to signing the consent form for body piercing. In addition, nipple or genital piercings are not performed on anyone younger than 18 years.

Evaluation

History

All teenagers should be interviewed alone, after their parent or legal guardian has had an opportunity to discuss their concerns with the health care provider (see Chapter 6). A visible tattoo or body piercing allows the health care provider to inquire about the circumstances surrounding the body art at the beginning of the interview in contrast to body art noted in an inconspicuous area of the body during the physical examination. Whether parental consent was obtained prior to the procedure should be addressed directly because this issue could be a basis for familial conflict both currently and in the future. The type of facility where the tattoo or piercing was obtained should be reviewed, along with whether universal precautions were followed. A general review of systems should be performed to exclude systemic conditions such as viral hepatitis as well as any other complications related to obtaining the tattoo or piercing. Specific questions about the area of the body that has been pierced also should be reviewed (Questions Box). For example, the teenager with a tongue piercing should be asked if he or she has problems with mastication, swallowing, loss of taste or movement, or permanent numbness.

It has been reported that amateur or self-administered tattoos are associated with increased psychosocial problems including substance abuse at a younger age, hard drug use, lower academic achievement (ie, grades), and a greater number of tattoos overall.

Other studies have shown, however, that not all adolescents and young adults with tattoos or body piercing engage in high-risk behavior (Box 134-1). Successful academic achievement and close family support have been reported in both tattooed and non-tattooed college students. Despite the fact that they are permanent, more than 50% of academically successful high school students with consistently good grades have reported an interest in tattoos.

Whether body art is seen as an expression of individuality, rebellious behavior, or succumbing to peer pressure, the presence of a tattoo or body piercing on an adolescent probably warrants an in-depth psychosocial assessment for both risk-taking behavior and possible exposure to a viral infection such as hepatitis C.

Questions

Tattoo and Body Piercing

- When was the tattoo or body piercing obtained?
- Did the teenager obtain the parent or legal guardian's consent prior to obtaining the tattoo or piercing?
- Is the adolescent satisfied with the tattoo or piercing?
- Was the tattoo or body piercing placed by a professional?
- Where was the studio located? Was it licensed? Was it clean "like a medical facility"?
- Did the tattooist or piercer wash their hands before gloving? Use new disposable gloves? Open all equipment in front of the teen?
- For tattoos, did the tattooist remove a sterile needle and tube set from a new envelope? Did he or she pour new ink in a new disposable container?
- For body piercing, did the piercer use individually wrapped sterile needles? Did he or she use a method not involving a piercing gun?
- Did the teen receive aftercare education, including written material?

Physical Examination

The routine physical examination in most adolescents with a tattoo or body piercing is completely normal unless there has been a past complication with the tattoo or piercing or there is a current problem. Poor aftercare and hygiene can prolong healing time in body piercings. In addition, smoking can delay the healing time associated with oral piercings. If the teen has recently had a tongue piercing performed, a larger barbell will be seen through the tongue. Larger barbells initially are placed with tongue piercing to accommodate the swelling associated with the procedure. Later the barbell is replaced with a shorter rod.

Both infectious and noninfectious complications from tattoos and body piercings can be seen and are listed in Box 134-2. While local infection occurs in only approximately 5% of tattoos, infectious complications have been reported in as many as 30% of body piercings. Signs of infection include erythema, warmth, swelling, and pain at the site, in addition to drainage in some cases. Rarely, a fluctuant, fluid-filled mass is seen if an abscess has developed.

Because some of the noninfectious complications can be related to the type of metal found in the jewelry, knowledge of this specific information is useful with body piercing. Only jewelry made from surgical stainless steel, titanium, solid 14k or 18k gold, or solid platinum should be used to avoid allergic dermatitis. Certain metals such as nickel, cobalt, and chromium have been associated with the development of contact dermatitis in sensitive individuals. Permanent makeup also has been reported to cause severe allergic contact dermatitis that can take from months to years to completely heal. The reported reactions included tenderness, itching, and "bumps" at the site of the permanent makeup application. Hypersensitivities to dyes or pigments from a professional tattoo also can appear as an

Box 134-1. The Association Between Body Modification and High-Risk Behavior in Teens

Numerous studies have been conducted to explore the association between high-risk behavior and body modification in adolescents. To date, while there are no definitive answers, research has shown

- Adolescents with tattoos and/or body piercings were more likely to have engaged in risk-taking behaviors and at greater degrees of involvement than those without either. Risk-taking behaviors included disordered eating behavior, gateway drug use (cigarettes, alcohol, and marijuana), hard drug use (cocaine, crystal methamphetamine, and ecstasy), sexual activity, and suicide. Additionally, violence was associated with males having tattoos and with females having body piercings. Gateway drug use was associated with younger age of both tattooing and body piercing. (Carroll ST, Riffenburgh RH, Roberts TA, Myhre EB. Tattoos and body piercings as indicators of adolescent risk-taking behaviors. *Pediatrics*. 2002;109:1021–1028.)
- Adolescents with body modification had 3.1 times greater odds of problem substance use compared with those without body modification. (Brooks TL, Woods ER, Knight JR, Shrier LA. Body modification and substance use in adolescents: is there a link? *J Adolesc Health*. 2003;32:44–49.)
- Tattooing was significantly associated with older age, living in a single-parent household, and lower socioeconomic status. There also was greater involvement in sexual intercourse; higher levels of substance abuse in themselves as well as their peers, increased violent behaviors, and school problems. (Roberts TA, Ryan SA. Tattooing and high-risk behavior in adolescents. *Pediatrics*. 2002;110:1058–1063.)
- A correlation between body piercing in teens and increased rate of sexual intercourse, smoking, marijuana use, school truancy, running away, suicidal ideation/attempts, and peer substance use. (Armstrong ML, Roberts AE, Owen DC, Koch JR. Contemporary college students and body piercing. *J Adolesc Health*. 2004;35:58–61.)

erythematous outline of the original work. This also can occur with temporary tattoos from henna, which is approved as a hair dye and not for use on the skin. Its use has been associated with severe contact dermatitis, especially if an additive containing phenylenediamine is mixed with the henna to give the normal red-brown paste an additional black and blue color.

Keloids and hypertrophic scars can appear as a flesh-colored mass at the area of the tattoo or piercing and differ in their timing and resolution. A hypertrophic scar generally appears within 6 weeks of the tattooing or piercing, is confined to the margins of the wound, and has a tendency to regress spontaneously. In contrast, a keloid may present as long as 1 year after the initial wound, often grows beyond the border of the wound, and persists. Keloids are seen primarily in African American and Asian patients and can cause an itching or burning sensation that may prompt referral for removal.

Box 134-2. Complications of Tattoos and Body Piercing: Infectious and Noninfectious**Tattooing Complications****Infectious***Bacterial etiologies*

- Local skin infections
 - Superficial pyodermas
 - *Staphylococcus aureus*
- Systemic infections
 - Syphilis
 - *Mycobacterium tuberculosis*
 - *Mycobacterium leprae*
 - Chancroid
 - Tetanus
 - Endocarditis

Viral etiologies

- Human papillomavirus
- Hepatitis B and C
- HIV

Noninfectious

- Hypersensitivity to dyes or pigments
- Allergic granulomas
- Malignant melanoma and basal cell carcinoma at tattoo site
- Keloid formation
- Swelling and burning during magnetic resonance imaging

Body Piercing Complications**Infectious***Bacterial etiologies*

- *S aureus*
- *Pseudomonas aeruginosa*
- Group A beta-hemolytic streptococcus
 - Cellulitis
 - Septic arthritis
 - Acute glomerulonephritis
 - Erysipelas
 - Endocarditis
- *M tuberculosis*
- *Clostridium tetani*

Viral etiologies

- Hepatitis B and C
- HIV

Noninfectious*Body jewelry, in general*

- Artifact on radiographs

High-ear piercing

- Pinna deformity

Tongue piercing

- Airway obstruction
- Chipped/cracked teeth
- Interference with mastication/swallowing
- Permanent numbness
- Articulation disorders
- Loss of taste/movement
- Oral mucosa inflammation

Lip piercing

- Injury to salivary ducts
- Aspiration of jewelry

Navel piercing

- Allergic dermatitis

Nipple piercing

- Trauma/avulsion of nipple

Genital piercing

- Tissue inflammation in sexual partner
- Scarring
- Interruption of urinary flow (in males)

Laboratory

In general, laboratory studies are not necessary if the adolescent is not engaged in high-risk behavior and is certain that universal precautions were followed when the tattoo or piercing was placed. In most cases, however, the teen may be uncertain and not remember the details. If this is the case, a serum test for viral hepatitis B and C should be obtained because it has been reported that hepatitis C virus is found in approximately 30% of people with tattoos compared with 3.5% of people without them. Additionally, an antibody test for

HIV should be sent as it continues to be a major public health concern with regard to the industry. However, there have been no definitive documented cases of HIV transmission from tattooing or body piercing in the literature to date.

A serum test for syphilis also should be sent because unlike HIV, transmission of this and other sexually transmitted infections has been reported from tattooing or piercing.

If there is evidence of abscess formation such as what may be seen with perichondritis, a specimen of the purulent fluid should be obtained and sent for culture and antimicrobial sensitivities.

Management

Although not ordinarily requested by most adolescents, tattoo removal or modification is available for the patient that no longer wants their tattoo or is unhappy with its current appearance. Even with the newer techniques, however, tattoo removal is difficult, and only about 70% of tattoos can be completely cleared because of impurities in tattoo pigments, different ink densities and depths, and the presence of certain metals in the dyes. More importantly, the cost for tattoo removal is not negligible; while the cost for tattoo placement might be \$50 to \$100, it can cost as much as \$1,000 for its removal. Techniques for removal include laser treatments, dermabrasion, salabrasion (using a salt solution), scarification, and surgical removal using tissue expanders. Camouflaging also can be performed: a new pattern is made using skin-toned pigments or the tattoo is modified and made into another one. For instance, the name of a person can be incorporated into a new tattoo of an animal. Certain nonprofit organizations also offer tattoo removal to ex-gang members as a part of their employment and educational services.

Although it seems counterintuitive, removal of jewelry is not recommended if a piercing appears infected. The concern is that, without a wick or surgical drain, any potential space left at the site when the jewelry is removed could result in the development of an abscess. Instead, the adolescent should be instructed to leave the jewelry in place to allow drainage of the wound, use warm compresses, and clean the area with an antimicrobial soap and water. The use of topical antibiotic ointments is controversial because they can be occlusive and contribute to delayed healing.

Oral antibiotic coverage against skin staphylococcus and streptococcal species should be administered if the tattoo or piercing appears superficially infected and other measures have not been effective. More aggressive treatment is required if the piercing site involves the cartilage such as with high-ear piercings. Auricular infections can occur even after the use of strict antiseptic techniques and may appear a few weeks after the initial piercing. The cartilaginous helical area of the ear is particularly prone to infection because it is poorly vascularized and takes a long time to heal. Additional antimicrobial coverage against *Pseudomonas aeruginosa* is essential in these cases, along with diligent follow-up to monitor the initial response to oral antibiotic therapy. Currently, oral fluoroquinolones offer good anti-pseudomonal as well as anti-staphylococcal coverage and penetrate cartilage well. Inpatient hospitalization for intravenous antimicrobial therapy and subsequent drainage of the site may be required for moderate or unresponsive infections. Early recognition of perichondritis and its appropriate treatment are essential to prevent the development of a persistent infection as well as to minimize a permanent auricular deformity. In addition, timely consultation with a plastic surgeon or otolaryngologist early in the course of the suspected infection is recommended for early incision and drainage of a perichondrial abscess, appropriate wound care, and possible reconstruction of any disfigurement.

Role of the Primary Care Provider

For the adolescent who has not yet obtained a tattoo or piercing, or who already has one and is contemplating the placement of another, education is essential. The practitioner should inquire where the adolescent plans to have the procedure performed and educate them regarding what key questions to ask and how to find a reputable studio. Additional information such as the APT and APP Web sites should be shared with the teenager, and written materials that contain the safety guidelines should be given to the adolescent at the visit. Teenagers are often reluctant to ask their health care providers for information about obtaining tattoos and piercings and almost never contact them if they believe they may have a complication associated with tattooing or piercing. Instead, they tend to ask their peers or contact the establishment where the tattoo or piercing was initially placed. Primary care providers should be a nonjudgmental resource during health maintenance visits to ensure the adolescent's continued health and safety. Additionally, the appearance of an uncommon medical condition such as unexplained hepatitis, endocarditis, or toxic shock in the adolescent patient warrants careful consideration of a possible complication related to tattooing or body piercing.

Prognosis

Most teens experience no adverse effects from body modification. Complications, while uncommon, are usually amenable to medical management. Risk-taking behavior that may occur in conjunction with body modification may carry long-term sequelae.

CASE RESOLUTION

Because the presence of one tattoo puts this adolescent at risk for obtaining another, the primary care provider should review safety guidelines for obtaining a tattoo and body piercing with the adolescent and offer the teenager educational material and/or Web site references to reinforce the discussion. The immunization status of the teenager also should be checked, with particular attention to tetanus and hepatitis A and B. Additionally, while alone with the teenager, the provider should review their concern regarding the adolescent's current high-risk behavior and its possible consequences. It also may be worthwhile to begin a discussion with the teen about telling her parents about the tattoo before they find out inadvertently.

Childhood Obesity

H. Mollie Greves Grow, MD, MPH, and Lenna Liu, MD, MPH

CASE STUDY

A 10-year-old girl is brought to your office by her mother to discuss concerns about the child's weight, which is 59 kg (130 lb). Her height is 140 cm (55 in), giving her a body mass index (BMI) of 30 kg/m² (>95th percentile for age). The rest of the physical examination, including vital signs, is normal. The mother, who also is overweight, says she doesn't want her daughter to "end up like me." The patient says she gets teased at school for being "fat". The history reveals that this patient is an only child who lives with her single mother in low-income housing in a large urban city. The mother works the day shift as a nurse's aide at a nearby nursing home. Because the mother is often tired, meals are simple and frequently consist of prepackaged foods such as pastries for breakfast and frozen dinners for supper. At school, the girl buys her lunch, which usually

includes whole milk, a processed entrée, and a dessert. After school, the girl goes home, where she watches television and snacks on chips and soda until her mother arrives home from work. The mother does not allow her daughter to play outside because the neighborhood is unsafe.

Questions

1. How is obesity defined and measured, and what are some pitfalls in measurement?
2. How do genetic susceptibility and environment interact to influence a person's risk for obesity?
3. What are the complications of obesity?
4. What is the role of primary care providers in addressing childhood obesity?
5. How can obesity be treated?

Childhood obesity is of significant concern because overweight children are more likely to become overweight adults and are at increased risk for multiple chronic conditions. In addition, being obese carries a tremendous psychosocial toll for affected adults and children, as it remains one of the most stigmatized conditions. Obese children are often shunned by peers at school, feel isolated, and have fewer friends, while obese adolescents complete less schooling, go on to have lower household incomes, and are more likely to live in poverty than their non-obese counterparts. The primary care provider is usually the first (and frequently only) resource available to families to help screen for, inform about, and initiate treatment for childhood obesity.

Defining obesity presents certain challenges. Ideally, a measure of obesity would correlate with adiposity and predict morbidity and mortality. Body mass index (weight in kilograms/[height in meters]²) is the best and most widely used surrogate measure for obesity, but does not completely correlate with adiposity for all individuals. Standards for adults have established a BMI of 25 or greater as overweight and 30 or greater as obese, based on increased risk of morbidity and mortality above these levels. While BMI is the current preferred method for assessing degree of obesity in children, other criteria are also used (Dx Box). Experts classify children at 85% to 95% of BMI-for-age as **overweight** and those greater than 95% of BMI-for-age as **obese**. Since BMI is not a direct measure of adiposity, it is important to recognize that children who meet the BMI criteria for overweight and obesity will not all have adverse health effects of their weight status. A general helpful rule of thumb is that the higher the

BMI goes above the 95th percentile, the greater likelihood of adverse health effects. The BMI category with the most rapid increase in risk for adverse health affects is BMI above the 99th percentile, which is associated with the most comorbidities (at that point switching to a BMI number, like adults, is often used). The BMI changes as children grow older due to changes in their proportion of bone mass and lean-to-fat tissue composition. After about 1 year of age, BMI-for-age values begin to decline and continue to do so during the preschool years until the BMI reaches a minimum around 5 to 6 years of age, before rising throughout the remainder of childhood, into adolescence and adulthood. This phenomenon of increasing BMI after the nadir in the preschool years is referred to as **adiposity rebound**. Early adiposity rebound (age <4.8) is a predictor of later obesity, and can be used clinically to identify children at risk.

Dx Obesity

- Body mass index \geq 95th percentile for age (\geq 85 percentile = overweight)
- Weight-for-height \geq 95 percentile
- >120% of ideal body weight for height and age

Epidemiology

The prevalence of obesity is on the rise in developed countries. Between 1980 and 2000, the percentage of overweight children and adolescents in the United States tripled, reaching 17.1% in 2003 to

2004. Since then, no significant increases have been seen overall among the US youth population, except for increases in the highest BMI group (>97th percentile). Hispanics, African Americans, and Native Americans are disproportionately affected. Prevention and treatment of obesity is important to avoid health risks that affect the individual and are costly to society as a whole. In the United States, the overall spending associated with overweight and obesity was \$93 billion in 2002 dollars, half of which was publicly financed through Medicare or Medicaid.

Clinical Presentation

Obese children usually present to the physician in 1 of 2 ways. The parents or the child may come in concerned that the child is overweight. The physician must then consider the growth parameters and BMI-for-age to make an appropriate determination of the child's overweight status. The more common presentation involves parents who do not recognize that their child is overweight, and in fact may believe that being "pudgy" is a sign of health. The lack of awareness of their child's risk may particularly affect parents during the time of the adiposity nadir (ie, the preschool and early school age years), when early intervention to improve energy balance might yield the most benefit. Measurement of the child's height and weight and determination of the BMI-for-age is important at all ages to identify children who are overweight or obese, or gaining weight more rapidly than expected; it is especially critical during early childhood when outward appearances may be most unreliable. Seeing change in percentiles is particularly helpful to differentiate children who may be healthy and who grow steadily along a higher BMI curve, such as those 5% at the 95th percentile who are naturally in the high BMI range but are not actually "overfat."

Pathophysiology

Our understanding of the pathophysiology of obesity continues to evolve. Certain neurohormones affect appetite, satiety, and the balance between fat storage and energy production. In the end, obesity results when energy intake exceeds expenditure. The storage of excess calories was an advantage to our ancestors who faced intermittent food shortage; however, in our current setting where the environment provides highly palatable, convenient foods that are high in calories (but low in nutrients) and opportunities for physical activity are more limited, this predisposition to store excess calories has contributed to increasing rates of obesity.

It is known from twin and other studies that susceptibility to obesity is influenced substantially by **genetics**. Yet the magnitude of recent increases in obesity rates suggests the genetic susceptibility interacts with an "**obesogenic**" environment that facilitates unhealthy behaviors. National surveys indicate that Americans are consuming more calories now than they were 35 years ago. This trend is most related to increasingly widespread and easily available calorically dense foods in larger portions than ever before. A smaller but also important contribution of the population weight gain comes

from less physical activity and more sedentary lifestyles. The reasons for this are myriad and include changes in transportation patterns, shifts in the workforce to less manual jobs, and automation of household work. Children have decreased opportunities for activity owing to safety concerns; parental work habits; the availability of television, computers, and other electronic toys; and reduced availability of physical education in school and after-school programs.

Differential Diagnosis

Most children who present to physicians as overweight have primary obesity (resulting from excessive caloric intake and low activity levels). Only a small proportion of overweight children will have an organic cause, although many parents may initially inquire about an organic etiology. A thorough history including review of systems, physical examination, and evaluation of growth parameters will help differentiate primary from organic obesity in most cases. While children with primary obesity tend to have normal or increased height-for-age, children with an organic etiology, such as hypothyroidism, are typically shorter than normal or have a delayed rate of linear growth. Certain genetic syndromes, such as Prader-Willi syndrome, pseudohypoparathyroidism, and Laurence-Moon-Biedl syndrome, are associated with obesity. However, children with these syndromes have other findings, such as developmental delay, dysmorphic features, and short stature, which are usually identifiable during the physical examination. While there may not be an organic cause of weight gain initially, there is evidence that weight gain can be exacerbated by acquired diagnoses, such as sleep apnea, that develop as complications of obesity.

Evaluation

History

The history should include the age of the child, parental weight, and lifestyle information (Questions Box). Knowledge of a child's birth weight and gestational age may be helpful. Full-term babies weighing more than 9 lbs are at increased risk of obesity. Prematurity is also a risk factor for subsequent obesity, possibly related to early metabolic effects of rapid "catch-up" weight gain after birth. Breastfeeding has been found to be somewhat protective against obesity in many epidemiological observational studies. A diet history, such as the 24-hour recall method or alternatively use of screening questions filled out by the parent in the waiting room, can be helpful to understand the dietary factors contributing to the child's overweight status as well as to identify areas for potential change. In addition, a history of signs or symptoms of complications of obesity should be elicited. For example, a teen may complain of hip pain suggestive of a slipped capital femoral epiphyses (SCFE). There may be a history of snoring, or apneic pauses followed by gasping for breath during sleep, and daytime sleepiness indicating sleep-disordered breathing and necessitating further evaluation for obstructive sleep apnea (OSA). A history of irregular menstrual periods is useful in the evaluation for polycystic ovary syndrome (PCOS).

Questions

Obesity

Open-ended questions to engage (lifestyle and family changes rather than targeting the child)

- How concerned is the parent/child about the child's weight?
- How has current weight affected their life (eg, teasing, difficulty exercising or with sleep)?
- What is the parent/family already doing to help the family with healthy eating and activity?
- Specific probes to learn more about the child's usual daily activities and home environment
 - Who cares for the child during the day? (Home-based child care provided by grandparents or other family members is associated with increased risk of overweight.)
 - How often does the child get to be physically active (ie, recess, physical education class, after school, on weekends)?
 - Where are there opportunities to add more activity (ie, to or from school, on weekends, playing sports or recreation, with parents)?
 - How much time does the child spend watching TV, playing video games, or using the computer?
 - On a typical day, starting first thing in the morning, what does the child eat?
 - How often does the family go to fast-food restaurants or go out to eat?
 - Who does the shopping and food preparation? Are there financial, time limitations?
 - What kitchen facilities are available at home?

Questions to set a mutual agenda

- What are some things the parent/family would like to change for healthier eating and activity?
- Who might support the parent/family in making changes?

Some additional questions for older children/adolescents include

- Has the child tried to lose weight before? How?
- Is the child/teen depressed?
- Has the child/teen participated in fad dieting? Fasting? Laxative use? Diuretic use?
- Has the child/teen used drugs to lose weight (illicit, over the counter, or prescription)?
- Has the child/teen used nutritional supplements for weight loss?
- Has the child/teen ever binged? Purged?
- Does the child/teen use tobacco? Alcohol?

Physical Examination

The accurate measurement of height and weight using appropriate equipment and plotting growth parameters on a BMI chart should be essential components of every well-child visit. The revised 2000 growth curves (developed by the US National Center for Health Statistics and available at www.cdc.gov/growthcharts) enable the physician and other health providers to evaluate BMI-for-age (for children ≥ 2 years) relative to other children of the same gender. Prior to age 2 years, the clinician should use the World Health Organization weight-for-length curves (see Centers for Disease

Control and Prevention Web site at www.cdc.gov) to assess proportional growth. Children should also be examined for any dysmorphic features suggestive of an underlying genetic syndrome.

The clinician should assess for potential complications of obesity when examining the overweight child. While many complications of obesity do not manifest until adulthood, overweight children are at risk for a number of conditions, including hypertension, hyperlipidemia, type 2 diabetes, nonalcoholic fatty liver disease, OSA, and orthopedic problems such as Blount disease and SCFE. One-third to one-half of obese children will have evidence of **metabolic syndrome**, a cluster of traits that include hyperinsulinemia, obesity, hypertension, and hyperlipidemia. The higher the BMI-for-age, the greater the risk that the child or teen will have metabolic complications. Blood pressure should be accurately measured with an appropriate-sized cuff (larger cuffs are needed for overweight youth) and compared with age-based standards. The physician should be alert for additional physical findings. The skin should be examined for striae and acanthosis nigricans, the velvety pigmented lesion commonly found on the neck or axilla, which is associated with insulin resistance in overweight children. Skin findings of hirsutism and acne in obese adolescent girls may indicate the presence of PCOS. The musculoskeletal examination should assess for Blount disease (severe tibial bowing), SCFE, or other degenerative joint diseases. Tanner stage should be assessed for evidence of premature puberty.

Laboratory Tests

If a genetic condition is suspected, an evaluation by a geneticist is indicated and high-resolution karyotype and other genetic tests, as directed by the suspected syndrome may be considered. For the rare cases in which an underlying endocrinologic disorder is suspected, thyroid function studies and/or cortisol levels may be considered. Laboratory studies to evaluate for potential complications of obesity are recommended starting at age 10 years, or before if there are specific concerns such as severe obesity (eg, >99 th percentile BMI-for-age), or a strong family history of type 2 diabetes or hyperlipidemia. Children age 10 years and above with a BMI above the 95th percentile (and for those above the 85th percentile with family or other risk factors), are recommended to have fasting glucose and a fasting lipid panel. Some experts also recommend checking liver enzymes and fasting insulin levels. If the fasting glucose is abnormal, a glucose tolerance test is indicated. Children with a history of sleep-disordered breathing should be referred for a sleep study. Higher rates of nutritional deficiencies reported among overweight youth have included vitamin D, calcium, and iron, so screening for these should be considered based on dietary history and other risk factors.

Imaging Studies

Radiologic studies are indicated when orthopedic complications of obesity such as Blount disease or SCFE are suspected. An echocardiogram for evaluation of ventricular hypertrophy is a consideration in children with long-standing hypertension (left ventricle may be affected) or OSA (right ventricle may be affected).

Management

Since not all children who are obese will go on to be obese adults, a **staged approach** is now recommended in treating childhood obesity. The pediatrician's first task is to help prevent obesity through identifying risk and using patient-directed counseling to promote healthy target behaviors (and avoid unhealthy ones). Risk is largely determined by the child's age and history of parental obesity; however, race/ethnicity may also play a role. Obese children younger than 3 years without obese parents are at low risk for future obesity. These children should be monitored but, for the most part, do not require intervention. Between the ages of 3 and 5 years, parental obesity substantially increases the risk of a child becoming an obese adult. The chance of adult obesity in an obese preschooler with at least one obese parent is above 60%. In older children, the child's own obesity is an increasingly important predictor of adult obesity, regardless of whether the parents are obese. The probability that an overweight child older than 6 years will be obese as an adult is 50%, regardless of parental obesity status. Children determined to be at high risk for future obesity require close surveillance and intervention by the clinician.

Once a child has been identified as overweight, the **recommended stages of obesity treatment** are

- Stage 1 "Prevention Plus:" Initial treatment in the primary care office focuses on behavioral strategies for eating and activity changes to address causes of energy imbalance.
- Stage 2 (if no improvement within 3–6 months after Stage 1): "Structured weight management" involving specific targeted goal behaviors for eating, activity, and reducing sedentary time, and should include self-monitoring in the office or another setting for individual or group treatment.
- Stage 3 (if no improvement within 3–6 months after Stage 2): "Comprehensive multidisciplinary management" in pediatric weight management center or equivalent program.
- Stage 4 (for patients with BMI above 99th percentile or more severe comorbidities): "Tertiary Care Intervention" in a tertiary care facility that oversees more targeted medical weight loss and may offer surgical approaches.

The core of child obesity treatment focuses on behavior and lifestyle modification, the aims of which are to reduce BMI through sustainable and appropriate healthy eating and physical activities that do not lead to disordered eating or inappropriate body image. Throughout assessment and management of obesity, primary care clinicians need to help families recognize the importance of physical fitness and overall health, not just body size, and that the whole family needs to be involved. In addition, clinicians should monitor children and teens for inappropriate focus on weight or engaging in unhealthy weight loss practices including laxative abuse, induced vomiting, and fasting (see Chapter 133).

The initial weight change goal in caring for the prepubertal overweight child is slowing weight gain or maintaining weight during normal linear growth. If more advanced treatment is indicated, the goal may move to weight loss, but not more than 1 pound per month

is recommended for ages 2 to 5 years. Youth ages 12 to 18 years (or postpubertal) may start at any of the 4 treatment stages, depending on severity and readiness to change. Initial treatment goals for the older age group may be slowed weight gain or weight loss. The weight loss recommendation is not more than 2 pounds per month above age 5. As a quaternary intervention, surgical treatments for obesity are available for teenagers in some centers, but due to cost, complications, and side effects, they are reserved only for those with extreme obesity already resulting in health problems.

Box 135-1. Brief Motivational Interviewing (MI) Approach to Child Obesity Management

Goal: Through nonjudgmental questions and reflective listening, elicit a realistic plan for addressing child's weight/health consistent with family's values and goals.

Use: Basic MI Skills or "OARS"

O: Open-ended questions

(eg, those starting with "How...", "What...", or "Tell me about...")

A: Affirmations

(eg, "You are already doing a good job with...")

R: Reflections

(eg, "It sounds like you would like some help with changing...")

S: Summaries

(eg, "Let me see if I can summarize our discussion and plans between now and the next visit...")

Steps: Basic approach in 15 minutes

1. Assess body mass index (BMI), inform parent/patient, elicit response
eg, "Your child's BMI is in a range where we start to be concerned about extra weight causing health problems. What concerns, if any, do you have about his/her weight?"
2. Set agenda: assess what they have already done, their goals for change, possible target behaviors
eg, see sample Questions Box above
3. Assess motivation and confidence to make the changes
eg, "On a scale of 1–10 with 10 being highest, how important are the changes we have talked about for you? Why are you an 'x' [number they chose] and not a 'y' [lower number]?"
4. Ask about ways to implement their plans/goals
eg, "Who can help you with your plans? What will help you be successful? How have you been able to make a change in the past?"
5. Summarize: review plans (including follow-up), express confidence in the family, offer further help
eg, "Let's summarize our discussion today. You have planned to _____ and this is important to you because _____. You will get some help from _____ to be successful. This sounds like a plan that can work. I know you can do it if you set your mind to it. I suggest we meet again in 1 month to check in. I look forward to hearing about how well you are doing. At that time we can discuss other ways I might be able to help, like a referral to a nutritionist or an exercise program."

Clinicians can feel most successful and efficacious in managing obesity if they tailor recommendations for the individual child and family, and access available community resources. **Motivational interviewing** techniques (Box 135-1) can be helpful in determining and promoting a family's readiness to make changes to address weight concerns. For families that are less ready, the clinician's role can be more focused on understanding values and current barriers, ordering appropriate testing to help families assess risk, checking back in frequently, and providing encouragement while respecting autonomy. For more ready families, the clinician's role moves into actively eliciting from the patient and parent what they consider to be important and feasible lifestyle changes, and how they want to go about reaching their goals. Because it is difficult to modify habits and behaviors related to food and activity, patients and their families require ongoing support and attention from their primary care providers and additional clinical and community resources as they attempt to integrate and maintain healthy behaviors in their lives. Engaging with the family to elicit solutions and problem-solve barriers is more likely to yield positive results than blanket advice or recommendations. Even if well-intentioned, clinician recommendations are unlikely to be implemented if they are inconsistent with a patient's and family's values, culture, and/or resources. For example, a child's participation in an after-school sports program may not be a realistic option if a family cannot afford the fees or transportation to and from the program is not available; instead, a school-based after-school program or an evening or weekend class at a community center with their parent might be an option.

In preventing and treating childhood obesity, clinicians must also recognize the gaps between knowledge and behavior: Understanding that good nutrition and physical activity are important does not necessarily translate into healthy eating or regular exercise. For example, a parent may know to limit fat and sugar but may still buy a lot of processed foods because of convenience or price, or because of not knowing how to prepare healthier foods. Alternatively, some families may have food insecurity or have periods of time with inadequate food that may lead to overeating inexpensive, energy-dense foods. These families should be connected with nutrition assistance programs (eg, Special Supplemental Program for Women, Infants, and Children (WIC), Supplemental Nutrition Assistance Program [formerly known as food stamps]). Most families need additional education on appropriate serving sizes, healthful food preparation, interpreting food labels, and making healthy food choices among the many mixed nutrition messages in the media. Given time limitations to provide this kind of support in primary care office visits, referral to a dietitian or nutrition classes through WIC can be an initial step in providing the education and planning needed for families to change eating habits. Dietitians can be particularly useful for motivated families in providing ideas to plan healthful daily meals and snacks.

Since the options for actively treating childhood obesity are currently limited in the primary care setting, it is critically important for clinicians to be aware of what treatment programs are available in

Box 135-2. 10 Guidelines to Help Families Toward a Healthier Lifestyle

1. Learn about the child's and family's usual diet and activity pattern so that you can elicit ideas about helpful changes they are interested in and capable of making.
2. Promote "5-2-1-0" simple guidelines for healthy living: 5 fruits and vegetables a day, 2 hours or less of screen time, 1 hour or more of physical activity, and 0 sugar-sweetened beverages per day.
3. Encourage intake of more "natural" foods such as fruits and vegetables (fresh or frozen). Limit processed and prepackaged foods and snacks (which have added sugar that overweight/obese children/teens don't need), by keeping them out of the house as much as possible.
4. Set family guidelines on recreational screen time or "seat time" with a goal of less than 2 hours a day including TV, videos, and computers.
5. Keep TVs out of children and teens' bedrooms (easier to do if providers help educate about not putting them there in the first place).
6. Promote "fitness over fatness": Incorporate physical activity into the child's and family's daily routine with a goal of 60 minutes per day. Find sports or activities that the child enjoys and can master.
7. Teach healthy beverages for all ages: milk and water is all we need. For children older than 1–2 years, change to 1% or fat-free milk. Limit milk to 16 to 20 oz per day after the first year of life. If parents serve juice, limit to less than 4 oz per day for toddlers and 6 oz for older children. Limit soda to special occasions (like a birthday).
8. Limit eating out, especially at fast food restaurants.
9. Have regular family meals cooked at home.
10. Encourage appropriate portion sizes for family members based on need (teach parents to respond to hunger cues when children are infants and toddlers).

the local area and take full advantage of these. Successful, evidence-based programs are now increasingly available to help children attain a healthier weight. To date, the most efficacious programs are moderate intensity family-based behavioral treatment, generally of 3 to 12 months' duration. Clinicians can play an active role in referring to structured treatment programs by being a knowledgeable source of information and helping families learn about and become interested in these programs. Families often need support and encouragement from a trusted provider to participate. If structured overweight treatment programs are not available in the local area, the clinician can recommend and refer to structured physical activity programs, such as at local YMCAs or community centers, which can help patients improve physical fitness and lower metabolic risks related to obesity, even if not leading to weight loss per se.

A basic set of guidelines that clinicians can use to help families move toward a healthier lifestyle are listed in Box 135-2. Items on this list are evidence-based from the standpoint that families who have implemented these generally have children with healthier weight. Some involve fairly simple changes, such as reducing the intake of sugar-sweetened beverages, or switching to a lower-fat milk. Other suggestions may require more knowledge or motivation to implement

successfully. Many Web Sites provide excellent educational resources for families such as the US Department of Agriculture Food and Nutrition Service “MyPlate” (www.ChooseMyPlate.gov) and *Dietary Guidelines for Americans* published every 5 years (www.healthier.us.gov/dietaryguidelines), Nemours Health (www.kidshealth.org), and the Let’s Move campaign (www.letsmove.gov) initiated by First Lady Michelle Obama.

There are no quick fixes to the management of obesity. Appetite suppressing medications are neither recommended nor approved for use in children and teens. Their use in adults has also proved hazardous. Metformin, which is used in some obese teens, is indicated to address the insulin resistance in patients with metabolic syndrome.

Given the complexity of managing obesity, there are increasing options for clinical tools and additional training for pediatric providers. Resources include the American Academy of Pediatrics (AAP) and other specific online curricula (eg, Health and Obesity Prevention and Education curriculum available to providers at no cost by requesting materials from hopeproject@ucsd.edu).

Prevention

Prevention of obesity is our best option for reversing the growing epidemic of obesity and obesity-related comorbidities. Prevention of obesity should be a priority for all clinicians who care for children and should focus on 3 broad areas: (1) anticipatory guidance starting in infancy on healthful eating, minimizing screen time, and providing access to regular physical activity with an emphasis on promoting overall health; (2) early intervention for families whose children are at higher risk for developing obesity; and (3) advocacy for public health measures to increase opportunities for healthful eating and regular physical activity within our communities. Pediatric providers can take an active role to improve obesity trends in supporting changes in school and child care institutions, communities, and national policies (see resources available through the AAP at www.aap.org/obesity).

Prognosis

Without intervention, the average American life expectancy is currently projected to decrease, owing to the increasing incidence of diseases associated with obesity such as diabetes. Poor diet and sedentary lifestyles rival smoking as a preventable cause of premature death. Obese children who remain obese into adulthood are at greatly increased risk for all of the complications of obesity. However, there is hopeful evidence that early intervention at the family and community levels can change this trajectory. Pediatric providers continue to improve rates of BMI screening and referral; those who have had training in obesity, management are even more likely to implement current recommendations. Globally, more and more providers and organizations are taking an active role in preventing and treating childhood obesity and treatment options continue to evolve and improve. The fact that current childhood obesity rates in the US have stabilized may be a positive sign for the future.

CASE RESOLUTION

The opening vignette describes an obese girl. She is at substantial risk for remaining obese into adulthood based on her present weight and her mother’s history of obesity, as well as social and economic risk factors. Working with a dietitian, the mother and her daughter learn about simple changes for healthy diets. They begin to plan meals and snacks that include fruits and vegetables and can be prepared in advance. The girl starts making her own lunch each night before school. The mom changes her grocery shopping: she buys 1% milk instead of whole milk, and she stops buying cookies, chips, and soda, except as an occasional treat. A social worker helps find an after-school program at the nearby YMCA. The patient starts attending and, with some special attention from the coach, finds she enjoys basketball and would like to try out for the school team next year. The mother wants to exercise more, and so the girl and her mother plan after-dinner walks around the track at the local high school.

Over the next 6 months, you follow the girl and her mother closely. The most recent growth parameters show that the girl has maintained her weight at 59 kg but has grown 5 cm to 145 cm, giving her a body mass index of 28. The mother has lost 5 lb during this period, and both are excited about continuing their new lifestyle.

Divorce

Carol D. Berkowitz, MD

CASE STUDY

A 7-year-old girl who has been your patient for 5 years is brought in by her mother with abdominal pain that occurs on a daily basis and is not associated with any other symptoms. The pain is periumbilical. In obtaining the history, you learn that the father has moved out of the home and the parents are planning a divorce. The mother believes that her daughter's symptoms may relate to the impending divorce, and she wants to know what else to expect.

Questions

1. What are the problems faced by children whose parents are undergoing divorce?
2. What are the age-related reactions of children in families undergoing divorce?
3. What is the role of pediatricians in counseling families undergoing divorce?
4. What anticipatory guidance can be offered about custody and remarriage?
5. How can pediatricians help stepfamilies adjust?

Divorce represents the “death” of a marriage, and in some ways may be more devastating for children than the death of a parent. When a parent dies, that parent becomes idealized in the mind of children, but when parents divorce, the noncustodial parent is often devalued. In fact, each parent is frequently devalued by the other. For children, parents are no longer the idealized figures that they once were. The challenge for pediatricians is to maintain a neutral position. This may be particularly difficult because much of the contact has been with one parent rather than the other, usually the mother.

Pediatricians play a specific role in managing children going through a parental divorce because other resources are few. **Extended families** are no longer as available to provide help. Religious institutions have often failed to assume a counseling role in this area; some religions view divorce unfavorably. Most families do not seek out mental health services unless the problems are overwhelming. Therefore, it is important for pediatricians to become involved in anticipatory guidance of families undergoing divorce. This guidance focuses on preparing children and families for times ahead. In addition, practitioners serve as child advocates. The parents themselves are so consumed by their emotional turmoil that they are often not available or are not even aware of the stress and trauma their children are experiencing. Physicians should be aware of the effect of the divorce on children and their subsequent psychological development. In addition, pediatricians can help as new families form, assisting the transition of caretakers into the role of stepparents.

Epidemiology

Divorce affects nearly 50% of marriages though the rate recently has decreased to closer to 40% attributed in part to the decrease in the marriage rate. **Ethnic differences** exist; 38% of European American compared with 75% of African American children's parents divorce

prior to the children's 18th birthday. The US Office of National Vital Statistics reported 1,045,289 divorces for 2009, a figure that is lower than the actual number of cases because California, Georgia, Hawaii, Louisiana, and Minnesota do not report their data. Divorce usually occurs in the first 14 years of marriage (mean: 7.8 years). Approximately 1 million children per year are affected by divorce. Nearly one-third of all children live in households in which parents are divorced or remarried. Children between the ages of 3 and 8 years are the major age group affected. Children involved with parental divorce take 2½ to 3 years to regain their equilibrium and master a sense of control. Divorce usually results in a decline of **economic resources** to mothers and children. In the first year after divorce, income is reduced to 58% of the pre-divorce level. Even after 5 years, income for mothers and children is only 94% of the pre-divorce amount; for intact couples, income has risen to 130% during that period. Decreased income is often associated with multiple moves to more affordable housing along with change in schools and loss of friends. More affordable neighborhoods may not provide the same resources and environment to which the children were previously accustomed.

Types of custody include **single-parent custody**, **joint custody**, **joint legal custody**, and **joint physical custody**, where parents have physical access to the child with equal frequency. **Birds-nest custody** is joint custody where children remain in the home and parents take turns moving in and out. Many states now allow for joint custody. Joint custody is associated with higher levels of involvement by the biological father, increased child support payments, and greater paternal satisfaction. Issues of **remarriage** and **stepsiblings** are also important. Eighty percent of divorced men and 75% of divorced women remarry, and 40% of these remarriages end in divorce. As a result of the high rate of remarriage, 1 in 3 children in

the United States has a stepparent. Eighty-six percent of stepfamilies include the biological mother and a stepfather. Children in stepfamilies often have to readjust to differing roles in differing households and differing relationships between their biological parents, stepparents, biological siblings, and stepsiblings.

Psychophysiology

The experience that children have following parental divorce is influenced by many factors, including the individual child's **temperament** and **personality**. An easygoing child with strong self-esteem and a positive outlook fairs better than the child with a difficult temperament and less positive personality traits. The reaction to divorce also depends, to a large extent, on the age of the child (Table 136-1). In general, children do not have the cognitive ability to understand the meaning of divorce until they are 9 or 10 years of age. The experience is also different for children without siblings, "onlies." Not only do they lack brothers or sisters with which to commiserate, they may also experience parental "overconcern" manifested by being asked repeatedly how they are feeling and how they are doing. Studies have demonstrated that the negative effect of parental divorce on adolescent academic performance is mitigated by increased sibship size.

Table 136-1. Children's Reaction to Divorce

Age	Symptoms
2½–4 y	<ul style="list-style-type: none"> • Regressive behavior
3½–5 y	<ul style="list-style-type: none"> • Aggressive behavior
5–6 y	<ul style="list-style-type: none"> • Whiny, immature behavior
6 y–adolescence	<ul style="list-style-type: none"> • Disequilibrium • Depression • Somatic complaints • Poor school performance

Children up to the age of 2 years experience **sleeping** and **feeding disturbances**, as well as spitting up and clinginess. Between the ages of 2½ and 4 years, children usually manifest **regressive behavior**. They become needy and dependent, and their behavior is characterized by irritability, whining, crying, fearfulness, increased separation anxiety, and sleep problems. Both aggression and regression, particularly in the area of toilet training, may develop. One-third of children in this age group continue to exhibit regressive behavior 1 year after divorce.

Preschool-aged children between the ages of 3½ and 5 years often show more aggressive patterns of behavior with hitting, biting, and temper tantrums. Regressive behavior may also be seen. Young children feel particularly responsible for their parents' divorce (ie, the parents are divorcing the child). At this point in development, children experience what Piaget has referred to as an egocentric way of thinking. Self-blame, decreased self-esteem, and a high level of fantasy, particularly about parental reunion, are apparent. Approximately 1 year after divorce, 65% of these children still show decreased levels of functioning.

Children who are 5 to 6 years of age are often **depressed** and may exhibit immature behavior. Girls in this age group seem to handle a divorce more poorly than boys. Two-thirds of girls are less well-adjusted 1 year after the divorce, as opposed to only about one-fourth of boys. These children seem moody and daydream. They may also be whiny and have temper tantrums.

School-aged children between the age of 6 years and adolescence seem to experience profound disequilibrium, with feelings of shame, anger, and loneliness. This anger may be manifested by antisocial behavior. Older children also talk about an overwhelming feeling of sadness and grief. Their somatic complaints include headache, abdominal pain, and an increase in symptoms of preexisting medical conditions such as asthma. Sometimes the somatic complaints of children, particularly those in the school-aged group, are attributed by one parent to the poor living conditions at the other parent's household.

It is important for physicians to anticipate that 50% of children involved in parental divorce show a deterioration in their school performance. Therefore, the school should be notified about the divorce and changes in family structure. Decreased school performance is attributed to decreased ability to concentrate, sadness, and depression.

Parental divorce is particularly difficult for adolescents, who describe it as "extraordinarily painful." The experience is worse for younger adolescents. During the first stages of divorce, they experience a personal sense of abandonment and a loss of parental love. Older adolescents are concerned about their future potential as marital partners. They also feel anxious about financial security, especially money for college. **De-idealization** of both parents is precipitous. Adolescent girls do better than boys early on, but this reverses with time. This pattern is referred to as a **sleepier effect** or **delayed effect**, with girls subsequently feeling rejected and unattractive as they reinterpret their parents' divorce with their additional maturation. Divorce during adolescence sometimes leads to **precocious sexual activity** or risk- or thrill-seeking behavior. Studies suggest that paternal involvement following the divorce reduces the risk of alcohol abuse. Adolescents from divorced families are more likely to experience teenaged parenthood. Adolescent girls from divorced families are less likely to succeed academically than girls from families where there has not been a divorce. In addition, the adolescent may turn to alcohol or drug use to help cope with the stress of parental divorce. Boys may engage in illegal activities such as burglary.

Differential Diagnosis

Children who present with complaints including headache, abdominal pain, enuresis, and poor school performance should always be assessed for environmental factors that may be contributing to their symptomatology. When evaluating a child with suspected **somatic complaints**, it is appropriate to consider organic etiologies.

Many parents who are undergoing a divorce do not appreciate the impact the divorce is having on their children. They are often caught up in their own personal feelings and are not aware of their

children's symptomatology. In addition, divorcing parents actually experience a deterioration in their physical and mental well-being, and divorced mothers have an increased rate of illness.

Parents engaged in custody disputes may express concerns that their child is maltreated by the other parent. These concerns may include allegations of sexual abuse, which may require a referral to a child advocacy center (see Chapter 128).

Evaluation

The focus of the evaluation should be on the interviewing process. Determination of the full extent of the impact of the home factors on children's symptomatology may take several visits. It is not appropriate to pursue extensive laboratory tests without first adequately determining what changes are occurring within the household.

History

The medical evaluation of children experiencing a parental divorce should include a review of the medical history and a discussion with the child of factors of change (Questions Box). This may help open up a discussion that reveals that the parents are in the process of divorce or that the father has moved out of the household. Specific parental concerns related to child maltreatment should be noted in detail.

Questions

Divorce

- Is there anything different about the child's house now?
- Who lives in the house?
- How are things going between the parents?
- Has the child shown any regressive or aggressive behaviors?
- Has the child been eating and sleeping normally?
- How is the child doing in school?

Physical Examination

Any symptom or specific complaint, such as headache or abdominal pain, should also be addressed (see Chapters 112 and 116). Depression and the risk for suicide should also be evaluated (see Chapter 140). A complete physical examination is usually warranted because children who are experiencing stress may also develop stress-related medical problems. If there are concerns about the genital findings, a careful anogenital examination is indicated.

Laboratory Tests

Some simple baseline laboratory studies may be warranted, particularly in children who have complaints such as abdominal pain or enuresis. These tests may include a complete blood cell count or urinalysis.

Management

Management of children whose family is undergoing divorce is complex. In addition to treating any somatic complaints that may be related to the divorce, physicians play a key role in anticipatory guidance. Children need to understand that they didn't cause the divorce and that they will not be able to "cure" it. Physician involvement before parents actually separate helps. Initially, physicians should advise parents about how to talk to children and what to expect in terms of their reaction. It is important for parents to tell children that they are separating from one another and not from the children. As stated previously, parents undergoing a divorce are in so much turmoil that they themselves may not see their children's problems. In addition, their parenting skills may suffer, and routine procedures such as meals and bedtime may become disrupted, sporadic, and irregular.

Box 136-1 summarizes advice given to parents when talking with their children. **When, how, who, and what** to tell should be discussed. Generally, children should be told of impending divorce by both parents with support from the extended family. Unfortunately, studies report that 80% of preschoolers were told by one parent.

Box 136-1. Talking to Children About Divorce

Who

- Who tells? Both parents
- Who is told? Children, physicians, teachers, neighbors

When

- Before either parent leaves
- Age-dependent
- Older children: weeks ahead
- Younger children: days ahead

How

- Calmly, with emotional control

Where

- Privately, in the home

What

- Stress that children are not to blame; that the divorce is between parents, not between parents and children; it is the parents who cannot get along.
- Explain expected living arrangements.

When to tell depends on children's ages. Younger children should be told a few days before the actual separation. Older children should be told at least several weeks before. Practitioners should advise parents about **how** to tell. Displays of emotion are permissible. Parents should be encouraged to show their emotions, but not to the extent that they appear overwhelmed or uncontrollable.

Who to tell includes not only the children but also the neighbors and the school, so that the feeling of shame or secrecy is less. **What** to tell involves freeing the children of any blame for the divorce and answering their questions.

It is important for physicians not to become involved in custody disputes, but if they are asked to give an opinion, they should try to evaluate the parenting skills of both parents. In the past, custody was given to the mother in 90% of cases, but this is now decreasing. Questions that physicians should ask themselves when advising about custody include: What are the emotional ties between parents and children? Do children indicate a preference for one parent? Children may be overwhelmed by feelings of loyalty and be torn if asked to choose one parent over the other, which makes this a difficult problem. What is the capacity of each parent to provide emotional and physical support for children? It is important to consider a need for continuity, and it is vital to keep conditions as close as possible to the pre-divorce situation. Children should not have to move. Living arrangements need to be reassessed on a periodic basis.

Physicians should be aware of the factors that support joint custody. Joint custody tends to maintain a parent-child attachment, and children experience less of a sense of loss. They have more cognitive and social stimulation. Joint custody relieves the burden of single parenthood, and parents who have joint custody are less likely to use children as bargaining tools. Parents themselves are freer to enter into different relationships and are less emotionally dependent on their children. Although physicians should not become involved in monetary issues, concerns related to payment, insurance coverage, and cost of medical care are appropriate to discuss. Practitioners should consider involving noncustodial parents in children's health care. Such parents could be notified if medical problems occur.

Pediatricians may also be helpful in counseling noncustodial parents about interacting with children. Unfortunately contact with noncustodial parents may decrease rapidly following a divorce. While 25% of children have weekly visits with their noncustodial father, 20% of children see their father only several times a year or not at all. In general, visitation should reflect previous relationships as closely as possible. Noncustodial parents should be advised not to become camp counselors who focus on fun and games but to be influential figures who help the children meet the challenges of normal living, such as completing homework and doing chores and tasks. It is also important for noncustodial parents to be consistent. If a meeting is planned, the parents must show up. Although the parents are no longer married, they can still be co-parents rather than rivals. Noncustodial parents should be encouraged to participate in school and sports activities. Multiple modalities such as e-mail and texting can facilitate more frequent communication.

Custodial parents may attribute children's somatic complaints to poor care while under visitation with noncustodial parents. Allegations related to abuse, most often sexual abuse, may also arise. These allegations should be taken seriously. An appropriate medical and psychological evaluation is necessary (see Chapter 128). The most difficult situations involve allegations of sexual abuse of preverbal children, where conclusions may be contingent on the physical findings, which are usually inconclusive.

Issues related to parental dating and remarriage should be addressed at an early stage. Parents should be advised that pediatricians may be a resource in helping families readjust. Remarriage is often a difficult time for children because they experience feelings of rejection secondary to displacement by stepparents. Grandparents may also be a source of support.

The pediatrician can also serve as a resource for stepparents. Although stepparents do not have legal rights to consent for medical care of their stepchildren, they should become familiar with the children's medical history. Stepparents grow into their parenting role, and it takes 2 to 7 years for families to become blended. The pediatrician can help families adjust by recommending books or giving referrals to organizations such as the National Stepfamily Resource Center (www.stepfamilies.info).

Prognosis

The prognosis for children undergoing a parental divorce depends, in part, on the degree of dysfunction that existed in the family before separation and the ability of the children to communicate their concerns. Supportive intervention by family, friends, and physicians is key to facilitating the necessary adjustment. For adolescents, a positive belief about parental divorce is a major predictor of their adjustment. Family resilience and hardiness as well as family communication are associated with a good adjustment. Being a child of divorced and remarried parents has been likened to having dual citizenship. The experience is rewarding if the countries are not at war with one another.

CASE RESOLUTION

The case history reflects that functional somatic complaints are not uncommon, especially in school-aged children of divorced parents. The mother and her daughter should be advised about how stressful divorce is for children. A careful medical examination may reassure both the mother and child about the child's physical well-being. Issues related to custody, financial responsibility, and the need for consistency should all be addressed. In addition, the pediatrician should refer the family to outside agencies if necessary.

School-Related Violence

Elizabeth A. Edgerton, MD, MPH

CASE STUDY

A mother brings her 9-year-old son, Alex, in complaining of recurrent abdominal pain. His pain has become so severe that Alex misses school frequently. He denies any vomiting or diarrhea. His weight has been stable over the last 6 months. Alex's mother reports that lately he seems more withdrawn and passive. He used to be engaged in his schoolwork but now with his frequent absences has lost interest in school. His mother says he is often anxious or nervous about new situations.

Questions

1. How does school-related violence affect children's health and well-being?
2. What is the relationship between bullying and adult criminal behavior?
3. What is cyberbullying?
4. What are strategies to address school-related violence?
5. What can pediatricians do to help address violence in the school, home, and communities?

Violence is defined as an act of aggression that can be **physical, sexual, or psychological** and is usually deliberate and intended to cause harm. Its form, level of severity, and frequency are impacted by biological, individual, clinical, intrapersonal, situational, and socio-cultural factors. Categorization of violence is also dependent on the relationship of the perpetrator and victim, as well as their ages. Domestic or **intimate partner violence** occurs among individuals in an established relationship, **child abuse** predominantly occurs between an adult and a minor, and **bullying** is usually between peers. From a developmental perspective, bullying may be the earliest form of violence promulgated by children and can progress to intimate partner violence, **criminal delinquency, suicide, or homicide** in adolescence and adulthood. While violence may be considered a social issue, it impacts the physical and mental health of all of those involved. The primary care physician has unique opportunities to prevent violence and identify those potentially at risk.

Prevalence

Suicide and homicide represent the most lethal forms of violence. Suicide and homicide are responsible for approximately one-fourth of deaths among persons aged 10 to 24 years in the United States. Approximately 3 million youths are at risk for suicide, with 37% of at-risk individuals attempting to kill themselves (see Chapter 140). Suicide is the third leading cause of death among 15- to 24-year-olds, and over the last 20 years has increased 100% among 10- to 14-year-olds. It is estimated that approximately 12 youths die each day in the United States from suicide. Homicide is also increasing among children and adolescents. According to the Centers for Disease Control and Prevention, homicide is the fifth leading cause of death for youths 10 to 14 years of age and the second leading cause of death for 15- to 19-year-olds in the United States.

In 2007 emergency department data documented that more than 500,000 youth younger than 24 years were treated for injuries sustained due to violence. Nationwide surveys of high school students note that 33% report being in a physical fight one or more times in the 12 preceding months. An additional 17% reported carrying a weapon such as a gun, knife, or club on one or more of the 30 days preceding the survey. Furthermore, 6% of students reported not going to school on one or more days in the 30 days preceding the survey because they felt unsafe at school or on their way to and from school.

Those that admitted to being bullies in middle school had at least one criminal conviction by age 24 years, and 35% to 40% had 3 or more convictions by 24 years of age compared with 10% among control boys who were neither bullies nor victims as children. The aggressive antisocial behavior of bullying seems to contribute to future serious criminal behavior. Many of the recent killing sprees in the United States were committed by individuals who as children felt they were victimized. A review of 37 mass school shootings found more than two-thirds of perpetrators felt they had been persecuted, bullied, threatened, or attacked; often, they were acting out of revenge.

In a national survey of 6th- to 10th-grade students, approximately 30% reported moderate or frequent involvement in bullying; this could include being the bully, the victim, or both (known as the *bully-victim*). Those who reported being a bully or victim were more likely to carry weapons to school, as well as to be involved in frequent fights. Bullying itself is most common in the early school years. Initially, boys are more likely than girls to be involved in bullying. This gender gap decreases in middle and high school, as does the prevalence of bullying. Boys tend to participate in physical and verbal bullying, while girls use more subtle and indirect forms of bullying such as alienation or ostracizing.

Risk factors associated with violence are complex and involve the individual, family, peers, and community (Box 137-1). Demonstrated risk factors associated with violent behavior include exposure to violence as a witness or victim, childhood aggression and **antisocial behavior, substance abuse, depressed mood, and hyperactivity**. Protective factors include academic achievement and parent–family connectedness. Families that provide positive and consistent discipline and supervision can prevent involvement in violence.

Box 137-1. Risk Factors Associated With Violence

Individual Risk Factors^a

- History of violent victimization or involvement
- Attention deficit, hyperactivity, or learning disorders
- History of early aggressive behavior
- Involvement with drugs, alcohol, or tobacco
- Low IQ
- Poor behavioral control
- Deficits in social, cognitive, or information-processing abilities
- High emotional distress
- History of treatment for emotional problems
- Antisocial beliefs and attitudes
- Exposure to violence and conflict in the family

Family Risk Factors

- Authoritarian childrearing attitudes
- Harsh, lax, or inconsistent disciplinary practices
- Low parental involvement
- Low emotional attachment to parents or caregivers
- Low parental education and income
- Parental substance abuse or criminality
- Poor family functioning
- Poor monitoring and supervision of children

Peer/School Risk Factors

- Association with delinquent peers
- Involvement in gangs
- Social rejection by peers
- Lack of involvement in conventional activities
- Poor academic performance
- Low commitment to school and school failure

Community Risk Factors

- Diminished economic opportunities
- High concentrations of poor residents
- High level of transience
- High level of family disruption
- Low levels of community participation
- Socially disorganized neighborhoods

^a Adapted from the Centers for Disease Control and Prevention. Youth Violence Fact Sheet. www.cdc.gov/ncipc/factsheets/yvfacts.htm.

Bullying

Recently more attention and formal research regarding bullying is occurring in the United States. Tragic mass killing events, especially those at schools, coupled with reports of the perpetrators being victims or bullies during childhood, has raised the awareness of the seriousness of bullying as an early form of violence. Bullying has been extensively studied in Europe. Research, especially by Dr Olweus from Norway, demonstrates the serious consequences of this early form of aggression. Unfortunately, many parents, teachers, and health professionals still see bullying as a normal behavior of children.

Bullying is a type of aggression in which the intent of the behavior is to cause harm or disturb an individual. An imbalance of power exists with the more powerful attacking the less powerful. Opposed to what might be called “normal childhood conflicts,” bullying occurs repeatedly over time. Bullying does not occur in isolation, but rather in an environment that supports the behavior. Participants include the bully, the victim, and the bystander. The bully is often an aggressive individual that uses violence to dominate others; he or she has little empathy for the victim. In contrast to common perception, bullies do not have poor self-esteem, but rather have a strong desire to control others. The victim may be more passive and anxious. This individual is often less secure than their peers and may be lonely, playing alone at school. When they are attacked by a bully, they usually withdraw rather than retaliate. A minority of youth may be classified as a bully-victim or a provocative victim. These individuals are both anxious and aggressive; while they are primarily victims of bullying, they may provoke the bully.

Bullying predominantly occurs in a school environment, during recess, at lunch, or on the way to or from school. Children often do not report bullying to adults for both fear of and retaliation by the bully and the concern of disbelief by the adult. Studies demonstrate that adults underestimate the prevalence of bullying events compared with student reports. Clinicians need to consider this when asking the parent or child about bullying.

Consequences of Bullying

Bullying impacts the physical and mental health of all of those involved. Fear and anxiety about the school environment is most common. This can progress to avoidance of school, low self-esteem, and depression. Children with chronic illness are more vulnerable because they may suffer worsened body image with frequent teasing. In adulthood, higher rates of depression and poor self-esteem are seen among individuals with a history of being bullied. Strong associations in adolescence and early adulthood have been made between bullying and suicide and murder. The child who was victimized may react later in life with self-destructive acts or lethal retaliation.

A prospective cohort study of children 9 to 11 years of age in the Netherlands found that victims of bullying had significantly higher chances of developing new psychosomatic and psychosocial problems compared with children who were not bullied. A larger

proportion of victims had underlying depression and anxiety prior to being bullied but still suffered significant psychosomatic and psychological problems after being bullied. Common complaints included depression, anxiety, abdominal pain, sleeping problems, headache, feeling tense, bedwetting, feeling tired, and poor appetite. These complaints were present significantly more among children who had been victims of bullying.

Bystanders are also impacted because bullying distracts from the learning environment. Furthermore, they develop strategies to avoid being bullied that can include avoiding the restroom and staying home. One study reported that 1 in 5 secondary school children avoid restrooms out of fear at school. Another study stated that 7% of eighth graders stay home at least 1 day a month out of fear of other students.

Longitudinal studies report that bullies and bully-victims go on to more criminal activity than their counterparts. One study of Finnish boys reported 9% being bullies in childhood. These same individuals accounted for 37% of criminal activity in the study when the individuals reached adulthood. Bullies were more likely to commit occasional infractions while bully-victims were more likely to commit repeated offenses. Among bullies that participated in criminal activity, they were more likely to have underlying psychiatric symptoms. Other studies suggest that bullies have higher rates of conduct disorder.

In recent years there have been increasing reports of cyberbullying, where modern technology is used to pester, annoy, harass, and intimidate others, or to spread derogatory comments through chat rooms or other Internet sites. This represents yet another new problem related to computers (see Chapter 9).

Role of the Primary Care Physician

Childhood bullying is a complex abusive behavior with demonstrated serious consequences. Physicians are poised to identify at-risk individuals, screen for psychiatric comorbidities associated with bullying, counsel families, and advocate for school-based interventions. Because bullies or victims will not identify themselves as such, physicians need a systematic approach to screen for this early form of violence. Integrating screening during anticipatory guidance may be optimal for toddlers and school-aged children, while assessing risk factors at well and acute care visits may be needed for adolescents.

Multiple instruments have been used in a research setting for identifying bullying or associated internalizing or externalizing symptoms, but they have not been widely implemented in the primary care setting. Screening younger patients requires conversations with the child and family members. The American Academy of Pediatrics developed Connected Kids: Safe, Strong, Secure, which can be integrated into Bright Futures for well-child care visits. This preventive program focuses on discussing possible stressful developmental milestones that can lead to tension and on providing families with alternative approaches. When talking directly with adolescents, the use of the psychosocial interview **HEADDSSS** (*home environment, employment and education, activities, diet, drugs, sexual activity/sexuality, suicide/depression, safety*) may be useful in

screening for high-risk behaviors and risk factors for violence (see Chapter 6).

When questioning a family about bullying, keep in mind that children will often not tell their parents that bullying occurred. When parents are told about bullying they may consider the situation as being normal behavior for young people and dismiss the event. Multiple forms of bullying exist. These include physical fights, verbal or cyber (text messaging or e-mail) harassment, and social isolation. Boys are more commonly involved in physical and verbal bullying while girls are more often involved in manipulative forms of bullying. As children become adolescents, intimate partner violence, suicide, and homicide are more likely consequences of bullying.

Prevention efforts need to focus on the individual, family, and community. In early childhood, parents can model for children appropriate social interaction, how to resolve conflict, and how to manage frustration and anger. School-wide bullying prevention programs are effective and should be advocated. The Olweus program focuses on adults at home and school showing positive interest in students, setting firm limits for unacceptable behavior, using consistent nonphysical or hostile consequences when rules are broken, and acting as positive role models to ultimately change the social and behavioral norms. For older children and adolescents, identifying psychiatric symptoms and providing the appropriate intervention may prevent more serious violent behavior. At the individual level, physicians and parents can counsel children who are bullies or victims regarding appropriate behaviors (Box 137-2).

Box 137-2. Physician's Role

- Be vigilant for signs and symptoms of bullying and other psychosocial trauma and distress in children and adolescents.
- Increase awareness of the social and mental health consequences of bullying and other aggressive behaviors.
- Screen for psychiatric comorbidities in at-risk youth, and provide appropriate referrals for treatment for affected youth.
- Counsel affected youth and their families on effective intervention programs and coping strategies.
- Advocate for family, school, and community programs and services for victims and perpetrators for bullying and other forms of violence and aggression.

In a randomized controlled study, Borowsky and colleagues demonstrated the effectiveness of identifying at-risk youth aged 7 to 5 years in a primary care setting and of providing a **family-level intervention** to reduce violent behavior and injuries among youth. Families that received the telephone-based intervention focusing on positive parenting reported decreased parent-reported bullying, physical fighting, fight-related injuries requiring medical care, and child-reported victimization by bullying.

The Maternal and Child Health Bureau in partnership with other federal agencies developed a resource kit on bullying, which is available online at www.stopbullyingnow.hrsa.gov. Online vignettes are

directed at children in their preteen years and are geared toward helping the youth identify what role they might have in bullying and what appropriate behavior might allow them to better handle the situation. Printed resources are available for parents and teachers. For adolescents, the Centers for Disease Control and Prevention launched **Choose Respect**, a Web-based program on relationships available online at www.chooserespect.org. It provides tools for adolescents to identify healthy peer relationships and appropriate responses if they are concerned about intimate partner violence.

Physicians are a vital component of youth violence prevention (Box 137-3). Prevention begins early in the child's development by providing positive reinforcement of appropriate pro-social behavior. Bullying is an early form of aggression. In and of itself bullying may seem harmless, but longitudinal studies as well as analysis of mass school shootings demonstrate the large impact aggression early in life can have on the future well-being of children, adolescents, and adults. Successful interventions require cooperation by parents, teachers, students, and health professionals.

Box 137-3. Individual-Level Prevention Strategies

Advice for Victims of Bullying

- Resist reacting to the bully; hold your frustration and anger.
- Walk away from the situation; ignore the bullying.
- Avoid retaliation or bullying back.
- Tell an adult.
- Talk about the bullying event with your family.
- Use a buddy system at school and traveling to and from school.
- Develop friendships by joining social organizations.

Management of Bullies

- Reinforce that bullying is a serious problem.
- Set limits and provide consequences for acts of aggression.
- Emphasize tolerance for people's differences; everyone deserves respect.
- Determine whether friends are also involved in bullying; seek a group intervention.
- Provide positive reinforcement for appropriate behavior.
- Work closely with schoolteachers and staff regarding behavior modification.
- Emphasize that it's the "behavior" that is not acceptable.

CASE RESOLUTION

Victims of bullying often present with psychosomatic symptoms such as headache or abdominal pain. Once organic etiologies have been ruled out, further questioning should focus on psychosocial stresses. Alex's abdominal pain is worse in the morning before going to school. When asked specifically about bullying, Alex states that a few of his classmates tease him and rough him up each day on his way to school. In the last few weeks they are text messaging him about how they are going to haze him the next day. Alex has not told anyone about the experience because he thought he would be viewed as a coward. Alex shares that he would rather avoid going to school than face potential bullying.

The physician needs to assure Alex that it is not his fault that he is a victim of bullying. Prevention should include interventions at the individual, family, and school level. Alex should walk away from the conflict when possible and not feel uncomfortable about reporting the event to school staff. He may want to find a friend to walk to school with. His family needs to understand that bullying is not just a normal kid behavior. He should be encouraged to talk about bullying events and jointly identify solutions. The school should be notified about the event and encouraged to promote a non-bullying school environment.

Intimate Partner Violence

Sara T. Stewart, MD

CASE STUDY

A 6-year-old boy is brought in by his mother for an annual well-child visit. He sits quietly as his mother reports no significant medical history. His medical records reflect that at his last visit he was talkative, doing well in school, and enjoyed playing baseball. As you speak with his mother, she seems reticent and does not spontaneously offer information. You determine that the boy's school performance has declined significantly over the past year and that he no longer wants to play baseball.

On physical examination, the boy has linear ecchymoses over his buttocks, and you notice bilateral areas of bruising on his mother's upper arms. When you ask about the marks, she becomes tearful. You ask her if she would like to speak privately with you.

Questions

1. How often do child abuse and intimate partner violence (IPV) co-occur?
2. What are potential strategies to screen for IPV?
3. What are common clinical presentations of victims of IPV and children exposed to IPV?
4. What are the long-term consequences of IPV on children?
5. What are key factors to take into account when determining the degree and immediacy of danger to a victim of IPV?

Introduction

Intimate partner violence has been defined as a pattern of assaultive and coercive behaviors that may include repeated battering and injury, sexual assault, progressive social isolation, deprivation, and intimidation. It is perpetrated by an individual who is or was involved in an intimate relationship with an adult or adolescent, and whose intent is to establish control over the other partner. It is not only associated with negative physical and mental health outcomes for the victim but is also associated with negative mental health outcomes for children in the home. Childhood exposure to IPV is considered to have occurred when a child sees, hears, or observes the effects of verbal or physical assaults between partners. Intimate partner violence is also associated with the occurrence of child abuse in the home.

Epidemiology

Intimate partner violence affects both sexes and occurs in all ethnic, socioeconomic, sexual orientation, and religious groups. Approximately 2 to 4 million women and 500,000 to 1 million men report victimization annually in the United States. In 2005, 1,500 homicides were the result of IPV nationwide, and 78% of victims were female. While both men and women fall victim to IPV, there is increasing disparity between victimization rates with increased severity of physical assault, as women are more likely to sustain life-threatening injuries. The financial cost of IPV to society has been estimated at \$8.3 billion, including medical and mental health costs

as well as the indirect cost of lost productivity. In total, victims lose millions of days of paid work time annually.

While there is no uniform profile of either a victim or perpetrator of IPV, risk factors for victimization include a personal history of maltreatment as a child, adolescent or young adult age, disparity of status (educational, professional) between partners, and high level of dependence of one partner on another. Batterers have also been found to frequently have a history of emotional or physical maltreatment as a child, a history of substance abuse, very low levels of self-esteem, and difficulty identifying and expressing emotion.

Between 3 and 15 million children are exposed to IPV in their homes annually, and these children are at risk of victimization themselves. They are almost 5 times more likely than unexposed children to sustain physical abuse and 2.5 times more likely to be victims of sexual abuse.

Clinical Presentation

Adult victims of IPV may present for medical care for themselves, or may present for care of their children for issues related to the violence. Approximately one-third of victims injured in an assault by a partner seek medical care for their injuries. While these injuries vary in severity, skin injuries are most common. Injury can occur on any part of the body; however, injury to the head, neck, and face has been particularly associated with IPV.

Many victims present to primary care providers and to emergency departments, and only a fraction are correctly identified as

suffering from IPV. A recent report noted that only 28% of abused women who sought care frequently (at least 7 times) were ever identified as victims of IPV. Barriers to diagnosis are both patient and provider based. Patients may not disclose the abuse due to fears of social, financial, or legal repercussions; concerns for safety based on prior threats from the abuser; feeling ashamed at being a victim; and inability to trust that others can help. They fail to appreciate that violence frequently escalates. Often they fear an investigation by child protective services and that they may lose custody of their children in the process. They may fabricate a story such as a fall to explain their injuries, thereby detracting the physician from further inquiry. Even in the absence of a story, physicians may avoid inquiring about the injuries, citing time constraints and lack of the knowledge to effectively respond if a disclosure is made.

Parents may also seek care for their children who manifest effects of the trauma, altered stress physiology, and disrupted caretaker attachment (Box 138-1). Children exposed to IPV are more likely than their peers to be anxious, fearful, and hypervigilant, and have difficulty with peer relationships. Adolescents are more likely to have school failure, substance abuse difficulties, high-risk sexual behaviors, and violent dating relationships. As they move to adulthood, these children are at higher risk for mental health disorders and substance abuse. In fact, the Adverse Childhood Experiences Study enumerates multiple negative overall physical and mental health consequences in adults exposed to IPV as children.

Box 138-1. Signs and Symptoms of Childhood Exposure to Intimate Partner Violence

- Depression
- Anxiety
- Somatization
- Attention-deficit/hyperactivity disorder
- Aggression
- Developmental delay
- Low self-esteem
- Hypervigilance
- Poor academic performance or truancy
- Antisocial or delinquent behaviors

Pathophysiology

The prevalent dynamic in relationships with IPV is the need for one partner to dominate or have power over the other. Often, this characteristic is interpreted as devotion early in a relationship, but an abuser eventually isolates the victim both socially and financially. Ultimately, the violence includes a physical and/or sexual component as well as a psychological one. The psychological component, which typically precedes any physical violence, includes threats, humiliation, and intimidation, and can be the most difficult to treat.

The cycle of violence between intimate partners is chronic and cyclical in nature with 3 phases. The first is the tension-building phase when the abuser uses verbal, emotional, and physical threats.

Next is the violent episode, which includes some combination of physical, sexual, emotional, and psychological assault. The final phase is the honeymoon phase, when the abuser apologizes and assures the victim that it will not happen again, and re-bonding occurs. These phases escalate over time, as the violence becomes more frequent and more severe and the honeymoon phase shortens. At least 50% of women who suffer sexual IPV report multiple rapes, and two-thirds of men and women with physical violence report multiple episodes of assault as well. The violence can also continue after the relationship has ended, and this most commonly manifests as stalking of the victim by the abuser. The violence also becomes intergenerational, as children exposed to IPV are at increased risk for victimization and perpetration of violence in their future intimate relationships.

There are particular circumstances that place IPV victims at even higher risk of harm. Threats from the perpetrator to harm or kill the victim or another person, the use of drugs or alcohol at the time of the violent episode, and the use of a weapon are all associated with an increased risk of injury. Approximately 4% to 8% of women report having experienced IPV during a pregnancy, though the reason for this increased incidence during this vulnerable period is unclear. It has been hypothesized that this is a time of increased stress as well as a time when a woman's attention may be diverted from her partner. Victims are also at increased risk of injury or death at the time they report the abuse or attempt to leave the relationship. In comparison to the systems in place for children, there are no protective service agencies with mandates to protect these adult victims and, as a result, disclosure of IPV may not occur unless the victim feels that she or he has a plan for escape.

Differential Diagnosis

Adult or adolescent victims of IPV often present with vague complaints, and abused women are 3 times more likely than non-abused women to present with gynecologic complaints, such as recurrent sexually transmitted infections, vaginal bleeding, or chronic pelvic pain. These victims may also present with nonspecific symptoms of sleeping difficulties, appetite changes, weight loss, chronic pain, or syncope. They are 3 times more likely to experience depression and 4 times more likely to experience post-traumatic stress disorder (PTSD) than non-abused women, and may present to their physician with symptoms of anxiety or following a suicide attempt. Other complaints reflect conditions associated with stress, such as irritable bowel syndrome, headaches, or temporomandibular joint disorder. Pregnant victims may present with vaginal bleeding, preterm labor, placental abruption, or fetal distress. The most common adverse birth outcome attributed to IPV during pregnancy is low birth weight of the infant.

The mental health manifestations of childhood exposure to IPV may vary depending on the developmental stage of the child; however, these children may present with developmental delay, low self-esteem, symptoms of PTSD and hypervigilance, poor academic performance or truancy, or antisocial behavior. Exposed children

also have significantly more internalizing (depression, anxiety, somatization) and externalizing (attention-deficit/hyperactivity disorder, aggression) disorders than nonexposed children.

There is limited research on the short-term effects of IPV on the physical health of children. Some studies have shown a higher incidence of asthma, failure to thrive, and malnutrition. Children in the home may also sustain direct trauma, whether as the result of being held in a parent's arms during an episode of violence or as the result of an effort to intervene and protect a parent during a violent episode. The children may also be direct targets of the violence and present with head, skin, skeletal, or abdominal findings consistent with intentional trauma (see Chapter 127).

Evaluation

History

Many victims of IPV do not freely offer information about the violence occurring in their relationships, even if they present with overt injuries. Screening for IPV in medical settings is cited as the optimal approach and is an area of continued research. Proposed approaches in the primary care or emergency department environment have included both universal screening of all women and targeted screening of women with high-risk signs and risk factors. While there are proponents of each of these approaches, a US Preventative Services Task Force (USPSTF) statement in 2004 noted that there was insufficient evidence at that time to recommend for or against universal screening. Universal screening may detect increased numbers of cases of IPV and open the door to effective intervention, but the question remains as to whether there have ultimately been improved social, physical, or mental health outcomes with this approach. Critics of universal screening argue that forcing the issue before a woman is psychologically and logistically ready to leave the situation may put her at increased risk of harm and decreased likelihood of success. The universal screening approach has also not typically addressed the population of male victims of IPV. Supporters of universal screening decried the USPSTF for adversely affecting a program that was finally gaining some traction and being implemented in the medical community.

Alternatively, targeted screening is performed in some medical settings on patients who present with risk factors for IPV (Box 138-2). Studies have shown that self-administered, written screening tools are generally preferred by victims over verbal questioning. Such written screening tools have been validated for use in clinical settings and are available from the Centers for Disease Control and Prevention (CDC) at www.cdc.gov/NCIPC/pub-res/images/IPVandSVscreening.pdf.

Since IPV has been shown to have a direct effect on the health and well-being of children in the home, the pediatric medical setting is one potential site for IPV screening to occur. Targeted screening practices may focus on families of children with anxiety, depression, or somatization, or when child abuse is suspected. Surveys of mothers generally support IPV screening in the pediatric office setting. Two written sets of screening questions have been validated for use

Box 138-2. Risk Factors for Intimate Partner Violence

- History of childhood abuse
- Adolescent or young adult age
- Disparity in professional or educational status of partners
- Geographic or cultural isolation
- Dependency on partner due to chronic illness or disability
- Pregnancy
- Depression
- Anxiety
- Frequent physical injury
- Substance abuse
- Poor compliance with medical care

in the pediatric setting and are available through the CDC Web site noted previously. Sensitivity to whether children should witness discussions of positive screening questions is necessary, as older children may react to or repeat portions of an overheard conversation, ultimately placing the victim, their mother, at higher risk of harm.

Physical Examination

Caregiver Injuries

Although blunt trauma from a hand or fist is the most common scenario for the abused partner, IPV can result in injuries from either blunt force or penetrating trauma. Injury can occur on any part of a victim's body; however, studies have shown that trauma to the head, neck, and face is most specific for IPV as an etiology than other traumatic events. Findings may also include bruising of the bilateral upper arms from being grabbed and patterned injury from being hit with an object. Strangulation may result in bruising or abrasions on the neck, facial petechiae, or subconjunctival hemorrhage.

Child Injuries

Children in the home where IPV is occurring are at increased risk of physical abuse, and a complete unclothed physical examination should be performed to look for evidence of skin, head, skeletal, or abdominal trauma. Accidental injuries typically result in cutaneous bruises over bony prominences, such as knees and elbows, anterior shins, and the forehead. Unusual areas for accidental injury include the neck, ears, cheeks, medial thighs, and genital area. If physical abuse is suspected, additional radiographic imaging and an ophthalmology examination may be indicated (see Chapter 127).

Management

The response to any disclosure of IPV should be supportive and should focus on a safety assessment to determine the severity and the immediacy of danger (Box 138-3). This should include an assessment of the pattern of escalating violence, the availability of weapons to the abuser, and the comfort level of the victim to return home. More imminent danger necessitates the creation of an emergent safety plan, and social work colleagues or professionals from an IPV shelter,

Box 138-3. Components of Safety Assessment

- Is the violence escalating?
- How severe has the violence been in the past?
- Is the victim comfortable returning home?
- Is child abuse occurring?
- Are weapons available to the perpetrator?
- Does the perpetrator have substance abuse issues or a mental health disorder?
- Does the victim have a social support network?

hotline, or advocacy organization can assist with this. It is important to remain sensitive to the fact that leaving an abusive home is disruptive to the daily lives of the adult and child victims, and may be a difficult step to take.

If immediate safety is of less concern, a victim may opt to take more time in creating a safety plan for leaving. This may include things such as collecting money, car keys, house keys, and important documents; asking neighbors to contact police if violence is overheard in the home; establishing a code that the victim can use to communicate to others that violence is occurring and understanding what will be done if the code is used; and disarming or removing weapons from the home.

While all states require that medical providers report cases of suspected child abuse and neglect to child protective agencies, there is variability in the mandated reporting statutes for IPV and child exposure to IPV. State statutes fall into the following general categories with respect to IPV: requirement to report injuries caused by weapons, requirement to report injuries resulting from a crime, requirement to report IPV, and no mandatory reporting law. For those states with no mandatory reporting requirement, factors that may influence a provider's decision to report may include the potential for danger, the caregiver's ability to plan for safety, a victim's level of connection to family or community support, and the degree of suspicion that a child's exposure to IPV constitutes emotional abuse. Online resources such as www.endabuse.org can assist with the determination of local state laws regarding mandatory reporting of IPV. Any suspicion of child abuse should be reported to child protection authorities, regardless of whether IPV is being reported as well. If child abuse and IPV are co-occurring, it is important to note this in the child abuse report so that appropriate measures can be taken in the child protection response.

Prognosis

Direct victimization from IPV and childhood exposure to IPV are both associated with increased risk of adult morbidities. Women who have experienced interpersonal violence are at risk for depression, anxiety, and PTSD and are 15 times more likely to abuse alcohol and 9 times more likely to abuse drugs. Childhood exposure to IPV is associated with an increased risk of adult morbidities, including

substance abuse disorders, obesity, physical inactivity, depression, and suicide attempts. This is of particular concern because of the limited availability of and often limited recognition of the importance of mental health resources in addressing the psychological impact of IPV.

For those women who do disclose the abuse and are referred to advocacy programs, preliminary data indicate that intensive programs may have a beneficial effect on reducing physical violence for several years. For other intervention strategies, the research is often limited and does not yet provide sound evidence of positive effects on physical, emotional, and quality of life outcomes. Further research is necessary to determine what components of the programs and what intensity and time frame of involvement are most beneficial in different clinical scenarios.

Although many IPV shelters and advocacy organizations have legal assistance available to victims, most victims do not obtain temporary restraining orders. Of those who do, approximately two-thirds have the orders violated by the abuser. Most cases are not prosecuted, and for those cases that do progress in the legal system, courts often struggle with how to address the IPV issues in the child custody and family treatment plans. While there are multiple models of treatment programs for perpetrators of IPV, there is evidence of only a small reduction in the likelihood of repeat violence. Further research is necessary to modify treatment approaches to reduce this recidivism.

Prevention

Prevention efforts may be primary, secondary, or tertiary. In this setting, primary prevention includes attempts to change social norms regarding violence and acts at the level of the individual, relationship, or community. Current efforts in that regard include attempts to break the generational cycle by studying and supporting resiliency factors in those who do not perpetuate violence after childhood exposure, the development of safe dating programs to reduce adolescent dating violence, the creation of peer empowerment programs for adolescents and young adults to enhance their ability to identify and intervene in IPV that they witness, and the development of family-based interventions to enhance nonviolent communication skills.

Secondary prevention includes early detection of IPV, and a significant amount of research is underway on screening practices in the medical setting. Tertiary prevention attempts to prevent death and disability in families where IPV occurs.

Sound research on IPV prevention is still a work in progress. Much of the current research has had methodological challenges, and many prevention strategies are not yet validated by sound evidence of benefit. Also, traditional thinking has been that most abusers are male and most victims are female, and prevention programs were built on this premise. Recent data, however, suggest that females also instigate IPV, so the subtleties of the patterns of violence of men versus women and how best to prevent them is a new area for growth and understanding.

CASE RESOLUTION

When alone with you, the mother reports that the boy's bruising occurred after her boyfriend hit him with a belt and that her marks occurred when the boyfriend was drunk and angry about the dinner she had prepared. She has contemplated leaving the relationship but is financially dependent on him, and pregnant with his child. He has threatened to harm her son if she leaves. She is currently afraid to return home but is not sure what to do.

You contact a social worker who assists in referring the mother and child to an IPV shelter and an IPV advocacy group. The social worker and the agencies work on an immediate safety plan while the mother and child wait in the office. As a mandated reporter of child abuse, you contact the child abuse hotline. The social worker assists you with the requirements in your state to report IPV or childhood exposure to IPV. The mother should be advised that a child abuse report was initiated, and the child protective authorities should also be made aware that IPV and child abuse are co-occurring in this family.

Disaster Preparedness

Elizabeth A. Edgerton, MD, MPH

CASE STUDY

A family comes in for their children's well-child visit with their 9-month-old daughter who has complex congenital heart disease and their 7-year-old son. The mother is concerned after a recent tornado in the next town resulted in prolonged power outages and what the family might do in this situation. Their daughter needs daily breathing treatments and often requires oxygen at nighttime. She is on multiple medications and a special formula. All of her specialty doctors are at the children's hospital, which is more than an hour from their house. She is also concerned because her husband has a seizure disorder that requires medication. She asks whether the family should stay together in a disaster or separate to get her daughter to the children's hospital.

Questions

1. How should families prepare for disasters, particularly natural ones known to occur in their area?
2. What should be included in disaster preparedness kits? How should medications for all family members be included?
3. When should families consider getting a generator?
4. How can families notify the utility company that they need to be flagged for priority return of service during a power outage?
5. What is the role of the local hospital and emergency medical services provider when families have children with special health care and critical medical needs?
6. What should the pediatrician recommend to families about children's immunization records and important medical history?
7. How do you assess for the impact of traumatic events on children and their families?

Disaster preparedness is not a new concept in our society. We have always had natural disasters such as earthquakes and hurricanes. The potential of war or pandemic infections has been present for decades. In the past these threats were managed by the state and federal programs. With increasing population density, global warming, international trade, and terrorist threats, our view of disaster preparedness is broadening to include natural disaster; chemical, biological, and radioactive exposure; and emerging pandemic infections. Major disasters, including man-made events such as terrorist attacks in New York City and natural events such as hurricane Katrina, demonstrate the vulnerability of a community and the need for extensive local preparation for potential disasters. In both of these disasters, the community response in the first hours to days was vital to the well-being of others. While the state and federal systems are a vital component of disaster preparedness, communities may play a greater role than in the past.

Children are more vulnerable than adults during a disaster. Studies from refugee camps have found that children younger than 5 years had a higher mortality rate than the crude mortality rate of adults during the emergency situation. In the United States, children represent 30% to 85% of disaster victims and response teams often lack appropriate pediatric equipment or protocols for their care. Furthermore, children are reliant on others for food, shelter and, importantly, for psychological support. Their immune systems

are often less mature; this puts them at greater risk of infection. Their unique nutritional needs put them at risk for malnutrition. Developmentally, they are at risk for acute and long-term psychological trauma from a disaster. The impact of being separated from their families can be devastating. Furthermore, children are at increased risk for exposure from chemical, biological, and radiation disasters due to their unique physiology. Infants and children have higher minute ventilation, resulting in increased inhalation of aerosolized agents. Their smaller height increases their exposure to high-vapor density agents, which are in higher concentrations closer to the ground. Infants' and children's skin is more permeable due to less keratinization; they also have a larger surface area to body mass ratio. As a result, exposed children receive a higher dose of transdermally absorbed toxins than adults exposed under identical circumstances.

A public health emergency occurs when the event exceeds the ability of community resources to provide routine care. This can be a result of any type of disaster. Preparedness experts suggest looking at public health emergencies from what is called an **all-hazards approach**. This approach focuses on the key elements that are needed to ensure that routine care can still be provided during a disaster. Specific case scenarios that occur rarely, such as chemical or radiation exposure, will require access to specialized resources that may be impractical to stockpile or are limited in availability. From a practical view, it is more effective to have the essential resources that are

needed across all types of disasters. The primary care pediatrician plays a vital role in disaster preparedness on the local, regional, and national level, not only as a medical service provider but also as an advocate to the special needs of children.

Pediatrician's Role With Families

Pediatricians serve as a resource to families in preparation for disasters. Disaster preparedness can be incorporated into the primary care pediatrician's anticipatory guidance with families. The US Department of Homeland Security in collaboration with the American Academy of Pediatrics recommends families focus on 4 areas: a community evacuation plan, a family emergency response plan, disaster supply kit, and finally a maintenance of the emergency response plan. Pediatricians may need to assess a family's level of readiness for a disaster and then tailor their anticipatory guidance accordingly. It is important for families to realize that everyone is susceptible to some type of disaster whether natural, chemical, biological, or radiation. Pediatricians need to ensure families understand the importance of preparation as well as the special needs of children during a disaster. Families should prepare an emergency kit that provides up to 3 days of basic essentials, including food, water, and clothing. Families need to include formula and diapers for infants and any daily medications for all family members. Copies of immunization and general medical information can be useful as well as pictures of family members in case the family unit is separated. Parents need to be prepared to handle non-emergent problems because medical care may be limited to the seriously ill and injured. If a family needs acute medical care, children may have to be treated in adult facilities; alternatively, for the family unit to remain together, adults within the family may need to be treated in pediatric facilities. The more information families can provide about any medical conditions requiring attention, the easier it will be to receive appropriate care in a disaster.

Families of children with special needs are especially vulnerable following a disaster because access to routine medical care may not be available. Common supplies such as a feeding tube or catheters may be in short supply or unavailable during a disaster. Families should not only have a sufficient supply of medication, but a surplus of medical equipment and nutritional supplements if necessary. Families with a child on a ventilator or who is oxygen dependent should notify the local utilities to flag their address for priority status during power outages. These families would also benefit by notifying their local emergency medical services (EMS) and local hospital of their child's medical needs. The American Academy of Pediatrics (AAP) has **emergency information forms** that can be completed with the pediatrician and should be part of the emergency preparedness kit. Families can also contact the National Organization on Disability and Emergency Preparedness (www.nod.org) or Family Voices (www.familyvoices.org) for more detailed information regarding preparing for a disaster with a special needs child. Some communities have developed systems where posters are disseminated that are

to be placed in the window specifying if any occupant may require special services from EMS should a disaster or terrorist attack occur.

After a disaster, children and adolescents may have chronic problems depending on the type of disaster. Such problems need to be addressed case by case. What is universal among all types of disasters is that there is a psychological impact on children. Multiple studies of various types of disasters demonstrate the increase in mental health symptoms among children and adolescents exposed to a disaster. This is true even if a family is not directly impacted by the disaster but is exposed to the event within the community, on the television, or via the Internet. Children may present with somatic complaints such as headaches and stomachaches, or may not want to participate in their normal activities. Long-term effects include depression, anxiety, aggression, and substance abuse. Age-appropriate discussions should be encouraged along with validation of the child's concerns while ensuring their individual safety. Post-traumatic stress disorder should be considered in patients with persistent symptoms that are not responding to family support. Families and health care providers can obtain further information through the AAP (www.aap.org) and the Substance Abuse and Mental Health Services Administration (www.samhsa.gov).

Pediatrician's Role in the Community

Pediatricians can participate in both the disaster preparedness planning as well as community surveillance to identify potential disasters. Many state and regional disaster preparedness plans are tailored for an adult population and may not consider the special needs of children. From an operational standpoint, it is more effective to have one plan that can take into consideration the needs of multiple vulnerable populations rather than have separate disaster preparedness plans for each population. Pediatricians can serve as consultants about local preparation, providing guidance about children's medical, nutritional, and psychological needs. For example, more staffing is required when caring for younger children, especially infants. Infants require formula and a sterile water supply, and young children require frequent meals. Ideally, children need to be with their caregiver, but if this is not possible then a child advocate needs to be with the child at all times. Children may not respond well to new environments and disaster protocols. The simple process of decontamination can be devastating to a young child without a parent. A child may have concerns about being sprayed with water or refuse to disrobe in front of strangers. This may impact the success of decontamination for children and adolescents. While adults may have similar issues, it is presumed they will comply with protocols; however, such compliance is less predictable in a pediatric population. Other issues may need to be addressed, such as providing for increased staffing in adult facilities caring for children, as well as the need for those facilities to stockpile pediatric supplies. Facilities also need to plan for children arriving without a caregiver and the need to establish an identification system allowing children to be reunited with their families. This was a significant problem for children displaced during hurricane Katrina. Refugee

camp often use digital cameras to photograph children on arrival as a way to reunite families. Recommendations include photographing children in their original clothing.

Triage systems need to take into account physiological differences of children as well as their psychological response to strangers. They may not be able to communicate their complaint, and because their vital signs are normally different from those of adults, medical personnel accustomed to working with adults may misinterpret their findings, resulting in children being over-triaged (judged to be sicker than they are). Stockpiling of medications for biological, chemical, or radiation disasters needs to take into consideration dosing differences in children compared with adults. Suspensions of medications will need to be available in addition to pill forms. Furthermore, many of the recommended antidotes and treatments are not approved for use in the pediatric population. Policies regarding the risks and benefits of their use in disasters should be established.

Pediatricians can also assist schools in developing disaster preparedness plans should a disaster occur during the school day.

Pediatrician's Role in Disaster Surveillance and Management

Pediatricians function as key public health workers. Their knowledge and diligence aids in local and regional surveillance for potential chemical, biological, and radiation disasters. Families are more likely to seek care from their pediatrician than an emergency department for early symptoms during and after a disaster. Although it is beyond the scope of this chapter to provide details about signs and symptoms following every type of disaster, the following section highlights important concepts in identifying and treating patients with exposures to chemical and biological agents and radiation.

Chemical exposures usually result in immediate symptoms and require special protection for emergency personnel as well as decontamination for the victims. Nerve agents, the most toxic of chemical agents, inhibit the enzyme acetylcholinesterase, resulting in accumulation of acetylcholine and excessive cholinergic stimulation in smooth muscles, exocrine glands, skeletal muscle, and preganglionic fibers. Symptoms include increased salivation, lacrimation, urination, gastric distress, and emesis, referred to as the **SLUDGE toxidrome**. Vesicant exposure leads to irreversible damage to mucous membranes, skin, and the respiratory system that occurs within minutes of exposure, often without any antecedent symptoms. Agents include mustard and lewisite. Cyanide is another common chemical agent, known for its "bitter almond" taste. Agents other than nerve agents usually do not result in severe mortality but rather incapacitate the victim.

Biological agents include bacteria, viruses, and preformed toxins. These agents are easy to disperse and, thus, can affect large populations. Unlike chemical exposures, the onset of symptoms is delayed by hours to days, and symptoms are more difficult to distinguish from common ailments. Secondary transmission of the infection is also of concern. Management of biological disaster requires detailed surveillance and containment of exposed populations.

Although there are far too many biological agents to discuss in any detail in a brief chapter, a few of particular relevance for disaster planning are mentioned here. **Anthrax**, from *Bacillus anthracis*, is a gram-positive sporulating rod, which presents with severe influenza-like symptoms with a high case fatality rate. Fever and dyspnea associated with a widened mediastinum are common and may progress to shock. Ciprofloxacin and doxycycline are recommended for prophylaxis and treatment among adults, but ciprofloxacin is not approved by the US Food and Drug Administration (FDA) for children younger than 18 years and doxycycline is contraindicated in children younger than 8 years. Clinicians need to consider consulting with experts to assist in assessing the risks and benefits associated with using these medications. Among the viruses, variola, more commonly known as **small pox**, is of concern. After its global eradication in 1980, children were no longer immunized, leaving all children and most adults susceptible to the virus. Similar to varicella, it presents with vesicles with umbilicated centers but is associated with a higher mortality rate of 3% to 30% among non-immunized individuals. Exposure to **botulinum toxin**, one of the most potent toxins, results in cranial nerve disturbances, descending paralysis, and respiratory distress. **Ricin**, derived from the castor bean, is another potent toxin. Inhalation results in fever, cough, and pulmonary edema, often resulting in death within days. Ingestion presents with severe vomiting and diarrhea, resulting in hypovolemic shock. There is no antidote or treatment for these biological toxins. For a complete list of biological agents, presenting symptoms, and potential treatment and/or prophylaxis, clinicians should consult the Centers for Disease Control and Prevention (www.cdc.gov).

Radiation exposure may occur as a result of damage to a facility that contains nuclear material, detonation of a nuclear weapon, or dispersal of nuclear material by a radioactive dispersal device. Ionizing radiation, high-frequency energy, presents the greatest health risk. It causes chromosomal breaks in cells that can persist for years. There are 5 types of ionizing radiation that have specific characteristics, behaviors, and toxicities: alpha particles, beta particles, gamma rays, x-rays, and neutrons. Alpha particles have limited ability to penetrate, but when inhaled or ingested can cause damage to epithelial tissues. Beta particles usually are used in a medical setting or are a by-product of nuclear reactors, have greater penetration, and can cause skin damage as well as internal damage. Gamma rays and x-rays are part of the electromagnetic spectrum. Gamma rays are high-energy and cause significant damage. This type of radiation would be seen after a nuclear detonation or from radioactive materials. Much less common are neutrons, which can produce 10-fold more damage than gamma rays. Furthermore, exposure is classified as external, internal, whole body, and partial body. The effects of radiation can be directly on target tissue, or indirectly due to free radicals created by the radiation. Tissue sensitivity is based on the cell's rate of division and level of differentiation. The most sensitive to least is as follows: lymphoid>gastrointestinal>reproductive>dermal>bone marrow>nervous system. The severity of exposure is also dependent on the dose of radiation, type of radiation, and age of victim.

Radiation exposure is quantified by the amount of energy absorbed (the *rad*, for radiation absorbed dose) and the relative biological effectiveness of doses (RBE) based on the type of ionizing radiation. The rem is the product of the rad and RBE. Under the International System of Units, the rad and rem are being replaced by the gray (1 Gy = 100 rad) and sievert (1 Sv = 100 rem). Radiation exposure from common radiographic procedures can range from 0.00005 to 0.0001 Sv (5–10 mrem) for a chest radiograph and 0.05 Sv (5,000 mrem) for a computed tomography scan.

The symptoms associated with radiation exposure depend on the total exposure. Nausea and vomiting can present with exposures of 0.75 to 1.0 Gy, and lymphoid and bone marrow suppression with exposures of 3.0 to 6.0 Gy. The mean lethal dose, the radiation dose for which half of the population is expected to die within 60 days, is 4.0 Gy. Long-term effects of radiation include increased incidence of cancer and psychological distress. Evacuation is the ideal intervention to decrease exposure, but may not be feasible in highly populated areas. Seeking shelter can greatly decrease the level of exposure, with large cement structures providing the best protection. The use of potassium iodide is effective in exposures to radioactive iodine, which is associated with nuclear power facilities. It can be dispensed in a pill form, and home suspensions can be made for pediatric patients. Dosage is based on level of radiation exposure and the age of the patient. Clinicians should consult the FDA (www.fda.gov) or the Nuclear Regulatory Commission to determine the appropriate dosage of potassium iodide depending on the level of radiation exposure. For individuals seeking medical care, containment and decontamination are essential. Removal of clothing and washing the skin with warm water is very effective. Supportive medical care is essential in managing patients with radiation exposure. Radiation results in significant immune suppression, neutropenia, and lymphopenia, which last for weeks. Clinicians should be aggressive in managing infections and consider treatments to increase bone marrow regeneration.

In addition to caring for patients, the pediatrician needs to take into consideration the well-being of his or her family as well as that of the office staff. During a disaster, office staff may not be able to come to work. For those able to report to work, extra supplies of food and water need to be available in case they are not able to return to their homes. An office disaster plan should be implemented with emergency contacts and preparation for the staff's basic needs. Basic medical supplies should be available to care for patients during a disaster. Depending on the type and severity of the disaster, access to the office facility may be prohibited. Plans for backup of patient medical records should be implemented as well as alternative sites in which medical services can be delivered.

Clinicians need to review their medical liability policies regarding providing care in a disaster situation. Most policies only provide coverage of care that is provided in the office setting. Good Samaritan laws vary in each state regarding what level of protection is provided

to the health care worker. The AAP recommends that during a disaster situation, pediatricians who volunteer do so under the auspices of an official disaster agency or recognized relief organization to ensure the greatest protection from liability.

Conclusion

Pediatricians have a vital role in pre-disaster, disaster, and post-disaster management. The essential components of disaster management are to provide for all basic human requirements, reduce an individual's vulnerability to disasters and, once a disaster has occurred, reduce the exposure risk. Pediatricians can educate and assist families in preparing for disasters. In addition, they can guide communities in their disaster preparedness planning to address and plan to accommodate the particular vulnerabilities of children. As with other health care providers, pediatricians also can contribute to the essential medical and public health workforce during a disaster. Pediatricians can access the most current guidelines and recommendations through multiple professional and governmental resources. It is imperative for the practitioner to have easy access to phone numbers and Web sites specific to pediatric disaster preparedness and response for the relevant local, state, and federal agencies.

CASE RESOLUTION

The family is relieved to discuss the importance of preparing for a disaster. They now have an idea of what is involved in disaster preparation (emergency kit with food, water, and medication) and feel less vulnerable. They will complete an emergency medical information form for the kit and call their local utility company to identify their house as a priority during a power failure. The mother shares with the pediatrician that her son has been sleeping less since the tornado and does not want to go to school because he is afraid of being away from the family. The pediatrician encourages the family to discuss his fears while ensuring his safety. Having the son participate in making the emergency kit and creating a family plan may help. A follow-up visit is scheduled to reassess his symptoms and decide if a further intervention is needed.

Adolescent Depression and Suicide

Monica Sifuentes, MD, and Robin Steinberg-Epstein, MD

CASE STUDY

A 15-year-old girl is brought to your office by her mother with the chief complaint of easy fatigability. The mother is concerned because her daughter is always tired, although several other physicians have told her that the girl is healthy. The adolescent, who states no complaints or concerns, appears very shy. She is currently in the 10th grade, likes school, receives average grades, and speaks both English and Spanish. The mother, a single parent, moved to the United States from El Salvador approximately 2 years ago with her 2 daughters. They are currently living with relatives in a 2-bedroom apartment. The mother is employed as a housekeeper, and the patient and her sister help their mother clean homes on weekends. During the week they make dinner for the rest of the family as a means of contributing to the rent. When you speak to the girl alone, she acknowledges she has a few friends at school and adamantly denies any drug, alcohol, or tobacco use. She has never been sexually active and

reports no history of sexual or physical abuse. The girl's physical examination is entirely normal, although her affect appears somewhat flat.

Questions

1. What is the significance of nonspecific symptoms, such as fatigue, during adolescence?
2. What factors contribute to depression in adolescents?
3. What are the classic signs and symptoms of depression in adolescents?
4. What are some important historical points to cover when interviewing adolescents with suspected depression?
5. How is the risk of suicide assessed in adolescent patients?
6. How should suicidal behavior (ie, suicide attempts) be managed in adolescents?

Depression has been identified as one of the multiple risk factors that predispose adolescents to suicide. However, not all teenagers who try to take their own life are depressed and, conversely, not all depressed adolescents attempt suicide. This distinction is important to keep in mind when evaluating adolescents for either depression or suicidal behavior. Early identification of risk factors in the susceptible adolescent along with early intervention for those with depressive symptoms will hopefully benefit the teenager at risk for suicide and allow the primary care pediatrician to provide the first line of intervention for their adolescent patient experiencing emotional distress.

Epidemiology

Depression

The exact prevalence of depression in adolescents is difficult to determine because depression is both an illness and a symptom. However, it is considered one of the main psychiatric conditions affecting children, along with anxiety. Depressive symptoms have been reported in as many as 50% of girls and 40% of boys in the 14- to 15-year age group. The overall prevalence of depression as an illness is approximately 5%; mild depression is reported in 13% to 28%

of teens, moderate depression in 7%, and severe depression in 1.3%. Depression occurs more commonly in adolescents than in prepubertal children and is more frequent in females than males after puberty.

Several risk factors contribute to the development of depressive disorders in adolescents (Box 140-1). Certain psychiatric conditions also are associated with depression, including anxiety disorders, eating disorders, substance abuse, conduct disorders, and borderline personality disorders.

Suicide and Suicidal Behavior

Suicide is the third-leading cause of death in the United States in individuals 10 to 24 years of age; only motor vehicle crashes and homicides result in more deaths in young people. In 1960 the annual suicide rate in this age group was 5.2 per 100,000, and by 1990 it had more than doubled to the highest recorded level of 13.2 per 100,000. By 2007 the rate had decreased to 6.7 per 100,000 in part due to the use of selective serotonin reuptake inhibitor (SSRI) antidepressants, the first of which came out in 1990. This amounts to more than 4,000 completed suicides in adolescents 15 to 24 years old in 2007. It has been stated that for every suicide that is completed successfully, 50 to 100 suicides are attempted.

Box 140-1. Risk Factors Associated With Depressive Disorders in Adolescents

- Family history of psychiatric illness (eg, parent with an affective condition or another family member with a bipolar or recurrent unipolar disorder)
- Age at onset of depression in the affected parent (the earlier the age of onset, the greater the likelihood of depression in the children)
- Exposure to an unexpected suicide attempt/completion in the school or community
- History of environmental trauma (eg, sexual or physical abuse, loss of a loved one)
- Chronic illness
- Certain medications (eg, propranolol, phenobarbital, prednisone)

According to the 2006 Youth Risk Survey of the Centers for Disease Control and Prevention, 16.9% of all students in grades 9 to 12 nationwide had seriously considered attempting suicide during the previous 12 months. Approximately 13% of these students had made specific suicide plans, more than 50% of students with suicide plans reported attempting to take their lives, and 2.3% of the individuals who attempted suicide required medical attention. Rates also differ by race and ethnicity, with African American teenagers having lower suicide rates than white youth, and African American females having the lowest suicide rate of all adolescents. American Indian/Alaska Native males have the highest suicide rate among this age group.

Several risk factors associated with adolescent suicide have been identified (Box 140-2). Although adolescent females are more likely to attempt suicide than males (22% vs 12%), males are more likely to succeed (ratio of 4:1 boys to girls). This fact may result from the lethality of the methods, such as firearms or hanging, that males usually choose. While females are more likely to ingest pills, the role of firearms is increasing. The availability of firearms and alcohol, which varies from state to state, greatly contributes to the occurrence of suicide. Up to 45% of individuals who have committed suicide show some evidence of intoxication at the time of death. Although most suicide attempts are impulsive, studies have shown that adolescents often have communicated their suicidal intent or ideation to someone before the attempt. Fifty percent of adolescents who attempt suicide have sought medical care within the preceding month and 25% within the preceding week. In contrast, only one-third have received previous mental health care.

Clinical Presentation

Depressed or suicidal adolescents may visit physicians for a variety of clinical reasons, but rarely do they seek professional assistance for feeling “depressed.” Adolescents have a difficult time accurately understanding their emotions. A depressed teen often presents as irritable, argumentative, or angry, rather than sad. They may exhibit diminished interest or pleasure in activities or relationships, changes in cognitive functioning (eg, concentration), sleep, appetite, or energy, which lead to impairments in multiple areas of daily living. They may also present with seemingly non-emergent complaints

Box 140-2. Risk Factors Associated With Suicide in Adolescents

- History of a previous suicide attempt (most important)
- Male gender
- Preexisting psychiatric condition (depressive/bipolar disorder, conduct disorder post-traumatic stress disorder)
- Alcohol and illicit substance abuse or dependence
- Psychological characteristics such as aggression, impulsivity, and hopelessness or severe anger
- Family history of psychiatric disorders, especially depression, substance abuse, and suicidal behavior
- Family disruption or stressful life event, including violence, divorce, or the death of a loved one
- Impaired parent–child relationship
- Exposure to an unexpected suicide attempt/completion in the school or community
- Chronic debilitating illness
- Anxiety about sexual identity (homosexuality or bisexuality)
- History of physical/sexual abuse or exposure to violence
- Availability of firearms in the home
- Living outside the home (homelessness or in corrections facility or group home)

and a flat affect or with multiple somatic concerns and an anxious appearance. Additionally, the teen may have frequent visits to the primary care practitioner’s office for acute conditions that on first glance seem unrelated, but later indicate possible substance abuse or a mood disorder. Some adolescents are accompanied by a family member or friend, which initially may make the teen reticent to discuss psychosocial issues with the provider. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision*, major depressive disorder (MDD) is diagnosed when at least 5 out of 9 listed symptoms or signs occur for at least 2 weeks. At least one symptom must be sadness or loss of interest for most of every day and there has to be a significant change in function. Changes can be manifested by poor academic performance, school attendance issues (including truancy and disruptive behaviors), and difficulties with peer and familial relationships (see Box 140-1).

Pathophysiology

The exact neurobiological etiology of depression remains elusive. It is believed to involve impaired serotonin and norepinephrine transmission in critical areas of the brain, most notably the frontal lobes. Like other complex psychiatric conditions, the etiology of depression seems to be multifactorial, with a strong genetic and psychosocial/environmental basis. The **genetic basis** of depression is suggested by statistics that indicate for instance that 25% of children who take their own lives have a family member or close relative that has committed suicide. Similarly, a family history of major depression is a significant risk factor for the development of depression in children. Studies suggest the incomplete penetrance of a dominant gene as a possible etiology for this finding. Regardless of the exact mechanism,

genetic influences can increase the adolescent's vulnerability for depression. Specific **environmental events** can occur in an adolescent's life that may precipitate a depressive episode, such as the loss of a loved one or parental divorce. Other events such as physical or sexual abuse also can trigger depression in a susceptible teen. Major depressive disorder is diagnosed when the symptoms last for at least 2 weeks and there is a change in usual function.

Differential Diagnosis

The differential diagnosis of depression includes any condition that may alter the patient's cognition or affect. For example, if a disease alters the nutritional status and leads to malnourishment, this may alter affect and energy, which may resemble depression (Dx Box). Examples include cancer, tuberculosis, and eating disorders such as anorexia nervosa. Endocrine disorders such as hypothyroidism, hyperthyroidism, and Addison disease can mimic depression. Central nervous system (CNS) pathology, although rare, includes tumors, infections, postconcussive syndromes, and cerebrovascular accidents. Concomitant systemic illnesses such as systemic lupus erythematosus, diabetes mellitus, and AIDS can have CNS manifestations that may be mistaken for an isolated episode of depression. While the above diseases can occur, they pale in comparison to the prevalence and significant contribution of substance and alcohol abuse. Comorbid conditions such as early-onset bipolar disorder can present initially with depressive symptoms. In fact, 20% to 40% of children who have MDD eventually develop bipolar disorder. Children with autism often develop comorbid depression during adolescence as a manifestation of their isolation and poor coping skills. Other psychiatric diagnoses to consider include adjustment disorders, uncomplicated bereavement, separation anxiety, and dysthymia, which is more chronic and sometimes less severe than major depression. Lastly, side effects of both prescribed and over-the-counter medications may produce clinical symptoms consistent with depression and therefore should be considered in the differential diagnosis.

Evaluation

History

The assessment of an adolescent for depressive symptoms is an important part of any routine encounter, but the diagnosis of depression may be difficult to make after just one interview. At the initial visit, a complete psychosocial or **HEADDSSS** assessment (*home, employment and education, activities, diet, drugs, sexual activity/sexuality, suicide/depression, safety*) should be performed on all adolescents (see Chapter 5). The parent or guardian should be included during the first part of the interview to review their observations and concerns regarding their adolescent's behavior and mood. The teenager then should be interviewed alone, and a thorough history of recent feelings, behaviors, and attitudes should be obtained (Questions Box: Adolescent Depression). Mood changes should be noted; a labile affect can be a symptom of ongoing depression. Physicians should keep in mind that patients who are malnourished for any reason can have a depressed or seemingly flat affect. A full

Dx Adolescent Depression

SIG: E CAPS Mnemonic

- S:** Sleep changes
- I:** Interests—decreased interest in school or activities
- G:** Guilt, helpless, hopeless
- E:** Energy (decreased), fatigue
- C:** Concentration decreased
- A:** Appetite (increased or decreased)
- P:** Psychomotor agitation and retardation
- S:** Suicidal ideation

- Depressed or irritable mood
- Decreased interest in most daily activities, including school
- Significant weight changes
- Sleep problems
- Psychomotor agitation or retardation
- Low energy or fatigue
- Feelings of worthlessness or guilt
- Diminished ability to concentrate or think
- Preoccupation with death or suicide

Questions

Adolescent Depression

- Does the adolescent occasionally feel sad or "blue" and not understand why?
- Does the adolescent have unexplained crying spells?
- Does the adolescent feel "mad," "bored," or "grouchy"?
- Does the adolescent seem inappropriately jovial?
- Have there been any recent losses in the adolescent's life that may explain his or her feelings?
- Is the adolescent having trouble with concentration or memory?
- Does the adolescent have trouble falling asleep at night or have early morning awakening?
- Has the adolescent lost weight recently or shown any disinterest in food?
- Does the adolescent have feelings of hopelessness and have any desire to hurt himself or herself? Has the adolescent made any previous suicide attempts?
- Do the parents or siblings have a history of drug or alcohol use?
- Is there a family history of affective disorders? What has been their response to treatment?
- Is there a history of family violence?

psychiatric assessment also should be completed to obtain information about a possible comorbid condition. This includes features of psychosis, anxiety disorders, disruptive behaviors, and mania. However, severe depression can be accompanied by symptoms of psychosis. Information about a family history of psychiatric illness or substance abuse, including alcohol abuse, also should be reviewed with both the teenager as well as the parent/guardian.

To identify youth at risk for suicide, practitioners must inquire about specific areas of adolescents' lives including a history of sexual/physical abuse, violence, or neglect and current interpersonal conflicts. Almost all females with a history of sexual abuse develop suicidal ideation by age 15. Feelings of hopelessness, agitation, and impulsivity should be identified, along with frequent thoughts of suicide or death. It has been reported that having frequent thoughts of suicide is the best predictor of suicide attempts. Adolescents who are suspected of being at risk for suicide must be questioned directly about suicidal ideation, specifically whether they have a plan in mind and access to firearms, medications, or other means of suicide. Previous suicide attempts also need to be reviewed with the teenager because 35% to 45% of adolescents that complete suicide have a positive history of a previous attempt. Nonlethal suicide gestures or other methods of self-inflicted harm should never be taken lightly or minimized. As is recommended in other arenas, initial questions should be nonspecific and become more specific as the interview proceeds, especially if answers to the previous questions are positive (Questions Box: Adolescent Suicide).

Promises to maintain confidentiality with depressed adolescents who are considered at risk for suicide are discouraged because parental involvement is strongly advised. Precipitating and motivating factors for any previous suicide attempts should be determined prior to the development of a treatment plan. More importantly, the lethality of previous attempts must be evaluated.

Physical Examination

A thorough physical examination and a review of systems should be completed to rule out a chronic medical condition such as hypothyroidism, inflammatory bowel disease, lupus, or anemia, or an organic etiology for nonspecific complaints. If patients have a history of sexual abuse, assault, or sexual activity, a genital examination should be performed to evaluate for sexually transmitted infections. In most cases, the physical examination may be of little yield in the adolescent with a true affective disorder, but careful examination may reveal findings such as cut marks, track marks, skin picking, or loss of tooth enamel, any of which may be helpful in comorbid conditions such as substance abuse or eating disorders. A careful detailed neurologic examination, including a mental status examination looking at eye contact, rate of speech, spontaneity in conversation, thought content, affect, and processing, is essential in differentiating various psychiatric conditions such as bipolar disorder and schizophrenia.

Laboratory Tests

While no routine laboratory studies are regularly recommended, to rule out organic etiologies for depression one should consider thyroid, glucose, hemoglobin, or sodium abnormalities as contributing factors and test as indicated. Screening for substance abuse and for pregnancy in females is strongly advised. Obtaining screening laboratories may serve as baseline parameters if pharmacotherapy is indicated. A complete blood cell count with differential, glucose, electrolytes, blood urea nitrogen, creatinine, liver function tests,

Questions

Adolescent Suicide

- Is the adolescent on any prescribed medications (eg, phenobarbital)?
- Is the adolescent experiencing any psychiatric difficulties, social maladjustments, or family or environmental challenges (eg, recent parental divorce, school expulsion)?
- Does the adolescent have a history of symptoms of depression, conduct problems, or psychosis?
- How is the adolescent progressing in school?
- Does the adolescent have a history of substance abuse?
- Does the adolescent have any legal problems?
- Does the adolescent suffer any social isolation or have interpersonal conflicts with family or friends?
- Has the adolescent suffered any personal losses recently?
- Has there recently been a suicide in the school or community?
- Are there any family problems such as abuse or neglect?
- Has the adolescent ever thought that life was not worth living?
- Does the adolescent ever feel hopeless?
- Has the adolescent ever thought of hurting himself or herself?
- Does the adolescent have a previous history of suicide attempts?
- Does the adolescent presently have a plan for suicide?
- Does the adolescent have access to firearms, medications, or other means of suicide?

and thyroid function tests would be included. Psychometric testing may help rule out a concomitant learning disability or attention-deficit/hyperactivity disorder.

Imaging Studies

Radiographic imaging, such as computed tomography of the head or magnetic resonance imaging of the brain, would be indicated if the history of physical examination suggests a CNS process.

Management

Depression

Treatment for depression typically follows 1 of 3 paths: **psychotherapeutic**, **pharmacotherapy**, or a **combination**. Recent research conducted by the National Institute of Mental Health supports psychotherapeutic intervention for mild depression. The types of therapy shown to be most effective for adolescents with depression include cognitive behavioral therapy and interpersonal therapy for adolescents. For more severe depression, or depression with suicidal ideation, the current first-line medical treatment in the primary care setting involves the use of SSRIs. Pharmacotherapy may be used with the aforementioned talk therapies. It should be noted that not all therapists are trained in the delivery of these therapeutic methods and in many communities these interventions are not readily available. Prescribing SSRIs earlier in these instances may be necessary.

If depressive symptoms are associated with a specific adjustment disorder such as divorce, a recent move, or death, and if family, peers,

or school factors are affected, **supportive counseling** is indicated. The duration and depth of counseling depends, in part, on how comfortable the primary care practitioner feels performing this task and how receptive the youth and his or her family are to this intervention. Identification of the specific problem, exploration of the teen's response to the problem, and development of a reasonable solution with the adolescent and the parents may be helpful to improve adherence to psychotherapy.

If family difficulties or dysfunction is the major issue, family members and the physician or counselor should meet to assess the magnitude of the problem and the motivation required to address it. Physicians should use this opportunity to educate both adolescents and families about the signs and symptoms of depression and the undeniable impact that depression has on school functioning, family and peer relationships, and social interactions. The need for individual cognitive-behavioral therapy as well as family therapy should be discussed as well as the effectiveness of psychiatric medication in the appropriate setting. Attention to parental mental health and to understanding the strategies necessary to manage the adolescent's irritability and isolation also are extremely important. Psychological referral should be initiated if patients require more prolonged or intensive psychotherapeutic treatment, the degree of depression seems to increase, suicidality becomes an issue and additional mental health consultation is needed, or a comorbid psychiatric condition is suspected.

Immediate **psychiatric consultation and referral** are indicated if adolescents have severe depressive features that interfere with daily functioning or if they are suicidal, homicidal, or psychotic. Ensuring the adolescent's safety is the priority. A mental health referral is also appropriate if supportive counseling by the primary care physician has been ineffective or when the depression is recurrent or chronic.

Psychiatric intervention generally includes **pharmacotherapy** in conjunction with psychotherapy because most cases of depression include psychological, social, and environmental components. Although much attention has been given to safety concerns regarding the use of antidepressant medications among children and adolescents, SSRIs are considered first-line medications for the treatment of moderate to severe depression in teenagers (see Chapter 114). Two SSRIs, fluoxetine (Prozac) and escitalopram (Lexapro), have been approved by the US Food and Drug Administration (FDA) for treating depression in adolescents. The side effects tend to be dose related, and most subside with time (1–2 weeks) or with a decrease in dosage. Common adverse effects include headache, abdominal pain, diarrhea, sleep changes, and jitteriness or agitation. Serious behavioral symptoms, such as aggression, hostility, and impulsivity, must be reviewed with a psychiatrist.

The black box warning for antidepressant medications was added by the FDA in 2004 stating that on rare occasions children and adolescents treated with these drugs are more likely to display suicidal behavior, but no increase in the risk of completed suicides was noted. This was based on a meta-analysis conducted by the FDA. Subsequently, physicians decreased their use of antidepressants,

which resulted in an increase in the rate of completed suicides. It now is generally accepted that although there may be a small risk of suicidal behavior, the benefits of prescribing antidepressants outweigh the risks if patients are monitored. This caution should be put in context with the risks of untreated depression and discussed openly with the parent or guardian and the adolescent. Prior to starting the medication, informed consent must be obtained from the parent or guardian as well as assent from the teenager. Patients should be observed closely for worsening of symptoms, suicidality, or unusual changes in behavior. Families should be educated regarding the importance of close follow-up and immediate, open communication with the provider if these symptoms should occur. Initially, the adolescent should be seen or the family contacted frequently during the first 6 weeks. Improvements in vegetative functions such as sleep and appetite often can occur within the first 3 weeks. Family observations are initially more telling than self-observation. In fact, the last feature to improve often is the patient's self-report of mood. An adequate trial of SSRIs is reported to be at least 4 to 6 weeks. Frequent medication adjustments are not advised, and abruptly stopping SSRIs is not recommended due to withdrawal or flu-like symptoms. Stopping medication after several weeks should include a slow taper.

Suicide and Suicidal Behavior

Adolescents who are considered at risk for suicide must be asked directly at every visit if they are, in fact, suicidal and if they have a plan (Questions Box: Adolescent Suicide). Response to this inquiry determines whether adolescents will be treated on an inpatient or outpatient basis. In most cases, the adolescent with no previous suicide attempts, ambivalence regarding suicidal thoughts, no real intent to die, and a good family support system may be managed as an **outpatient**. In patients who deny current suicidal ideation, a written or verbal "no suicide" contract can be made between the physician or psychologist and the adolescent, although research does not support the conclusion that such contracts actively prevent suicide. Unwillingness to sign such a contract should raise alarming concern. The patient is asked to agree to contact the clinician, parent, or another responsible adult if he or she feels a suicidal urge or experiences suicidal intent. The precipitants for possible suicidality must be reviewed, and alternative methods for coping should be rehearsed with the teenager. In addition, all potential means of suicide, particularly firearms and toxic medications, must be removed from the home or place of residence. It is not enough to "secure" firearms; they must be removed. Referral to a therapist is recommended as soon as possible. Preferably, this should be arranged while adolescents are in the office, and they should be given a definite time and date for the appointment. Ideally, the therapist should meet with the family before the first appointment with the adolescent alone. Detoxification from drugs or alcohol, if necessary, also should be addressed.

Because all suicidal threats, gestures, or ideations by adolescents must be taken seriously, emergent psychiatric referral is required for most of these individuals. Adolescents judged to be at serious risk for suicide should be managed as **inpatients** and admitted to a pediatric

or adolescent unit for 24 to 48 hours of observation. The purpose of this brief hospitalization is 3-fold: (1) to stabilize patients medically, if necessary; (2) to observe and evaluate patient–family dynamics; and (3) to impress on patients and families that the attempt has been recognized and taken seriously. Intervention requires the involvement of mental health professionals in addition to social services. Transfer to an inpatient psychiatric treatment center is indicated for those adolescents who are judged by mental health consultants to have serious suicidal intentions or an underlying psychiatric illness.

Prognosis

The risk of recurrence of major depression in adolescents who have recovered is substantial. One study reports that 5% of patients relapse within 6 months of recovery, 12% within 1 year, and an estimated 33% within 4 years. Higher rates of recurrence have been reported, however, with approximately 70% of teens with MDD experiencing another depressive episode within 5 years. In addition, youth who have a depressive disorder have a 4-fold risk of the same disorder as an adult. Prepubertal-onset depression is associated with an approximately 30% risk of developing future bipolar disorder or mania.

The risk of repeated suicidal behavior seems to be greatest within the first 3 months following the initial attempt. Reported reattempt rates are 6% to 15% in the first 1 to 3 years following the initial attempt.

CASE RESOLUTION

In the case history presented at the beginning of this chapter, the girl's symptoms may be indicative of depression because she has a flat affect and seems to be somewhat isolated (insufficient time for friends and just recently moved to the United States). She seems to be at low risk for suicide, however. The physician should nonetheless inquire about symptoms of depression and ask her directly about suicidality, and then make arrangements to follow the girl's condition closely. If depression is confirmed at future visits or if she becomes suicidal, both she and her family should be referred to a mental health professional for immediate consultation and intervention.

Cancer in Children

Wendy Y. Tcheng, MD

CASE STUDY

A 10-year-old boy has a history of intermittent fevers of 102.2°F (39.0°C) for 1 month. For 2 days, he has experienced increasing shortness of breath with rapid respirations. His face is dusky and plethoric, and the veins in his neck are prominent. He has bilaterally enlarged cervical lymph nodes. The remainder of the examination is normal.

The blood cell count is normal, but the erythrocyte sedimentation rate is 110. A chest radiograph reveals a large mediastinal mass.

Questions

1. What signs and symptoms are associated with malignant conditions in children?
2. What oncological emergencies require immediate attention?
3. What factors correlate with the development of cancer in children?

Epidemiology

Childhood cancer is rare. Approximately 12,400 children and adolescents younger than 20 years are diagnosed with cancer each year in the United States. The likelihood of a child developing cancer before the age of 20 years is 1 in 300 for males and 1 in 333 for females. Cancer remains the leading disease-related cause of death in children younger than 15 years. The incidence is higher in children younger than 5 years and in children between the ages of 15 and 19 years. Acute leukemia is the most common childhood cancer, followed by brain tumors, lymphomas, neuroblastoma, Wilms tumor (nephroblastoma), and other less common pediatric solid tumors.

Environmental factors, genetic predisposition, and developmental processes may all play a role in influencing the cancer risk of a child. Case-control epidemiology studies looking for the causes of pediatric cancer have evaluated foods, prenatal exposures of parents and affected offspring, electromagnetic fields, radon, and various other environmental factors with no conclusive evidence of causality to date. Although many environmental factors are known to induce carcinogenesis, current evidence does not support a major causative role for exogenous factors in childhood cancer. Most childhood cancers result from aberrations in early developmental processes. Some known risk factors for selected childhood cancers include (1) *infectious agents* such as Epstein-Barr virus (B cell lymphomas [Burkitt], Hodgkin lymphoma, nasopharyngeal carcinoma), HIV (B cell lymphomas, Kaposi sarcoma, leiomyosarcoma), hepatitis B and C (hepatocellular carcinoma); (2) *ionizing radiation* (leukemia, osteosarcoma, brain tumors); (3) *chemotherapeutic agents* (leukemia, osteosarcoma); (4) *immunodeficiency* (non-Hodgkin lymphoma); and (5) *genetic conditions*. Approximately 4% to 10% of childhood cancer results from inherited genetic mutations that

result in a cancer predisposition. Children with trisomy 21 syndrome have an increased risk of leukemia (both lymphoid and myeloid). Beckwith-Wiedeman syndrome is associated with an increased risk for hepatoblastoma and Wilms tumor. Inheritance of mutations in tumor suppressor genes such as the retinoblastoma gene or the p53 gene (Li-Fraumeni syndrome) predispose affected children in families with these mutations to particular malignancies at a greater frequency and an earlier age than in unaffected individuals.

Clinical Presentation (Table 141-1)

The signs and symptoms of childhood cancer are varied, often non-specific at the start, and can mimic many common pediatric conditions. Acute lymphoblastic leukemia (ALL) is the most common childhood cancer, accounting for 80% of pediatric leukemia cases. Acute myeloid leukemia (AML) accounts for the remaining 15% to 20% of cases. Children with **acute leukemia** present with signs and symptoms that reflect leukemic infiltration of the bone marrow and extramedullary locations. Children commonly present with generalized bone pain and signs and symptoms related to pancytopenia (fever, fatigue, pallor, bleeding, bruising, and infections). Disseminated intravascular coagulation is characteristic of AML, especially acute promyelocytic leukemia. Leukemic infiltration of extramedullary sites can lead to hepatosplenomegaly, lymphadenopathy, chloromas, central nervous system (CNS) and, rarely, testicular involvement. Children with high white blood cell counts at presentation (leukocytosis) can present with signs and symptoms of leukostasis typically involving the lung or brain. Tumor lysis syndrome can occur, either spontaneously or with the initiation of chemotherapy. Tumor lysis syndrome occurs as a result of breakdown of leukemic blasts that results in the release of metabolic by-products. It is characterized by a metabolic triad of hyperuricemia,

Table 141-1. Signs and Symptoms of Childhood Cancer

<i>Disease</i>	<i>Symptoms</i>	<i>Signs</i>
Leukemia	Fatigue Bone pain Fever, infection Petechiae, purpura, bleeding Disseminated intravascular coagulation Superior vena cava (SVC) syndrome Headache Seizures Oliguria/anuria	Anemia Neutropenia Thrombocytopenia Lymphadenopathy Hepatosplenomegaly Mediastinal mass Petechiae, purpura Papilledema Cranial neuropathies Renal failure
Brain tumors	Supratentorial tumors Seizures Visual dysfunction Unilateral motor dysfunction Infratentorial tumors Deficits of balance Difficulty breathing Increased intracranial pressure Headache Vomiting Diplopia Motor weakness Loss of developmental milestones	Upper motor neuron signs Marcus Gunn pupils Parinaud syndrome Diabetes insipidus Appendicular dysmetria Sixth nerve palsy Cranial neuropathies Horner syndrome Papilledema Systemic hypertension Sixth nerve palsy "Setting sun" sign Large head size
Lymphoma		
Non-Hodgkin	Supradiaphragmatic (lymphoblastic) Respiratory difficulty, cough SVC syndrome Enlarged/enlarging lymph nodes Infradiaphragmatic (small, non-cleaved) Abdominal obstruction Intussusception Abdominal distension	Mediastinal mass +/- effusions Lymphadenopathy Abdominal mass Hepatosplenomegaly Obstructive jaundice
Hodgkin	Constitutional symptoms (fever, weight loss, pruritus)	Lymphadenopathy +/- matted nodes
Neuroblastoma	Abdominal mass Skin nodules Proptosis, "raccoon eyes" Nystagmus Diarrhea Spinal cord compression symptoms	Hypertension Hepatosplenomegaly Horner syndrome
Rhabdomyosarcoma	Related to primary site	

Table 141-1. Signs and Symptoms of Childhood Cancer, continued

Disease	Symptoms	Signs
<i>Lymphoma, continued</i>		
Wilms tumor	Rapid development of abdominal swelling Painless hematuria	Abdominal mass Hypertension Associated congenital anomalies Aniridia Hemihypertrophy Urogenital anomalies
Ewing sarcoma	Painful swelling of bone Constitutional symptoms (fever, fatigue)	
Osteosarcoma	Painful swelling of bone	

hyperkalemia, and hyperphosphatemia, which places a child at risk for renal dysfunction or failure secondary to precipitation of urate or calcium phosphate crystals within the renal tubules. Involvement of the CNS by leukemia can result in signs of increased intracranial pressure (ICP) (ie, headache, vomiting, hypertension, seizures, cranial neuropathies).

T-cell ALL or T-cell lymphoblastic lymphoma can present with a large anterior mediastinal mass and symptoms related to compression of the mediastinal mass on the trachea and blockage of venous return and lymphatic drainage (superior vena cava [SVC] syndrome). Children with SVC syndrome can present with wheezing, dyspnea, dysphagia, plethora, and cyanosis. Pleural and/or pericardial effusions may also be present. Superior vena cava syndrome can rapidly progress and constitutes a true oncologic emergency that requires prompt intervention.

Lymphomas in children can be divided pathologically into either Hodgkin or non-Hodgkin lymphoma. Children with **Hodgkin lymphoma** typically have a prolonged history (often at least 2–3 months) of painless enlarging cervical or supraclavicular lymphadenopathy. Affected lymph nodes can be firm, immobile, rubbery, and non-tender. In two-thirds of cases, mediastinal adenopathy may be present resulting in cough or wheeze. Constitutional symptoms such as fatigue, pruritus, and anorexia can occur, as well as the classic “B” symptoms (ie, fever, night sweats, weight loss greater than 10% of body weight). **Non-Hodgkin lymphoma** can be distinguished as lymphoblastic or non-lymphoblastic. Children with **lymphoblastic lymphoma** often present with supradiaphragmatic disease and may have cervical or supraclavicular lymphadenopathy, sometimes in association with a mediastinal mass or SVC syndrome (as previously described for T-cell lymphoblastic lymphoma). Central nervous system disease in such children is associated with signs of increased ICP. Patients with **non-lymphoblastic lymphoma** of the Burkitt or non-Burkitt type often present with intra-abdominal disease that can manifest as intussusception, abdominal obstruction, hepatosplenomegaly, or obstructive jaundice. Children with sporadic Burkitt lymphoma can present with a rapidly enlarging abdominal mass associated with tumor lysis syndrome. Endemic Burkitt lymphoma (African) presents with facial or isolated jaw tumors. In

addition, patients with lymphoma can manifest a number of paraneoplastic syndromes. These include idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia, nephrotic syndrome, and peripheral neuropathies, which may be mediated by abnormal and lymphoma-driven humoral or cell-mediated processes. Children with lymphomas are also at risk for tumor lysis syndrome as described for leukemia. In general, patients may either have entirely normal blood cell counts or a mild anemia, but occasionally their bone marrow may be infiltrated, giving a clinical picture consistent with leukemia with anemia, thrombocytopenia, or neutropenia.

Children with **brain tumors** can present with diverse signs and symptoms, depending on the anatomical location of the tumor (infratentorial, supratentorial, or brain stem), age of the child (ie infants with open sutures), and presence and degree of increased ICP. Infratentorial tumors, which are more common in children, typically present with gaze palsies, cerebellar signs (especially truncal ataxia), dysmetria, or vomiting. Supratentorial tumors can cause seizures, upper motor neuron signs (ie, hemiparesis, asymmetrical hyperreflexia, clonus), sensory changes, behavioral changes, decreased school performance, and disorders of the midbrain (Parinaud syndrome—paralysis of upward gaze). Signs and symptoms of ICP are often in the forefront of complaints. Recurrent morning headaches, headaches that awaken the child at night, intense headaches, vomiting, lethargy, sun-downing (eyes deviating downward like a sun setting on the horizon), increasing head circumference and loss of developmental milestones in infants, and change in school performance in older children all warrant close evaluation.

Children with spinal cord involvement from a primary spinal tumor or a paraspinal tumor (neuroblastoma, Ewing sarcoma, leukemic chloroma) may present with persistent back pain, intense radicular pain, local bony tenderness of the affected vertebrae, abnormal reflexes, abnormal dermatomal sensory examination, weakness/evolving paralysis, and subtle symptoms of bowel or bladder dysfunction (constipation, difficulty urinating). Suspicion of a spinal cord compression is an oncologic emergency for which timely, appropriate consultation must be sought.

Neuroblastoma is a malignancy of sympathetic ganglionic cell origin and can arise anywhere along the sympathetic nervous system.

Most tumors arise in the abdomen (adrenal or paraspinal); additional sites include the neck, chest, and pelvis. At presentation, tumors may be localized, with or without regional lymph node extension, or disseminated involving bone, bone marrow, and liver. Children with localized disease are often asymptomatic and the tumor is detected when radiographic imaging is performed for other medical purposes. Children with disseminated disease are ill-appearing and may present with fever, bone pain, and irritability. Paraneoplastic syndromes may also be present at diagnosis with a variety of features such as opsomyoclonus/myoclonus/ataxia (random dysconjugate eye movements, myoclonic jerking), cerebellar ataxia, and diarrhea. Proptosis and hemorrhage due to metastases involving the periorbital region can result in periorbital swelling and ecchymoses (“raccoon eyes”). A cervical tumor may be associated with unilateral Horner syndrome (unilateral ptosis, miosis, and anhidrosis).

Nephroblastoma or **Wilms tumor**, which arises in the kidney, usually presents as a painless abdominal mass, often detected by a parent while bathing the child. Associated symptoms may include fever, abdominal pain, or hematuria. If there is abdominal trauma, these bulky masses can rupture and hemorrhage and a child may present with acute abdominal pain and swelling. On examination, children may have hypertension, stigmata of associated genetic syndromes (Beckwith Wiedeman syndrome, Denys-Drash syndrome), or other isolated congenital anomalies such as aniridia, hemihypertrophy, or hypospadias.

The **bone sarcomas** that occur in children include Ewing sarcoma, osteosarcoma, and other rarer sarcomas. These tumors are most common in adolescents and rarely seen in young children. Bone tumors can present with pain at the site of tumor, with or without an associated soft tissue mass. Osteosarcomas classically involve the metaphyseal portions of the long bones, with the distal femur and proximal tibia being the most frequently involved sites. Metastatic disease, if present (15%–20% of cases), primarily involves the lung, although other sites of bone can be involved. Ewing sarcomas that occur in bone, most commonly involve the flat bones of the axial skeleton. When affecting the long bones, they tend to arise in the diaphyseal region (unlike osteosarcoma). Twenty-five percent of cases will have metastatic disease at presentation involving lung, bone, or bone marrow. Children with Ewing sarcoma may also have associated constitutional symptoms such as low-grade fever, fatigue, and weight loss.

Rhabdomyosarcoma, a soft tissue sarcoma of childhood, presents with signs and symptoms dependent on the location of the primary tumor. Sites include the head, neck, chest, abdomen, genitourinary tract, or extremities. Less than 25% of children will present with metastatic disease, but when present can involve lymph nodes, lungs, bone marrow, and bone. Head and neck sarcomas commonly arise in parameningeal and orbital sites and can present with recurrent headache, vomiting, visual problems, and proptosis. Abdominal and pelvic primary tumors can present with a palpable abdominal mass, pain, constipation, urinary obstruction, or dysuria. Genitourinary tract tumors most often involve the bladder or prostate and can present with pain, constipation, and urinary obstruction. One classic

presentation occurs in girls who present with a grape-like mass at the introitus and vaginal bleeding. This is due to tumor involving the vagina or uterus and is known as sarcoma botryoides. Primary tumors involving an extremity present with swelling at the site of tumor that can be painful and tender on palpation.

Pathophysiology

Although the macroscopic causes of pediatric cancer are not well elucidated, significant research has been made in determining some of the cellular and subcellular events that either actively trigger or fail to prevent malignancy. Growth factors are responsible for stimulation of cellular proliferation, and growth factor receptors transduce this signal into the cell via cytoplasmic secondary messengers, which in turn transmit the signal to nuclear regulatory factors. These factors ultimately regulate transcription of new RNA and protein, resulting in the desired cellular response of either stimulation or inhibition of growth. Malignant cells have a genetic makeup that differs from the constitutional karyotype of the host. A series of mutations occurs in genes that regulate cell growth and differentiation resulting in dysregulation of cell growth, differentiation, and death. Oncogenes promote cell growth and tumor suppressor genes inhibit cell division. When there is inappropriate overexpression of a normal oncogene or underexpression of tumor suppressor genes, inappropriate cell growth and division occur resulting in a malignant transformation.

There are usually multiple genetic aberrations present that lead to malignant transformation of a cell. One of the most important tumor suppressor genes is *p53*. The *p53* gene encodes for a nuclear protein that is expressed in all cells of the body and serves to induce cell cycle arrest or apoptosis in response to DNA damage. Inactivation of *p53* has been identified in numerous cancers. An initial event can alter or knock out one allele of a *p53* gene pair, and a second event results in loss of heterozygosity for that genetic locus. Either an inherited abnormality of *p53* (Li-Fraumeni syndrome) or a serendipitous accident to *p53* can cause heterozygosity for that gene. If a second event knocks out complete function of *p53*, a DNA-damaged cell can escape the signal to arrest its growth or to undergo apoptosis. The result can be a malignant transformation that allows the abnormal cell to grow unchecked.

Cancer's threat to a living organism lies in its uncontrolled growth. By growing unchecked and invading, compressing, and metastasizing to vital organs, malignant cells threaten normal life functions and cause symptoms specific to the affected area of the body.

Differential Diagnosis

Cancer is rare and often challenging to diagnose in children. Many of the presenting symptoms can be nonspecific and easily attributed to more common childhood complaints. To add to the difficulty, a pediatric practice will on average see a case every 5 to 7 years.

The differential diagnoses for some of the common childhood complaints that may suggest an underlying malignancy will be discussed. **Lymphadenopathy** is a common pediatric complaint and is most frequently due to infections (see Chapter 85). Acute bacterial adenitis, usually involving the head and neck region, is typically

associated with local signs of inflammation such as erythema, warmth, and tenderness. Cervical adenopathy due to viral illness is typically bilateral, and the lymph nodes are usually mobile, soft, and non-tender. Generalized lymphadenopathy or regional lymphadenopathy characterized by firm, matted, rubbery lymph nodes should raise the suspicion for an underlying malignancy. Lymphadenopathy that is persistent or progressive, despite empiric antibiotic therapy or resolution of infectious symptoms, also merits further evaluation for malignancy. Leukemia often presents with generalized lymphadenopathy, usually in association with hepatosplenomegaly and abnormal laboratory findings. Lymphoma typically presents with regional lymphadenopathy, often in the cervical or mediastinal region, in conjunction with other signs of systemic illness. Metastatic disease (neuroblastoma, rhabdomyosarcoma) may also present with regional lymphadenopathy. Nonmalignant causes of neck masses that can be mistaken for cervical lymphadenopathy include structural anomalies such as branchial cleft cysts or cystic hygromas (see Chapter 79).

Bone and joint pain are common complaints in children with acute leukemia, because of bone marrow involvement, and may be generalized. This presentation can be confused with various rheumatologic conditions. Localized bone pain is a common presentation for children with primary bone cancers (osteosarcoma, Ewing sarcoma) and is often attributed by the child or parents to some trauma. It is not unusual for the diagnosis to be delayed several months. Differential diagnosis includes infection (osteomyelitis), trauma, musculoskeletal conditions, and benign bone lesions.

Headache is a common complaint facing the general pediatrician, and few of these headaches are caused by intracranial brain tumors. When evaluating a child with headaches, signs to raise the index of suspicion for a brain tumor include persistent vomiting, recurrent morning headaches or headaches that awaken the child, worsening headaches, associated neurologic abnormalities, and visual changes (papilledema on examination). In infants, increasing head size, sun-downing, and loss of acquired developmental milestones are red flags. The differential diagnosis for headaches in children is broad and includes infections (meningitis, sinusitis), migraines, hydrocephalus, hemorrhage, and seizures.

An **abdominal mass** in an infant or child is always concerning and merits an evaluation. The most common malignant causes for an abdominal mass in this age range include neuroblastoma, nephroblastoma (Wilms tumor), hepatoblastoma, non-Hodgkin lymphoma (ie, Burkitt lymphoma), sarcomas, and germ cell tumors. Massive hepatosplenomegaly due to leukemic or lymphomatous infiltration can also be palpated as an abdominal mass. Nonmalignant etiologies of an abdominal mass may include hepatomegaly or splenomegaly, renal cysts, hemangiomas, or constipation.

Pancytopenia or **single cytopenias** are always worrisome for a malignancy involving the bone marrow. Acute leukemia is the most common malignancy involving the bone marrow and can present with leukopenia, anemia, thrombocytopenia, or in combination. Any malignancy that can metastasize to the bone marrow (neuroblastoma, lymphoma, Ewing sarcoma, rhabdomyosarcoma) can also produce pancytopenia or depression of one of the cell lines due

to replacement of the bone marrow. Pancytopenia can occur as a primary bone marrow failure syndrome, such as Fanconi anemia, or as an acquired aplastic anemia due to infections (post-hepatitis), drugs (chloramphenicol, anticonvulsants), radiation, or idiopathic causes. Transient mild depression of the cell lines (most often leukopenia or anemia) due to infectious causes is very common during childhood. Depression of 2 of the 3 bone marrow cell lines merits a closer evaluation.

Evaluation

History

The history should focus on the duration and evolution of symptoms as well as the presence or absence of constitutional symptoms (eg, anorexia, fever, night sweats, weight loss). The impact of the symptoms on daily activities (eg, school attendance, sports) should be determined and will clue the physician to the scope of the illness. Recent or persistent infections, medications, or unusual environmental exposures should also be ascertained (Questions Box). Relevant medical history should be considered. A previous cancer diagnosis would raise the index of suspicion for relapse or a secondary malignancy. Certain immunodeficiencies and genetic syndromes are associated with an increased risk for malignancy (eg, trisomy 21 syndrome and leukemia) and should also be considered. A family history of childhood cancers or genetic syndromes is also important.

Questions

Cancer

- How long has the child had the symptoms?
- Does the child have a family history of cancer?
- Does the child have a history of constitutional symptoms (eg, fever, weight loss)?
- Does the child have a history of recent onset of pallor, fever, bleeding, pain, swelling, hematuria, or malaise?
- Has the child been attending school or participating in routine activities?
- Has the child been exposed to any environmental toxins?

Physical Examination

A thorough physical examination is essential, with particular attention to symptomatic areas (see Table 141-1). In general, the lymph nodes should be carefully assessed for enlargement or malignant characteristics (firm, fixed, rubbery nodes) and the abdomen for organomegaly or masses. The skin should be evaluated for the presence of pallor, petechiae, or purpura that would suggest anemia or thrombocytopenia. A thorough search for signs of infection or persistent infection should be performed and, if present, may reflect bone marrow disease with neutropenia. Neurologic symptoms, including headache, vomiting, or focal complaints, warrant a full neurologic examination. Increased ICP may manifest as papilledema or

sixth nerve palsy. In infants, increased ICP can manifest with a large head size, full fontanelles, or sun-downing. A complaint of back pain also merits a full neurologic examination with close attention to any signs of spinal cord compression, suggesting a possible spinal or paraspinal mass

Laboratory Tests (Table 141-2)

In a child with nonspecific or constitutional symptoms concerning for malignancy, it is reasonable to begin with a screening complete blood cell count (CBC), peripheral blood smear, and comprehensive chemistry panel (electrolytes, renal and liver function). If a malignancy is suspected, lactate dehydrogenase is useful as a nonspecific marker for increased cell turnover. If leukemia or lymphoma is suspected, evaluation for tumor lysis syndrome (by checking uric acid, potassium, phosphate, and calcium) should be performed. In addition, certain tumors secrete or synthesize characteristic markers and metabolites that are pathognomonic for their diagnosis. For example, elevated levels of the sympathetic neurotransmitter metabolites vanillylmandelic acid and homovanillic acid are found in the urine of individuals with neuroblastoma or pheochromocytoma. Tumor markers such as α -fetoprotein and β -human chorionic gonadotropin are characteristic of germ cell tumors. α -fetoprotein is a useful tumor marker for hepatoblastoma as well. Monitoring of these levels is useful as an indicator of response to therapy or relapse. Other laboratory values, such as ferritin or erythrocyte sedimentation rate, can be elevated and reflect an underlying systemic illness (see Table 141-2).

Imaging Studies

Radiographic studies are a necessity in the initial evaluation and staging of most childhood cancers. Once the diagnosis of malignancy has been confirmed, appropriate imaging studies to assess the local and metastatic spread of the disease should be performed before the initiation of therapy. The type of studies performed depends on the specific malignancy and its associated pattern of metastatic spread. Common studies performed include radiographs, computed tomography (CT), magnetic resonance imaging, and gallium or positron emission tomography (PET) scans. For leukemias and lymphomas, an initial chest radiograph is necessary to evaluate for a mediastinal mass (most commonly seen in T-cell leukemia/lymphoma). Additional imaging is typically not necessary for leukemia; however, lymphomas warrant further diagnostic imaging for staging (CT, gallium, or PET scans). Required imaging for evaluation of specific childhood cancers is provided in Table 141-2.

Pathology

Children with suspected malignancies should be referred to a children's cancer center where there are specialized pediatric oncologists, radiologists, surgeons, and pathologists who can work together to establish the best approach for diagnosis (biopsy or removal of tumor) and handling of tissue. Collection of fresh tissue at biopsy for specialized genetic tests and tumor banking is important and can contribute significantly to a complete pathologic diagnosis.

There are certain clinical scenarios where obtaining tissue for pathologic diagnosis is difficult. Children who present with a large mediastinal mass may be in respiratory distress (secondary to SVC syndrome), and at high risk during anesthesia. In this situation, coordinated efforts should be made to obtain pathology specimens in the least invasive manner, before the initiation of therapy. Diagnosis can often be made by less invasive procedures (CBC, peripheral blood flow cytometry, bone marrow aspirate/biopsy, pleurocentesis) that may require very minimal sedation. If therapy needs to be started, then biopsy should be performed as soon as clinically tolerated.

Management

If a diagnosis of cancer is suspected or confirmed in a child, then referral to a pediatric cancer center is important where appropriate diagnostic procedures, tissue handling, and treatment can be provided.

Diagnosing and treating childhood cancer requires a multidisciplinary team consisting of pediatric oncologists, surgeons, radiation oncologists, pathologists, and other pediatric subspecialists. In addition, supportive ancillary services such as social work, childlife, child psychology, pain service, palliative care programs, and religious support are important. When making a referral for a child with a suspected cancer, the referring physician should prepare the family with his or her suspicions and the likely workup that will ensue at the accepting center.

Because the management of specific childhood cancers is beyond the scope of this chapter, the discussion will focus on the general principles of pediatric oncologic management. The primary therapeutic modalities for the treatment of childhood cancer include **chemotherapy, surgery, radiation therapy, and stem cell transplantation**. Increasingly, as the molecular aberrations of cancer are becoming understood, cancer-targeted therapies are becoming more prevalent. Conventional, cytotoxic anticancer therapy is likened to a "shotgun" approach in which both cancer cells and normal cells are subject to toxicity. The effects of therapy on normal tissues and organs can manifest acutely (limiting dose) or in the long term (affecting quality of life). As more and more children are surviving childhood cancer, the late effects of therapy are increasingly evident, further emphasizing the need for risk-adapted therapy, cancer-targeted therapy, and a reduction of treatment-related toxicities.

Optimal outcome depends on several factors: correct pathologic diagnosis; careful medical management, including administration of chemotherapy and monitoring of side effects; precise customization of radiation fields if radiation therapy is necessary; optimal surgical resection, if indicated; and therapeutic ability and experience with administration of treatment to children. Centers that specialize in the treatment of pediatric cancer are experienced in the diagnosis and treatment of rare malignancies and are thus best equipped to treat affected children. In addition, the standard of care for children with cancer is treatment according to research study protocols from national collaborative research groups (Children's Oncology Group), available at most specialized pediatric cancer centers. Posttreatment

Table 141-2. Diagnostic Tests and Imaging Studies Used in the Evaluation of Childhood Cancer

<i>Disease</i>	<i>Diagnostic Tests</i>	<i>Imaging Studies</i>
Leukemia	Bone marrow aspirate and biopsy Cytogenetic analysis of bone marrow CBC with platelet count, differential PT, PTT, fibrinogen Serum electrolytes, Ca, PO ₄ BUN, creatinine, uric acid, LDH CSF cell count, cytology	Chest radiograph (look for mediastinal mass)
Brain tumors	None usually indicated except in case of suspected teratoma: serum and CSF α -fetoprotein, β -human chorionic gonadotropin, carcinoembryonic antigen	MRI of brain with gadolinium MRI of spine for selected tumors
Lymphoma	Bone marrow aspirate and biopsy CSF cell count and cytology Serum LDH, electrolytes, Ca, PO ₄ ESR, ferritin	Gallium scan, PET scan CT of chest, abdomen, pelvis
Neuroblastoma	Serum ferritin CBC with platelet count Serum electrolytes, liver and renal panel Serum LDH Bone marrow aspirate and biopsy	CT or MRI of primary tumor site CT of chest, abdomen, pelvis (+/- head) with contrast Bone scan MIBG scan
Rhabdomyosarcoma	CBC with platelet count Liver and renal panel Bone marrow aspirate and biopsy CSF cell count and cytology (head and neck primary tumors only)	CT or MRI of primary tumor site CT of chest, abdomen, pelvis Bone scan
Nephroblastoma (Wilms tumor)	Urinalysis	CT of primary tumor site Ultrasound of inferior vena cava CT of chest Bone scan
Ewing sarcoma	ESR CBC with platelet count Bone marrow aspirate and biopsy Serum LDH	CT or MRI of primary tumor site CT of chest Bone scan
Osteosarcoma		MRI of primary tumor site CT of chest Bone scan

Abbreviations: BUN, blood urea nitrogen; Ca, calcium; CBC, complete blood cell count; CSF, cerebrospinal fluid; CT, computed tomography; ESR, erythrocyte sedimentation rate; LDH, lactate dehydrogenase; MIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging; PET, positron emission tomography; PO₄, phosphate; PT, prothrombin time; PTT, partial thromboplastin time.

analysis of children treated on protocols at specialized pediatric cancer centers have 4-year disease-free survival rates that are significantly better than those of children treated outside this setting. Similarly, treatment of adolescents and young adults on protocols at specialized pediatric cancer centers yields better outcomes than those treated by oncologists who typically treat adults.

The placement of indwelling central venous catheters is standard in cancer therapy in pediatrics, making frequent venous access for both diagnostic and therapeutic purposes more easily tolerated by children. External catheters (Broviac, Hickman) or internal subcutaneous catheters (Port-a-Caths) are selected depending on the underlying diagnosis and intensity of therapy. All indwelling catheters are

at risk for infection, either from contamination of blood (line infections) or infections around the catheter site itself (tunnel infection). Most central line infections can be treated with intravenous (IV) antibiotic therapy; however, certain pathogens (fungi) are difficult to clear and require line removal. Central venous catheters may also be complicated with thromboses requiring local thrombolytic therapy.

In the interest of cost-containment and convenience as well as children's well-being, it is often more feasible for children to be closer to home between chemotherapy cycles. Primary care physicians should be familiar with the management of various infectious complications to which children undergoing cancer therapy are subject. Fever in children with neutropenia (absolute neutrophil count <500 cells/ μ L)

requires a different therapeutic approach than fever in otherwise normal children. Until proven otherwise, children with fever and neutropenia (usually induced by chemotherapy, sometimes in combination with radiation therapy) must be assumed to have a serious bacterial infection. They should be treated accordingly, with hospitalization, IV antibiotics, thorough examination for site of infection, and careful hemodynamic monitoring. Initial treatment consists of antibiotic coverage for *Staphylococcus aureus*, gram-negative enteric organisms, and *Pseudomonas aeruginosa* (eg, cefepime with or without tobramycin, vancomycin). Additional coverage for anaerobic infection (eg, mucositis), viral infection (eg, herpes stomatitis, varicella), and other pathogens (eg, fungi) depends on the child's treatment history and clinical findings.

Prognosis

The prognosis for children with all forms of cancer has dramatically improved over the past 4 decades. Nearly 80% of children diagnosed with cancer can expect to be long-term survivors. Figure 141-1 shows the improvement in cure rates for ALL, the most common childhood cancer. This success is largely due to the efforts of national collaborative group science and treatment protocols. However, with increased survivorship, new concerns have arisen with respect to the long-term effects of treatment, the risks of secondary malignancies, and complex social and psychological issues. In a large study of childhood cancer survivors, adults treated for a childhood cancer in the 1970s and 1980s were 3 times more likely than their siblings to have developed a chronic health condition. Continued multidisciplinary surveillance of childhood cancer survivors through adulthood will help to optimize a favorable outcome.

Figure 141-1. Five-year relative survival rates for specific cancers of children (0–14 years), 1973–2001. Data are from the Surveillance, Epidemiology, and End Results (SEER) program regions (9 areas). (From Pizzo PA, Poplack DG. *Principles and Practice of Pediatric Oncology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:5.)

CASE RESOLUTION

In the case history, the boy undergoes a mediastinoscopic biopsy of the mediastinal mass, which reveals lymphoblastic lymphoma. No evidence of disease in the bone marrow or spinal fluid is present, which would indicate a worse prognosis. Treatment involves chemotherapy, and the prognosis is quite good. Symptoms of superior vena cava syndrome due to obstruction from the tumor resolve with shrinkage of the tumor secondary to therapy.

Chronic Kidney Disease

Justine Bacchetta, MD, PhD; Walter Jimenez, MD; and Isidro B. Salusky, MD

CASE STUDY

During a consultation for diarrhea and dehydration the pediatrician notes that a 7-year-old boy has concomitant growth retardation. His parents report decrease in appetite as well as in physical activity level over the last few months associated with bedwetting, despite having been previously potty trained. His medical history is significant for multiple episodes of fever due to supposed ear infections during his first years of life and one episode of urinary tract infection without further studies. After hydration the physical examination reveals a pale and short patient (height 101 cm, <5th percentile) with blood pressure above 99th percentile for age, gender, and

height. Routine laboratory studies reveal anemia, a serum creatinine of 1.4 mg/dL, and 3+ proteinuria.

Questions

1. How do you estimate renal function in children?
2. What are the relevant questions to ask about medical and family history in children who present with **chronic kidney disease (CKD)**?
3. What additional diagnostic tests should be performed to determine the etiology of the kidney disease?
4. What are the approaches to the management of children with CKD?

Although the kidney is mainly responsible for excretion or “clearance” of waste products it also has a role in the synthesis and regulation of erythropoietin, renin, 1,25-dihydroxycholecalciferol, acid-base, electrolytes, and water. When the kidney is affected, regulation of multiple functions is disturbed. Currently **glomerular filtration rate (GFR)** is the best method to detect, evaluate, and manage CKD. The GFR varies according to gender, age, and body size and reflects the amount of plasma cleared by the kidney (Box 142-1). It can be challenging to evaluate GFR in children but the 2009 Schwartz formula has been shown to be accurate both in children with CKD and in children with normal renal function, thus allowing its easy use in clinical practice. Early recognition of children with CKD is important in order to prevent the complications associated with the progressive decline in renal function. The signs

and symptoms of CKD in children are nonspecific; thus it is vital that the primary medical caretaker, usually the pediatrician or family practitioner, recognize the earliest signs and symptoms and institute proper medical care. Prompt referral to a pediatric nephrologist must be made, and follow-up consultations by both physicians should be performed regularly to optimize the management of these children.

Depending on the GFR, the physician can classify kidney function in 5 stages as defined by the National Kidney Foundation (Table 142-1). Stages 1 and 2 are defined with GFR of more than 90 mL/min/1.73 m² and 60 to 89 mL/min/1.73 m², respectively. The staging of CKD provides guidelines for the management of these patients because there are specific primary and comorbid conditions associated with the primary cause of renal failure as well as those that are associated with progression of CKD. Indeed, the reduction of some of those associated factors may reduce the risk factors for cardiovascular disease (CVD) and vascular calcifications. Particular importance should be placed on managing **growth, proteinuria, acidosis, anemia, hypertension, and metabolic bone disease** among others. Once GFR declines to 15 to 29 mL/min/1.73 m²

Box 142-1. How to Evaluate Glomerular Filtration Rate (GFR) in Children

1- Measuring the true GFR

Reference standard: inulin clearance, iothalamate, iohexol

Expensive, time-consuming

Not for everyday practice

2- Evaluating the GFR

A- Measured from a 24-hour urine collection

$$\text{GFR} = \frac{\text{Urine creatinine [mmol/L]} \times \text{Volume of urine [mL]}}{\text{Time of urine sampling [min]} \times \text{Plasma creatinine [mmol/L]}}$$

GFR (normalized for 1.73 m²) = Cl × 1.73/body surface area

B- Estimated by a spot blood (2009 Schwartz formula)

$$\text{GFR} = 0.413 \text{ Height (cm)}/\text{Plasma creatinine (mg/dL)}$$

Table 142-1. Classification of Chronic Kidney Disease

Stage	Glomerular Filtration Rate (mL/min/1.73 m ²)
1	≥90
2	60–89
3	30–59
4	15–29
5	≤15

(stage 4), patients and families should be prepared for **renal replacement therapy** and **renal transplantation**. **End-stage renal disease (ESRD)** (or stage 5) is defined as GFR less than 15 mL/min/1.73 m² or the need of **dialysis/transplant**. The staging of CKD is based on estimation of GFR but also additional factors are considered in the overall management of the patient, and the characteristics of the growth curve are very important in the assessment of the consequences of renal failure in childhood. All children with CKD should be referred early to pediatric nephrologists in order to carefully facilitate the future steps in the care of the patient and family. In adult patients with CKD, late referral is associated with increased rates of morbidity and mortality.

Epidemiology

The incidence of CKD in children is unknown. Current estimates are based on the number of children accepted for dialysis and renal transplantation; however, some children do not require dialysis or transplantation until adulthood. In 2008 the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) reported 7,037 patients with an estimated GFR 75 mL/min/1.73m² or less. The causes of CKD can be broadly categorized into 2 main groups: congenital and acquired. Congenital conditions such as **obstructive uropathy**, **aplasia/hypoplasia/dysplasia**, **reflux nephropathy**, and **prune belly syndrome** accounted for the majority (53%) and are summarized as CAKUT (congenital abnormalities of the kidney and urinary tract). Among the acquired conditions, **focal and segmental glomerulosclerosis** are the most prevalent diagnoses, accounting for 9%, with African Americans having a worse prognosis. Overall males are more often affected (64%), and 20% of children have entered the registry before the age of 2 years, 16% between 2 and 5 years, 32% between 6 and 12 years, 28% between 13 and 17 years, and 4% after the age of 17 years; however, time at entry into the registry does not strictly correspond to the age at time of CKD diagnosis.

Clinical and Biological Presentation

Children with CKD often present with no, or nonspecific, symptoms, and the abnormality is detected during routine health examinations or screening. For a small percentage of these patients, CKD is inadvertently discovered when they present with another illness such as diarrhea and dehydration. Patients may be referred to the physician because of **growth retardation**, **hypertension**, or **anemia** (Box 142.2). Frequently, a history of recurrent episodes of fever

without a source, or partially treated urinary tract infections (UTIs) secondary to undiagnosed vesicoureteral reflux, is uncovered. Children may also complain of vague generalized symptoms, including malaise, anorexia, and vomiting, which may be associated with advanced renal failure.

Metabolic and Water/Electrolyte Abnormalities

Children with congenital abnormalities such as obstructive uropathy and/or renal dysplasia may develop polyuria due to inability to concentrate urine, and salt wasting may become a prominent feature as well as polydipsia; in such a case, blood pressure is usually normal. A history of **bedwetting** may thus be a clue to CKD. In contrast, children with advanced CKD may have impaired sodium excretion leading to water retention and, consequently, fluid overload and secondary hypertension. **Hyperkalemia** is not an unusual component of CKD, and it becomes evident when the GFR falls below 10 mL/min/1.73 m². **Hypokalemia** is a less common problem and may be secondary to excessive diuretic use or a strict dietary restriction; it can also be the hallmark of a tubulo-interstitial disease (proximal tubulopathy) at the early stages of CKD.

Metabolic acidosis is mainly caused by the overall decrease in ammonia excretion from a reduced number of nephrons. Decreased excretion of titratable acid and bicarbonate wasting in cases of proximal renal tubular acidosis may play a role as well.

Glucose intolerance may occur in some children with CKD despite elevated insulin levels, independent of genetic diseases, which induce renal cysts and atypical diabetes mellitus (HNF1β mutations). The linear correlation between a decline in renal function and insulin resistance even at early stages of CKD has been shown in adults. More than 50% of children develop **hyperlipidemia** by the time they reach ESRD. The characteristic plasma lipid abnormality is a moderate **hypertriglyceridemia**. There is also a high prevalence of **hypercholesterolemia** and low levels of high-density lipids and albumin. These derangements have a role in the developing of CVD.

Growth Failure

Failure to thrive is the hallmark of CKD in children, and the degree of growth retardation varies according to the age of presentation. Indeed, because maximal growth occurs during the early years in life, children with congenital renal problems are the most affected. In the NAPRTCS study, height deficits were greatest for children younger than 5 years, with nearly 50% below the third percentile for age and gender. Growth failure develops early in the course of CKD and affects up to 35 % of this population; by the time of renal transplantation, most children present with severe short stature. Moreover, children with more severe degrees of affected renal function tended to have greater height deficits. Sexual development is often delayed in affected patients, as well as bone age. Uremia, anorexia, and frequent vomiting also explain the **protein and calorie malnutrition** frequently observed in the younger children; it requires an early and intensive management.

Box 142-2. General Symptoms Associated With Chronic Kidney Disease

- Growth retardation/growth failure
- Anorexia
- Anemia
- Bone disease
- Metabolic acidosis
- Hypertension

Mineral and Bone Disorders (MBD) associated With CKD (CKD-MBD)

The impact of CKD-MBD may be immediate (biological disequilibrium of calcium, phosphate, vitamin D and parathyroid hormone (PTH) or delayed (growth retardation, bone pain, fractures, bone deformities, extra-skeletal and vascular calcifications, increased morbidity and mortality). The development of CKD-MBD begins early in the course of CKD, and clinical manifestations include growth retardation and skeletal deformities such as **genu valgum**, **ulnar deviation of the hands**, **pes varus**, and **slipped capital femoral epiphyses**. As defined by the 2006 Kidney Disease: Improving Global Outcomes (KDIGO), the term renal osteodystrophy refers specifically to the different bone lesions as defined by bone histomorphometry. In contrast, the term CKD-MBD is used to define the clinical and biochemical abnormalities as well as the long-term consequences of alterations of bone and mineral metabolism associated with CKD. Thus, CKD-MBD is manifested by either one or a combination of the following abnormalities: (1) abnormalities of calcium, phosphorus, PTH, or vitamin D metabolism; (2) abnormalities in bone histology, linear growth, or strength; and (3) vascular or other soft tissue calcification.

Anemia

The anemia of CKD is normochromic and normocytic. Insufficient erythropoietin (EPO) production occurs when the GFR is less than 30 mL/min/1.73 m². Anemia is frequently accompanied by decreased serum iron levels, increased total iron binding capacity, and low reticulocyte counts. Dialysis patients are predisposed to develop bleeding tendencies because of platelet dysfunction and mechanical hemolysis.

Hypertension

The incidence of **hypertension** in children with CKD varies from 38% to 78%. Prolonged hypertension may accelerate deterioration of renal function. An acute rise in blood pressure usually results in seizures in children. Other manifestations include headache, epistaxis, congestive heart failure, nerve palsies and, not uncommonly, cerebral hemorrhage. Hypertension is frequently seen in children with CKD secondary to polycystic kidney disease or chronic glomerulonephritis.

Cardiac Dysfunction

In addition to the increased risk of vascular calcifications, **congestive heart failure** may be a prominent clinical finding associated with fluid overload, uncontrollable hypertension, severe anemia, or presence of uremic cardiomyopathy. Left ventricular hypertrophy diagnosed by echocardiographic assessment is present in 3 of 4 adults with CKD, with anemia and hypertension being the principal predisposing factors. Such findings are seen even in the pediatric population, with a prevalence of 10% to 20% in CKD stages 3 and 4.

Neurologic Dysfunction

Children with CKD may have **impaired neurodevelopment** related to the age of presentation. Memory deficits, lack of concentration, depression, and weakness may occur. Children younger than 5 years are more affected because significant brain growth and maturation occur during the early years of life. Children who are severely uremic may suffer from global developmental retardation and seizures. Unless neurodevelopmental delays are recognized promptly and early intervention is instituted, problems are most often progressive. Of note, some genetic diseases involving both cerebral and renal development may also play a role in the developmental delay.

Pathophysiology

The Global Final Pathway of the Reduction in the Nephron Number

Regardless of the type of initial injury to the kidney, glomerular hyperfiltration and tubulointerstitial damage are the final common pathways of glomerular destruction. Hyperfiltration occurs as a response by the residual glomeruli to compensate the loss of nephrons, as summarized on Figure 142-1. The reduced filtration results in increased production of **renin** and **angiotensin-converting enzyme (ACE)**. The resulting vasoconstriction of the efferent arteriole increases the hydrostatic pressure on the capillary wall, leading to a compensatory higher filtration rate per nephron but also to protein transit across the wall. Proteinuria recruits inflammatory cells and upregulates proinflammatory and profibrotic genes. Protein overload in the tubular cells stimulates their differentiation into myofibroblasts, thus favoring fibrosis. The inflammatory cascade activates at the same time as the complement cascade, leading

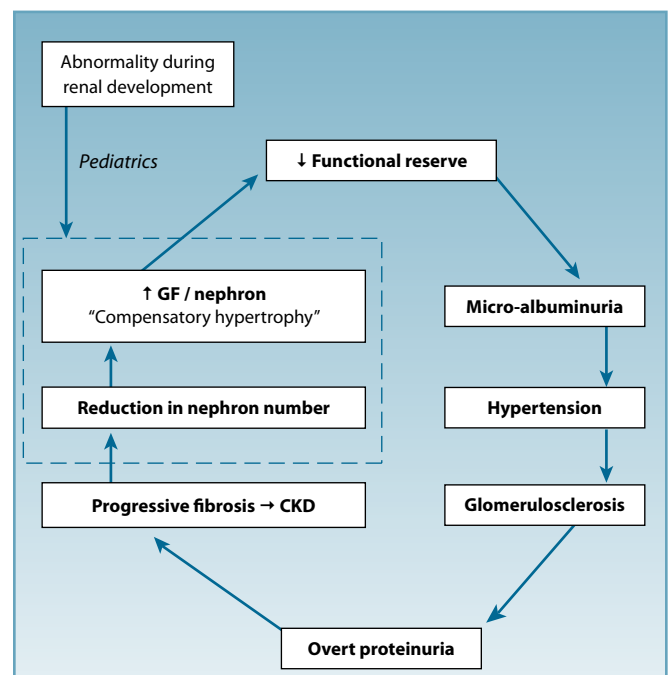

Figure 142-1. The consequences of the reduction in the nephron number. CKD, chronic kidney disease; GF, glomerular filtration.

to additional kidney damage. The interstitial fibrosis impairs oxygenation of the tubular cells; the chronic hypoxia then further activates the renin-angiotensin system. The activation of fibroblasts by hypoxia is another stimulus to the differentiation of the tubular cells. Reducing intraglomerular pressure, proteinuria, and the consequent tubulointerstitial fibrosis is the rationale for prescribing ACE inhibitors or angiotensin receptor blockers (ARBs) in order to slow the rate of progression of CKD, in addition to their anti-hypertensive properties.

Growth Failure

Multiple factors are involved in the pathogenesis of growth retardation in children with CKD, and the most predominant are deficient calorie and protein intake, decreased erythropoietin production, metabolic acidosis, decreased serum level of **insulin-like growth factor I**, peripheral resistance to growth hormone due to decreased levels of growth hormone-binding proteins and growth hormone receptors, renal osteodystrophy, hypogonadism, and drug toxicity (corticosteroids), further inducing major consequences for both physical and mental well-being in this population. A particularity of renal osteodystrophy in children is the alteration of the growth plate cartilage architecture, another possible detrimental element in the growth failure. Both adynamic bone lesions and severe hyperparathyroidism increase the severity of growth retardation, explaining that optimal target values for serum PTH should be related to the stage of CKD; in that setting the overuse of vitamin D analogs can also worsen the growth retardation. In CKD teenagers, the loss of the pulsatile release of the gonadotropin-releasing hormone also explains the delay and the shortening of the pubertal growth spurt, in association with a reduced growth velocity.

Mineral and Bone Disorders Associated With CKD (CKD-MBD)

The development of **renal osteodystrophy** is also multifactorial. The reduced renal mass results in a decreasing synthesis of 1,25-**dihydroxycholecalciferol**; therefore, the stimulus to absorb calcium from the gut decreases concomitantly. The resulting hypocalcemia and the lack of feedback by vitamin D on the parathyroid stimulate the production of PTH, facilitating the rapid mobilization of calcium and phosphorus from the skeleton, thus normalizing the serum calcium. In the early 2000s, another phosphaturic hormone of the bone kidney/axis (ie, the fibroblast growth factor 23, [FGF23]) was identified to play a key role in bone mineralization from rare genetic diseases such as hypophosphatemic rickets, autosomal-dominant hypophosphatemic rickets, and tumor-induced osteomalacia. FGF23 is both a phosphaturic factor and a suppressor of 1 α -hydroxylase activity in the kidney, it also inhibits PTH synthesis in the parathyroid. Therefore in the context of CKD, FGF23 levels increase as GFR decreases, from early stages of CKD, before serum phosphate has become abnormal. This increase could be explained by different factors, such as (1) a decreased clearance of FGF23, (2) an increased synthesis by osteocytes, (3) a compensatory mechanism in an attempt to excrete the excess serum phosphate, or

(4) a response to the treatment with active vitamin D analogs. In CKD adult patients, serum FGF23 levels are positively correlated with serum phosphate and negatively with serum calcitriol and PTH. FGF23 may also provide prognostic information in CKD patients, mainly in terms of CKD progression, therapeutic response, and cardiovascular mortality: FGF23 is an independent predictor of CKD progression in adults, as well as a predictor of refractoriness to intravenous calcitriol therapy at 24 weeks and an independent risk factor for mortality in adults undergoing hemodialysis. One may thus hypothesize that a therapeutic reduction of FGF23 could have a clinical importance to delay the onset of secondary hyperparathyroidism, the onset of CKD-MBD, and may be the global morbi-mortality in CKD patients, but the question of whether FGF23 could exert both direct and systemic toxic effects will need further longitudinal studies. Very little data on FGF23 are available in children but some reference values have been proposed, and other authors have described a positive effect of FGF23 on bone mineralization in CKD children.

There is also skeletal resistance to PTH when CKD advances. The cycle is aggravated by an early alteration in the regulation of PTH gene transcription, a reduction in the calcium sensing receptor, and a progressive resistance to FGF23 in the parathyroid glands. **Hyperparathyroidism** and resulting high bone turnover produces fibrosis in bone, which is also called **osteitis fibrosa**. Hyperphosphatemia develops when the few remaining nephrons lose the ability to excrete the daily load of phosphorus from the diet; it is a late phenomenon, mainly in stages 4 and 5. The external administration of vitamin D and its derivatives can suppress such bone remodeling, but if not adequately monitored can result in low turnover bone disease (adynamic bone). In this later case, serum PTH and alkaline phosphatase levels are generally lower when compared with patients with secondary hyperparathyroidism. In the past, aluminum-containing phosphate binders were the main factors involved in the pathogenesis of osteomalacia and adynamic bone, but currently the use of large doses of calcium-based binders and active vitamin D sterols are implicated. The presence of abnormal calcium-phosphate metabolism and hyperparathyroidism, and increased FGF23 levels in association with other traditional risk factors as hypertension, hyperlipidemia, hyperhomocysteinemia, anemia, and oxidative stress are also associated with CVD, the leading cause of death in ESRD. In young adults with childhood-onset CKD, the prevalence of coronary artery calcification can be as high as 92% when evaluated by sequential computed tomography (CT) scan with electrocardiogram (ECG) gating.

Anemia

The anemia of CKD begins when the GFR falls below 30 mL/min/1.73 m² and is multifactorial: decreased EPO production, decreased red cell survival, bone marrow inhibition, iron deficiency, vitamin B₁₂ and folate deficiency, inflammation, antibodies directed against EPO, and osteitis fibrosa. In the past, aluminum toxicity also explained partly the anemia observed during CKD. Some patients can worsen their hemoglobin levels with blood loss during the hemodialysis sessions. In a similar manner as in the understanding of

the CKD-MBD pathophysiology when the FGF23 was identified, a new hormone involved in the anemia in CKD has also been recently described. Indeed, hepcidin is a peptide hormone synthesized in the liver; the loss of hepcidin activity induces severe iron overload. In contrast, patients with increased hepcidin levels experience anemia. Hepcidin allows the internalization of ferroportin, the only cellular receptor of iron that exports iron from the intracellular to the extracellular compartment. Iron loading and inflammation increase while a treatment with EPO decreases hepcidin levels. In adults, there is an inverse relationship between GFR and hepcidin serum levels; in CKD children, ferritin and hepcidin levels are strongly correlated, as well as hepcidin and high-sensitivity C-reactive protein. Hepcidin could be a marker of EPO resistance and of the functional iron status; however, it is not used yet in clinical practice.

Differential Diagnosis

Instead of crafting a differential diagnosis, the main challenge for the physician initially will be to determine whether the renal impairment is acute or chronic and if chronic, its etiology. A variety of kidney problems, whether congenital, hereditary, acquired, or metabolic, may result in CKD. Although specific cures are not available for most of these renal conditions, it is essential to perform a complete diagnostic workup to determine the etiology of the renal problem. Such information may identify the presence of an inherited problem that may require genetic counseling and, in some cases, anticipation of problems associated with renal transplantation. Some renal diseases may in fact recur after renal transplantation (eg, focal segmental glomerulosclerosis or atypical hemolytic uremic syndrome); parents and children must be informed early about this possibility in preparation for future strategies for renal transplantation. The different etiologies of CKD, as well as their respective prevalence in the 2008 NAPRTCS registry, are summarized in Table 142-2.

It is also necessary to differentiate between acute and chronic renal failure at initial presentation because the therapeutic strategies may differ, and the long-term renal prognosis can be quite different. Patients with CKD present with retarded linear growth and signs of clinical and radiographic evidence of renal osteodystrophy. In advanced disease the renal ultrasound frequently reveals small, shrunken kidneys. The hereditary diseases most commonly encountered are hereditary nephritis (Alport syndrome or PAX2 nephropathy), branchio-oto-renal syndrome (BOR), and juvenile nephronophthisis. Acquired diseases such as chronic glomerulonephritis, membranoproliferative glomerulonephritis, and focal and segmental glomerulosclerosis, affect a large percentage of older children who progress to CKD. Anemia, hypertension, and fluid and electrolyte abnormalities are often associated with either chronic or acute renal failure.

Evaluation

A complete evaluation of children presenting with renal failure must be performed.

Table 142-2. Etiologies of Pediatric CKD (NAPRTCS 2008)

	<i>Disease</i>	<i>Percentage</i>
CAKUT	Obstructive uropathy	20.7
	Aplasia/hypoplasia/dysplasia	17.3
	Reflux nephropathy	8.4
	Prune belly	2.7

	Others	15.8
	Unknown	2.6

Abbreviations: CAKUT, congenital abnormalities of the kidney and urinary tract; CKD, chronic kidney disease; FSGS, focal segmental glomerulosclerosis; GN, glomerulonephritis; HUS, hemolytic uremic syndrome; IgA, immunoglobulin A; MPGN, membranoproliferative glomerulonephritis; NAPRTCS, North American Pediatric Renal Transplant Cooperative Study; SLE, systemic lupus erythematosus.

History

A thorough history must be obtained, including a complete and detailed family history that may provide some clues to the diagnosis of the patient's condition (Box 142-3).

Physical Examination

A complete physical examination is required. Height and weight must be measured accurately, and the result must be plotted in the

Box 142-3. Questions

- Does the child have
 - Abnormalities on prenatal ultrasound such as hydronephrosis or polyhydramnios/oligohydramnios?
 - A history of prolonged illness, pallor, weakness, vomiting, or loss of appetite?
 - Any history of headaches or visual or hearing problems?
 - Any history of hematuria, proteinuria (foamy or bubbling urine), urinary tract infections, or episodes of fever with unknown source?
 - Impaired growth or development compared with siblings and other children?
 - Any problems with micturition, such as dribbling or weak stream?
 - Polyuria or polydipsia?
 - Daytime or nighttime enuresis?

If so, what was the age at presentation?

- Does any family member have
 - Any kidney diseases (including hematuria, proteinuria, kidney cysts, urinary tract infections) or have they undergone any urology surgery?
 - Need of dialysis or kidney transplantation?
 - History of ear/hearing or eye abnormalities?

same growth curve as in healthy children. The weight can be overestimated if fluid retention is present. Blood pressure, using the appropriate cuff size, must be taken by the primary physician. Blood pressure must be compared with 50th percentile for age, gender, and height (www.nhlbi.nih.gov). The presence of tachycardia, heart murmurs, or adventitious heart sounds that may indicate uncompensated anemia or cardiac or pericardial involvement must be noted. Gross eye examination should be performed, including fundal examination, to assess for evidence of chronic hypertension. In addition, macular abnormalities and hearing problems may provide clues to a heritable disease (eg, Alport syndrome). Any ear abnormalities (eg, preauricular pits or ear tags) accompanied by hearing deficits are usually associated with some form of renal disease (eg, BOR). Undescended testes may be evident in some children with urogenital problems.

Laboratory Tests

For the initial laboratory workup, complete blood cell count, electrolytes, blood urea nitrogen, creatinine, calcium, phosphorus, and urinalysis must be obtained (Figure 142-2). Glomerulonephritis usually presents with numerous red blood cells, white blood cells, proteinuria, and a variety of casts in the urine. In cases of proteinuria, if a 24-hour collection is impossible, quantified excretion should be estimated by a protein-creatinine ratio in a spot urine sample. A ratio greater than 0.2 is abnormal and is well correlated with urinary protein excretion greater than 4 mg/m²/hour in a 24-hour urine collection. In nephrotic syndrome, the proteinuria is usually greater than 40 mg/m²/hour. Immunologic studies including C₃, C₄, antinuclear antibody, and anti-double-stranded DNA, as well as a minimal infectious evaluation (hepatitis B and C), should be obtained if the

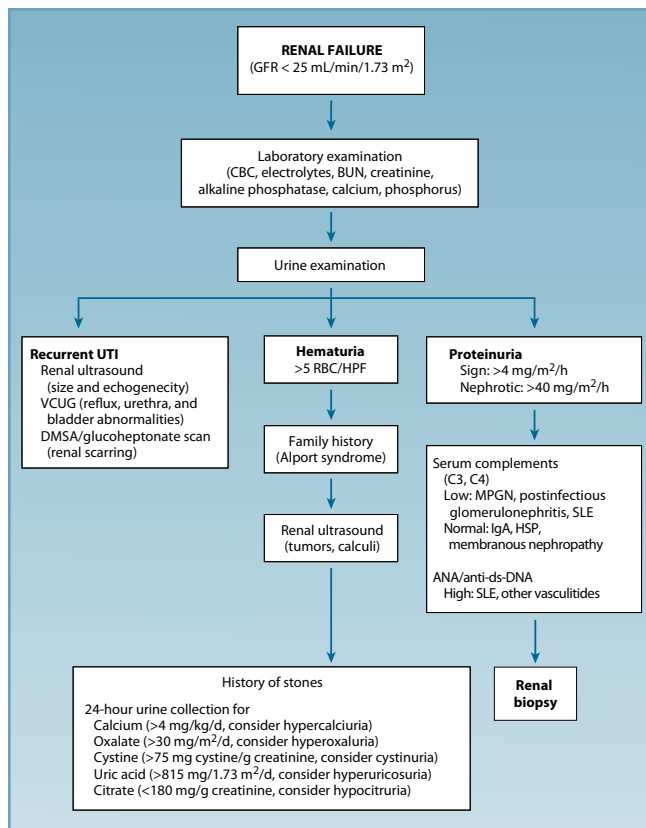

Figure 142-2. Initial diagnostic workup of a pediatric patient with chronic renal failure. ANA, antinuclear antibodies; ds, double-stranded; BUN, blood urea nitrogen; CBC, complete blood cell count; DMSA, dimercaptosuccinic acid; GFR, glomerular filtration rate; HPF, high-power field; HSP, Henoch-Schönlein purpura; IgA, immunoglobulin A; MPGN, membranoproliferative glomerulonephritis; RBC, red blood cell; SLE, systemic lupus erythematosus; UTI, urinary tract infection; VCUg, voiding cystourethrogram.

renal disease suggests the presence of an immune complex-mediated nephritis (eg, systemic lupus erythematosus, post-infectious glomerulonephritis, or membranoproliferative glomerulonephritis).

Imaging Studies

Ultrasound is by far one of the best radiographic tools in the assessment of patients with CKD. Renal ultrasound yields important information (eg, kidney size, echogenicity, presence of hydronephrosis, cysts or stones) that may help establish the diagnosis of the renal disease. The presence of small kidneys usually indicates chronic disease that may date back to fetal development. Increased echogenicity with normal kidney size indicates the presence of medical renal disease in more than 90% of cases.

A **voiding cystourethrogram** (VCUG) is indicated in patients with recurrent UTIs in order to diagnose vesicoureteral reflux and evaluate the anatomy of the upper urinary tract. The use of the spiral CT scan in the evaluation of patients with renal failure has increased over the last few years. This procedure requires relatively less time than the standard CT scan and can be used to evaluate the kidney parenchyma, and the upper and lower urinary tract.

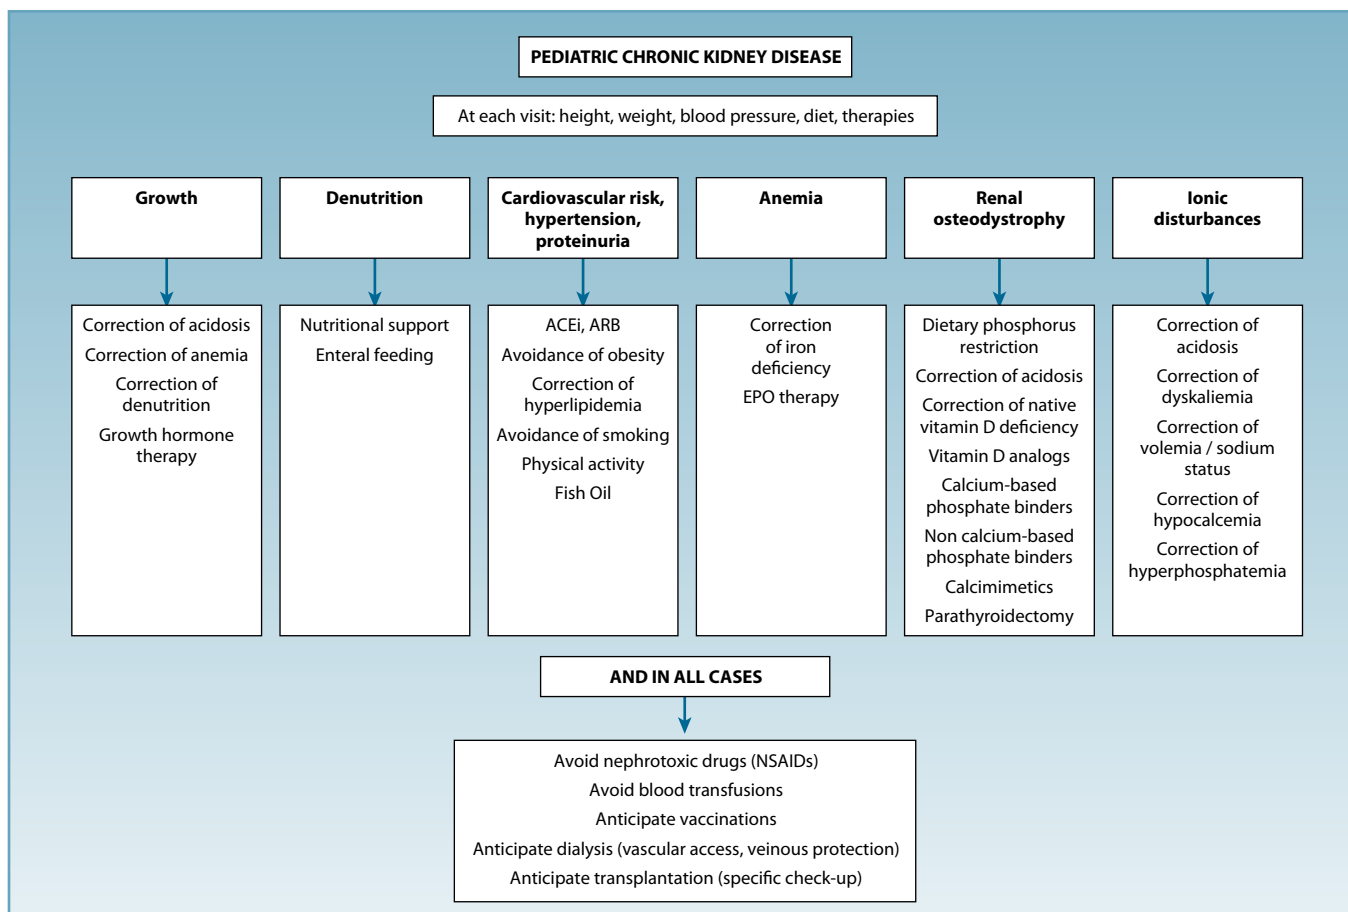

Figure 142-3. Overall management of pediatric CKD. ACEi, angiotensin converting enzyme inhibitors; ARB: angiotensin receptor blockers, sartans; EPO: erythropoietin; NSAIDs: non steroidal anti-inflammatory drugs.

Nuclear imaging of the kidneys has provided vital information in the workup of children with CKD. In general, nuclear studies are not routinely done unless specifically indicated. In some centers, the technetium (Tc)-99m-mercaptoacetyltriglycine is being used to evaluate the renal plasma flow, whereas Tc-99m-dimercaptosuccinic acid is currently done to assess renal parenchymal involvement in both acute pyelonephritis and recurrent UTIs. This nuclear imaging study provides an excellent image of the renal parenchyma, and is frequently used in the detection of renal scars in patients with recurrent UTIs. Significant renal parenchymal scars portend the development of hypertension later in life.

Management

The management of children with CKD has markedly improved over the last 2 decades and it is summarized in Figure 142-3. Newer modes of treatment and early intervention have made great improvements in the lifestyles and psychological well-being of affected children. These patients must be managed by a multidisciplinary team involving the primary care physician and nephrologists, nurses, social services, nutritionists, and psychologists. Such management includes the treatment of the primary disease and comorbid conditions, an optimization of growth, a slowing of the progression, a preservation of the residual renal function, a prevention of CKD-MBD

and CVD, as well as the preparation for renal replacement therapy and renal transplantation as CKD progresses. Available measures to retard the progression toward ESRD and cardiovascular mortality include strict control of hypertension; prevention of obesity; control of proteinuria with ACE inhibitors or ARB administration; control of serum calcium/phosphorus/PTH levels; and prompt control of infections, anemia, and hyperlipidemia.

Malnutrition; Metabolic and Water/Electrolyte Abnormalities

Dietary management remains an important and challenging part in the overall management of children with CKD. Frequently, these children are anorectic and require supplementation with fat, carbohydrates, and protein. Some patients, especially younger children, may require enteral feeding by nasogastric or gastrostomy tube in order to meet their daily nutritional requirements. A strict follow-up of nutritional status may therefore be performed at each visit, with a measurement of height and body weight; in children younger than 3 years, the cranial perimeter will also be measured and the brachial/cranial perimeter ratio will be calculated.

Children with CKD should receive the recommended daily allowance for protein and calories according to age and gender; adjustments need to be made depending on weight gain. Protein restriction

is not advised; studies have shown that restriction of protein intake does not retard the progression of renal failure in these patients. In patients with hypertension, appropriate salt intake must be given but infants and children with congenitally obstructed, dysplastic kidneys or nephronophthisis often have polyuria, salt wasting, and acidosis, thus requiring a sodium supplementation and an adapted hydration. Sodium chloride or sodium bicarbonate must be administered to these children, and their required daily fluid intake may be higher to maintain normal intravascular volume.

Oral base therapy should be used to maintain a bicarbonate level in plasma above 22 mEq/L in order to facilitate skeletal growth, as recommended by the National Kidney Foundation Disease Outcome Quality Initiative guidelines since metabolic acidosis can have many deleterious effects (eg, worsening of bone disease and growth retardation, increased muscle wasting, decreased albumin synthesis, resistance to insulin, stimulation of inflammation, and eventually increased global mortality).

Most children with CKD do not become hyperkalemic unless their renal function falls below 10 mL/min/1.73 m². Initially dietary intervention may be sufficient, but this is difficult in infants and small children whose diet is limited to formula and only a few solid foods. Pharmacologic interventions (eg, diuretics, polystyrene sulfone) are used to manage **hyperkalemia** in these children. In situations where there is an acute rise in serum potassium level, emergent measures must be implemented (Box 142-4). Intravenous and inhaled β_2 -agonists (eg, albuterol) acutely decrease serum potassium level by facilitating intracellular potassium uptake. If hyperkalemia is unresponsive to conservative medical measures, dialysis must be performed immediately. The use of a diuretic may be indicated in cases of fluid overload and hyperkalemia (potassium-sparing diuretics such as spironolactone should not be used). Diuretic therapy should not be used in patients with disturbed concentrating and diluting mechanisms because some of these children may have polyuria and develop dehydration on diuretic therapy.

There is increasing concern regarding the management of **lipid disturbances** due to their role in the progression of CKD. At present, no recommendations have been made about the use of lipid-lowering agents in children with hypercholesterolemia and

hypertriglyceridemia because of reported liver and muscle toxicity associated with some of these medications. Further studies are warranted to test the efficacy and safety of these medications in the pediatric population.

Growth failure

Recombinant human growth hormone therapy has improved the management of growth retardation in children with CKD; recombinant human growth hormone (rhGH) therapy should be rapidly discussed in children with a statural height below the 5th percentile: the 2009 KDIGO international guidelines recommend that CKD stage II-VD children and adolescents with related height deficits should be treated with rhGH when additional growth is desired, after first addressing malnutrition and biochemical abnormalities of CKD-MBD. Several studies have demonstrated a positive effect of rhGH on linear growth but with variable results according to CKD stage at the initiation of rhGH: In the NAPRTCS database, a catch-up growth after rhGH therapy was observed in 27% of children with chronic renal insufficiency, 25% of transplanted children, and only 11% of children undergoing renal replacement therapy, highlighting the need of an early management of growth failure in pediatric CKD. Moreover, the response during the first year correlates with final height. Growth hormone administration is continued until the patient reaches the 50th percentile for mid-parental height or renal transplant is achieved. Of note, such a therapy is contraindicated in case of history of malignancy, hyperglycemia, hyperinsulinemia, or significant scoliosis.

A recent retrospective multi-center US study noted the underprescription of rhGH therapy in pediatric CKD patients and reported that more than half of short CKD children did not receive rhGH. The most common reasons were family refusal, secondary severe hyperparathyroidism, and noncompliance; however, in up to 25% of cases, no evident rationale was determined. Of note, waiting for an insurance company approval induced a significant delay in the initiation of rhGH therapy in 18% of patients. Access to rhGH therapy should be a high priority. Newer treatment modalities, targeting preferentially growth hormone resistance (such as recombinant IGF1, recombinant IGFBP3 or IGFBP displacers for example) are under investigation for the treatment of growth retardation in pediatric patients with CKD.

CKD-MBD

For the management of renal osteodystrophy, dietary phosphorus restriction is reinforced in children with CKD but is generally not well followed because of unpalatability of food. Moreover, hidden phosphate intakes in processed food are usually not taken into account but are important. As such, calcium-containing phosphate-binding medications have become an integral part in the management of these patients. Aluminum-containing phosphate-binding agents are infrequently used today because of the risk of aluminum toxicity and should be avoided as first-line therapies. If used, precautions must be taken in children who are concomitantly treated with citrate-containing medications (eg, sodium citrate) because citrate

Box 142-4. Treatment of Hyperkalemia

- Calcium gluconate, 0.5 mL/kg of 10% solution, or calcium chloride, 0.2 mL/kg of 10% solution (intravenous [IV])
- Sodium bicarbonate, 2 mEq/kg/dose (IV)
- Glucose-insulin solution, 0.5 g/kg glucose with 0.25 U of insulin per gram of glucose (IV, monitor serum glucose closely)
- Diuretics (loop diuretics; do not use potassium-sparing diuretics): furosemide, 1 mg/kg/dose (IV)
- Polystyrene sulfonate (Kayexalate), 1 g/kg/dose orally (if awake) or rectally (do not use in patients with any gastrointestinal problems or anomalies)
- Dialysis (if hyperkalemia persists despite the above measures)

enhances the absorption of aluminum and, thus, enhances the risk for aluminum intoxication. Recent developments in the understanding of the interaction between vitamin D, PTH, and the calcium-sensing receptor have led to novel treatment modalities for patients with CKD. Vitamin D, in the form of calcitriol, alfacalcidol, and doxercalciferol, has been used in the treatment of children with CKD. Earlier studies with vitamin D therapy demonstrated increases in linear growth in children with CKD; however, recent studies have not shown the same findings. In addition, concerns about a more rapid deterioration of renal function have also been raised in these patients. The 2010 Cochrane meta-analysis emphasized the lack of evidence-based long-term data for the management of pediatric CKD-MBD; however, bone disease (as assessed by changes in PTH levels) was improved by all vitamin D preparations, without consistent differences between routes of administration (eg, oral versus intraperitoneal calcitriol), frequencies of administration (eg, daily versus intermittent), or types of vitamin D preparations. Moreover, although fewer episodes of hypercalcemia occurred in patients receiving the non-calcium phosphate binder such as sevelamer, it was not possible to draw other conclusions since other biochemical parameters were not different. However, sevelamer hydrochloride therapy led to a safe utilization of active vitamin D sterols in a randomized trial in children undergoing peritoneal dialysis. In contrast, a recent prospective study has shown that sevelamer carbonate could be a safe and efficient phosphate binder with a better acid-base status in 24 pediatric dialysis patients. Such compounds have not been used in pediatric patients with CKD prior to dialysis; they should be used cautiously since their tolerance and efficacy in this pediatric population may be different than those observed in adults.

The use of large doses of calcium-based binders has been found to be associated with increased risk for vascular calcifications. To avoid these complications, certain biochemical markers including calcium, phosphorus, alkaline phosphatase, and PTH levels (intact assay, always in the same laboratory) must be followed closely in any child being treated with any vitamin D preparation and calcium-containing salts. The 2009 KDIGO guidelines recommend a serum PTH level within the normal range during CKD stage I–II, and between 2 to 9 times the upper normal levels of PTH in dialysis patients. Between 15 and 60 mL/min/1.73 m², the optimal level of PTH is not known; if PTH levels are above the normal range, serum calcium, phosphorus, and 25-OH vitamin D levels should be checked.

Last, 25-OH vitamin D deficiency should be regularly ruled out. Indeed, vitamin D deficiency seems to be more and more prevalent worldwide, due to several combined factors (eg, decreased sunlight exposure, relative scarcity of vitamin D in occidental diets, lack of supplementation in vitamin D due to the current underestimation for recommended daily intake, increased body fat mass in populations) and current data demonstrated that optimal levels should be above 30 ng/mL (ie, 75 nmol/L). Vitamin D deficiency is highly prevalent in pediatric patients across the spectrum of CKD (between 40% and 80% of children), resulting from several factors such as low dietary intake, chronic illness, skin changes, and sometimes urinary losses in proteinuric patients.

Anemia

The use of recombinant human EPO in the anemia associated with CKD has become a standard of treatment. The correction of anemia results in improved appetite, increased physical activity and, more importantly, avoidance of the risks associated with blood transfusion. Prior to the availability of EPO, most patients received frequent blood transfusions, increasing their risks of infection, transfusion reaction, and development of antibodies. The goal is to keep the hemoglobin between 11 to 12 g/dL. Iron stores are assessed by transferrin saturation and ferritin levels and should be maintained between 20% to 50%, and 200 to 800 ng/mL, respectively. With the description of the hepcidin pathway and the better understanding of the pathophysiology of anemia, new therapeutic modalities will probably be available in the future to improve the management of anemia during pediatric CKD, such as prolylhydroxylase inhibitors, EPO-receptor agonists (hematide), oxygen-carrier products, or GATA-inhibitors.

Arterial Hypertension

For chronic management, antihypertensive medications should be started in children if blood pressure levels are above age-matched controls and after failure of conservative therapy, such as dietary changes. Drugs currently used to treat hypertension in children with CKD include ACE inhibitors, diuretics, adrenergic blockers, peripheral vasodilators, and calcium channel blockers. As mentioned previously, treatment with ACE inhibitors has been shown to be beneficial in reducing the degree of proteinuria and, thus, decreasing the associated hyperfiltration and tubulointerstitial fibrosis associated with hyperfiltration. Caution must be exercised when ACE inhibitors are used in patients with a solitary kidney and in those with renal artery stenosis because these medications can acutely decrease kidney function and precipitate hyperkalemia in patients with renal failure. Sexually active adolescent females must be informed about the adverse effects of ACE inhibitors in pregnancy, including renal tubular dysgenesis in the fetus. Calcium channel blockers, especially nifedipine, have been used in cases of severe hypertension because of their rapid onset of action. However, great caution must be exercised because blood pressure may acutely decline in these patients. For patients with poor adherence to daily oral medications, clonidine is currently available in the form of transdermal patches. However, patients should be warned of rebound hypertension and central nervous system side effects if the patch is removed abruptly. Patients with long-standing hypertension must have regular ECGs to evaluate left ventricular hypertrophy, and serial ophthalmologic examinations to follow eye-ground changes. If hypertension is secondary to fluid overload and salt retention, aggressive fluid removal with diuretic therapy should be added. Pericarditis, however, is usually a manifestation of severe uremia and may require pericardiocentesis. In some instances, the lack of response to medical management may be used as an additional criterion for the initiation of dialysis therapy (Box 142-5).

Box 142-5. Indications for Initiation of Dialysis**Severe fluid overload**

- Congestive heart failure
- Uncontrollable hypertension

Uremic neuropathy

- Paresthesia

Electrolyte abnormalities unresponsive to medical management

- Intractable metabolic acidosis
- Hyperkalemia

Pericarditis**Severe renal osteodystrophy**

- Extra-skeletal calcification
- Severe skeletal deformities

Progressive malnutrition and severe growth retardation, especially in the first year of life**Severe anemia or bleeding diathesis****General Measures**

In all cases, anticipation for dialysis and/or transplantation should be performed early in the course of CKD since it will be a life-long condition in these children, with probably both dialysis and transplantation periods, an early protection of the veins is required: Parents and nurses must be warned to avoid blood samples at the elbow, and to use the hand. Additionally, blood transfusions should be avoided as much as possible in order to avoid the development of hyper-immunization, potentially compromising a future transplant.

Children with CKD and their siblings and household contacts should receive all of the standard vaccines including varicella, influenza, and *Streptococcus pneumoniae*. Patients on immunosuppressive treatment due to glomerulonephritis or after transplant should not receive live-virus vaccines. Every attempt to administer live-virus vaccines such as measles, mumps, rubella, and varicella should be done before transplantation. Because children with CKD have a decreased ability to mount an immunologic response, repeated vaccination in order to induce protective serum antibody titers may be needed in dialyzed patients.

A review of all medications should be performed at every visit in order to adjust the dosages according to kidney function, detect possible adverse effects on the progression of the disease, and identify any drug interaction. Monitoring therapeutic dosage may be desirable when using antibiotics, anticonvulsants, digoxin, theophylline, and anticoagulants. In patients with reduced GFR, maintenance doses can be adjusted by increasing the interval between doses, reducing the individual dose, or both. Special care should be taken when using antibiotics such as aminoglycosides and vancomycin, as well as nonsteroidal anti-inflammatory drugs (NSAIDs), because of possible detrimental effects on residual kidney function, even in the early stages of CKD. Parents must be warned to avoid self-medication with NSAIDs.

Prognosis

The prognosis for children with CKD has changed in the last 2 decades. Options for dialysis (hemodialysis or peritoneal dialysis) and kidney transplantation (deceased or living-related donor) must be discussed prior to the occurrence of ESRD. Strategies such as pre-emptive transplantation (ie, transplantation before the need for dialysis) are probably preferred though may not be achievable because of the median time on the waiting list. Technical advances in dialysis allow the pediatric nephrologists to offer dialysis options to children of any age and have made long-term survival possible while children await renal transplantation.

Kidney transplantation is the ultimate treatment for children with CKD. Improvements in immunosuppressive medications and availability of other therapeutic strategies have considerably increased patient and graft survival after kidney transplantation. Full rehabilitation should be achieved after these children have undergone successful renal transplantation.

CASE RESOLUTION

The patient at the beginning of this chapter presents with a GFR of 30 mL/min/1.73 m² estimated by the 2009 Schwartz formula. The initial evaluation reveals hematocrit 28% (normal 36–48), a low serum bicarbonate (17 mEq/L, normal 22–26), hypocalcemia (8 mg/dL, normal 8.6–10), hyperphosphatemia (7 mg/dL, normal 2.7–4.5), and elevated PTH 700 pg/mL (normal 10–65). Diagnostic workup shows bilateral ureteral reflux on the VCUG. Small size and increased echogenicity of both kidneys are found on ultrasonography. Management of the primary disease is started with antibiotic prophylaxis to prevent further UTIs, and the patient is referred to pediatric urology. Measures to slow the progression to ESRD are initiated involving dietary intervention and treatment of comorbid conditions, including bicarbonate for metabolic acidosis, iron, and recombinant human EPO for anemia, and calcium carbonate as a phosphate binder/calcium supplement. The hypertension associated with proteinuria is best treated with an ACE inhibitor. Growth hormone will be considered once the acidosis, PTH, and anemia are corrected. Immunizations are up to date. An appointment with the pediatric nephrology team is scheduled.

Diabetes Mellitus

Jennifer K. Yee, MD, and Catherine S. Mao, MD

CASE STUDY

A 7-year-old girl presents with a 3-week history of nocturnal polyuria. Her mother reports that her daughter seems to have lost weight in the past 2 months although she has had a good appetite. Laboratory tests reveal that the girl's serum sodium level is 130 mEq/L; potassium, 3.2 mEq/L; glucose, 324 mg/dL; and 1+ ketones. Urinalysis reveals specific gravity of 1.025 and moderate glucose and ketones. Her height and weight are slightly below normal for her age, and the remainder of her physical examination is unremarkable.

Questions

1. What is the pathophysiology of type 1 and type 2 diabetes?
2. What are diagnostic criteria for differentiating type 1 and type 2 diabetes?
3. What are the objectives of therapeutic interventions in children with diabetes?
4. What diagnostic evaluations are used in the ongoing management of diabetes?
5. What are the acute and chronic complications associated with diabetes?
6. What is the role of "tight glycemic control" in children and adolescents?

Diabetes mellitus is the second most common chronic illness after asthma among children in developed countries. Diabetes mellitus is a metabolic imbalance that results from insulin deficiency, impairment of insulin action, or both. Advancement in the knowledge about the pathophysiology supports the assessment that diabetes is a heterogeneous disease involving immunologic, environmental, and genetic factors. This has led to a categorization of diabetes based on its pathophysiology rather than the therapeutic intervention. Diabetes associated with absolute insulin deficiency and impaired beta cell function is called **type 1** (previously juvenile onset or insulin-dependent), and diabetes associated with insulin resistance as well as impaired beta cell function is called **type 2** (previously adult-onset or non-insulin-dependent).

Epidemiology

In the past more than 97% of children with diabetes presented with type 1 diabetes mellitus (DM1), with an overall incidence of 18 in 100,000 cases per year. Recently, 2 population-based studies showed a dramatic increase in the number of older children and adolescents presenting with type 2 diabetes mellitus (DM2). One study reviewed newly diagnosed cases of diabetes over a 12-year period and found that DM2 made up 4% of such cases before 1992 and 16% in 1994 in one Midwestern metropolitan area. Among adolescents, the relative incidence of DM2 increased from 3% to 10% before 1992 to 33% in 1994. By 1999 the proportion of diabetes in children and adolescents attributed to DM2 ranged from 8% to 45% depending on the geographic location. In addition, the populations affected by DM1 and DM2 seem to differ. Type 1 diabetes mellitus is seen

equally among girls and boys, with the highest incidence among white youth. Type 2 diabetes mellitus is more prevalent among girls and has the highest incidence among African American, Mexican American, and Native American populations. The peak age of presentation for DM1 is between 5 and 15 years of age. Less is known about DM2 in children, but previous studies show a mean age of 13.8 years at presentation.

The SEARCH for Diabetes in Youth Study (SEARCH) is a population-based, observational study of physician diagnosed diabetes among youth younger than 20 years from 6 centers. The overall prevalence estimate for diabetes in children and adolescents was approximately 0.18%. Type 2 diabetes was found in all racial/ethnic groups but generally was less common than type 1, except in American Indian youth.

Clinical Presentation

Children can vary in their clinical presentation from being asymptomatic to having fulminate metabolic imbalance (Dx Box). Type 1 diabetes mellitus commonly presents with a classic triad of polydipsia, polyuria, and polyphagia. The most consistent presenting complaint is increased urinary frequency, manifested as nighttime polyuria or secondary enuresis. Alterations in appetite and thirst are most commonly recognized when disease onset occurs in the preschool years (probably because parents are most able to monitor eating and drinking behaviors during the first few years of life). Weight loss can be variable but is more common in DM1 than DM2. Diabetic ketoacidosis (DKA) occurs at the time of initial presentation in up to 45% in DM1 and 14% in DM2, and presents with vomiting,

Dx Diabetes Mellitus

- Symptoms (polydipsia, polyuria, and polyphagia) together with a random plasma glucose higher than 200 mg/dL
- Fasting blood glucose higher than 126 mg/dL (confirmed on a subsequent day)
- Oral glucose tolerance test with 2-hour peak plasma glucose higher than 200 mg/dL
- HbA1C \geq 6.5%

polyuria, dehydration, and Kussmaul respirations. Children and adolescents with DM2 also report having the classic triad of symptoms, but are often identified through screening urinalysis. Type 2 diabetes mellitus is highly associated with obesity (body mass index \geq 85th percentile [see Chapter 135]), acanthosis nigricans, and having a first-degree relative with DM2.

Pathophysiology

Patients with DM1 have an absolute insulin deficiency due to autoimmune destruction of the beta cells of the pancreas. The disease process is thought to be triggered by an environmental factor such as a virus or toxin in genetically susceptible individuals. The exposure occurs in early childhood, but disease progression can be variable. More than 90% of affected individuals carry either human leukocyte antigen (HLA) DR3 or DR4. Discordance of disease among twins supports the theory that DM1 involves an environmental exposure in genetically susceptible individuals. Twin studies show evidence of a preclinical autoimmune process, which also has predictive value in identifying susceptible individuals at risk for developing DM1. Immune changes include an increase in activated T-cells expressing HLA-DR, islet cell antibodies (ICA), insulin autoantibodies (IAA), and glutamic acid decarboxylase antibodies (GAD Ab) (Table 143-1).

Disordered immune function, in which some antigenic components of pancreatic islet cells are not recognized as self, seems to be the pathogenic mechanism for the development of DM1. It is generally believed that at least 90% of beta cell mass must be destroyed before problems with glycemic regulation are manifest. Endogenous insulin deficiency, occurring as a natural consequence of islet cell destruction, results in the inappropriate use of carbohydrate. Cellular uptake of glucose by liver, muscle, and adipose tissue is blocked. Synthesis of glycogen, protein, and fat is reduced, and a catabolic state marked by lipolysis, proteolysis, and ketone body formation ensues. Increased serum glucose and ketones present an overwhelming osmotic load to the kidneys, resulting in urinary losses of volume and cations (Na^+ , K^+ , NH_4).

The autoimmune phenomena described previously are not evident in DM2 as demonstrated by the absence of ICAs, IAA and GAD Ab. This disease, which is characterized by resistance to insulin, may assume different presentations in childhood. The more traditional form of DM2 presents in older children and adolescents and is highly associated with obesity and having a first-degree relative with DM2.

Table 143-1. Predictive Tests for Individuals Susceptible to Type 1 Diabetes Mellitus (DM1)^a

<i>Immunologic Marker(s)</i>	<i>Risk of Developing DM1 (Within 5–8 y)</i>
Islet cell antibodies (ICA)	25%–70%
Anti-glutemic acid decarboxylase antibodies	68% among siblings of DM1 proband and 50% in the general population
IA-2A	58% among siblings of DM1 proband and 43% in the general population
Insulin autoantibodies (IAA)	Variable (may not be specific to islet cell tissue)
Reduced first-phase insulin release	100%
ICA and IAA	90%
Human leukocyte antigen with index case	25%–30%

^a Individuals with first-degree relative with type 1 diabetes.

Differential Diagnosis

The diagnosis is usually straightforward given the symptomatology, except in children who present at a very young age. Although the onset of diabetes is rare before 1 year of age, the disease does occur but with nonspecific symptoms (eg, irritability, vomiting, tachypnea, and poor weight gain). When diabetes presents before 1 year of age, monogenic causes of diabetes needs to be considered. Chemotherapeutic agents (eg, L-asparaginase) and a variety of medications (eg, corticosteroids, diuretics, oral contraceptives, diphenylhydantoin, epinephrine) may induce glucose intolerance. Glycosuria without evidence of ketosis or elevated blood glucose occurs in certain renal conditions (eg, Fanconi syndrome, carbohydrate malabsorption syndromes, heavy metal intoxication). Transient hyperglycemia, with or without glycosuria, may occur in response to physiological stress (eg, burns, trauma, hyperosmolar dehydration). In most of these cases, glucose regulation returns to normal within several days.

Evaluation

Evaluation should focus both on the diagnosis of diabetes (hyperglycemia) and the category because DM1 or DM2 can have different treatment modalities and disease courses.

History

The history should focus both on classic symptomatology and whether there is a family history of diabetes. Up to 80% of youth with DM2 will report a positive family history of diabetes, compared with 20% of youth with DM1. In addition, exogenous causes of diabetes should be ruled out. Obtaining a history of viral infections or chemical exposures during early childhood may be useful (Questions Box).

Questions

Insulin-Dependent Diabetes Mellitus

- Is the child having increased urination (eg, nighttime urination, unusual bedwetting)?
- Is the child drinking or eating more than usual?
- Has the child experienced any weight loss?
- Has the child been taking or had access to any kind of medications (eg, corticosteroids, L-asparaginase, diuretics [“water pills”], birth control pills)?
- Are there any family members with diabetes (first- or second-degree relatives)?

Physical Examination

Growth parameters should be measured and plotted on standard growth curves. Obesity is present in 96% of DM2 youth, compared with 24% of DM1 youth. Even when obese, patients with diabetes may lose weight at the time of presentation. Youth with uncomplicated DM1 may have an unrevealing physical examination, while those with DM2 may have physical findings associated with obesity. One study demonstrated that 60% of adolescents with DM2 had acanthosis nigricans and 32% had hypertension at presentation. An intercurrent infection may trigger the symptomatology and should always be sought in cases of ketoacidosis. Children who present with ketoacidosis may have evidence of vomiting, dehydration, Kussmaul respirations and, in severe cases, altered mental status.

Laboratory Tests

Initial laboratory tests should include evaluation of the serum and urine for glucose and ketones. For patients presenting in DKA, evaluation should also include a full chemistry panel to assess for metabolic acidosis, hypokalemia, and serum osmolality. Once the diagnosis of diabetes is suspected, further testing can assist in categorizing the type of diabetes. Tests include insulin levels and C-peptide (a marker of insulin levels) levels. Both insulin and C-peptide levels are usually higher in patients with DM2 because they have insulin resistance rather than an absolute insulin deficiency. Insulin reserve can be measured by determining the basal and stimulated levels of C-peptide (>0.6 ng/mL basal level, >1.5 ng/mL 90 minutes after nutritional supplement such as Sustacal). In categorizing diabetes, it is important to note that some with DM1 can have insulin reserves up to 2 years after diagnosis.

Oral glucose tolerance tests may be necessary to confirm the diagnosis of diabetes in cases in which the onset of symptoms is not obvious. Two-hour postprandial values in excess of 200 mg/dL or fasting glucose of 126 mg/dL or higher are evidence of diabetes. The introduction of the intravenous glucose tolerance test with measurement of first-phase insulin release has allowed early diagnosis of individuals at risk for the disease prior to development of symptoms.

To assess children who are at risk for DM2, screening may be done every 2 years starting at age 10 years or at the onset of puberty

(whichever comes first) and may be done using fasting plasma glucose (as recommended by the American Diabetes Association) and/or by oral glucose tolerance test (as recommended by the World Health Organization). The children who should be screened are those who meet criteria for obesity and have 2 or more of the following risk factors: family history of DM2 in first- or second-degree relatives, at-risk race/ethnicity (African American, Asian/Pacific Islander, Native American, Hispanic), or associated signs and symptoms of insulin resistance (acanthosis nigricans, dyslipidemia, hypertension, polycystic ovarian syndrome).

Management

Early diagnosis together with a comprehensive program of education and aggressive management are essential to prevent acute and long-term complications. Long-term objectives of therapeutic intervention in children with diabetes are (1) to facilitate normal physical growth and psychological and sexual maturation, (2) to promote normoglycemia through regulation of glucose metabolism, (3) to prevent acute complications (ie, hypoglycemia, ketoacidosis), (4) to prevent or delay long-term sequelae, and (5) to accommodate physiological changes that alter therapeutic needs (eg, exercise, adolescence, intercurrent illness).

Effective management requires a multidisciplinary team of professionals skilled in handling the myriad issues that arise for families and children with diabetes. Most clinics specializing in the care of children with diabetes include a nurse educator, dietitian, social worker, psychologist or counselor, and a pediatric endocrinologist. In settings where such special care centers are available, the primary care physician serves as a key adjunct, underscoring the importance of ongoing patient–family involvement in disease management and ensuring optimal growth, development, and nutrition. In the absence of special care centers, the primary care physician assumes responsibility for all aspects of management, including the treatment of acute complications, monitoring compliance and control, and surveillance for long-term complications.

Effective therapeutic intervention is based on individual needs for energy, insulin, and exercise. A number of factors, including physical growth, insulin requirement, glycemic control, and activity level, influence those needs and must be assessed on a regular basis. For DM1, insulin therapy is the mainstay of management, whereas DM2 therapeutic options include weight control through diet and exercise (see Chapter 135), oral hypoglycemic agents, and insulin. Oral hypoglycemic agents can lower blood glucose by increasing insulin secretion, increasing insulin sensitivity, decreasing hepatic glucose output, or decreasing nutrient absorption. These agents include sulfonylureas and other insulin secretagogues, metformin, thiazolidinediones, and acarbose. While DM2 may initially be managed with exogenous insulin, metformin is the oral agent prescribed most often for DM2 in children and adolescents. A newer class of medication acts by an incretin effect and increases glucose-dependent insulin secretion. These medications include exenatide (administered by injection) and a drug that inhibits dipeptidyl-peptidase-4,

thereby prolonging the effect of endogenous insulin release after a meal. Similar to most drugs for the treatment of DM2, these newer drugs do not have a pediatric indication.

Insulin

The purpose of insulin therapy is to enable children to approach normoglycemia in response to adequate amounts of food, insulin, and exercise. The amount of daily insulin required is dependent on the child's age, weight, and development. On average for DM1, children younger than 5 years require 0.6 to 0.8 U/kg, children between 5 to 11 years of age require 0.75 to 0.9 U/kg, and 12- to 18-year-olds require 0.8 to 1.5 U/kg in a 24-hour period. Within 3 to 4 months of diagnosis, most individuals experience a partial remission, or "honeymoon" phase, during which time their insulin requirements decline dramatically. Conversely, illness, anxiety, and adolescence (ie, pubertal changes) may cause the insulin requirement to increase. Even under conditions of increased need, reported daily insulin dosages in excess of 2 U/kg of body weight should stimulate investigations into patient compliance.

A number of insulin regimens currently in use take advantage of the variable onset of action of the different insulin preparations (Table 143-2). The new insulin analogs are monomers of insulin rather than insulin aggregates. They provide a rapid onset and a shorter duration of action. This allows for easier adjustment of insulin dose depending on the child's appetite because the injection can be given immediately before the meal. Children with newly diagnosed diabetes should use semisynthetic or recombinant human insulin preparations to minimize the possibility of allergic reactions. Any change in insulin preparation should be undertaken cautiously and only under medical supervision because brands vary in strength, purity, and glycemic response.

Morning hyperglycemia may result from 1 of 2 phenomena, which must be distinguished because the appropriate therapeutic responses are opposite. The **dawn phenomenon** probably involves

a nocturnal surge of growth hormone, resulting in hyperglycemia that is present during the night (2:00–4:00 am) and is sustained until morning. The treatment involves increasing the evening dose of intermediate-acting insulin or moving the evening insulin to bedtime. In the **Somogyi phenomenon**, morning glucose is high as a physiological response to nighttime hypoglycemia. Treatment of this condition requires decreasing the evening intermediate-acting insulin or increasing the carbohydrate content of a bedtime snack.

Adolescents require special consideration. The sexual maturation process occurs in the setting of relative insulin resistance, other hormonal alterations, and a burden of developmental tasks, which make glycemic control problematic at best. Daily insulin requirements may increase to 1.5 to 2 U/kg during adolescence, but return to prepubertal levels at the end of the teenage years. Particular efforts must be made to ensure physical and psychological growth in the context of these special tasks. Dietary manipulation and consideration of alternative (usually more intensive) insulin and monitoring regimens is critical for successful glycemic control during this challenging period.

External infusion pumps are not widely used in young children because of the danger of mechanical malfunction (leading to hypoglycemia or hyperglycemia). Their use may be considered, however, in children with unstable diabetes or severe, chronic, intercurrent illness.

Glucose Monitoring

Self-monitoring of glycemic response through the in-home assessment of blood glucose levels is critical to effective therapy. The introduction of reflectance meters (glucometers) has obviated the need for inaccurate, visually read strips of glucose-sensitive paper. Patients who are taking insulin should measure glucose 3 to 7 times daily. Most endocrinologists advocate testing before each meal and at bedtime during the first year after diagnosis. Testing may also be done at 2:00 am to test for hypoglycemia or hyperglycemia. Depending on the age of the child, an acceptable range for glycemic control is 80 to 150 mg/dL. Additional short-acting insulin may be given to correct for high blood glucose. Patients also need to monitor their urine for ketones whenever their blood glucose readings exceed 240 mg/dL.

Glycosylated hemoglobin (HbA_{1c}) measurements reflect glucose control over the preceding 2 to 3 months. The normal value is 4% to 6% of total hemoglobin. Glycosylated hemoglobin values less than 7% are excellent, between 7% to 8% are good, between 8% to 10% are average, and more than 10% are poor. The Diabetes Control and Complications Trial studied the effect of different levels of glycemic control on the complications of diabetes. Although the study only included pediatric patients 13 years or older, the study did show that patients with "tight glycemic control" had lower HbA_{1c} levels and fewer long-term complications than patients not tightly controlled. Adolescents with tight glycemic control had a greater risk of hypoglycemic events than the control group, a fact that must be taken into consideration in determining the ideal glycemic control for a child. In general, tight glycemic control is not recommended for children younger than 5 years; for older children, glycemic control should be individually tailored. Whenever children's routines undergo dramatic change, stepped-up home monitoring and medical

Table 143-2. Commonly Used Insulin Preparations^a

Type	Onset of Action	Duration of Effect
Rapid-acting analogs Lispro, aspart, glulisine	Within 15 min	<5 h
Short-acting Regular	Within 30 min	5–8 h
Intermediate-acting (zinc or protamine) Neutral protamine Hagedorn	1.5–2.5 h	18–24 h
Long-acting Glargine Detemir	70 min 1.5–2.5 h	22–24 h 20–24 h

^a Twice-daily injections: Two-thirds of the total daily dose before breakfast made up of intermediate- and short-acting insulin in 2:1 ratio. One-third before dinner made up of intermediate- and short-acting insulin in 1:1 ratio.

Basal bolus: Intermediate-/long-acting insulin at bedtime with regular insulin or short-acting insulin analog before each meal.

consultation are advisable. Caution should be used in interpreting HbA_{1C} values in infants and others in whom fetal hemoglobin or other hemoglobin variants are present because these hemoglobin variants may falsely elevate or lower the value of HbA_{1C}. Although compliance with intensive regimens is an indisputable challenge (particularly as responsibility for management shifts from parent to child), increasing evidence underscores the importance of tight glycemic control.

Nutrition

The timing, amount, and types of foods eaten for meals and snacks should be relatively consistent from one day to the next to match the relative constancy of the exogenous insulin. Daily caloric requirements should be distributed in the following way: carbohydrate, 50% to 55% (<10% in the form of sucrose); protein, 20% to 25%; and fat, 25% to 30% (6%–8% polyunsaturated, <10% saturated). The distribution of these calories should be approximately 25% for breakfast, 25% for lunch, 30% for dinner, and 20% for snacks. Snacks are an important part of the nutrition regimen for children with diabetes. Most nutritionists recommend 3 snacks for young children (between meals and at bedtime) and 2 for older children. Some investigators promote the ingestion of cornstarch at bedtime as a means of stabilizing the serum glucose. Dietary discipline is a tremendous challenge for many children. Introducing one change at a time may make such dietary manipulations more acceptable over the long run. In addition, establishing healthy eating habits requires availability of healthy choices in the child's environment. Cooperation from the school and home enhances the likelihood of a child developing healthy eating practices.

Carbohydrate counting is an important part of matching insulin requirements to nutritional intake. For patients on multiple daily insulin injection schedules, there is flexibility in tailoring each dose of insulin based on the carbohydrate content of each meal or snack. For patients on twice-daily insulin injection regimens, consistent carbohydrate content of the meals and snacks is important in maintaining blood glucose levels. Learning carbohydrate counting takes time for the patient and families, and they need ongoing nutrition support to become familiar and comfortable with how different foods affect their blood glucose levels.

Exercise

Exercise contributes to glucose control by facilitating the use of glucose without the assistance of insulin. If not carefully undertaken on a regular basis, exercise can precipitate acute hypoglycemia. Physical activity enhances the body's sensitivity to insulin and can even decrease the daily insulin requirement. Thoughtful planning of exercise involves compensatory changes in food intake and insulin doses. For example, extra energy intake at bedtime may offset the nighttime hypoglycemia that accompanies late afternoon exercise. Seasonal physical activities may necessitate an adjustment in the insulin regimen at certain times of the year.

Education

The role of education is pivotal to the successful management of diabetes in childhood and throughout life. During childhood, educational efforts must be focused on the entire family unit. Affected children must be involved as early as possible and in ways that are developmentally appropriate. The process should involve the early introduction of basic survival information, such as insulin therapy and management of complications. This can be followed by more detailed information, including strategies to reduce long-term sequelae.

Prognosis

Diabetic ketoacidosis is the major cause of morbidity and mortality in children and adolescents, followed by **hypoglycemia**. Clinical signs of hypoglycemia in older children include shakiness, blurred vision, and dysarthria. Concerns about the neurodevelopmental impact of hypoglycemia in young children have led to the recommendation of more liberal glycemic control in early onset disease. Diabetic ketoacidosis, precipitated by an intercurrent infection or poor compliance, is a metabolic derangement that always requires urgent medical attention and often necessitates hospitalization. Replacement of fluids, attention to electrolyte abnormalities, and insulin therapy are the mainstays of treatment in the face of this complication.

There has been an increase in the number of pediatric patients presenting with hyperglycemic hyperosmolar syndrome (HHS). Since the treatment of HHS is different from DKA, the clinician needs to be aware of this entity. In fact the treatment for children with HHS may be different than the treatment of this disorder in adults.

Long-term complications include **proliferative retinopathy, nephropathy, peripheral and autonomic neurologic impairment, and early onset of cardiovascular disease**. Ophthalmologic evaluation, overnight urine protein measurement, and a detailed neurologic examination should occur once or twice each year depending on the duration of disease. Intensive therapeutic intervention results in significant reduction in retinopathy, nephropathy, and cardiac and peripheral vascular disease. Preliminary evidence warrants consideration of such therapy with the expectation of benefit in long-term outcomes.

CASE RESOLUTION

The girl in the opening case history is admitted to the hospital to help determine appropriate insulin dosing. She and her family require ongoing education. Careful management is necessary to optimize normal growth and development as well as delay or prevent long-term sequelae.

Juvenile Idiopathic Arthritis/ Collagen Vascular Disease

Elizabeth A. Edgerton, MD, MPH

CASE STUDY

A 4-year-old girl is evaluated for pain in the legs and arms for 4 months' duration. Symptoms began with pain and swelling in the left elbow. Initially she was diagnosed with a bad sprain and was treated with a course of nonsteroidal anti-inflammatory drugs. The elbow improved, but it still caused occasional discomfort. About 2 months ago, the child was evaluated for painful knees and was diagnosed with growing pains. She has had no history of trauma, fevers, or rashes, but her activity level has decreased since the symptoms began. The mother has noted swelling in all 3 of the joints at one time or another but reports no redness. On physical examination the vital signs are normal. Both knees are swollen but not erythematous. Her range of motion in the knees and elbow is decreased.

Questions

1. What findings are indicative of juvenile idiopathic arthritis (JIA)?
2. How can the clinical history and laboratory evaluation assist in determining the subtype of juvenile idiopathic arthritis?
3. What are the long-term outcomes for patients with juvenile idiopathic arthritis?
4. What similar clinical findings are present in other collagen vascular diseases?
5. What types of agents are used in the treatment of juvenile idiopathic arthritis?

Collagen is a protein that represents 30% of the body's protein and is glue-like, shaping the structure of tendons, bones, and connective tissues. Malfunctioning of the immune system can affect these structures and result in what is termed *collagen vascular disease*. Diseases categorized as collagen vascular diseases include JIA, systemic lupus erythematosus (SLE), dermatomyositis (DM), and scleroderma (SD). While primarily known as collagen vascular diseases, they are also considered a subset of connective tissue disorders with a prominent immune component referred to as diffuse connective tissue diseases. They are also included in the category of secondary vasculitides.

An abnormal autoimmune reaction is common to all of these disorders, and it is not until specific vascular damage within an organ system occurs that more characteristic symptoms allow for diagnosis. Furthermore, the prevalence of these disorders is difficult to determine since their symptoms may overlap and no diagnostic gold standard exists. Each disease, though, has characteristic clinical presentations and serologic findings that guide in diagnosis. Treatment usually requires the use of anti-inflammatory and immunosuppressive therapy. Morbidity and mortality are dependent on the level and duration of inflammation, the target organs affected, and secondary complications that may arise from treatment.

Epidemiology

In JIA the predominant symptom is chronic arthritis that presents in children younger than 16 years. Juvenile idiopathic arthritis is the most common pediatric rheumatologic disease and one of the more common chronic diseases of childhood. The estimated worldwide incidence is 0.8 to 22 per 100,000 and the prevalence is 7 to 400 per 100,000 children. It is most prevalent among non-Hispanic whites. The International League of Associations for Rheumatology (ILAR) system is used for classification of the disease. Based on presenting symptoms, serology, age, gender, race, and/or ethnicity, the disease is divided into the following subtypes: oligoarthritis, polyarthritis, systemic, enthesitis-related, and psoriatic arthritis in decreasing frequency. Clinically, symptoms may change over time leading to a reclassification of a patient's subtype of JIA.

The incidence of SLE varies greatly by gender and ethnicity, with females and Hispanics, African Americans, Native Americans, and individuals from Southeast and South Asia most commonly affected. For individuals with onset before the age of 19 years, the incidence is approximately 6 to 18.9 per 100,000 among white females, 20 to 30 per 100,000 among African Americans females, and 16 to 36.7 per 100,000 among Puerto Rican females. The male-female ratio varies

from 1:4 to 1:7 depending on the ethnicity of the cohort. Five- and 10-year survival rates have improved to as high as 100% and 86%, respectively, among pediatric patients. Survival is impacted by organ involvement, with those with renal and central nervous system (CNS) involvement fairsing worse.

The incidence of juvenile DM (JDM) is 2.5 to 4.1 per million among children younger than 17 years. It is predominantly seen in white, non-Hispanic individuals (65%). Median age of presentation is 7 years of age, with girls affected more often. The clinical presentation and course of JDM is less severe than of adult-onset DM.

Overall, the annual incidence of systemic SD is 0.45 to 1.9 per 100,000 with a prevalence of 15 to 24 per 100,000. Scleroderma is very rare in childhood, with fewer than 10% of all patients younger than 20 years. While the adult-onset disease has a strong female predominance, gender and age specifics have not been identified in the juvenile form. Localized SD is 10-fold more common than systemic SD based on data from rheumatology referrals. Few epidemiological studies exist, but the overall prevalence of localized SD is estimated to be 1 in 100,000.

Clinical Presentation

Collagen vascular diseases may present with a variety of symptoms including joint pain or swelling, skin rashes, kidney disease, or neuropsychiatric problems depending on the specific disorder.

Differential Diagnosis

The differential diagnosis of collagen vascular diseases includes JIA, SLE, DM, and SD.

Dx

Juvenile Idiopathic Arthritis

- Systemic: arthritis with daily fevers, rash, and general malaise
- Oligoarthritis: arthritis affecting 1 to 4 joints in the first 6 months
- Polyarthritis: arthritis affecting more than 5 joints in the first 6 months
- Enthesitis-related: arthritis and/or enthesitis and presence of human leukocyte antigen-B27
- Psoriatic: arthritis and psoriasis or arthritis and dactylitis, nail abnormalities, and family history of psoriasis

Juvenile Idiopathic Arthritis

The diagnosis of JIA is based on the clinical symptoms during the first 6 months following presentation (Dx Box).

The ILAR system of classification defines the following subtypes: systemic, oligoarthritis (persistent and extended) polyarthritis rheumatoid factor positive and negative, enthesitis-related arthritis, psoriatic arthritis, and other. Each subtype has varying clinical symptoms and long-term complications.

The **systemic form** is present in 10% to 20% of patients with JIA and is associated with the greatest morbidity and mortality. This subtype lacks gender, age, or human leukocyte antigen association seen

among other subtypes. It is characterized by fever, rash, lymphadenopathy, hepatosplenomegaly, and serositis. The arthritis may present with or separate from these other symptoms. Classically the fever peaks twice a day and is associated with an evanescent rash that consists of discrete salmon-colored macules seen predominantly on the trunk and proximal extremities. The arthritis is polyarticular, affecting both large and small joints, and is present within the first 6 months of symptoms.

Up to 37% of patients develop chronic disease with destructive arthritis while the others may experience disease remission. Predictors of poor prognosis are age younger than 6 years at diagnosis, disease duration of more than 5 years, and persistence of systemic symptoms requiring treatment. Overall mortality is 0.3% in North America. A rare but life-threatening complication is macrophage activation syndrome. Patients present with hepatosplenomegaly, lymphadenopathy, and purpura and may progress to multiorgan failure. Sedimentation rate is low in macrophage activation syndrome in contrast to elevated during a disease exacerbation. Treatment involves steroids and immunosuppressive therapy. Triggers to macrophage activation syndrome include viral infections and addition or change in medications such as nonsteroidal anti-inflammatory drugs, sulfasalazine, and etanercept.

Oligoarticular JIA is the most common form. Arthritis is present in fewer than 5 joints during the first 6 months of disease. Often the large joints of the lower extremities are affected, and children may present with single joint involvement. Oligoarticular JIA is divided into persistent and extended forms, the latter associated with more severe disease course. Extended oligoarticular JIA can only be diagnosed after the first 6 months of symptoms in which patients suffer involvement of greater than 5 joints. Individuals, especially girls, who are antinuclear antibody (ANA)-positive have an increased risk of uveitis (asymptomatic). The American Academy of Pediatrics suggests frequent screening examinations because the uveitis can result in significant ophthalmologic morbidity. Among individuals with persistent oligoarticular JIA, 75% report remission of disease while only 12% of those with extended subtype report remission, with the remaining continuing to suffer symptoms into adulthood.

Polyarticular JIA presents with involvement of 5 or more joints during the first 6 months of disease. Rheumatoid factor (RF) negative disease is the more common subtype and tends to present in early childhood while RF positive disease presents later. Rheumatoid factor positive patients are often adolescent girls with symmetrical small joint disease and characteristic subcutaneous nodules. The arthritis is erosive and results in boutonniere deformities (proximal interphalangeal joint flexion and distal interphalangeal joint hyperextension) and swan-neck deformities (proximal interphalangeal joint hyperextension and distal interphalangeal joint flexion). Uveitis is present in approximately 10% of patients.

Enthesitis-related arthritis is characterized by inflammation where tendons insert at the bone. It usually affects the axial and peripheral skeleton. This subtype includes patients with ankylosing spondylitis and reactive arthritis associated with inflammatory bowel disease. Ankylosing spondylitis generally affects boys aged 8 years or

older. This subtype is RF and ANA negative. Extra-articular symptoms include anterior uveitis, which is acute and painful in contrast to uveitis seen in oligoarticular and polyarticular arthritis, which is more insidious in onset.

Psoriatic JIA occurs in patients with chronic arthritis and psoriasis or those who meet 2 of the following criteria: dactylitis, nail pitting or onycholysis, and family history of psoriasis. Peak onset is in middle childhood. The arthritis, which is asymmetrical, may present before the psoriatic rash, making the diagnosis difficult. Up to 17% of patients will have asymptomatic uveitis and require routine slit-lamp examinations for diagnosis.

Systemic Lupus Erythematosus

Diagnosis of SLE is based on both clinical and laboratory findings and exclusion of other autoimmune diseases. Most patients have at least 4 of 11 of the American College of Rheumatology Classification Criteria for SLE. Criteria can be present over any period together or in isolation. Median age of presentation among pediatric patients is approximately 12 years of age. Patients usually present with constitutional symptoms such as fever, fatigue, weight loss, and systemic inflammation as demonstrated by lymphadenopathy and hepatosplenomegaly. The most common organs affected are skin and musculoskeletal and renal systems and their level of involvement directs treatment decisions.

A predominant feature of SLE is the rash. **Mucocutaneous involvement** includes classical malar rash or butterfly rash that spares the nasolabial folds, photosensitivity, and discoid rash. Approximately 10% to 30% of patients will have painless oral and nasal ulcers. Most patients also have some level of **musculoskeletal involvement** that includes arthritis, arthralgia, or tenosynovitis. The arthritis is usually a symmetrical polyarthritis affecting both small and large joints. In contrast to JIA, this arthritis is usually non-erosive as demonstrated radiographically, but clinically appears more painful. Musculoskeletal pain can be secondary to treatment resulting in what is called pain amplification syndrome attributed to glucocorticoid therapy.

Neuropsychiatric manifestations affect 20% to 70% of patients with SLE. This variation is due to the difficulty of diagnosing the often vague and varied symptoms. Headache is the most common symptom and can be isolated or be part of a constellation of other neurologic symptoms. Headaches that are refractory to treatment may be secondary to active CNS vasculitis, increased intracranial pressure, or cerebral vein thrombosis. Elevated levels of lupus anticoagulant (LAC) are usually present with cerebral vein thrombosis and are an indication for emergent imaging. Psychosis manifested by visual and tactile hallucinations may be present in 30% to 50% of patients. Psychotic symptoms will usually present with other neurologic symptoms. Imaging studies of the CNS provide little assistance in diagnosis. When psychosis is in isolation, secondary effects of glucocorticoids need to be considered. More difficult to delineate is cognitive impairment, which may present as a broad range of symptoms ranging from confusion and difficulty concentrating to coma. Other

less common neurologic symptoms include seizures, movement disorders including chorea, and cranial nerve abnormalities.

Lupus nephritis is present in 29% to 80% of patients, with most presenting during the first year of diagnosis. In contrast, less than 10% of patients suffer from renal vasculitis. Prognosis for patients is based on the histologic classification of nephritis as established by the World Health Organization using renal biopsy (class I–V). Unfortunately, clinical markers (proteinuria, hematuria, creatinine level) may not correspond to histologic classifications, but when renal function is impaired patients have class III or IV disease. Hypertension is common along with lupus nephritis and, when present with peripheral edema, carries a worse prognosis. Overall survival for patients with renal involvement has improved. The 5-year survival for class IV is 88% to 93% and 10-year survival of 85%.

Hematologic manifestations including anemia, thrombocytopenia, and leukopenia may be present in 50% to 75% of patients. Patients have a normochromic normocytic anemia typical of anemia of chronic disease. Of patients who are Coombs positive, only 10% suffer significant hemolysis. Thrombocytopenia is present in 15% of patients. Patients with chronic autoimmune idiopathic thrombocytopenic purpura (AITP) with ANAs have a greater risk of developing SLE, as do patients with Evan syndrome (AITP and Coombs positive anemia). Leukopenia is thought to represent a general marker of disease activity.

Cardiac manifestations of SLE most often affect the pericardium. Patients suffering from pericarditis complain of chest pain exacerbated by positional changes. Up to 50% of patients have Libman-Sacks endocarditis, which results in sterile verrucous vegetations, putting them at risk for subacute bacterial endocarditis. The major cardiac mortality associated with SLE is premature atherosclerosis; this is attributed to the chronic inflammation.

Pleuropulmonary disease is seen in 25% to 75% of patients with SLE. Again the variation in prevalence is due to the lack of specificity of symptoms. Pleuritic chest pain secondary to effusion can be a presenting symptom. Abnormal pulmonary function tests are common among asymptomatic patients. Patients can suffer acute respiratory failure secondary to SLE or opportunistic infection. **Gastrointestinal (GI) symptoms** are difficult to distinguish from the disease process versus adverse side effects of treatment. Abdominal pain can be secondary to peritoneal inflammation (serositis), vasculitis, pancreatitis, malabsorption, pseudo-obstruction, paralytic ileus, or direct bowel involvement (enteritis). **Endocrine abnormalities** can also be the result of the disease process or adverse effects of treatment. Hypothyroidism is associated with the presence of antithyroid antibodies while diabetes is secondary to steroid use. Delayed puberty and menstrual abnormalities are a consequence of chronic disease. Female patients managed with cyclophosphamide can suffer secondary ovarian failure.

Serologic presence of ANA is universal among patients with SLE. These include anti-DNA (60%–70%), anti-RNA-binding proteins (70%–90%), anti-U1RNP and anti-SM antibodies (40%–50%). Anti-Ro and La antibodies (30%) are seen less frequently.

Anticardiolipin (50%) and LAC (20%) are the most common antiphospholipid antibodies. The greatest risk of thrombosis is associated with LAC rather than with the other antiphospholipid antibodies.

Inflammatory Myopathies

Inflammatory myopathies are rare conditions in pediatrics but are discussed here because their symptoms overlap with other collagen vascular diseases. **Juvenile DM** is the most common myopathy presenting with rash and muscle weakness. It is a vasculopathy resulting from intimal proliferation of small blood vessels. Skin and muscle are the primary systems affected, but the vasculopathy can target any organ. **Juvenile polymyositis** is an idiopathic myositis without the dermatologic manifestations.

Patients present with proximal muscle weakness of the shoulders, hips, neck flexors, and abdominal musculature. Muscle tenderness and inflammation are less common. Patients can have both positive Gower (using one's hands to go from a supine to a standing position) and Trendelenburg (see Chapter 100) signs. Muscle weakness may also present with swallowing difficulties. When arthritis is present it is mild, transient, and non-erosive. As with other autoimmune diseases, fever, malaise, anorexia, and weight loss can be associated with disease activity.

Further diagnostic evaluation is essential in confirming the diagnosis of JDM. Muscle biopsy may show necrosis, atrophy, or inflammatory exudates. Electromyogram may or may not be abnormal. Evaluation of muscle enzymes often shows an elevated creatinine phosphokinase, aldolase, and/or lactate dehydrogenase.

The clinical course is varied, and multiple organ systems can be affected. Patients develop dystrophic calcinosis on the extremities. Although a characteristic finding of DM, it is usually not present at the time of diagnosis. Lipodystrophy, a progressive and symmetrical loss of subcutaneous fat, affects approximately 14% to 25% of patients. Patients may suffer esophageal dysmotility and malabsorption. Vasculopathy of the GI tract may result in pain, bleeding, or perforation. One-third of patients may have respiratory weakness during their disease course, primarily following an asymptomatic restrictive pattern. Up to 78% of patients have decreased ventilatory capacity. Although rare, patients are at increased risk of aspiration secondary to pharyngeal muscle weakness and to pneumonia secondary to immunosuppressive therapy.

Rash is critical for the diagnosis of DM and can occur prior to or after the presentation of muscle weakness. The heliotrope eyelid rash and Gottron papules are pathognomonic for DM. Eyelid or facial edema may be present with the rash, which may also have a malar component that includes nasolabial folds, in contrast to systemic lupus. Gottron papules or collodion patches are flat-topped, violaceous or red papules that can be scaly. They are seen predominantly on the extremities (extensor aspect of knuckles, elbows, knees, and medial malleoli). Nail bed changes demonstrating vasculopathy are also present. Neurologic symptoms are rare, but may present as generalized tonic-clonic seizures. Unlike adult-onset DM, malignancy is uncommon in juvenile DM.

Scleroderma

Juvenile SD is characterized by the presence of hard skin before age 16. Localized SD involves only the skin and related tissues while systemic SD is a multisystem autoimmune disorder.

In **systemic SD**, skin, musculoskeletal system, GI tract, lungs, and heart are the organs most commonly affected. While the skin and musculoskeletal systems are the most common among pediatric cases, disease complications of the cardiopulmonary system are associated with the greatest mortality.

The diagnosis of systemic SD is based on the presence of major criteria that include sclerosis and/or induration, sclerodactyly, or Raynaud phenomenon in addition to minor criteria of the targeted organ systems. Diagnosis is often delayed due to the slow onset of disease and the initial subtlety of symptoms. Characteristic presentation starts with Raynaud phenomenon with associated tightening, thinning, and atrophy of the skin overlying the hands and face. Cutaneous changes start with edema, followed by induration and finally sclerosis. The skin becomes tightened by contractures and atrophy, giving the appearance of being hard, waxy, and tight. There may be either hypopigmentation or hyperpigmentation, and deposits of calcium may appear in the subcutaneous skin.

Musculoskeletal symptoms are the next most common symptom among patients and usually occur near the onset of disease. Arthralgias are usually mild and transient. Patients may suffer joint contractures over the proximal interphalangeal joints and elbows. Muscle inflammation occurs in approximately 38% of pediatric cases.

Up to 40% of patients will eventually have upper GI involvement. Dysphasia is caused by esophageal dysmotility or gastroesophageal reflux. Half of patients suffer small bowel involvement. Functional tests demonstrate GI abnormalities even among asymptomatic patients. Similarly, patients may have pulmonary involvement as demonstrated by abnormal function but initially appear asymptomatic. As the disease progresses, patients develop dry, hacking cough with dyspnea on exertion. A rare but severe complication is interstitial pulmonary fibrosis. Cardiac involvement is less common but is the primary cause of morbidity. Cardiac fibrosis leads to conduction defects, arrhythmias, and impaired ventricular function. Aggressive immunosuppressive therapy is required when the cardiomyopathy is severe.

As with many of the collagen vascular diseases, patients will have ANA (80%). Approximately 20% to 30% of patients have Scl-70 (anti-topoisomerase I), in contrast to adult onset in which only 7% of patients have this antibody. Approximately 25% of pediatric patients will have blood indices consistent with the normocytic normochromic anemia of chronic disease.

Localized Scleroderma

Similar to systemic SD, **localized SD** is secondary to abnormalities of fibroblast regulation, collagen production, and autoimmune regulation. Localized SD predominantly affects the skin and only occasionally involves other organs. Localized SD is divided into 5 subtypes: plaque morphea, generalized morphea, bullous morphea,

linear SD, and deep morphea. **Morphea** are areas of indurated, waxy skin with an ivory center and violaceous halo and are most commonly found on the trunk. When they become confluent they are classified as generalized morphea. **Linear SD** is the most common form of localized SD among children and adolescents. One or more linear streaks are present on the extremities. These cutaneous changes can extend into the subcutaneous tissue and muscle leading to significant deformities. Linear lesions on the face or head are referred to as *coup de saber* SD. Deep morphea involves subcutaneous morphea, eosinophilic fasciitis, and morphea profunda, in which the entire skin is thickened and feels bound down. This form is the least common and considered the most disabling.

The presence of extra-cutaneous involvement in cases of localized SD raises the controversial issue of whether localized SD can transition to systemic SD. Approximately 25% of patients with juvenile localized SD have extra-cutaneous involvement, most commonly articular. Diagnosis is based on clinical presentation and skin biopsy. Antinuclear antibodies and antihistone antibodies may be present. Approximately 13% of patients will have anticardiolipin antibodies, but unlike SLE their presence is not associated with thrombosis. Cosmetic appearance is often the focus of disease management. Systemic treatment is reserved primarily for subtypes with significant disability such as linear SD and deep morphea.

Pathophysiology

Autoimmune diseases result from an alteration in the selection, regulation, or death of T-cells or B-cells, which results in an abnormal response to a particular antigen. Genetic factors increase an individual's vulnerability but are not sufficient for disease expression. It is the interplay of environmental triggers and genetic susceptibility that leads to clinical manifestations. In JIA, the T-cell arm of the cell-dependent inflammation is best understood. It supports many of the clinical and biochemical factors into the subtypes of JIA. T-cells are dependent on the major histocompatibility complex (MHC) to recognize an antigen. Human leukocyte antigen types that have been classically associated with certain subtypes of JIA play a role in the presentation of a specific antigen. Studies of synovial fluid in JIA patients demonstrate specific families, or cohorts, of T-cells depending on the subtype of JIA. Furthermore, each subtype of JIA has a specific T-cell response with key inflammatory mediators and secondary effects. Current theory suggests that JIA is linked to an antigen-specific response in the synovial fluid. Systemic lupus erythematosus is characterized by abnormal autoantibody production against nucleic acids, especially double-stranded DNA. The T-cell and B-cell receptor-signaling pathways may be abnormal, as well as have an abnormal clearance of self-antigens, resulting in autoactivation of lymphocytes. In SD, autoantibodies target topoisomerase, centromeric proteins, and RNA polymerases, resulting in dysregulated fibroblast activation. Over-expression of MHC I is a major component of inflammatory myopathies. Local injury of vessels and muscles results from complement-mediated immune response and soluble adhesion molecules.

The molecular understanding of JIA has increased greatly, providing insight to the disease process and leading to a new classification system for the disease. Juvenile idiopathic arthritis is the result of an inflammatory process in the synovial fluid of a joint. The inflammatory process consists of an innate inflammatory phase and a cell-dependent phase. Initially there is an egress of cells and proteins from the bloodstream. The inflammation progresses with migration of neutrophils and monocytes to the location of tissue injury. Cell-dependent inflammation involves both T-cells and B-cells. T-cells are dependent on MHC to recognize an antigen. Furthermore, each subtype of JIA has a specific T-cell response with key inflammatory mediators and secondary effects. While B-cells are known to play a role in the pathogenesis of JIA based on their presence in synovial fluid, their specific mechanisms of action are only hypothesized.

Evaluation

History

The history should clearly delineate the duration and the extent of the symptoms (Questions Box). Has there been joint involvement and, if so, which joints? Do the joints ache and are there also visible changes such as swelling and erythema? Are the symptoms more pronounced at specific times of the day, such as in the morning on arising? Has the patient experienced weakness? If so, which muscle groups are most affected? Has the patient had a rash? What is the nature and location of the rash? What other symptoms are present, such as headache, fever, fatigue, and weight loss?

Questions

Juvenile Idiopathic Arthritis/Collagen Vascular Disease

- Has the child ever had any swelling, warmth, or redness of joints?
- Does the child have difficulty walking or running? If so, does it occur at any particular time of the day?
- Has the family noticed any type of skin rash or skin changes?
- Has the child had any eye complaints?
- Has the child had any recent illnesses such as gastroenteritis?
- Has the child traveled recently or been bitten by a tick?

Physical Examination

Patients should undergo a complete physical examination that includes a full assessment of the skin, all joints, flexibility of the spine, the strength of the muscles, and a neuropsychiatric assessment. Lymphadenopathy should be noted as well as the presence of organomegaly. Patients suspected of having JIA should also undergo a slit lamp examination of the eyes.

Laboratory Tests

In general laboratory testing includes a complete blood cell count, erythrocyte sedimentation rate, C-reactive protein, urinalysis, and other studies as determined by the differential diagnosis. Evaluation of patients for JIA includes rheumatoid factor, ANAs, and complement. Patients suspected of having SLE should have an anti-DNA, anti-RNA-binding protein, anti-U1RNP and anti-SM antibodies, and complement analyzed. Electrocardiograms and echocardiograms are appropriate in patients with SLE suspected of having cardiac involvement. Patients suspected of inflammatory myopathies should have creatine phosphokinase, aldolase, and lactate dehydrogenase levels and possibly myositis specific antibodies. Electromyogram and muscle biopsy may also be undertaken to complete the evaluation.

Imaging Studies

Magnetic resonance imaging is playing a larger role in the diagnosis and management of JIA and JDM. For SLE patients with neuropsychiatric symptoms, computed tomography scans and magnetic resonance imaging are rarely abnormal.

Management

The management of collagen vascular diseases varies with the specific condition.

Juvenile Idiopathic Arthritis

The objective of treatment for JIA is to control pain and inflammation while preserving function and normal growth, development, and well-being. Physical and occupational therapy are essential to maintain function. Medications used for the treatment of JIA include nonsteroidal anti-inflammatory drugs (NSAIDs), disease-modifying antirheumatic drugs (DMARDs), and tumor necrosis factor inhibiting agents. Corticosteroids are reserved for patients with serious systemic manifestations and are not considered ideal for long-term use in JIA secondary to the side effects. Most patients respond to the various NSAIDs, although the time to respond may vary greatly. Only nonspecific cyclooxygenase inhibitors are approved for pediatric use. Individuals with persistent joint disease require DMARDs, with methotrexate being the most common. Clinical improvement may not be seen for 1 to 6 months, but eventually 70% of patients will respond. A recent controlled trial demonstrating early use of DMARDs was associated with improved long-term prognosis measured by improved health status and decrease use of DMARDs long term, suggesting that treating JIA early with DMARDs may be of benefit. The study also highlighted the poor compliance with medications. Gastrointestinal disturbances are the most commonly seen side effects, with hepatotoxicity being rare. Sulfasalazine is another DMARD that is especially effective in patients with enthesitis-related JIA. Etanercept is a biological agent that is a tumor necrosis factor receptor antagonist reserved for patients not responding to methotrexate.

Systemic Lupus Erythematosus

A multidisciplinary team is essential to care for patients with SLE. Specific therapies are tailored to the symptoms, severity, and level of response. Initial treatment of musculoskeletal symptoms, primarily arthritis, is with NSAIDs combined with an antimalarial drug such as hydroxychloroquine. Resistant symptoms may require steroids or methotrexate. Treatment of neuropsychiatric manifestations is based on symptoms and severity. These include steroids, immunosuppressive medications (azathioprine or cyclophosphamide), antiepileptics, and antidepressants. The treatment of renal manifestations is based on the histologic classification of renal involvement. Medications include steroids and immunosuppressive agents and may also include angiotensin-converting enzyme inhibitors to decrease proteinuria. In practice, patients at risk for thrombosis may be treated with low-dose aspirin, although not all studies support the efficacy.

Complications of treatment with glucocorticoid steroids include avascular necrosis of the femoral head, affecting approximately 10% of patients. Furthermore, patients are at increased risk for osteoporosis due to low calcium and vitamin D intake and diminished physical activity. A severe complication of SLE is antiphospholipid antibody syndrome with severe microangiopathic thrombolytic changes, resulting in thrombosis to multiple organs. It is primarily associated with elevated antibody levels of lupus anticoagulant. It can occur anywhere in the body and can be difficult to recognize. Although antiphospholipid antibodies can be present in patients with JIA, DM antiphospholipid antibody syndrome is rare.

Dermatomyositis

Methotrexate is the primary medication for treatment of DM. Corticosteroids are often used when initiating treatment due to the slow onset of clinical improvement with methotrexate. Methylprednisolone pulses, immunoglobulin intravenous, and cyclophosphamide are reserved for nonresponsive cases or severe exacerbations.

Systemic Scleroderma

As with other collagen vascular disease, the treatment of systemic SD focuses on optimal function and control of inflammation. Many of the medications used in SD lack rigorous evaluations regarding efficacy. Immunosuppressive agents that are often used include methotrexate, mycophenolate, and cyclophosphamide in severe cases. Glucocorticoids are primarily effective for the inflammatory phase of muscle involvement or edematous phase of cutaneous disease. Vasodilator agents, especially calcium channel blockers, are used for symptomatic relief of Raynaud phenomenon. Few studies exist on the long-term survival of patients with juvenile systemic sclerosis. Clinically, as the skin tightens and contractures progress, the disease becomes extremely disabling. Cardiac, renal, and pulmonary disease progressions are most often responsible for premature death. The extent of sclerosis may be a prognostic factor.

Prognosis

Making the diagnosis of a collagen vascular disease requires a thorough history and physical examination, as well as a broad differential diagnosis. While there is no gold standard for diagnosing these diseases, each type has characteristic symptoms and laboratory findings as well as specific ages for presentation. Consultation with rheumatologists, neurologists, nephrologists, and infectious disease specialists may be required to assist in the final diagnosis.

Likewise, the care of a child with a collagen vascular disease also requires a multidisciplinary approach involving a primary care physician, rheumatologist, and subspecialists with expertise in affected target organs. The role for the primary care physician is to ensure optimal function of the patient as well as prevention of long-term disease and treatment sequelae. Because many of the agents used to manage collagen vascular disease have significant side effects, it is vital for the primary care physician to be well versed with a patient's medication regimen. Patients with collagen vascular disease often suffer from growth failure either from the disease process or its treatment. Ensuring appropriate diet and physical activity is vital. Supplementation with calcium and vitamin D is beneficial to prevent osteoporosis. Periodic ophthalmologic screening is essential for patients with uveitis. In the long term, patients with collagen vascular disease are at a higher risk for cardiovascular disease (CVD) secondary to chronic inflammation. They may require annual cardiovascular risk assessments that include lipid profiles. While pediatric patients often don't have other CVD risk factors, it is important to ensure healthy behaviors. Individuals that have suffered thrombotic events or are at high risk for thrombosis may benefit from low-dose aspirin prophylaxis. As with any patient with a chronic disease, maintaining a feasible quality of life is essential. Disease management for patients suffering from collagen vascular disease is a balance of optimal function, minimal complications, and improved quality of life.

CASE RESOLUTION

The young girl in the case scenario has a presentation consistent with oligoarthritic JIA based on the number of involved joints (3 joints) and her age (between 1 and 5 years). She has a number of laboratory studies including a complete blood cell count, erythrocyte sedimentation rate, RF, and ANA. Her ANA is positive. She is referred to a pediatric ophthalmologist for an eye examination to determine if she has uveitis. She is also referred to a pediatric rheumatologist for assistance in managing her disease and a physical therapist to address her limitation of motion.

Nephrotic Syndrome

Elaine S. Kamil, MD

CASE STUDY

A 2-year-old boy is brought to the office because of abdominal distention. He has just recovered from a runny nose that lasted a week, with no fever or change in activity. His mother complains that his eyelids were very swollen that morning, and she says that his thighs look “fat.” She has noticed that he has fewer wet diapers. He has always been a healthy child, and his immunizations are up to date. The family has a history of asthma and allergic rhinitis. Physical examination shows an active 2-year-old boy. Head and neck examination is clear, except for a few shotty anterior cervical lymph nodes and some minimal periorbital edema. Chest examination reveals some decreased breath sounds at the bases. The abdomen is moderately distended; bowel sounds are active and a fluid wave is detectable. There is 2+ pitting edema of the lower legs, extending up to the knees. The urine has a specific

gravity of 1.030; pH 6; 4+ protein; and trace, nonhemolyzed blood. Microscopic examination shows 4 to 6 red blood cells per high-power field and 10 to 20 hyaline and fine granular casts per low-power field.

Questions

1. What is the differential diagnosis of edema and ascites in previously healthy young children?
2. What criteria are used to determine if children with nephrotic syndrome require hospitalization or can be managed as outpatients?
3. What laboratory evaluation and therapy are instituted initially?
4. What are the important issues to address in parent education?
5. What is the prognosis of young children with nephrotic syndrome?

Although nephrotic syndrome is not a common childhood disease, every pediatrician can expect to care for 1 to 3 nephrotic children at some time. Nephrotic syndrome may have serious or even fatal complications, and the disease tends to follow a chronic, relapsing course. Thus it is important for the pediatrician to become familiar with the signs and symptoms of the disease and with the most current treatment modalities aimed at keeping affected children healthy and active.

Nephrotic syndrome occurs when an individual excretes a sufficient quantity of plasma proteins, primarily albumin, in the urine to cause hypoalbuminemia. Substantial urinary protein losses, hypercholesterolemia, and hypoalbuminemia characterize nephrotic syndrome. The condition is usually accompanied by obvious edema, but occasionally edema is not clinically detectable (Dx Box).

In children, proteinuria of more than 40 mg/m²/hour (>50 mg/kg in 24 hours) is considered nephrotic range proteinuria. (In adult-sized patients, proteinuria of more than 3.5 g in 24 hours is associated with

nephrotic syndrome.) Collection of a 24-hour urine sample is cumbersome in children, and the urinary total protein/creatinine ratio (U TP/CR) done on a random urine sample, preferably a first morning urine, is a useful alternative. Whereas a ratio greater than 3.5 is considered nephrotic range proteinuria in adults with normal renal function, a ratio greater than 1.0 is considered diagnostic in children (see Chapter 94). Twenty-four-hour urine protein losses (g/m²/day) in children can be estimated by multiplying the U TP/CR by 0.63.

Epidemiology

Minimal change disease (MCD) is the most common form of nephrotic syndrome in childhood. The annual prevalence of new cases of nephrotic syndrome is 2 in 100,000 to 3 in 100,000 children in the population younger than 16 years. The cumulative prevalence of this chronic disease is 16 in 100,000. Ninety percent of childhood cases are not associated with any systemic disease, and two-thirds of cases of childhood nephrotic syndrome present before age 5 years. The ratio of boys to girls in young children with nephrotic syndrome is 2:1. By late adolescence, both sexes are equally affected.

Clinical Presentation

The typical child presenting with nephrotic syndrome is a preschool-aged boy who is brought to the physician because he appears swollen to the parents. Some children are active and relatively asymptomatic despite the edema, whereas others may be very uncomfortable, with

Dx

Nephrotic Syndrome

- Heavy proteinuria (>40 mg/m²/hour or 50 mg/kg/24 hours in children)
- Hypoalbuminemia
- Hypercholesterolemia
- Edema

markedly swollen eyelids, abdominal discomfort, scrotal or labial edema, and even respiratory compromise. Usually children have a history of preceding infection, most typically an upper respiratory infection (URI). Occasionally children develop diarrhea secondary to edema of the bowel wall.

Occasionally children with nephrosis are critically ill due to peritonitis, bacteremia, or (rarely) a major thrombotic episode. Because their immune state is compromised, rapid evaluation and treatment of children with these complications of nephrotic syndrome are essential for survival. The primary peritonitis associated with nephrotic syndrome may be confused with an acute abdomen, such as may be seen with appendicitis. Some children who are experiencing a severe relapse have hypotensive symptoms secondary to intravascular volume depletion.

Pathophysiology

The exact cause of MCD and focal segmental glomerulosclerosis (FSGS) is not known. Although this is controversial, many nephrologists believe that FSGS may result from severe, treatment-resistant MCD. The best current theory postulates that some stimulus (usually infectious) causes a clone of lymphocytes or monocytes to proliferate and produce one or more cytokines that are toxic to the glomerular epithelial cells (podocytes), cells that maintain the glomerular basement membranes. The cytokine induces a reduction in the net negative charge across the glomerular basement membrane. The constituents of this membrane and of the chemicals coating the glomerular epithelial and endothelial cells normally bear a net negative charge. The presence of these negatively charged chemicals creates a charge-selective barrier to filtration. This barrier plays a significant role in the ultrafiltration of macromolecules present in the plasma, enhancing the filtration of molecules bearing a positive electrical charge and retarding the filtration of molecules bearing a negative electrical charge. During episodes of relapse, patients with MCD show a breakdown in the normal charge-selective barrier to filtration, often resulting in massive proteinuria. Kidney biopsies from patients with nephrotic syndrome demonstrate a net reduction in anionic sites during periods of relapse. In addition, some children have mutations in podocyte proteins such as nephrin and podocin that lead to nephrotic syndrome. Children presenting with nephrosis before 1 year of age have a high likelihood of having a genetic mutation causing nephrotic syndrome, and any child with steroid resistant nephrotic syndrome should also be screened for such genetic mutations.

Evidence indicating that the proteinuria in the MCD or FSGS patient may be due to some soluble factor is 3-fold. (1) Some patients who develop end-stage renal disease from idiopathic nephrotic syndrome (particularly FSGS) have experienced a relapse of the nephrotic syndrome with massive proteinuria immediately after transplantation of a normal kidney. (2) Infusion of peripheral blood mononuclear cell products from nephrotic children induces albuminuria in rats. (3) Removal of serum proteins by adsorption to a protein A Sepharose column has led to remission of proteinuria in

some patients who have experienced a recurrence of nephrotic syndrome after transplantation. The remission of the proteinuria after treatment with immunosuppressive medication provides further evidence that the nephrotic syndrome is mediated in some way by the immune system.

Normal adults are able to synthesize 12 g of albumin per day in the liver, and adults with nephrotic syndrome may synthesize 14 g of albumin per day. Therefore, the **hypoproteinemia** characteristic of nephrotic syndrome cannot be explained completely by measured amounts of urinary protein losses (about 3.5 g/day). The difference between the hepatic synthetic capacity for albumin and the measured urinary losses can be explained by protein catabolism in the kidney. Renal tubular epithelial cells reabsorb filtered plasma proteins and catabolize them to amino acids, which then reenter the amino acid pool of the body. Thus the magnitude of losses of plasma proteins at the glomerular level is far greater than the amount measured in a 24-hour urine sample.

The **hypoalbuminemia** seen in nephrotic syndrome is a result of the massive proteinuria, and the **hypercholesterolemia** occurs as a consequence of the hypoalbuminemia. The hyperlipidemia is partially the result of a generalized increase in hepatic protein synthesis that also involves the overproduction of lipoproteins. In addition, less lipid is transported into the adipose tissue, because the activity of lipoprotein lipase is reduced in adipose tissue during active nephrotic syndrome. Hyperlipidemia is most pronounced in children with MCD. Serum albumin and serum cholesterol are generally inversely correlated. The hyperlipidemia is the last biochemical abnormality to clear after the child achieves remission from an episode of nephrotic syndrome.

Differential Diagnosis

Nephrotic syndrome is considered either primary or secondary. Primary nephrotic syndrome is not associated with a systemic disease. Secondary nephrotic syndrome is a feature of a systemic disease such as anaphylactoid purpura, immunoglobulin (Ig) A nephropathy or systemic lupus erythematosus (SLE). Most children with nephrotic syndrome have the primary form of the disease.

Children with primary nephrotic syndrome are also classified according to their response to steroid therapy. Affected individuals may be categorized as steroid-sensitive, steroid-dependent, or steroid-resistant. Typically, children who are steroid-sensitive and remain so have MCD although, strictly speaking, a renal biopsy must be performed before the diagnosis of MCD is made. Sensitivity to or dependence on corticosteroids is a critical factor in determining a child's prognosis.

Nephrotic syndrome is also classified by the appearance of the glomeruli on renal biopsy. A summary of the histologic lesions causing nephrotic syndrome appears in Table 145-1. About 95% of young children with nephrotic syndrome have MCD. In these children, light microscopy shows normal-appearing glomeruli. Immunofluorescent microscopy is generally negative but may show some mesangial IgM deposits, and electron microscopy simply shows foot process

Table 145-1. Distribution of Histologic Type by Age of Onset in Children With Nephrotic Syndrome

Age (y)	MCD ^a	FSGS	MN	MPGN	Other GN
1–4	95%	3%	2%	—	—
4–8	75%	15%	1%	7%	2%
8–16	52%	15%	2%	25%	6%

Abbreviations: FSGS, focal segmental glomerulosclerosis; MCD, minimal change disease; MN, membranous nephropathy; MPGN, membranoproliferative glomerulonephritis; other GN, other forms of glomerulonephritis.

^a MCD remains the dominant histologic type through mid-adolescence but becomes relatively less important in later childhood and adolescence.

effacement of the podocytes. In individuals with FSGS, light microscopy may show enlarged glomeruli and glomeruli with segments of sclerosis. Immunofluorescence may reveal some IgM and complement in the sclerotic segments, and electron microscopy shows areas of foot process effacement of podocytes. Biopsies performed later in the disease course show some totally sclerotic glomeruli, areas of interstitial fibrosis, and atrophy. Several recent series have noted an apparent increase in the incidence of FSGS among nephrotic children.

Other primary renal diseases that can cause nephrotic syndrome in children include membranous nephropathy, membranoproliferative glomerulonephritis, IgA nephropathy and other forms of chronic glomerulonephritis, congenital nephrotic syndrome, and diffuse mesangial proliferative glomerulonephritis. Chronic hepatitis B infection may cause membranous nephropathy or membranoproliferative glomerulonephritis. In endemic areas the incidence of hepatitis B associated membranous nephropathy has been reduced since the implementation of universal hepatitis B vaccination programs. Rarely, post-streptococcal acute glomerulonephritis and other forms of postinfectious acute glomerulonephritis may also cause nephrotic syndrome. With the exception of congenital nephrotic syndrome, all of these diseases show (1) the presence of immune deposits in the glomerular mesangial regions or along the glomerular basement membrane and (2) some element of cellular proliferation, which may be severe. In these disease states, the presence of nephrotic syndrome is indicative of marked injury to the glomerular capillary wall. Infants with congenital nephrotic syndrome, Finnish type, have a mutation of the gene encoding the nephrin molecule, a podocyte protein with a large extracellular domain that is an integral part of the glomerular slit diaphragm. These infants have massive proteinuria beginning in utero and have severe nephrotic syndrome presenting in the first month of life.

Because of the varying distribution of edema fluid at presentation, nephrotic syndrome may be confused with sinusitis or an allergic reaction (periorbital edema), obesity (ascites), or an abdominal mass (ascites). Other causes of generalized edema, such as congestive heart failure or liver disease, can be easily excluded.

Evaluation

History

The clinical evaluation should include a careful history (Questions Box).

Questions

Nephrotic Syndrome

- Has the child recently had any infections, such as pharyngitis or an upper respiratory infection?
- Are the child's eyelids swollen? Do they look more or less puffy at certain times during the day, especially on awakening or after crying?
- Does the child have a history of rashes characteristic of diseases that are associated with nephrotic syndrome?
- Is there a history of fever, oliguria, or abdominal pain?
- Is there a family history of nephrotic syndrome or kidney disease?
- Is the child playful and active, or is the edema so significant that movement is uncomfortable?
- Are the ascites and pleural effusions so severe that some respiratory compromise is evident?

Physical Examination

A complete physical examination is necessary. Blood pressure should be monitored because hypertension or hypotension may occur. The extent of the peripheral and central edema, including swelling of the eyelids, should be assessed. The physician should obtain a reliable, overall impression of the child's level of comfort and activity. The examination should also include a careful search for infection, particularly life-threatening infections such as pneumonia or peritonitis. Examination of the head and neck should focus on signs of recent infection such as otitis media. The presence of dullness to percussion at the bases of the thorax is consistent with large pleural effusions. Ascites may be minimal or massive. With severe ascites, scrotal or labial edema may occur. If the child has a history of abdominal pain, a careful check for signs of peritoneal irritation should be made. The skin should be inspected for infection and rashes.

Laboratory Tests

The laboratory evaluation of children with nephrotic syndrome begins with a urinalysis. The dipstick shows 3+ or 4+ protein, although a dilute urine may be only 2+. Microscopic hematuria may be present in up to 25% of children with MCD. The presence of associated glycosuria in a nephrotic child who is not on steroid therapy raises a concern for FSGS. Careful microscopic examination of the urine is necessary. Casts are seen frequently because urinary proteins precipitate in the tubules. The casts are hyaline, fine, and coarse granular. White blood cell (WBC) casts are sometimes seen because

some children with nephrotic syndrome may also have increased amounts of leukocytes in their urine. Large amounts of red blood cells (RBCs) and RBC casts are not seen in uncomplicated MCD and, if present, indicate another cause for the nephrotic syndrome. If RBC casts are seen together with substantial hematuria, an antistreptolysin-O titer should be added to the preliminary evaluation. A random U TP/CR should be done to determine whether children have nephrotic range proteinuria.

If the urine shows only proteinuria, with perhaps some microscopic hematuria, blood tests should include a complete blood cell count (CBC), serum creatinine and blood urea nitrogen (BUN), electrolytes, serum calcium, serum albumin, cholesterol, complement component 3 (C3), and antinuclear antibody (ANA). The CBC may show a high hematocrit from hemoconcentration because many children experience volume contraction as a complication of hypoproteinemia. Children may also have very high platelet counts (sometimes >1 million/ μL). The BUN and creatinine help assess renal function. A hyperchloremic metabolic acidosis is sometimes seen. The serum albumin and cholesterol are required to differentiate nephrotic syndrome from other edematous states. A low level of C3 is associated with other renal diseases such as membranoproliferative glomerulonephritis, acute postinfectious glomerulonephritis, and SLE. The ANA is useful in screening for SLE and other collagen vascular diseases. Hepatitis B serology is helpful in children who come from a population at risk for hepatitis B infection, such as recent immigrants from Southeast Asia or children of intravenous (IV) drug abusers. Although not part of the routine laboratory evaluation, measurement of quantitative Ig often shows low IgG levels and elevated IgM levels. The febrile child should also have blood and urine cultures, and if there are signs of peritoneal irritation, a culture of peritoneal fluid. Though not part of the routine evaluation, if there is a family history of thrombotic events, a thrombophilia evaluation should be considered because of the association between renal vein thrombosis and nephrotic syndrome, particularly in adults.

Imaging Studies

Chest radiographs help assess the severity of pleural effusions in children with marked ascites and respiratory compromise.

Management

Hospitalization

The decision to admit a child with nephrotic syndrome to the hospital is determined by the child's functional status. All children with severe edema compromising ambulation or respiration should be admitted. Other indications for admission include unstable vital signs, fever, marked oliguria, and severe hemoconcentration (hematocrit $>48\%$ – 50%).

Most children with nephrotic syndrome are hospitalized for control of edema or treatment of a complication such as infection. The management of children in relapse is aimed at minimizing edema and preventing complications until the disease can be controlled

with immunosuppressive therapy. Intake, output, and weight need to be closely monitored. Blood pressure should be followed, although hypertension is not common. If children have a fever (temperature: $>100.7^\circ\text{F}$ [38.2°C]), blood and urine cultures should be obtained and antibiotics started pending culture results. If signs of peritoneal inflammation are evident, paracentesis should also be performed to obtain samples of the ascites fluid for Gram stain, cell count, and culture. Broad-spectrum antibiotics should be given to cover respiratory pathogens, especially pneumococcus, and enteric pathogens. All children who are newly diagnosed with nephrotic syndrome should have a purified protein derivative test because immunosuppression associated with steroid therapy may facilitate reactivation of tuberculosis infection.

Intravenous albumin (25%) should be used selectively because albumin infusions are expensive, and the infused albumin is excreted very rapidly in the urine. Infusions are indicated in children with marked ascites, scrotal or labial edema, or significant pleural effusions. They are also helpful in maintaining blood pressure and renal perfusion in septic children with nephrotic syndrome. The usual dose is 1 g/kg, up to 25 g, infused over 2 to 4 hours, with close monitoring of blood pressure. Furosemide (1 mg/kg intravenously) is usually administered post-infusion. The albumin infusions may be repeated every 12 to 24 hours as necessary. If children with oliguria fail to increase their urine output after the first or second albumin infusion, they need to be evaluated immediately for the presence of acute renal failure (see Chapter 67). The albumin-induced mobilization of edema fluid in nephrotic children with acute tubular necrosis can precipitate pulmonary edema.

Children with nephrotic syndrome have an increased tendency to thromboembolic phenomenon. Increased risk factors for this complication include loss of antithrombin 3 in the urine, age 12 years or older, the existence of a central line, and secondary causes of nephrotic syndrome such as SLE.

Supportive Therapy

Diet

Because sodium plays a key role in edema formation, children with nephrotic syndrome should be placed on a no-added-salt diet that limits dietary sodium to 2 or 3 g/day. Technically, sodium restriction is indicated only during times of relapse, but a constant no-added-salt diet helps entire families maintain a consistent regimen. In general, fluid restriction is not necessary except in unusual circumstances (eg, a steroid-resistant patient with persistent edema). Although earlier teachings recommended the use of high-protein diets, newer research has shown that these diets may actually increase urinary protein losses.

Activity

In the past, children with nephrotic syndrome were treated with bed rest because the supine position somewhat reduces urinary protein losses. No evidence shows that bed rest has a significant impact on children's clinical state, however. Therefore, most pediatric nephrologists

recommend that children be allowed full activity. Boys with marked scrotal edema may be more comfortable resting in bed while diuresis is being initiated. Children with nephrotic syndrome should not be isolated from other children and should be allowed to attend school.

Diuretics

Diuretics are often helpful in children in relapse, particularly in children with steroid-resistant disease. Serum potassium levels, as well as clinical signs of intravascular volume, should be monitored. If children have moderate intravascular volume contraction, the injudicious use of diuretics could precipitate hypotension and increase the risk of thrombosis and acute tubular necrosis. The most commonly used diuretic is furosemide (1–2 mg/kg per dose given orally or intravenously). Spironolactone is sometimes added to the diuretic regimen for its potassium-sparing effect.

Long-term Management

The goal of long-term management is induction and maintenance of remission from active nephrotic syndrome. At the same time, the side effects of medications should be minimized. Spontaneous remission may eventually occur in children with MCD, but the 70% historical mortality rate makes waiting for a spontaneous remission unacceptable. Remissions are induced and maintained with the use of immunosuppressive medications. Figure 145-1 summarizes an

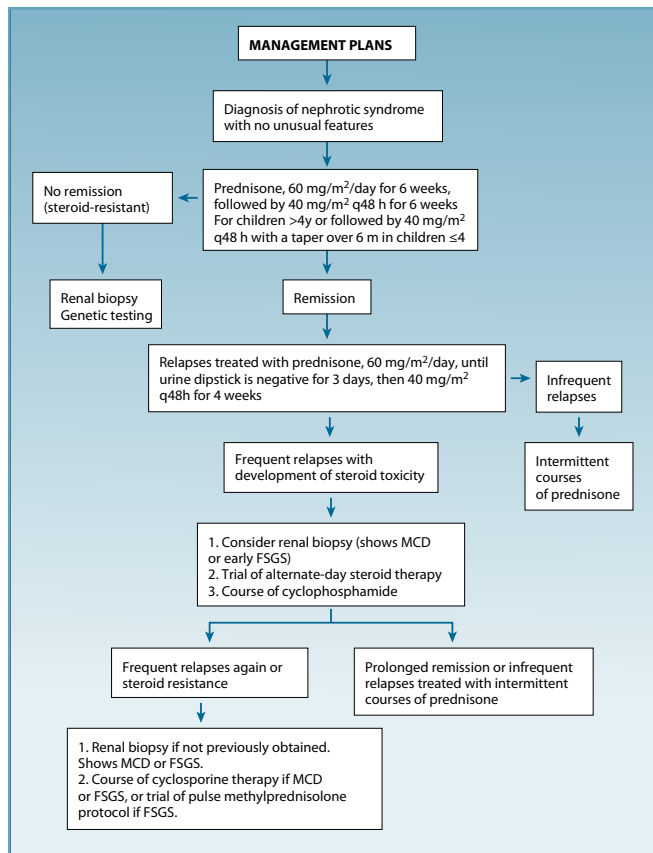

Figure 145-1. Management of nephrotic syndrome in children. FSGS, focal segmental glomerulosclerosis; MCD, minimal change disease; q, every.

Table 145-2. Treatment Options in Childhood Nephrotic Syndrome

Medication	Dose	Length of Therapy
Prednisone	60 mg/m ² /d	Varies
Cyclophosphamide	2–3 mg/kg/d (cumulative dose <200 mg/kg)	12 weeks
Chlorambucil	0.15–0.2 mg/kg/d (cumulative dose ≤8.2 mg/kg)	8 weeks
Cyclosporine	3 mg/kg every 12 h, monitor levels	Varies
Levamisole	2.5 mg/kg every other day	Varies
Mycophenolate mofetil	20 mg/kg every 12 h	Varies
Tacrolimus	0.1 mg/kg every 12 h, monitor levels	Varies

^a Levamisole is no longer recommended for childhood nephrotic syndrome in the United States.

approach to the overall management of nephrotic syndrome with these agents. A list of commonly used medications and dosages appears in Table 145-2.

Corticosteroids and Alkylating Agents

More than 90% of children with primary nephrotic syndrome respond to corticosteroid therapy. Steroids are, therefore, both diagnostic and therapeutic because failure to respond to steroids can be a marker for disease other than MCD or for a genetic cause of nephrotic syndrome. Even so, some children with MCD are steroid-resistant at some time in their disease. Steroids can be started in children who are newly diagnosed with nephrotic syndrome if they have no signs of systemic disease, no more than microscopic hematuria, a normal C3 (or results pending), and normal renal function. Acute infection should be managed with specific antimicrobial therapy to avoid infection-related steroid resistance.

Prednisone is usually started at 60 mg/m²/day. It can either be given once a day, in the morning, or divided into 2 or 3 daily doses. If first episodes of nephrotic syndrome are treated with a prolonged course of corticosteroids (60 mg/m²/day for 6 weeks followed by 40 mg/m²/48 hours for an additional 6 weeks), the children are subsequently less likely to follow a frequently relapsing course. Newly diagnosed children younger than 4 years are less likely to experience frequent relapses if their every-other-day steroids are tapered off over a 6-month period. Proteinuria resolves within 2 weeks in many children with MCD and by 4 weeks in more than 90%. Serum albumin normalizes soon after proteinuria clears, but hypercholesterolemia may take many weeks to return to normal.

The pediatrician can easily manage steroid-sensitive children, but children with more difficult nephrotic syndrome should be managed in conjunction with the pediatric nephrologist. Children with relapses are treated with daily prednisone (60 mg/m²) until the urine is protein-free for 3 days. This regimen is followed by 4 weeks of 40 mg/m² every other morning. An increased incidence of side effects

(eg, cushingoid appearance, hypertension, obesity, glucose intolerance, cataracts, osteopenia, decreased growth rate) occurs when children require frequent courses of prednisone therapy. In frequently relapsing children, a chronic course of alternate-day steroid therapy may eliminate relapses and reduce steroid toxicity. Usually prednisone 60 mg/m² is given every other morning initially. The dose is then gradually tapered over several months to the lowest dose that keeps the child in remission. A recent study has found that children on chronic low-dose alternate-day therapy are less likely to experience a relapse following a URI if they receive daily prednisone at their stable prednisone dose for 7 days during the illness.

If alternate-day steroid therapy fails to maintain remission, cyclophosphamide or chlorambucil is administered. Either of these alkylating agents may induce long-lasting remission, which persists for years in children with steroid-dependent or frequently relapsing nephrotic syndrome. Either agent is started while children are on steroid therapy, and the steroids are gradually tapered during the course of treatment with the alkylating agent. In the past a diagnostic renal biopsy was routine prior to starting an alkylating agent. Many pediatric nephrologists now consider such therapy in steroid-sensitive or steroid-dependent children without a biopsy, however, provided that renal function is normal. Initially a daily dose of cyclophosphamide (2 mg/kg) was recommended for 8 weeks. However, a 12-week course is more likely to induce prolonged remission and still be safe.

Potential toxicities of cyclophosphamide include bone marrow suppression with increased risk of infection, alopecia, hemorrhagic cystitis, gonadal toxicity, and possibly a small but indeterminately increased risk of developing a malignancy at some time. Complete blood cell counts should be monitored weekly, and parents should be cautioned about the increased risk of overwhelming varicella infections in children who have not yet had a varicella infection or immunization. The cyclophosphamide dose should be withheld if the WBC count falls below 4,000/ μ L and restarted when the WBC returns to or exceeds 4,000/ μ L. Alopecia and hemorrhagic cystitis are rare when the recommended dose is used. A 12-week course of cyclophosphamide (2 mg/kg/day) does not seem to increase the risk of infertility, but longer courses are associated with oligospermia, aspermia, and ovarian dysfunction. Postpubertal individuals may be at greater risk for gonadal toxicity than prepubertal children.

When steroid-sensitive or steroid-dependent children have failed to achieve prolonged remission after cyclophosphamide therapy, a diagnostic renal biopsy should be performed. Renal biopsy is indicated early in the course of illness for steroid-resistant children. If FSGS is identified on biopsy, treatment may involve a prolonged course of IV methylprednisolone therapy, cyclosporine, or tacrolimus. Therapeutic options for children with MCD who continue to be steroid-dependent after a course of cyclophosphamide include treatment with mycophenolate mofetil, cyclosporine, tacrolimus, or levamisole. Although cyclosporine is more likely to induce prolonged remission, it only maintains remission while being administered. Children trade steroid dependence for cyclosporine dependence. Nevertheless, for children with steroid toxicity, a 6- to 12-month

course of cyclosporine allows resolution of the adverse effects of steroids and is generally well tolerated when administered by an experienced physician. Side effects such as hirsutism and gingival hyperplasia are frequent at the onset of therapy. These effects regress as the dose is decreased or the drug is discontinued, however. Hypertension is not uncommon. The most common metabolic abnormality seen with cyclosporine use is hypomagnesemia. Long-term therapy may lead to significant nephrotoxicity and, rarely, patients experience liver toxicity. Tacrolimus, like cyclosporine, is a calcineurin inhibitor. It has a similar toxicity profile to cyclosporine, but it does not cause gingival hyperplasia or hirsutism.

Because of potential toxicity, cyclosporine and tacrolimus should only be prescribed by a physician familiar with the drug. Dosing requirements may change with remission and relapse, and the family and physician should be aware of several drug interactions. Any medication interfering with the cytochrome P-450 enzyme system in the liver, such as erythromycin, greatly increases cyclosporine levels and should be used only under extraordinary circumstances. Diarrhea may increase tacrolimus blood levels to a toxic range. Children who require prolonged treatment with cyclosporine or tacrolimus should have follow-up kidney biopsies performed after a year or two of therapy to assess for any nephrotoxicity.

Nephrotic children who fail to achieve a good remission with immunosuppressive therapy are given supportive therapy with angiotensin-converting enzyme inhibitors or angiotensin blockers, which reduce proteinuria and have also been shown to reduce the progression of glomerulosclerosis. These medications are also first-line therapy for nephrotic children who develop hypertension. There have been some promising preliminary results with the use of rituximab in children with difficult nephrotic syndrome. Other supportive measures for children with persistent edema include sodium restriction and the chronic use of diuretics. Genetic testing should be performed early in steroid resistant children, and further immunosuppressive therapy should be withheld until the results of the genetic testing is available.

Immunization Issues

Because of the unusual susceptibility to pneumococcal infections, children with nephrotic syndrome older than 2 years should receive the 23-valent pneumococcal vaccine, even if they have previously received Prevnar. The vaccine is best administered while the children are in remission, but it produces protective titers even in children who are on alternate-day steroid therapy at the time of immunization. Patients on multiple immunosuppressives should have their pneumococcal antibody titers measured, and a second dose of vaccine should be administered if they fail to seroconvert. Influenza vaccine should be administered each autumn to children with nephrotic syndrome using the age-appropriate schedule and dosage.

Some of the routine childhood immunizations (diphtheria-tetanus-pertussis, *Haemophilus influenzae* type b, hepatitis B, poliovirus vaccine inactivated) should be administered by the usual schedule but while children are in remission, if possible (see Chapter 32). Some controversy exists concerning the use of live virus vaccines in

children who require long-term immunosuppressive therapy. No vaccines should be administered if children are currently being treated with an alkylating agent. The measles-mumps-rubella vaccine could potentially cause a relapse. Based on the limited data on the use of varicella vaccine in nephrotic children, it is probably safe to administer varicella vaccine while the children are in remission and not on immunosuppressive medications.

Parent Education

Because nephrotic syndrome follows a chronic, relapsing course, parent education is essential for effective long-term management. Parents need to be instructed about using urinary dipsticks (Albustix) to monitor protein excretion. Generally urine dipsticks should be used daily during periods of active relapse and when medication is being tapered. Otherwise, the dipstick should be checked whenever children have infections, including URIs; whenever they look “puffy”; and weekly when asymptomatic.

Weight should also be monitored, especially during relapse. Children should be weighed each morning when they awaken. Urine output should be measured in more difficult cases. As parents become more familiar with the nephrotic syndrome, they may become partners with the physician about medication changes. Parents should also contact the physician about “danger signs” such as fever (temperature: $>100.7^{\circ}\text{F}$ [38.2°C]), significant abdominal pain, or exposure to varicella. If children do not have protective antibodies against varicella and if they are taking any immunosuppressive medication (including prednisone), the varicella-zoster Ig should be administered within 72 hours of exposure to varicella. If varicella infection develops, IV acyclovir should be instituted.

Prognosis

In the pre-antibiotic era, nephrotic syndrome was frequently fatal, usually because of overwhelming infection. After the introduction of antibiotics, the mortality rate fell. The use of corticosteroids has led to a further reduction in mortality. Currently the mortality rate is about 5%, almost exclusively due to infections from encapsulated organisms or from thrombosis. The greatest risk of death in children with nephrotic syndrome (approaching 50% over 20 years in some series) is among the children with resistance to corticosteroid therapy.

The long-term outlook for most children with nephrotic syndrome is favorable, particularly for steroid-sensitive patients. Relapses often disappear by the completion of puberty. Occasionally individuals continue to have relapses into adulthood. Approximately 20% of children with steroid-sensitive MCD still experience relapses 15 years after the onset of their disease. Disease recurrence is highly unlikely if 8 years pass without a relapse. Less than 10% of initially steroid-sensitive children with nephrotic syndrome develop end-stage renal disease. This occurs almost exclusively in children with FSGS. Focal segmental glomerulosclerosis may recur after kidney transplants, particularly in young children with aggressive FSGS.

CASE RESOLUTION

In the opening scenario, the child most likely has MCD. He appears stable enough to be managed as an outpatient and should be placed on a salt-restricted diet and prednisone. The overall prognosis depends on a close interaction among the parents, pediatrician, and consulting pediatric nephrologist.

Seizures and Epilepsy

Kenneth R. Huff, MD

CASE STUDY

A 6-year-old boy is evaluated for unusual episodic behaviors. The previous week his mother was awakened by the boy's brother and found her son lying in bed unresponsive and drooling, with his head and eyes averted to the right, his right arm slightly raised, and his body stiff. His face was jerking intermittently. When the paramedics arrived, the boy's posturing and movements had stopped. After the event he could speak but was somewhat incoherent. He was taken to the local emergency department, where his examination and mental status were normal. Screening blood and urine tests were normal, and he was discharged, with instructions to see his pediatrician for further recommendations.

His father remembers 2 or 3 other episodes of a somewhat different nature in the past month. These occurred as the boy was being put to bed. They involved some body stiffening and facial grimacing, with the mouth slightly open and the tongue twisted and deviated to one side. The child could not speak but appeared to be trying to talk. The

episodes lasted 20 to 30 seconds. Afterward the boy was his usual self and could tell his father what had been said to him.

The child has had no intercurrent illnesses or abnormal behavior apart from these "spells," and he has lost no abilities. A paternal cousin and grandfather had seizures during childhood but "grew out of them." The examination is completely normal.

Questions

1. How likely is it that the episodic behavior represents a seizure?
2. What historical data about an event support the diagnosis of a seizure disorder?
3. How does the electroencephalogram (EEG) help in classifying the type of seizure disorder?
4. What rationale should be used to formulate short-term and long-term treatment plans?

Seizures are a common medical problem in children. Diagnosing an episode that does not contain generalized convulsing movements as a seizure is sometimes problematic, however. Seizures are defined as episodic, stereotypical behavior syndromes of abrupt onset with loss of voluntary control by the patient, resulting in loss of responsiveness and rarely provoked by external stimuli. Frequently the occurrence of this behavior correlates with interictal brain electrical discharges on EEG, and the behavioral ictus (seizures) should match temporally with a period of electrical hypersynchrony if it occurs during the EEG recording.

A detailed history of the nature of the episodic behavior from an eyewitness is paramount, both in making the diagnosis of a seizure disorder and in elucidating the type of seizure problem. The EEG is most often an adjunct to diagnosis. It is abnormal in many individuals who do not have clinical seizures and it may be normal interictally in many patients with clinical seizures because of its sampling limitations. Special techniques can sometimes help alleviate these limitations.

The type of seizure problem is important information in devising the management plan. Seizures can simply be classified as primary generalized seizures (involving the whole cerebrum from the outset) or partial seizures. However, some partial seizures can secondarily generalize, thereby clinically mimicking primary generalized seizures after their onset. Distinguishing these entities illustrates

the importance of eyewitness information. Many treatment options are available, but the therapeutic plan must be individualized to the child's seizure type or clinical syndrome to optimize seizure control and minimize side effects. With appropriate treatment, most children with seizure disorders are not handicapped scholastically or socially and can enjoy normal lives.

Epidemiology

About 0.5% to 1.0% of all children experience at least one afebrile seizure. Recurrent seizures can occur as a component of a static encephalopathy after brain malformation or dysgenesis, encephalitis or meningitis, metabolic disorder, hypoxic-ischemic injury, or severe head trauma. Such secondary or symptomatic seizures make up approximately one-third of childhood epilepsies. The remaining two-thirds of epileptic seizures occur presumably as part of a genetic epileptic syndrome. As genetic knowledge increases, eventually it may no longer be true that most often seizures occur in children without any known cause or association.

Clinical Presentation

Children present with a history given by observers of an episode of abrupt onset characterized by a loss of ability to respond to external stimuli (Dx Box). The child themselves may experience various

Dx Seizures

- Abrupt loss of responsiveness
- Rhythmic clonic movements
- Sustained changes in posture or tone
- Simple automatic movements
- Staring without change in tone
- Simultaneous change in cerebral electrical activity (repetitive discharges)

difficult to describe sensory phenomena (aura) before losing consciousness. Observers then see convulsive muscle activity following which the patient may be sleepy. With some seizures, observers may note only an akinetic or staring spell, but with others, dramatic, rhythmic spasms of the face, extremities, or torso. Major motor seizures are frequently also associated with systemic autonomic changes, including changes in skin vascular supply causing color change, sweating, saliva production, and loss of sphincter control. Most seizure episodes are neither provoked nor attenuated by environmental factors (except for the provocative factors of fever, intercurrent illness, and sleep deprivation). Between episodes, children's general physical and neurologic examination may be entirely normal.

Pathophysiology

A seizure represents a sudden, synchronous depolarizing change in the electrical activity of a network of neurons that becomes widely propagated over the cortex, affecting awareness, responsiveness to external stimuli, and motor control. The propagation may be enhanced by defects in cell ion channels. Partial seizure disorders may result from a focal cortical lesion, such as a glial scar or dysplasia caused by a remote insult (eg, an infarct), or dysgenesis or primary cortical dysplasia that disrupts the electrical circuitry. The focal abnormality could also contain hamartomatous immature cells and synaptic properties; and allow for periodic, abnormal transmission of impulses.

Exactly what initiates the synchronous depolarization of the neurons and the widespread network propagation is not well understood. Several physiological mechanisms, including neuronal circuitry, membrane ion channel abnormalities, neurotransmitter production metabolism or uptake, and perhaps glial support mechanisms are probably involved. An understanding of the mechanism involved in familial epilepsy syndromes awaits the definition of relevant genes, their expression and product functions, and the effects of variability in base pair sequence and transcription on membrane polarization, synaptic function, and circuitry physiology. An example is cryptogenic West syndrome (infantile spasms), an "interneuronopathy," which has been associated with several genes including *LIS1*, *DCX*, and *ARX* (sometimes resulting in lissencephaly), which are important in GABAergic inhibitory interneuron development. Another example is the neuronal voltage-gated sodium channel alpha subunit type 1 gene, which is mutated in the mild phenotype of "generalized

epilepsy with febrile convulsions plus" and also mutated but in different regions of the gene sequence in the much worse phenotype of severe myoclonic epilepsy of infancy.

Seizure Types

Seizures can be simply classified as either **primary generalized seizures**, which include grand mal, generalized tonic-clonic convulsions, and petit mal (absence) seizures (so named because of the child's complete loss of awareness at the outset of the episode), or **partial seizures**, which include focal motor, psychomotor, and other partial disorders (Box 146-1). The examples presented here should not be considered an exhaustive list of seizure syndromes but some of the more important types encountered in practice.

Box 146-1. Classification of Epileptic Seizures

Partial seizures (seizures beginning locally)

- Elementary symptoms: focal seizures
- Complex symptoms: psychomotor seizures
- Partial seizures evolving secondarily to generalized seizures

Generalized seizures (bilaterally symmetrical; onset not local)

- Absence seizures (petit mal): typical and atypical
- Tonic-clonic seizures
- Tonic seizures
- Myoclonic seizures (minor motor)
- Atonic seizures (drop attacks)
- Infantile spasms

Unclassified seizures (includes neonatal "subtle" seizures)

Most seizures in older children result from a partial seizure disorder. **Psychomotor seizures** are partial seizures that are usually preceded by a sensory aura or sometimes emotional behavioral manifestations, and have a wide range of ictal behaviors, including focal clonic jerking, aversive or asymmetrical hypertonic posturing, and more complex stereotypic fumbling or fingering behaviors. The seizures may be followed by postictal confusion or drowsiness. In some instances, children have partial sensory awareness but are unable to respond during seizures. In other cases, however, they are completely unconscious. The initial partial motor manifestations may not be seen by the observer before the movements rapidly generalize. Partial seizures are more often associated with focal brain pathologic processes, including traumatic lesions, infarcts, malformations, infections (eg, viral encephalitis or cerebral cysticercosis), and hippocampal sclerosis. These etiologies each may have a characteristic appearance on magnetic resonance imaging (MRI), although in many cases the etiology is not visible on MRI.

Benign epilepsy syndromes occur in children with normal developmental history, respond well to therapy, and remit without sequelae. **Rolandic seizures** are a relatively common partial seizure syndrome that sometimes is familial and has a good prognosis for resolving by adolescence. These episodes commonly occur when children are falling asleep or awakening. Sensory auras precede the

motor manifestations, which involve the tongue, mouth, or face and which can sometimes generalize to the rest of the body. The clinical syndrome is accompanied by a characteristic focal EEG discharge over the central temporal region of the scalp. Other benign syndromes include **benign familial infantile seizures**, **benign infantile seizures with mild gastroenteritis**, and **Panayiotopoulos syndrome**, which is characterized by paroxysmal autonomic dysfunctions such as vomiting and other gastrointestinal (GI) motility problems, pallor, mydriasis, and cardiorespiratory and thermoregulatory abnormalities (lasting up to 30 minutes) ending often in generalized convulsing and largely occurring in sleep.

An **absence seizure** may sometimes be difficult to distinguish from a partial seizure (Table 146-1). The absence spell is a brief (2–15 seconds) loss of consciousness without loss of tone. Staring into space and minor movements such as lip smacking or semi-purposeful-appearing movements of the hands are often the only observed behaviors. There is no postictal period. Because absence seizures occur multiple times a day and children are often unaware of them, parents may dismiss the subtle behavior change as selective attention or daydreaming; however, these seizures may adversely affect learning and carry a risk of injury. Hyperventilation, a useful diagnostic test that can be performed in the office, may provoke absence seizures. The EEG is generally confirmatory and may also distinguish classic petit mal seizures with 3-per-second spike-wave discharges from variant syndromes. The classic petit mal is more often familial with dominant inheritance, age-specific occurrence between 4 and 16 years, and sensitivity to ethosuximide treatment; whereas the atypical variant has a poorer prognosis for early resolution and is more resistant to anticonvulsant therapy.

A number of age-related seizure syndromes exist, perhaps related to maturational events in brain circuitry. Although the appearance of these syndromes is stereotypical, in most cases the prognosis depends on the etiologic diagnosis.

Table 146-1. Partial Complex Versus Absence Seizures

<i>Characteristic</i>	<i>Partial Complex</i>	<i>Absence</i>
Aura	Frequent	None
Loss of consciousness	Sometimes partial	Complete
Motor movements	Sometimes complex	Blinking or none
Postictal state	Frequent	None
Duration	>30 seconds	<15 seconds
Frequency	Few per month to few per day	Many per hour or day
Hyperventilation provoked	No	Yes
Electroencephalogram findings	Variably localized discharge or normal	3/s spike-wave generalized
Prognosis past adolescence	Frequently persists	Rarely occurs

Neonatal seizures may be tonic, focal clonic, or multifocal clonic. The seizure problem is less often primary, and a vigorous search for an etiology of the seizure is more often successful than with older children. Problems commonly leading to neonatal seizures include hemorrhage (germinal matrix in the premature infant or subarachnoid from birth trauma in older neonates); hypoxic-ischemic damage from asphyxia; infections producing postnatal sepsis/meningitis or prenatal encephalitis; birth trauma; drug withdrawal in the infant of a substance-abusing mother; metabolic problems including hypoglycemia, hypocalcemia, or hypomagnesemia in the infant of a diabetic mother; amino or organic acidopathies occurring a few days after feedings have begun; and congenital brain malformations.

Infantile spasms are an age-related seizure syndrome with typical movements of flexion contraction of the trunk with the head bowed or sudden raising of the arms sometimes accompanied by a cry. These behaviors occur stereotypically several times in succession in a series. This syndrome occurs in infants between 3 months and 2 years of age. Another perhaps related but rarer syndrome of serial spasms, **Ohtahara syndrome**, occurs at a younger neonatal age and is associated with structural brain abnormalities and characterized by a different EEG pattern, but carries a similar ominous prognosis for impaired intellectual development. A third syndrome in older children that is also associated with a different but characteristic EEG pattern, **Lennox-Gastaut syndrome**, has the same poor prognosis for seizure control and cognitive development but produces several different behavioral seizure types, including tonic, absence, and drop attacks. Different types of brain lesions in these age groups (including focal lesions) can result in the same generalized seizure syndromes. Examples include tuberous sclerosis; neonatal ischemia, hemorrhage, or meningitis; and major central nervous system (CNS) malformations. These disorders most often coexist with moderate to severe learning disability or mental retardation.

Differential Diagnosis

Seizures are distinguished from non-epileptic paroxysmal disorders on the basis of history. The circumstances of place and time as well as details about the symptoms and nature of the behavior are important pieces of data. The syncopal episode is also frequently situational, unlike a seizure. It occurs when children are in hot or stuffy environments; when they have been standing in one place for a long time; or when they see or experience a painful event such as an injection or phlebotomy. Boys may experience micturition syncope standing in the bathroom shortly after arising in early morning. **Syncope** is often preceded by symptoms of lightheadedness, nausea, tinnitus, and eventually a gradual darkening of vision sometimes without total loss of auditory perception.

Breath-holding spells are characterized by apnea and loss of responsiveness accompanied by either cyanosis or pallid skin color. Breath-holding spells are also situational. Infants or children are often upset or crying just before such spells. They may be frightened by a seemingly minor injury or angry after a toy is taken away or they

are disciplined. Children may then throw themselves backward and stiffen while closing their glottis in expiration, and they may even have a few clonic jerks after losing consciousness (see Chapter 49).

Selective attention is frequently mistaken for absence seizures. This behavior often occurs when children are involved in relative passive activities (eg, watching television, playing a video game, or daydreaming) and do not respond to verbal stimuli such as hearing their own name called. Generally, the attention lapses do not occur during talking or eating; seizures will occur, however, even during these activities.

Epileptic seizures must also be differentiated from **pseudoseizures**, which actually occur most often in patients who have true seizures. Such episodes may resemble true seizures accurately, the psychodynamics of secondary gain or other motivation for the behavior may not be readily apparent, the “need” for attention may be legitimate, and the finding that the standard EEG is normal does not exclude a true seizure and thus is not helpful. Pseudoseizures should be suspected in children who may have witnessed seizures in relatives or close friends, who have seizures that consistently recur in the same situations, whose seizure frequency is not decreased with therapeutic levels of anticonvulsants, and whose seizures appear “suggestible.” Diagnosis can often be supported in complicated cases by simultaneous video EEG monitoring, which will show a lack of correlation of electrical abnormalities with the behavior in question. Postictal serum prolactin level also may be normal, and psychological assessment may detect underlying emotional problems related to prior trauma (eg, sexual abuse or other major psychological trauma). The prognosis of pseudoseizures in children generally is better than in adults and relates to the more acute psychosocial genesis of the problem in most children.

Paroxysmal events in sleep may also be a challenge for accurate diagnosis because the motor behaviors of non-rapid eye movement sleep or other **parasomnias** may mimic nocturnal frontal lobe epileptic seizures. Video EEG polysomnography will also help distinguish these, as the former will not be associated with ictal discharges. Infantile gastroesophageal reflux (Sandifer syndrome) may look like brief epileptic tonic spasms, but should have a consistent temporal relationship to feeding. Benign paroxysmal vertigo occurs in the infant or toddler and presages migraine later in childhood but does not cause loss of responsiveness.

Evaluation (Box 146-2)

History

The history should determine the exact events surrounding the seizure episode. A detailed history of the nature of the behavior from an eyewitness is extremely important (Questions Box). The physician must determine whether children experienced any loss of their normal level of responsiveness. Most often this change in mental status is abrupt, although a warning behavior or aura that lasts for a few seconds may precede complete loss of responsiveness. The warning behavior or aura may be a cry, an expression of fear or anxiety, or

Box 146-2. Initial Evaluation of Seizure Patients

- Eyewitness account of the episode
- Description of children's own experiences before, during, and after the episode if they are articulate enough
- History from caregiver concerning remote injuries to the nervous system, progressive neurologic symptoms, or intercurrent illness
- Careful neurologic examination looking for signs of cerebral hemisphere lateralization
- Brain imaging study when a partial seizure is observed, a crescendo history of neurologic symptoms is obtained, focal neurologic signs are found on interictal examination, or the postictal encephalopathy persists too long
- Waking and sleep electroencephalogram with hyperventilation

Questions

Seizures

- Where was the child and what was he or she doing when the episode began?
- Did the child experience a loss of responsiveness?
- Did the child show any warning behavior or aura (eg, a cry, a facial expression of fear, irritability)?
- Did any part of the child's body become stiff? Was any shaking or jerking apparent?
- What did the child's eyes do and was saliva produced at the mouth?
- Did the child's skin change color?
- Did the child experience a loss of sphincter control?
- How long did the episode last?
- Has the child been well recently?
- Did the child have a complicated birth, head trauma, meningitis, or other previous brain damage?
- Have episodes of a similar nature occurred previously? If so, when did they begin and how frequently do they occur?
- Has the child's development and school experience progressed normally?
- Does the child have any relatives who have had seizures?

nonspecific irritability. If children are articulate, they may be able to describe a discrete sensory phenomenon or relate a less distinct or even indescribable sensation.

A change in muscle tone and activity is frequently associated with the abrupt change in mental status unless the spell is an absence seizure. Most often, the tone is increased with general extensor posturing, more focal hypertonicity, or more complex torsion or “aversive” upper-body posturing. The patient may fall if not supported. Rhythmic jerking or clonic movements (focal or general), including the trunk, limbs, face, and eyes, may occur concomitantly. Respirations may involve gagging sounds, rhythmic grunting, or nearly imperceptible movements. Swallowing may not occur, so that saliva pools or forms bubbles at the lips. Autonomic changes including skin color change (circumoral cyanosis), increased pulse, and loss of sphincter control frequently occur with major motor spells. The

ictal period generally lasts 30 seconds to 2 minutes, although observers frequently overestimate this time. Postictal periods of sleepiness or lethargy may occur. Their length is often correlated with the length or intensity of the seizure.

Children and those around them are often unaware of the occurrence of absence seizures. Often an observant teacher brings the child's problem to a physician's attention. During a spell, a child has no change in tone or clonic movements and may have only subtle facial or hand movements. The episode lasts only a few seconds, and there are no preictal or postictal behaviors.

Historical information can also help determine potential etiologies of the seizure problem. A known distant brain insult or a hereditary disposition may be related to the cause. A progressive loss of skills indicates a need for a degenerative disease investigation.

Physical Examination

Children should be examined carefully for focal neurologic signs, particularly cerebral hemisphere-related asymmetries in strength, tone, or tendon reflexes. The examination should include a developmental assessment and mental status examination. The physician should look for signs of potential genetic problems, such as dysmorphic features or organ malformations, which often correlate with cerebral dysgenesis; abnormal skin pigmentation or vessels, suggesting a neurocutaneous disorder; and organomegaly or bony abnormalities, indicating the possibility of a storage disorder. Children who are old enough to cooperate should be asked to hyperventilate, which might provoke an absence spell if the history is suggestive of this type of seizure.

Laboratory Tests

An EEG should be requested to help with the diagnosis of the type of seizure disorder. In children with partial seizure disorders, the interictal discharge is helpful in localizing the initial site of abnormal electrical activity. A sleep record is often essential for observing any abnormalities. If a normal waking EEG is obtained and seizures continue to recur, it is sometimes useful to help ensure sleep during the record by prior sleep deprivation carried out by the parents or caretaker. Special techniques (eg, prolonged monitoring with telemetry or special anatomical electrode placements) can sometimes help overcome the standard EEG limitations of sample time and inaccessible areas of cerebral cortex. It should be noted, however, that even the standard EEG is rarely normal in petit mal disorders.

Historical information can frequently guide the need for metabolic tests. A blood sugar determination should be done acutely, but electrolytes are rarely abnormal in older children who have been well prior to the seizure. Neonates and infants with recurrent unexplained seizures should have metabolic screening including organic acid and amino acid levels and a diagnostic/therapeutic trial of pyridoxine. Tissue biopsy histologic analysis and specific assays may be indicated when physical signs suggest possible storage or other metabolic etiologies.

Imaging Studies

Magnetic resonance imaging scans are particularly helpful if a progression in neurologic symptoms or signs has occurred, if there is a history of prior neurologic insult, if an asymmetry of strength or tone is noted on examination, or if signs of dysgenesis are present in other parts of the body. Even in the absence of these factors, partial or focal seizures have a higher yield of abnormal imaging results than do febrile seizures or petit mal disorders, which have a low yield. Acutely, intravenous contrast should generally be given because loss of focal blood-brain barrier with an inflammatory or neoplastic lesion can help with diagnosing the cause of the seizure. Children with recurrent or resistant seizures should have an MRI scan, particularly when surgical treatment is under consideration. Coronal MRI scans can detect mesial temporal sclerosis, a lesion in the hippocampus seen in chronic temporal lobe epilepsy, and 20% of these will have had febrile seizures. Helpful additional modalities in studying surgical candidates include ictal positron emission tomography (PET) using fluorodeoxyglucose, interictal PET using α -methyl-L-tryptophan, single photon emission computerized tomography, functional MRI, and magnetoencephalography. These studies help define the nature of damaged or epileptic cortex and differentiate it from normal cortex.

Management

When there has been an episode of abrupt loss of consciousness or tone with a potential for recurrence, families need to be cautioned about the risks of drowning, falls from high places, and accidents with operating machinery including vehicles. Anticonvulsants are the mainstay of management of seizure disorders (Table 146-2). At the same time the clinician must realize seizures and antiepileptic drugs affect brain development and could have long-term consequences, such as altered cognition and epilepsy susceptibility. (This observation may be especially true in the case of neonatal seizures where the seizures themselves may contribute to adverse outcomes; the standard treatment of phenobarbital has been shown in some long-term treatment models to be inhibitory of learning.) Anticonvulsants are prescribed if the risk of recurrence of seizures, particularly prolonged seizures, is significant based on seizure classification and individual factors. A known structural lesion or the EEG may also suggest a higher recurrence risk. The choice of anticonvulsant depends on age, gender, neurologic diagnosis, seizure type or epilepsy syndrome, other conditions or medications, and social factors. The doses and combination of anticonvulsants prescribed for children depend on a balance of seizure resistance, risk of recurrence, and potential toxicity of medication. The initial goal is control with a single medication and as little toxicity as possible.

Oxcarbazepine and carbamazepine are often recommended for partial seizures. Toxicity is generally mild or nonexistent; adverse effects include GI upset, dizziness, and headache. Carbamazepine has been known to aggravate idiopathic generalized and myoclonic epilepsies, however. Phenytoin is also effective for partial types of seizures, and it can be given intravenously for status epilepticus. Phenobarbital

Table 146-2. Drugs Useful for Treating Seizures

<i>Seizure Type</i>	<i>Dose</i>	<i>Toxic Symptoms/Side Effects</i>
Partial Seizures		
Carbamazepine	Approx 15 mg/kg/d	Gastrointestinal distress, headache
Phenytoin	4–8 mg/kg/d	Ataxia, nystagmus, bone changes
Primidone	12–25 mg/kg/d	Drowsiness, ataxia
Oxcarbazepine	30 mg/kg/d	Drowsiness
Lamotrigine	4–7 mg/kg/d	Dizziness, sedation, rash (Stevens-Johnson syndrome)
Gabapentin	4–8 mg/kg/d	Somnolence, ataxia
Vigabatrin	15–50 mg/kg/d	Drowsiness, visual field defects
Topiramate	6–10 mg/kg/d	Weight loss, sedation, speech disturbance
Zonisamide	4–6 mg/kg/d	Sedation
Levetiracetam	10–60 mg/kg/d	Behavior or personality change
Rufinamide	10–45 mg/kg/d	Sedation, headache
Lacosamide	1.5–6 mg/kg/d	Dizziness, ataxia, caution with cardiac disease
Neonatal Seizures		
Phenobarbital	5–6 mg/kg/d	Lethargy, irritability, osteopenia
Topiramate	6–10 mg/kg/d	Sedation
Generalized Seizures		
Valproic acid	20–60 mg/kg/d	Tremors, hair loss, thrombocytopenia, weight gain
Felbamate	45 mg/kg/d	Insomnia, anorexia, bone marrow aplasia
Topiramate	6–10 mg/kg/d	Weight loss, sedation, speech disturbance
Clorazepate	0.1–0.4 mg/kg/d	Drowsiness
Clonazepam	0.15 mg/kg/d	Drowsiness, ataxia
Absence Seizures		
Ethosuximide	30 mg/kg/d	Nausea, hiccups
Valproic acid	20–60 mg/kg/d	Tremors, hair loss, thrombocytopenia, weight gain
Infantile Spasms		
Adrenocorticotrophic hormone	40 U/m ²	Increased appetite, irritability, acne
Valproic acid	20–60 mg/kg/d	Tremors, hair loss, thrombocytopenia, weight gain
Vigabatrin	15–50 mg/kg/d	Drowsiness, visual field defects

is effective in neonatal seizures but may have deleterious effects on behavior and learning in older children. Ethosuximide is used for petit mal seizures. Valproic acid is used for more common atypical petit mal and other seizure disorders resistant to other anticonvulsants. It should not be used in a woman who might conceive because of an increased risk of fetal neural tube defects, however. Felbamate is also effective in many difficult to treat epilepsy syndromes, although a small incidence of irreversible severe bone marrow suppression and liver toxicity has limited its use. Other anticonvulsants including gabapentin, lamotrigine, vigabatrin, topiramate, zonisamide, and levetiracetam have proven effective. Gabapentin and levetiracetam are useful as adjunctive agents because of their lack of interaction with other anticonvulsants. Lamotrigine is useful in both partial and primary generalized seizure disorders. Vigabatrin is useful in infantile spasms when caused by tuberous sclerosis. Topiramate is effective in

partial seizures, generalized seizures, and Lennox-Gastaut syndrome. Rufinamide, newly marketed, is also effective in the latter syndrome particularly. Zonisamide and levetiracetam are effective in both partial and generalized seizure disorders, and lacosamide, another new medication, is also effective in partial disorders. The latter 2 medications can also be used intravenously.

Periodic monitoring of efficacy and side effects is essential in children who take medication daily on a long-term basis. A log of seizure frequency helps assess medication efficacy. Gastrointestinal and neurologic symptoms (sedation and ataxia) are the most common side effects. The perception of symptoms being related to the medication as well as the actual presence of side effects or toxicity both contribute to the complex issue of compliance. Serum drug levels are useful in monitoring compliance, dosage, and the likelihood that symptoms are the result of drug side effects. Organ toxicity (bone marrow, liver,

and pancreas) must be considered and monitored with many medications. Hypersensitivity reactions and Stevens-Johnson syndrome usually, but do not always, occur within 2 months of beginning the medication. Drug interactions can be important and can include the liver cytochrome P450-inducing potential of barbiturates and the potential of other medications, such as erythromycin, to inhibit other liver detoxification systems, such as that involved with carbamazepine metabolism, which produce acutely high levels and clinical toxicity. The recent onset of educational problems in a child with epilepsy deserves aggressive evaluation, both for determining a common etiology to the underlying seizure condition and alternatively for assessing medication toxicity or long-term effects.

Non-medication therapeutic options are also available for refractory cases. The ketogenic diet has success in about 50% of cases but requires considerable knowledge and commitment. The vagal nerve stimulator delivers a regular electrical stimulus afferently to the CNS and also allows for an abortive intervention by the caretaker with an external magnet. It is also effective in about 50% of cases, and when this occurs less medication may be used, allowing a better overall quality of life. Intracranial surgery for epilepsy in childhood must sometimes be considered. Children with seizure-associated syndromes including Sturge-Weber syndrome, Rasmussen encephalitis, catastrophic seizure disorders of early childhood such as infantile spasms related to a localized zone of epileptogenic cerebral tissue, and hamartomatous cortex-producing seizures have benefitted the most often, but patients with refractory partial seizure disorders, including temporal lobe epilepsy, may also be candidates for surgical extirpation. Extensive pre-surgical imaging and physiological monitoring are necessary for resective surgery candidates.

Prognosis

In general, approximately two-thirds of children who have experienced a tendency for seizure recurrence have a good prognosis for prevention of further recurrence and little or no problem with side effects of medication. They can lead normal lives without handicap. The etiologic diagnosis is the most important prognostic factor. The type of epilepsy, EEG findings, child's age, difficulty of initial seizure control, and time since the last seizure are also important. Some seizure types have intrinsically poor prognoses. For example, infantile spasms are prognostically ominous because even in the absence of a metabolic diagnosis, children frequently suffer temporary brain growth and developmental arrest unless the seizures are controlled with medication. About 10% to 25% of children, most often those with generalized symptomatic epilepsies, frequent seizures, high anticonvulsant use, and early onset of epilepsy, show some intellectual decline. Partial complex disorders and the atypical variant

of petit mal disorders sometimes have a poorer prognosis for early resolution and may be more resistant to treatment with anticonvulsants. However, some of the seizure syndromes with a familial tendency such as Rolandic seizures and typical petit mal seizures have a relatively good prognosis for both control by medication and ultimate complete resolution.

The individualized decision to discontinue medication is often complex. The prognosis for recurrence of seizures, the parents' and children's reactions to seizures and to the prospect of their recurrence, and social factors such as school participation may all contribute to the decision. Children and parents must be aware that none of the prognostic factors, whether considered individually or in combination, is an absolute predictor of seizure recurrence or non-recurrence in a given child.

CASE RESOLUTION

The boy described in the case history at the beginning of the chapter had a generalized seizure when he was taken to the emergency department. The previous episodes recalled by the father had characteristics of partial seizures. The tonic-clonic seizure was probably a secondary generalized rather than a primary generalized seizure. The possibility of Rolandic seizures is suggested by the circumstances of the prior episodes, drowsiness, "facial" or "oral" symptomatology, and the family history. This diagnosis was confirmed by EEG. Oxcarbazepine was prescribed. The boy experienced no side effects or seizure recurrences and was successfully able to discontinue the medication 3 years later.

Pediatric Palliative Care: Principles and Practice

Rick Goldstein, MD

CASE STUDY

Jason is a 17-year-old boy with spastic quadriplegia, severe global developmental delays, a seizure disorder, cortical blindness, and dystonia. Since leaving the neonatal intensive care unit (NICU) at 3 months of age, he has lived in a skilled nursing facility and spends weekends at home with his family. He was born after 24 weeks' gestation and had a turbulent NICU course. During that hospitalization, in accord with his neonatologists, he was treated for comfort and extubated due to his severe respiratory failure, but managed to survive and breathe independently. Once beyond the newborn period, his medical course was fairly stable, notable for episodic respiratory decompensations requiring hospitalization and numerous orthopedic procedures. In the past 2 years, however, he has spent substantially more time in the intensive care unit due to increasing

respiratory fragility. With so much time spent in the hospital and so little time when he is comfortable "at home," his parents have begun questioning whether the intensive medical care he has been receiving translates into a quality of life and whether they should begin to limit efforts at resuscitation. They do not know what it would mean to place limitations on his care and, whatever their choices, they do not want Jason to suffer.

Questions

1. What is palliative care?
2. What is involved in the practice of palliative care?
3. How do children understand death? How does their understanding vary with their age?
4. What role does a primary care pediatrician play in the palliative care of her patients?

During the typical career of a primary care pediatrician, only a few patients die. Many more patients will develop complex medical conditions, sometimes life-threatening, generally requiring high levels of management. Caring for these patients can be among the most challenging yet rewarding experiences a pediatrician may have. Close, long-standing relationships with a family make it apparent how the impact of the illness on the child and family goes beyond biomedical issues, and many feel called to respond to the suffering that occurs. These children especially benefit from a medical home providing care that is accessible, continuous, comprehensive, family-centered, coordinated, and compassionate, led by an invested primary care pediatrician empathetic of their experience.

Even with the best of intentions, the care of these patients can accentuate changes in modern medical care. There can be a divide between the goals of subspecialty-based care provided in hospitals and those of the generalist care in the community. The increasing use of new medical technologies in the home setting can leave primary care pediatricians uncertain even as they are asked to sign the orders for home care. There can be uncertainty about whether unexpected symptoms can be managed quickly, effectively, and authoritatively in the community setting. Continuity of care can be challenging with

prolonged hospitalizations. And lastly, there is the matter of case ownership: Who is "in charge" and who will help the family and patient not only with the illness, but in accord with their hopes and wishes for their child?

A new subspecialty, pediatric palliative care, addresses many of the central concerns in the care of these children. It builds on an important cornerstone from hospice care, namely, acceptance of the fact that some children do die, and the circumstances of their death can be improved with specialized expertise directed toward improving the process and relieving pain and suffering. In all cases, it exists to help children and their families live as well as possible in the face of complex, life-threatening illness. The developing expertise of this subspecialty supports and augments the important work that emanates from the patient's medical home. Palliative care also deals with more complex cases that require enhanced care and coordination, and can assist the primary providers when they need help, or when most patient care is hospital-based. Far from signifying an abandonment of hope, palliative care practitioners work with families to redefine hope in a realistic way, and clarify what the family may need to align the treatment decisions with the child and family's vision of what is best.

The Scope of Pediatric Palliative Care

Each year more than 50,000 children in the United States will die and 10 times that number will cope with life-threatening conditions. In 2008, 55% of deaths of children younger than 19 years occurred in children younger than 1 year, with 20.1% of those infant deaths attributed to congenital malformations, deformations, and chromosomal abnormalities; 16.9% to short gestation and low birth weight; 8.2% to sudden infant death syndrome; 6.2% to newborns affected by maternal complications of pregnancy; and 4.6% to unintentional injuries. For older children, aged 1 to 19 years, the leading causes of death were unintentional injuries (38.8%); homicide (12.4%); malignant neoplasms (8.6%); suicide (8.0%); and congenital malformations, deformations, and chromosomal abnormalities (4.7%). Approximately 47% of US children die outside of a hospital.

Research by Feudtner and others has increased our understanding of children with complex chronic conditions (CCC) in the United States. These children are estimated to make up one-fifth of all pediatric deaths. Complex chronic conditions have been defined as medical conditions that can be reasonably expected to last at least 12 months (unless death intervenes) and that involve either several different organ systems or one organ system severely enough to require specialty pediatric care and probably some period of hospitalization in a tertiary center. The leading categories of CCCs leading to death are cardiovascular (22.2%), malignancy (21.4%), congenital/genetic (19.4%), neuromuscular (18.1%), and respiratory (9.3%). Increasingly, these children are dying at home, perhaps due to longer survival, the migration of advanced medical technology into the home, and shifting attitudes about what is better care, with a greater focus on quality of life among children with life-threatening conditions. Many studies indicate that, overall, home is the preferred site of ongoing care for children with life-threatening illnesses, regardless of their condition.

The American Academy of Pediatrics (AAP) endorses an integrated model of palliative and curative treatment where components of palliative care are offered at diagnosis and continued throughout the course of illness, whether the outcome is cure or death. The prevailing view is that the palliative care “approach should be instituted when diagnosis, intervention, and treatment are not limited to a disease process, but rather become instrumental for improving the quality of life, maintaining the dignity, and ameliorating the suffering of seriously ill or dying children in ways that are appropriate to their upbringing, culture, and community.” (See selected references, Himelstein.) Palliative care is often incorrectly equated with hospice care, a program of coordinated services offering comfort-centered care at the end of life in the home or community setting. While there is a shared philosophy and an overlap of many of the priorities of care, palliative care should not be considered only at the end of life, nor is it exclusive of curative care. Changes in hospice benefits for children, reviewed later, further blur the distinction.

Palliative care should be considered in 4 categories of illness: conditions for which curative treatment is possible but may fail (eg, cancer with a poor prognosis); conditions requiring intensive long-term

treatment aimed at maintaining the quality of life (eg, cystic fibrosis or advanced muscular dystrophy); progressive conditions in which treatment is exclusively palliative after diagnosis (eg, progressive metabolic disorders); and conditions involving severe, nonprogressive disability, causing extreme vulnerability to health complications (eg, holoprosencephaly or other severe brain malformations) (Box 147-1).

Box 147-1. Conditions Appropriate for Pediatric Palliative Care^{a,b}

Conditions for which curative treatment is possible but may fail

- Advanced or progressive cancer or cancer with a poor prognosis
- Complex and severe congenital or acquired heart disease

Conditions requiring intensive long-term treatment aimed at maintaining the quality of life

- HIV infection
- Cystic fibrosis
- Severe gastrointestinal disorders or malformations, such as gastroschisis
- Severe epidermolysis bullosa
- Severe immunodeficiencies
- Renal failure in cases in which dialysis, transplantation, or both are not available or indicated
- Chronic or severe respiratory failure
- Muscular dystrophy

Progressive conditions in which treatment is exclusively palliative after diagnosis

- Progressive metabolic disorders
- Certain chromosomal abnormalities, such as trisomy 13 or trisomy 18
- Severe forms of osteogenesis imperfecta

Conditions involving severe, nonprogressive disability, causing extreme vulnerability to health complications

- Severe cerebral palsy with recurrent infection or difficult-to-control symptoms
- Extreme prematurity
- Severe neurologic sequelae of infectious disease
- Hypoxic or anoxic brain injury
- Holoprosencephaly or other severe brain malformations

^b Premature death is likely or expected with many of these conditions.

In addition, there is an emerging role for palliative care in the NICU. At this point, it is unclear whether, from a palliative care perspective, the needs of newborns and their families in NICUs are fully addressed. Neonatologists certainly have expertise dealing with the medical needs of critically ill children and the care-related concerns of their families. The pace of the NICU and the absence of a primary care practitioner no doubt have some impact on the priorities of care. A palliative care approach emphasizes critical communication, symptom management, and assistance with shared decision-making and articulating goals. Alternatively, pediatric deaths due to sudden unexplained infant death and traumatic injuries, intentional and unintentional, occur largely outside of medical settings. First

responders and emergency medicine clinicians would benefit from palliative care guidance about symptom management in the face of imminent death and decision-making related to resuscitation.

Not every dying child requires the involvement of pediatric palliative care specialists. Realistically, primary care pediatricians provide essential contributions to the care of these children. Most children with life-threatening illnesses lead lives and receive at least some of their care in the community setting. There may be differences in the willingness of primary care practitioners to become involved or in the ability of practices to manage the complexities of care, but the primary care pediatrician can be the central coordinating figure in the medical care offered these children.

Efforts to enhance the quality of life for these children require a willingness to address biomedical, psychological, sociocultural, and spiritual matters. Families need guidance in navigating the administrative, financial, and coping challenges placed on them. Importantly, there is a fundamental need to promote the sense of a lived life of value and identity, in contrast to a life determined by the course of illness alone. These needs are best served when an interdisciplinary team attends to the unique needs of each child. Such a team may have a pediatrician leader, but benefits from involvement by nursing, social work, psychosocial clinicians, and pastoral care. Subspecialists are often involved, with varying relationships with the family. There may be a hospice program or a community-based palliative care program. The care of children additionally may involve representatives from the school, child life, and practitioners of functional therapies, whether occupational therapy, physical therapy, and speech therapy, or massage, hippotherapy, and Feldenkrais. Strong communication and reliable continuity within the team are essential to success.

Pain and symptom management for chronically ill or dying children is a foundation of quality of life and a core concern of pediatric palliative care. When the parents of children dying from cancer were asked about symptoms, 89% reported that their children suffered “a lot” or “a great deal” from at least one symptom as they were dying. Other research has found that parents list emotional distress, fatigue, nutritional concerns, and pain as troubling areas at the end of life. While the medical focus is on pain, there also is concern about symptoms such as dyspnea, nausea and vomiting, constipation, secretions, fatigue, anorexia, pruritis, sleep issues, anxiety, and anorexia. A full discussion of pain and symptom management can be found in Chapter 12.

Prognosis, Disclosure, Decision-making

The care of these children is marked by periods of intense uncertainty and fearful realities. Helping families determine the goals of care, appropriate treatment choices, and all aspects of planning for the child's life is facilitated when they understand their child's prognosis. To accomplish this, careful and thoughtful communication is of paramount importance. Yet research has found that many parents feel they receive confusing, inadequate, or uncaring communication related to prognosis and treatment. They are expected to reach decisions with a different understanding of medical details

than their children's health care professionals. Such decisions are especially difficult in a setting of misunderstanding, disagreement or, worse, lack of trust.

Most illness has prognostic uncertainty. Despite this, parents benefit from direct communication about the disease severity, and the timeline for progression and potentially death. This is a difficult task, not only because imparting bad news is an uncomfortable and complex task, but also the exact prognosis is truly uncertain. Studies of prognosis have found that physicians are accurate only 20% of the time and tend to be overly optimistic. While more experienced clinicians tend to have less error, there is also a correlation between the length of a relationship with a patient and a lowered likelihood that the prognosis will be correct. Parents nonetheless seek a clear disclosure. They interpret hidden or minimal information as their doctor withholding frightening information. Alternatively, parents who receive more elements of prognostic disclosure are more likely to report communication-related hope, even when the likelihood of cure is low. The benefits of honest communication about the prognosis exceed the hazards.

When parents and some children ask about prognosis, they are asking about both the time remaining and the pace of expected decline. Three typical trajectories for progressive chronic illness have been described in adults and are informative for pediatric patients as well (Figure 147-1). The first is a pattern of illness with a modest impact on function during most of its course followed by a precipitous decline near the time of death. Cancer death classically fits this pattern, and cancer research has led to models where timelines can be discussed with some accuracy. An implication for care with this trajectory is that there is life to live even in the face of imminent death and also that when decline comes, there has been time to review the priorities of care before circumstances at the end of life.

The second trajectory is one of long-term limitations with intermittent serious episodes. Cystic fibrosis and severe disability following prematurity are 2 examples of this trajectory. Although there is slow, steady decline that can generally be discussed with some clarity, there are unpredictable decompensations that often bring the child close to death, and which will affect the overall rate of decline. A predicted timeline to death can only be described in general terms. These patients sometimes survive their decompensations after seeming, to all appearances, beyond recovery. This can make it very difficult to talk about placing limitations on resuscitation, even when quality of life is extremely compromised. The third trajectory, described as prolonged dwindling, can apply to children with severe metabolic abnormalities, trisomy 13 or 18, or severe brain abnormalities. It is a life of ever-diminishing function. The families tend to become quite “medicalized” and organize their lives around the child's care. A key challenge in these cases is to help the family articulate what they see as giving the child's life meaning, and helping them evaluate interventions in terms of their goals, not simply whether they are possible.

Uncomfortable as it is, anticipating death and addressing it clearly and frankly allows families, and some patients, to make choices about the time remaining. The early recognition of a poor prognosis predicts

Figure 147-1. Typical illness trajectories for people with progressive chronic illness. (Modified with permission from Lynn J, Adamson DM. *Living Well at the End of Life. Adapting Health Care to Serious Chronic Illness in Old Age.* Washington, DC: Rand Health; 2003.)

an earlier do not resuscitate (DNR) order, less use of disease-directed therapies in the last months of life, and a greater chance of incorporating the child's comfort as a goal. It allows a narrative to evolve of who this child was and the terms under which he lived. It allows for some sense of control and expression of values in overwhelming circumstances. Mack and Wolfe have nicely outlined an approach to communicating with children and families once prognosis has been shared and palliative care is under consideration (Table 147-1).

The Burden of Suffering and the Power of Hope

It is indeed surprising that the topics of suffering and hope can seem, at first glance, to be nontechnical and not properly “medical.” It is hard to imagine how concepts so central to the call to heal can seem

peripheral. This is rooted in the bias that matters of the body are appropriate areas of treatment whereas matters of the mind and soul are left to other subspecialties or areas outside of medicine.

Disease and its treatment can cause physical distress, but suffering is much larger and more complex. Cassel defines suffering as “the state of severe distress associated with events that threaten the intactness of a person.” When a child or parent worries “what will happen...” or their complaints seem greater than their physical basis, they may be reflecting the suffering that comes from a threat to any of the multiple aspects of personhood—the lived past, the family's lived past, culture and society, roles, the instrumental dimension, associations and relationships, the body, the unconscious mind, the political being, the secret life, the perceived future, and the transcendent dimension. “In caring for patients with life-threatening illness, understanding all aspects of suffering is critical to effective care, and reflection and understanding are prerequisite to a healing presence. Pain and symptom management are foundational, but the relief of suffering requires helping a child and family struggle with issues of meaning and transcendence.

Hope involves expectations or belief in a worthy future. It carries a sense of trust and reliance. Life-threatening illness makes it complicated to know what to hope for, trust in, or rely on. Medical particulars aside, as Cassell has written, “the imperative to tell the truth seems an insufficient guide to what you should tell patients.” It is not that truth or the best understanding should be withheld, but rather it should be communicated with the goal of reducing uncertainty and providing a basis for action. Hope can be sustained when a meaningful way forward is elucidated even in the face of dismal diagnosis.

Barriers to Palliative Care

Parenting a child with chronic and potentially terminal illnesses can be frightening, confusing, frustrating, and exhausting. While a decision to involve palliative care practitioners is in no sense a decision to stop working strenuously for their child's life, it is crucial that palliative care is introduced with a sensitivity to this misinterpretation. If palliative care is viewed by the parents or child as an act of abandonment or disloyalty, the benefits of the consultation may not be forthcoming. Parents should be advised that a growing body of research has demonstrated that involvement of palliative care strategies leads not only to an improved quality of life for extremely ill patients even as their illness progresses, but also longer survival. Palliative care offers much more than “doing nothing and letting the disease take its toll.”

One of the greatest obstacles to palliative care and hospice has been a reimbursement model based on the Medicare Hospice Benefit, which required patients in hospice to forego curative care and gear care toward survival of 6 months or less. Parents, understandably, find it very hard to give up curative efforts for their children. They appreciate a quality of life in a developing though ill child that is different than in a dying geriatric patient. Because hospice was associated with the elderly, parents felt a disincentive against selection of hospice insurance as a benefit. While certain states offer palliative care programs to remedy this, the Patient Protection and Affordable

Table 147-1. Communicating With Children and Families About Integrating Palliative Care

Beginning the conversation	<ul style="list-style-type: none"> • What is your understanding of what is ahead for your child? • Would it be helpful to talk about how his or her disease may affect him or her in the months and years ahead? • As you think about what is ahead for your child, what would you like to talk about with me? • What information can I give you that would be helpful to you?
Introducing the possibility of death	<ul style="list-style-type: none"> • I am hoping that we will be able to control the disease, but I am worried that this time we may not be successful. • Although we do not know for certain what will happen for your child, I do not expect that your child will live a long and healthy life; most children with this disease eventually die because of the disease. • I have been noticing that your child seems to be sick more and more often. I have been hoping that we would be able to make him or her better, but I am worried that his or her illness has become more difficult to control and that soon we will not be able to help him or her to get over these illnesses. If that is the case, he or she could die of his or her disease.
Eliciting goals of care	<ul style="list-style-type: none"> • As you think about your child's illness, what are your hopes? • As you think about your child's illness, what are your worries? • As you think about your child's illness, what is most important to you right now? • You mentioned that what is most important to you is that your child be cured of his or her disease. I am hoping for that too. But I would also like to know more about your hopes and goals for your child's care if the time comes when a cure is not possible.
Introducing palliation	<ul style="list-style-type: none"> • Although I hope that we can control your child's disease for as long as possible, at the same time I am hoping that he or she feels as good as possible each day. • Although it is unlikely that this treatment will cure your child's disease, it may help him or her to feel better, and possibly to live longer.
Talking about what to expect	<ul style="list-style-type: none"> • Would it be helpful to talk about what to expect as your child's illness gets worse? • Although we cannot predict exactly what will happen to your child, most children with this disease eventually have [difficulty breathing]. If that happens to your child, our goal will be to help him or her feel as comfortable as possible. We can use medications to help control his or her discomfort.
Talking to children	<ul style="list-style-type: none"> • What are you looking forward to most of all? • Is there anything that is worrying you or making you feel afraid? • Is there anything about how you are feeling that is making you feel worried or afraid?

* From Mack JW, Wolfe J. Early integration of pediatric palliative care: for some children, palliative care starts at diagnosis. *Curr Opin Pediatr.* 2006;18:10–14, with permission from Wolters Kluwer Health.

Care Act of 2010 removed the prohibition against curative treatment as a hospice benefit by or on behalf of a Medicaid or Children's Health Insurance Program–eligible child. States are not required to provide hospice services, although this is increasingly the norm, but where hospice services are provided, concurrent curative treatment must be offered. Despite these changes, eligibility still requires a physician to certify the child as likely to die in the next 6 months.

A Child's Understanding of Death

Ultimately, death is a singular transcendent experience, likely beyond the understanding of the living. But parents want to know what their children can understand as they go through the process. Caregivers, too, wonder what a child knows as they try to anticipate needs or reckon with enigmatic statements from them. Most would agree that a child's suffering due to avoidance of discussions of their fears about their condition and death is especially tragic and counterproductive.

The pediatrician should communicate with children about what is happening to them, while respecting the cultural and personal preferences of the family. A developmental understanding of children's concepts of health and illness can help frame the discussion with children, or serve to advise parents in their discussions. The child's concept of death reflected in the medical literature has changed very

little from that extrapolated from Piaget's work in cognitive development and is based on the stages of sensorimotor, preoperational, concrete operations, and formal operations.

Up to 2 years of age (sensorimotor), there is probably no concept of death per se. Death is understood and responded to as a separation. Grief relates to the loss of an attachment figure and is expressed through protest and difficulty attaching to other adults. The degree of difficulty dealing with the loss depends on the availability of other nurturing adults who have cared for the child and with whom the child has had a good previous attachment.

Once they are 3 years of age, children can recognize death as a changed state. In the preoperational stage (ages 3–5 years), however, they cannot understand the meaning of a severe illness nor the finality and universality of death. Limited language abilities can give the appearance of little insight, and moods or behavior can be the means of expression. Bad things happen for an immediately identifiable reason, and death may be viewed as punishment. For instance, if a child's newborn sibling suddenly dies and the child had previously wished them to have died or gone back to where he or she came from, they may feel their wish was the cause of the death. Children this age can feel overwhelmed when confronted with the strong emotional reactions of their parents at the time of loss.

Ages 6 to 11 years (school age) are considered the late preoperational to concrete operational stages of cognitive development. In this age range, the finality of death comes to be understood. Eight-year-olds are aware of personal mortality, and work by Hinds has found that children as young as 10 years are able to speak about their experiences and decisions at the end of life. Magical thinking gives way to a need for detailed information to gain a sense of control. Older children in this range will often feel a need to control their emotions by compartmentalizing and intellectualizing.

The developmental stage of adolescents (>12 years old) is considered formal operations. The concept of death includes universality and finality, and they can understand personal mortality. Adolescents handle death issues at an abstract or philosophical level and can be realistic. They may seem closed off to information and resist frank discussions with undercurrents of deep emotion, and rely on anger or disdain. Communication with peers, perhaps involving social networking technologies, can be more open, although critically ill children are sensitive about not burdening their friends, just as they often feel their friends are unable to fully comprehend their situation. Adolescents can discuss withholding of treatments. Their personal goals should be understood, respected, and discussed on their own terms.

A child's cognitive limitations will obviously have an impact on their understanding. Another matter is how illness has affected their development—it is observed that chronically ill children may possess a precocious and advanced understanding of certain things, for instance the details of their illness or the way to address their symptoms, while simultaneously being less mature in other developmental areas.

Parents can struggle with whether they should talk with their child about their imminent death. While research supports a bias toward speaking frankly to dying children, each individual case presents its own complexities based on the child's age, cognitive development, disease, timeline of disease, and parental psychological state. In a study by Kreicsberg of parental disclosure to children with impending cancer death, no parent who talked with their child about their death regretted doing so and, of those who did not speak frankly about imminent death, 27% regretted not having done so. Among those who did not talk with their child about death, parents who sensed their child was aware of imminent death, parents of older children, and mothers more than fathers were more likely to feel regretful.

Primary Care at the End of Life: Normal and Extraordinary

There is no disputing the important role that primary care pediatricians can play in the care of children with life-threatening illness. The medical home is even more beneficial to these children. A constant, continuous physician who understands the child and his family holistically can contribute profoundly to their care. Because caring for these children is a rare experience in general practice, the complexities of care can be daunting. There is a need to understand an appropriate role and develop a supportive structure for the primary care pediatricians in a way that supports best practice.

Primary care is provided outside of the hospital and “at home.” Families and children may develop strong feelings about returning to the hospital, having spent difficult times there. They may feel relief in not having to deal with the logistical, seemingly less personal, hurdles of hospital-based care. Care provided in the normal setting of primary care tends to be more tolerable.

General pediatric care under the guidance of the primary care physician also can be an important affirmation of the normal and can contribute to quality of life. For the patient, routine health care visits, vaccinations, and developmental assessments are important because the rationale for this care is not their disease but the positive and ordinary characteristics of childhood. The focus on development, education and learning, social engagement, play, and involvement with family and community affirms the whole child and the importance of his life. The primary care pediatrician is often seen as a trusted advisor who understands the family and child in the normal context, and thus “knows” them best. He is the child's doctor without qualification.

A trusted primary care pediatrician also has a role in complex disease management. The primary care pediatrician is in the best position to assess the family's level of understanding and address any gaps. Importantly, he can help families understand complex medical information, terminology (medical jargon), or other specific medical details. An involved primary care practitioner also can help the medical team better understand the patient and family perspective. They can ease the adjustment between home and hospital and help ensure a more seamless transition in either direction. In order for the pediatrician to have relevant involvement in crucial developments, there must be a timely sharing of information between all members of the team, generalist, and specialist. Ideally the primary care physician should participate in hospital rounds on the patient and in team meetings. This is especially important for meetings with the family where goals of care and medical decision-making are the focus. Fostering collaboration between the primary care physician and the palliative care specialist is essential (Box 147-2).

When a child is facing the end of life at home, the primary care physician has additional opportunities to facilitate things for the child and family. The primary care physician works with the hospice

Box 147-2. Fundamental Elements of Successful Collaboration Between Primary Care and Palliative Care^a

- Timely sharing of information
- Mutual inclusion in clarifying goals of care and medical decision-making
- Coordinated designation of responsibilities
- Explicit review of case management and social work needs
- Technical backstopping for pain and symptom management
- Trusted, timely collaboration and assistance with urgent symptom management issues

^a Adapted from Steinhorn D, Goldstein R, Orloff S. Relationships with the community: palliative care and beyond. In: Wolfe J, Hinds P, Sourkes B. *Textbook of Interdisciplinary Pediatric Palliative Care*. Philadelphia, PA: Saunders; 2011.

team to continuously fine-tune approaches to pain and symptoms. Their greater availability and sense of the family are important assets. Primary care pediatricians can also play a central role in delineating resuscitation orders.

Research finds that parents consider end-of-life decisions to be the most difficult treatment decisions they face. It is not unusual for them to operate in a way that continues to seek a cure even as they accept the inevitability of death, and these decisions reveal the tensions of holding both views. It is not surprising that DNR orders are frequently instituted near the time of death. Paradoxically the child may spend less time at home as the parents still expect efforts toward an impossible cure. The proper timing to introduce these issues is early in the course of the child's illness, not in the midst of crisis or very late in the patient's course. Thoughtful conversation with a trusted primary care pediatrician who has a broad perspective on the medical details as well as the family identity and values is invaluable.

Most important is to help the family determine realistic goals for their child. This is facilitated by a frank discussion of whether resuscitation efforts support their goals or not. A powerful guide for these discussions is the document *Five Wishes*, or for younger children up to approximately age 11, *My Wishes*, distributed by Aging With Dignity. These are guided conversations that approach advance directives, and the *Five Wishes* document is legally recognized in 42 states (Box 147-3). Simply addressing "DNR orders" is inadequate. Another important contribution that differs in each state are comfort care forms and physician orders for life-sustaining treatment. These are DNR orders that are not particular to the inpatient setting. For instance, emergency medical technicians in the field must resuscitate a child found in cardiac or respiratory failure unless orders exist to refrain. Once a family has come to the difficult decision to limit interventions, it is important to advocate for their wishes in all potential settings.

Case coordination should explicitly address outpatient management and clarify the responsibilities of the primary care team as well of each of the subspecialists. The potential for this collaboration to improve the care offered by all of the members of the child's medical team is enormous.

Loss and After

The loss of a child or sibling changes life forever. It begins a process of bereavement, the psychological and spiritual accommodation to death on the part of the child and the child's family, and grief, the emotional response caused by the loss. Grief can cause pain, distress, and physical and emotional suffering but, except in cases of prolongation, is a normal adaptive human response, not a disease. Anticipatory grief begins with the awareness of impending loss or death in parents and in children with sufficient awareness and cognitive development. Palliative care attends to the grief reaction before and following death. Assessing the coping resources and vulnerabilities of the affected family system before death takes place is central to the palliative care approach.

Box 147-3. My Wishes and Five Wishes^a

My Wishes (for children up to approximately 11 years)

- How I want people to treat me
- How comfortable I want to be
- What I want my loved ones to know
- What I want my doctors and nurses to know

Five Wishes

- The person I want to make care decisions for me when I can't
- The kind of medical treatment I want or don't want
- How comfortable I want to be
- How I want people to treat me
- What I want my loved ones to know

^a Reprinted with permission from Aging with Dignity. Available at <http://www.agingwithdignity.org>.

Parental grief is more intense and sustained than other types of grief. Parents may never completely accept the loss of their child. Most parents work through their grief, though studies have found that more than one-fourth had not worked through their grief in 4 to 9 years after the loss of the child. Research suggests that parents who share their problems with others during the child's illness, who have had access to psychological support during the last month of their child's life, and who have had closure sessions with the attending staff are more likely to resolve their grief.

Surviving siblings are also burdened. The AAP recommends that primary care pediatricians reach out to children and families at the time of loss, evaluate their bereavement to understand the personal meaning of their loss and their process of mourning, and monitor their process, especially in the year following a death. There is a further role of explaining to parents how surviving children are managing their loss, and that children often reexamine the meaning of loss in their lives during each developmental period. When necessary, referrals to skilled mental health professionals should be offered.

Those involved in the care of children and families should appreciate how meaningful simple things like condolence letters and attendance at funerals or memorial services are to families. Notes remembering the anniversary of the deceased child's birthday, or helping the family think about developing the child's legacy or a remembrance also contribute to an improved bereavement. Helping bereaved children safely remember their deceased siblings and appreciating their success as they integrate the loss can be a powerful part of a health care visit.

CASE RESOLUTION

The hospital-based palliative care team arranges to meet with the parents. During their conversations, they help the parents articulate what gives Jason's life meaning, what happiness and unhappiness are for him, and what is a hopeful versus a hopeless existence. The parents decide they would still opt for intubation and respiratory interventions should he become compromised by an acute, likely reversible issue but could not imagine that a further deterioration of his condition after the need for cardiac resuscitation would prove consistent with their goals. Therefore, a limitation is placed on cardiac resuscitation. With their permission, the palliative care team speaks with personnel at the skilled nursing facility, their primary care pediatrician, and the palliative care team at the community hospital where Jason would be taken if ill. Documents are prepared and shared for use in all of the settings. The palliative care team continues to meet with Jason and his family for each hospital admission and has made visits to his nursing facility to help the staff.

Berkowitz's Pediatrics

A P R I M A R Y C A R E A P P R O A C H

4th Edition

Edited by Carol D. Berkowitz, MD, FAAP

What symptoms should you check for?

What diagnoses should you consider?

What tests should you order?

What is your best management strategy?

Look here first when you need on-target answers fast!

Berkowitz's Pediatrics is custom-built for confident, efficient primary care problem-solving. The revised and expanded 4th edition provides clear, concise guidance on all the issues—both clinical and psychosocial—you're most likely to encounter.

Here's practical, hands-on help on everything from benign concerns like temper tantrums, thumb-sucking, and tattoos to devastating conditions like childhood cancer, kidney disease, seizures, and diabetes.

"This is an outstanding book which I have already recommended to colleagues. One can easily read a chapter a day and feel confident that one has learned something new. No other book that I know of is so useful."

Doody's review of third edition

NEW in the 4th Edition!

13 all-new chapters on

- Global Health
- Cultural Considerations and Competence
- Pediatric Pain and Symptom Management
- Complementary and Alternative Medicine
- Principles of Pediatric Surgery
- Pediatric Radiology
- Genomics
- Quality Improvement
- Caring for Immigrant Children and Their Families
- Emerging Infections
- Fetal Alcohol Syndrome
- Interpersonal Violence
- Palliative Care

Quick and easy access to state-of-the-art pediatric primary care...

- **Outcome-centric focus**—Chapters open with a case presentation and list of focal questions; close with the case resolution.
- **Ready-reference organization**—Disease/disorder signs and symptoms are grouped by body system for fast lookup.
- **Expert recommendations**—Edited by a leading primary care authority; contributions from top-tier practitioners.
- **Valuable guidance on psychosocial issues**
 - *Behavioral concerns*: sleep disturbances, colic, toilet training, crying, enuresis, discipline, self-esteem, and more
 - *Health maintenance*: health promotion, well-child care, illness and injury prevention, nutrition, newborn screening, developmental surveillance, and more
 - *"People skills"*: talking with parents, children, and adolescents; encouraging family and community participation

Consistent problem-solving format

Each clinical chapter walks you through

- Patient presentation
- Pathophysiology
- Differential diagnosis
- Evaluation
- Laboratory tests
- Management
- Prognosis

This new 4th edition brings you state-of-the-art expertise and insight by Carol D. Berkowitz, MD, FAAP, past president of the American Academy of Pediatrics. She is currently executive vice chair in the Department of Pediatrics at Harbor-UCLA Medical Center and professor of clinical pediatrics at the David Geffen School of Medicine at UCLA.

For other pediatric resources, visit the American Academy of Pediatrics Online Bookstore at www.aap.org/bookstore.
