A weight-bearing anteroposterior (AP) radiograph of the pelvis along with a lateral radiograph of the affected hip should be obtained. The classical features of AVN on radiography include increased sclerosis in the early stages, the crescent sign indicating subchondral bone resorption and, eventually, flattening in the later stages indicating a segmental head collapse (Fig. 35.3). However, radiographs may be normal in the early stages of the disease and, therefore, the most sensitive and specific way of investigating these patients is with magnetic resonance imaging (MRI). MRI allows the disease to be recognised before it is apparent on radiography as it enables bone oedema and marrow changes to be identified, as well

A caisson is a watertight chamber used to protect construction workers during the building of underwater structures.
Philippe Charles Ernest Gaucher, 1854–1918, Physician, Hôpital St. Louis, Paris, France, described familial splenic anaemia in 1882.

Figure 35.3 (a and b) Radiological appearance of avascular necrosis of the femoral head.

as accurately revealing the extent of involvement of the femoral head, thereby helping in prognosis (Fig. 35.4).

In 1985 Ficat classified the disease into five stages. In 1995 Steinberg modified this classification into seven stages based upon the type of radiological change on MRI and radiography (Table 35.1).

Table 35.1 Steinberg's classification of avascular necrosis of the femoral head

Stage	Description
0	Normal or non-diagnostic radiograph, bone scan or MRI
I	Normal radiograph, abnormal MRI or bone scan
II	Sclerosis and cysts
III	Subchondral collapse, crescent sign
IV	Flattening of the head, normal acetabulum
V	Acetabular involvement
VI	Obliteration of joint space

MRI, magnetic resonance imaging

Figure 35.4 Magnetic resonance imaging scan of the hip joint showing avascular necrosis and the extent of involvement of the femoral head.

Stages I–IV are further divided into A, B or C depending upon the extent of involvement of the femoral head.

Treatment

The appropriate treatment of patients with AVN is dependent on the stage of the disease. Broadly, the seven stages can be divided into two groups: pre-collapse and collapse. In the pre-collapse group the principle is to preserve and preferably revascularise the femoral head, whereas in the collapse group the aim is to replace the femoral head. Conservative treatment in AVN usually leads to poor results and is therefore not recommended. The prognosis is largely dependent upon the extent of head involvement. Surgical treatment for the pre-collapse stage includes core decompression, which is aimed at relieving intravascular congestion in the femoral head and thereby pain. This can be achieved with or without bone grafting; a vascularised bone graft can also be used to enhance bone formation.

The post-collapse stage can be treated with a femoral osteotomy, which aims to transfer the weight-bearing area of the femoral head and thereby protect the collapsed segment; however, if degenerative change has set in, it is preferable to consider a replacement, either in the form of a resurfacing arthroplasty (Fig. 35.5) or a total joint replacement (Fig. 35.6) (Summary box 35.5).

Summary box 35.5

AVN of the femoral head

- Idiopathic AVN is the most common, followed by AVN secondary to trauma, alcohol abuse and the use of systemic steroids
- Patients are asymptomatic in the early stages and therefore a high index of suspicion is necessary for initial diagnosis
- MRI scans are essential for early diagnosis
- Treatment is based upon whether the patient presents in a pre-collapse or post-collapse stage
- The principle of treatment in the pre-collapse stage is to preserve the femoral head, whereas in the collapsed stage the aim is to replace it
- Prognosis is dependent upon the extent of head involvement

Figure 35.5 Anteroposterior (a) and lateral (b) radiographs of the hip showing a resurfacing arthroplasty.

Figure 35.6 Radiograph showing an uncemented total hip replacement *in situ*.

Osteoarthritis

Introduction and aetiology

Osteoarthritis is a non-inflammatory condition that is characterised by progressive damage and loss of the articular cartilage. The progressive nature of the disease process is the result of the body's innate inability to regenerate hyaline articular cartilage. Osteoarthritis is termed as primary or secondary depending upon whether a predisposing cause can be identified for its development.

A multitude of factors including genetic, biochemical and mechanical influences have been implicated in the development of primary osteoarthritis. Despite these theories the exact mechanism for the development of primary osteoarthritis remains unknown and it is thereby termed idiopathic. However, recently, femoroacetabular impingement (FAI) has been proposed as an aetiological factor responsible for the development of primary osteoarthritis. The theory is based on the observation that, in certain hips with aberrant morphological features, an abnormal contact occurs between the proximal femur and the acetabular rim during the terminal range of movement, leading to lesions of the acetabular labrum and/or the adjacent acetabular cartilage. This type of repetitive abutment in due course leads to progressive loss of the articular cartilage and labral lesions because of a sheering stress, resulting in degenerative joint disease if the underlying cause is not addressed.

Secondary osteoarthritis usually develops following trauma, AVN of the femoral head, developmental dysplasia, slipped capital femoral epiphysis, Perthes' disease and enzymatic degradation of the articular cartilage in septic arthritis (Summary box 35.6).

Summary box 35.6

Aetiology of osteoarthritis

Primary

- Cause unknown, termed idiopathic
- Femoroacetabular impingement implicated as a possible cause

Secondary

- Trauma
- AVN
- Perthes' disease
- Developmental dysplasia of the hip
- Slipped capital femoral epiphysis
- Septic arthritis

Clinical features

The most consistent symptom is pain in the groin followed by limitation of movement. Groin pain occurs secondary to irritation of the obturator nerve, which crosses the hip joint. The pain may also radiate down to the knee joint and in some cases the only presenting feature may be a painful knee. In the early stages of the disease, pain is activity related but as the disease progresses the patient also complains of pain at rest. The patient frequently complains of night pain and may also find it difficult to get into a comfortable position while sleeping. Functionally, most have difficulty in putting on their shoes/socks and getting into and out of

Georg Clemens Perthes, 1869–1927, Professor of Surgery, Tübingen, Germany, described osteochondritis of the femoral capital epiphysis in 1910.

a bath or a car. As the pain increases the joint gradually loses its movement because of muscle spasm, reluctance to move the joint and fibrosis of the capsule.

Clinical examination may reveal gluteal muscle wasting and an effusion with crepitus anteriorly. There may also be a limp with a positive Trendelenburg's sign. Shortening is a consistent feature and by the time that most patients present to the surgeon they are using a walking stick in the opposite hand for support. There is limitation of movement, particularly rotation in the earlier stages of the disease process; in the later stages of the disease the limb is in a position of fixed external rotation, adduction and flexion.

Investigations

Radiographs in the AP and lateral plane should be obtained (Fig. 35.7). The characteristic features include a reduction of joint space, which correlates to the loss of articular cartilage, sclerosis in the periarticular bone, which is a result of increased stresses on the surrounding bone, subchondral cyst and osteophyte formation. Eventually, a collapsed femoral head may also be evident. There may also be features suggesting previous trauma or surgical intervention, developmental dysplasia, Perthes' disease or slipped capital femoral epiphysis in cases of secondary osteoarthritis.

Figure 35.7 Anteroposterior (a) and enlarged anteroposterior (b) radiographs of the hip joint showing osteoarthritis.

Treatment

There is no specific pharmacological therapy for osteoarthritis; however, conservative treatment with non-steroidal anti-inflammatories, glucosamine sulphate, regular exercise and physiotherapy to improve muscle strength and range of movement, and modification of lifestyle with loss of weight does help. Also, patients are encouraged to use a walking stick in the opposite hand to offload the affected joint.

The indications for surgery are relentless pain, limitation of lifestyle and activities of daily living, and failure of conservative treatment. The surgical options include an arthrodesis, an osteotomy or a joint replacement in the form of a resurfacing arthroplasty or a total joint replacement. The choice of a particular procedure is based upon the age of the patient, the lifestyle and activity status and the stage of the disease. The principle behind each of these procedures is described in Surgical procedures of the hip.

The dictum that patients should receive a joint replacement only in the end stage of osteoarthritis when they are in severe pain and activities of daily living are markedly restricted has certainly evolved over the last decade. More and more joint replacements are now being performed based on limitation of lifestyle and individual needs, thereby making it a truly life-improving operation (Summary box 35.7).

Summary box 35.7

Osteoarthritis of the hip

- Osteoarthritis is a non-inflammatory condition leading to progressive damage of the articular cartilage
- The most consistent features are pain and limitation of movement
- Characteristic radiological findings include reduction of joint space, joint-line sclerosis, subchondral cysts and osteophyte formation
- Conservative treatment includes walking aids, non-steroidal analgesics, glucosamine and physiotherapy
- Surgical options include an arthroscopy, an osteotomy, an arthrodesis and a joint replacement

Inflammatory arthritis

The hip joint can also be affected by inflammatory arthritides; however, this is not as common as osteoarthritis. This group includes rheumatoid arthritis, ankylosing spondylitis, gout and chondrocalcinosis, juvenile rheumatoid arthritis and systemic lupus erythematosus. Of these, rheumatoid arthritis and ankylosing spondylitis are the most common conditions affecting the hip joint. These are discussed in Chapter 37.

Labral tears, articular cartilage and soft tissue injury

The hip joint is frequently a source of pain following injury in sport. Most of these injuries went undiagnosed in the past because of the unavailability of appropriate imaging techniques and also a lack of interest in and knowledge of sports medicine. However, this trend has changed following the recognition of sports and exercise medicine as a specialty in itself and the introduction of contrast-enhanced MRI and arthrograms.

A spectrum of injuries including muscle contusions and strains, acetabular labrum and ligamentum teres tears, and articular cartilage injuries can now be diagnosed and managed

effectively arthroscopically. A detailed account of these injuries is covered in Chapter 32.

Surgical procedures

Osteotomies around the hip

The goal of an osteotomy around the hip is to restore anatomy to as normal as possible and redistribute forces evenly across the joint, thereby eliminating excessive point loading. This can be achieved by performing an osteotomy on the femoral or the acetabular side, depending upon the desired goal, e.g. an excessive valgus neck–shaft angle and an uncovered femoral head on the lateral aspect can be corrected by carrying out a varus femoral osteotomy. Similarly, a redirection osteotomy on the acetabular side can also be performed to improve coverage of the femoral head. The common indications for an osteotomy around the hip include:

- developmental dysplasia of the hip;
- Perthes' disease;
- osteoarthritis in a young patient;
- slipped upper femoral epiphysis;
- AVN.

Ideally, an osteotomy should be considered in a young patient who maintains a good range of movement of the hip and has minimal symptoms. Radiographs should show a reasonable amount of joint space and thorough preoperative planning is essential to assess whether the desired position can be achieved postoperatively. Three-dimensional computerised tomography (CT) scans may be essential for appropriate preoperative planning. Osteotomies may also be performed when arthritic change has set in – these are termed salvage osteotomies.

Arthrodesis of the hip

Arthrodesis or fusion of the hip is an uncommon operation. It is generally reserved for young patients with severe osteoarthritis who have heavy manual jobs and in whom joint replacements would fail fairly quickly. The aim is to achieve a painless joint by fusing it in a functional position, which is about 30° of flexion, 15° of external rotation and 5° of abduction. This can be achieved by an intra-articular dynamic hip screw or by an extra-articular plate with screws.

Several problems can occur following an arthrodesis including excessive loading of the ipsilateral knee, the contralateral hip and the spine. In addition, degenerative change in these joints in the long term is the rule rather than the exception. Therefore, any pathology in these joints preoperatively does preclude an arthrodesis.

Joint replacement

Osteoarthritis of the hip affects 10–25% of those over the age of 65 years and over 50 000 total hip replacements are performed annually in the UK. The results of surgery are encouraging. In good hands, up to 95% of patients will have a well-functioning hip at 10 years. In the best series, 85% will still be functioning at 20 years, although many are still in place only because the patients are too old and infirm for them to be changed. Following surgery the quality of life approaches normal for a healthy individual. Pain is reduced, mobility increases and sleep as well as social and sexual function is improved. Nevertheless, with the ever-increasing number of patients with joint replacements, the

number of patients whose replacement has failed or worn out and who now want a revision, or even a revision of a revision, is rising rapidly.

The ideal joint replacement – principles and design

The decision of which implant to use is a difficult one as there are over 100 available on the market. However, the decision process can be made easier by considering the elementary features of an ideal joint replacement. The main purpose of implanting a joint in the body is to allow a mechanical device to take over the function of the native joint effectively. Therefore, for any joint replacement to be successful it should be biocompatible and made of inert materials. It should be well fixed to the host tissue and the design should incorporate features to allow a good range of movement. The bearing surfaces should produce the least amount of friction and the material released from the bearing surface should be non-toxic and non-carcinogenic. Finally, any joint implanted should ideally outlive the patient (Summary box 35.8).

Summary box 35.8

Features of an ideal joint replacement

- Biocompatible
- Made of relatively inert materials
- Well fixed to the host tissue and allowing a good range of movement
- Bearing surfaces should be designed to minimise friction
- Material released from the bearings should be non-toxic
- Should ideally outlive the patient

Materials

Most of the implants available currently are made of metal. The metals commonly used are stainless steel, titanium and cobalt–chrome alloy; of these, cobalt–chrome alloy is the most common. The advantages of using a metal alloy are that the implants are able to withstand high loads, are relatively inert and can be manufactured easily. However, they do pose problems in terms of ion release if they are used as bearing surfaces. Also, corrosion can be a cause for concern if two dissimilar metals are used.

Bearing surface

The total hip replacement designed by Charnley uses a joint surface of metal on high-density polyethylene. This is described as a hard-on-soft bearing surface and has a high coefficient of friction. High-density polyethylene has good shock-absorbing properties but does wear slowly over the years, producing small particles that can stimulate an inflammatory response in the joint, which can ultimately be responsible for aseptic loosening of the joint. The stimulated macrophages resorb bone and may also stimulate osteoclasts to do the same. There has therefore been a move towards using bearing surfaces that do not produce wear particles and the concept of hard-on-hard bearing is quite popular currently.

Ceramic femoral heads bearing on polyethylene cups have far

Sir John Charnley, 1911–1982, Professor of Orthopaedic Surgery, University of Manchester, Manchester, England.

lower friction, but ceramic femoral heads on ceramic acetabular cups have the lowest friction of all. They are, however, very difficult and very expensive to manufacture. Metal-on-metal bearings also have a low coefficient of friction and produce small-sized wear particles. These bearing surfaces were frequently used in the past but earned a bad reputation because of a high rate of loosening secondary to manufacturing problems. A summary of the advantages and disadvantages of each bearing surface is provided in Table 35.2.

Fixation

Artificial joints must be securely fixed into the bones on each side of the joint so that the implant does not work loose. This can be achieved with the help of cement or biological interdigitation between the prosthesis and bone (Table 35.3).

Traditionally, hip replacements were fixed into a bed of polymethylmethacrylate (PMMA) cement (Fig. 35.8a). The cement acted as a grout (spacer) between the implant and the bone and provided a static form of fixation. Cement does not possess the ability to remodel and it therefore loosens in time as the bone continues to remodel. Also, as the cement sets, some of the monomer is released into the patient's bloodstream, which can cause a drop in blood pressure.

On the other hand, biological fixation can be achieved by providing a rough surface on the prosthesis for bone to grow into the prosthesis or by bone growing onto the prosthesis; this is a dynamic form of fixation (Fig. 35.8b). This type of biological fixation can also be enhanced by coating the surface of the prosthesis with hydroxyapatite. Hydroxyapatite is an osteoconductive agent and bone essentially binds to it.

Surgical approaches to the hip, postoperative course and complications

Once a decision has been made on which implant to use, the operation can be performed via a posterior approach, an anterolateral or Hardinge approach, a trochanteric osteotomy or an anterior approach (Table 35.4). Each approach has its own

Figure 35.8 Radiographs of a cemented (a) and non-cemented (b) femoral component.

Table 35.2 Bearing surfaces

Type of bearing	Advantages	Disadvantages
Metal on polyethylene	Proven efficacy; easy to manufacture; cheap	High friction; high wear rates; wear particles excite an inflammatory response, which leads to osteolysis
Ceramic on polyethylene	Lower friction	Expensive; ceramic fracture can be a problem
Ceramic on ceramic	Low friction	Very expensive; ceramic can fracture
Metal on metal	Lowest friction	Bad reputation as has failed in the past; metal ion release is a problem; expensive

Table 35.3 Fixation of implants

Method of fixation	Advantages	Disadvantages
Cemented	Implant does not need to fit cavity exactly; well-proven results	Cement gets hot; fragments may cause third-body wear and stimulate aseptic loosening; difficult to remove at revision; non-biological and static fixation
Uncemented	No cement needed; fixation more secure; dynamic and biological fixation	Fit must be perfect; osseous integration does not always work; expensive

Table 35.4 Surgical approaches to the hip

Surgical approach	Anatomical interval and muscle
Posterior	Along the fibres of the gluteus maximus
Anterolateral/Harding	Parts of the gluteus medius and minimus are reflected off the greater trochanter
Anterior	Interval is developed between the sartorius and rectus femoris and the tensor fascia lata
Trochanteric	A trochanteric osteotomy is required

advantages and disadvantages and the description of each approach is beyond the scope of this chapter; however, the kind of approach used by any surgeon eventually depends on training and experience. There is also a move towards minimally invasive surgery and shortening the size of the incision. The proponents of this concept have described a two-incision approach wherein the femoral component is inserted via a small incision around the greater trochanter and the acetabular component via an incision in the groin. Although the concept is attractive no long-term benefits have been conclusively shown over the conventional technique. Eventually, whichever approach is taken, it is essential to be able to implant a prosthesis that has the correct offset, a correct centre of rotation, the correct component orientation and which equalises leg lengths and is able to relieve the patient's symptoms.

The preoperative preparation of the patient is covered in Chapter 13. The postoperative course involves a 5- to 7-day stay in hospital where the patient is encouraged to mobilise independently. Before discharge, the occupational therapist assesses the patient's home and arranges for any modifications that may be required to assist the patient, e.g. a raised toilet seat. Following discharge, physiotherapy is continued for a period of 6–8 weeks and the patient is advised to continue their own exercises subsequently. The clips/sutures are removed 2 weeks following discharge. The patient is advised to wear thromboembolic deterrent (TED) stockings and continue with oral anticoagulation for 6 weeks following surgery. Follow-up visits are arranged at 6 weeks, 3 months, 6 months and then yearly post-surgery. Although hip replacement is a fairly successful and safe procedure, it does have associated complications. A comprehensive list of complications is given in Summary box 35.9.

**Figure 35.9** Dislocation of the hip.**Summary box 35.9****Complications of total hip replacement***Intraoperative complications*

- Nerve injury – sciatic, femoral and obturator
- Vascular injury – femoral vein and artery
- Femoral fracture

Postoperative complications

- Deep vein thrombosis and pulmonary embolism
- Infection
- Dislocation (Fig. 35.9)
- Leg length inequality
- Heterotopic ossification
- Implant loosening

Revision total hip replacement

Revision of a total hip replacement is required if the patient is symptomatic secondary to implant loosening (Fig. 35.10), recurrent dislocations or a periprosthetic fracture. Loosening of the implant can occur because of an infection or as a result of aseptic osteolysis caused by an inflammatory response secondary to particle wear.

In the initial stages of loosening the patient complains of pain, which is experienced mainly on weight-bearing. A history of infection in the immediate postoperative period may suggest infection as a cause of implant loosening. The patient should be investigated with a full blood count, an evaluation of erythrocyte sedimentation rate and C-reactive protein, appropriate radiography, a radioisotope scan and a synovial fluid and tissue biopsy to determine whether the loosening is secondary to an infection.

**Figure 35.10** Acetabular loosening.

Once the definitive diagnosis has been made, a revision is planned. If the loosening is secondary to infection, a two-staged revision is usually preferred. The first stage consists of removal of the native implant, a thorough debridement and implantation of an antibiotic-loaded cement spacer with institution of appropriate antibiotics for a period of 6 weeks or more. Following this a second-stage procedure, which involves removal of the cement spacer and implantation of the new prosthesis, is performed.

In the case of aseptic loosening, revision is performed as a single-stage procedure. If there has been a significant amount of bone loss, bone grafting may be required and the patient should be advised of this preoperatively. The results following a revision hip replacement are not as good as those following a primary total hip replacement and the rate of complications, especially dislocation, is also higher.

THE KNEE

Applied anatomy

The knee joint is a complex hinge joint formerly described as *ginglymus* (meaning hinge). The joint is inherently unstable because of its articular morphology but stability is provided by a number of ligaments that hold the joint together and form the static stabilisers. The muscles acting across the joint form the dynamic stabilisers.

The medial and lateral menisci are fibrocartilagenous structures that help in deepening the joint surface and also aid shock absorption (Fig. 35.11).

The medial and the lateral collateral ligaments prevent trans-

lation in the mediolateral plane. The medial collateral ligament is a broad, flat, membranous band situated near the posterior aspect, which is attached to the medial condyle of the femur superiorly and to the medial condyle and the medial surface of the tibia inferiorly. The ligament is composed of a superficial and a deep layer, the deep layer being intimately adherent to the medial meniscus. The fibular or the lateral collateral ligament, on the other hand, is a rounded, fibrous, cord-like structure, which is attached to the lateral femoral condyle superiorly and to the head of the fibula inferiorly.

The cruciate ligaments are situated in the centre of the joint, nearer to the posterior than the anterior surface. The anterior cruciate ligament is attached to the tibial spine and passes upwards, backwards and laterally to attach to the medial and posterior aspect of the lateral femoral condyle. Its primary function is to prevent anterior translation of the tibia on the femur. The posterior cruciate ligament arises from the posterior aspect of the tibia and passes upwards, forwards and medially to insert on the anterior aspect of the medial femoral condyle. Its main function is to prevent posterior translation of the femur on the tibia.

The joint is covered by a synovial membrane throughout and has a number of bursae surrounding it, which are frequently the focus of inflammation and infection.

The dynamic stabilisers of the knee joint consist of the quadriceps femoris crossing it anteriorly; the biceps femoris and popliteus laterally; the sartorius, gracilis, semitendinosus and semimembranosus medially; and the popliteus posteriorly (Summary box 35.10).

Summary box 35.10

Anatomy of the knee joint

- The joint is a complex hinge joint
- It is inherently unstable because of its articular and bony anatomy
- Stability is provided by static and dynamic stabilisers
- Static stabilisers include the capsule, the menisci, the collateral ligaments and the cruciate ligaments
- Dynamic stabilisers consist of the muscles crossing the joint

Figure 35.11 Anatomy of the knee joint.

Ginglymus from the Greek *giglymos*, a hinge.

Biomechanics

Axes of the lower limb

The anatomical axes of the femur and tibia are along their respective shafts. However, the mechanical axis of the lower limb runs from the centre of the femoral head to the centre of the ankle. It passes just medial to the medial tibial spine in the knee. The anatomical axis of the lower limb is in 6° valgus compared with the mechanical axis. It is important to understand this concept because, when replacing the knee, the aim is to recreate the correct mechanical axis and not the anatomical axis (Fig. 35.12).

Kinematics and kinetics

The knee joint allows movement mainly in one plane, i.e. sagittal with a limited amount of rotation, which varies with the degree of flexion. As the flexion increases, so does the range of rotation. Normal range of movement is between 10° of hyperextension and 130° of flexion. Kinematic studies reveal that movement about the knee joint is a complex combination of rolling and sliding; in

Figure 35.12 Axes of the lower limb. Anatomical and mechanical axes are coincident. Adapted from Miller, M. *Review of Orthopaedics*, 4th edn. 2004, Elsevier, Philadelphia. By kind permission of the publishers.

addition, the femur internally rotates around the larger medial femoral condyle during the last 15° of extension.

Kinetic analysis reveals that loads as high as three times body weight are transmitted while level walking, and up to four times body weight while climbing stairs. The patella, apart from protecting the knee joint during injury, also helps in extension; it increases the lever arm and aids in load distribution. It has a thick articular cartilage that is designed to bear loads of up to seven times body weight while squatting and jogging. While descending stairs the compressive forces between the patella and femur are in the range of two to three times body weight (Summary box 35.11).

Summary box 35.11

Biomechanics of the knee joint

- The anatomical axis of the lower limb is 6° valgus to the mechanical axis
- The main range of movement of the knee joint is in the sagittal plane with minimal rotation, which increases as the flexion increases
- Three to four times body weight is transmitted via the knee while level walking and climbing stairs
- The patella has the thickest articular cartilage and loads as high as seven times body weight are transmitted while squatting or jogging

Conditions affecting the knee joint

The pathology of the knee joint secondary to trauma, in sporting injuries and in the paediatric age group is covered in Chapters 27, 32 and 38 respectively. This section deals with acquired pathology in the adult.

Osteoarthritis of the knee

The knee is one of the most common joints to be affected by osteoarthritis and the incidence is higher in women than in men. At least 3% of women over the age of 75 years are affected by the

disease. Secondary osteoarthritis in the knee may occur because of a previous fracture, a neuropathic joint, osteonecrosis or a previous meniscectomy. Primary osteoarthritis of the knee, as in the hip, is due to a multitude of causes and is therefore termed idiopathic.

Clinical features and investigations

Most patients present with pain that is fairly well localised to the compartment involved. In the initial stages of the disease the pain is related to activity but as the disease progresses the pain changes to a constant ache that can disturb the patient's sleep as well. Pain also occurs on changing position, i.e. getting up from a sitting position, and can be severe on weight-bearing. The patient's walking speed and distance are markedly reduced and climbing stairs can be cumbersome.

Clinical examination reveals that the patient has an antalgic gait and uses a walking aid. Examination of the knee per se may reveal a varus or a valgus deformity with a swelling. A varus deformity seems to occur more frequently in the osteoarthritic knee whereas the valgus deformity is a constant feature of the rheumatoid knee. The range of movement, especially extension, is restricted and the knee may be unstable in the sagittal or coronal plane. Crepitus is felt throughout the range of movement. It is essential to assess the distal pulses in these patients because of the higher incidence of peripheral vascular disease in this age group.

Weight-bearing AP and lateral radiographs along with a view of the patellofemoral joint should be obtained. The radiographs reveal joint-space narrowing, subchondral sclerosis, subchondral cysts and osteophytes (Fig. 35.13). In advanced stages, lateral subluxation of the tibial plateau on the femur may also be seen.

Treatment

Conservative treatment is commenced with advice on modification of lifestyle, losing weight and exercising to improve the quadriceps. Protective weight-bearing (walking aids) and using knee braces can be beneficial in relieving pain. Non-steroidal anti-inflammatories are helpful in reducing inflammation in acute stages and glucosamine sulphate has also been found to be useful in improving symptoms.

If conservative treatment fails then surgery must be considered. Surgical options include an arthroscopy if the patient complains of pain in a specific compartment secondary to a degenerate meniscal tear, an osteotomy, an arthrodesis, or a total

Figure 35.13 Osteoarthritis of the knee.

or unicompartmental knee replacement; the basis behind each of the above-mentioned surgical options is discussed in Surgical procedures, below (Summary box 35.12).

Summary box 35.12

Osteoarthritis of the knee

- More common in elderly women
- Activity-related pain is the initial symptom
- Clinical examination reveals a deformity with restriction in range of movement
- Radiographs show joint-space narrowing, subchondral cysts and sclerosis, and osteophytes
- Treatment is conservative in the initial stages followed by a joint replacement in the end-stage of the disease process

Surgical procedures

Arthroscopy of the knee

Arthroscopy of the knee has a well-established place in the diagnosis and treatment of cartilage, meniscal and ligament injuries. However, it should be noted that arthroscopy is not a substitute for a good clinical examination; the importance of getting a thorough history and eliciting appropriate clinical signs cannot be overemphasised.

The most common indications for performing an arthroscopy of the knee joint are summarised in Summary box 35.13.

Summary box 35.13

Indications for arthroscopy of the knee joint

- Meniscal tear – for repair or resection
- Anterior and posterior cruciate ligament tears – for reconstruction
- Loose bodies – for removal
- Osteochondritis dissecans
- Septic arthritis – for debridement and washout
- Inflammatory arthritis – for assessment of the joint and occasionally synovectomy
- Osteoarthritis – for assessment, resection of degenerate tears of the meniscus and a washout
- Diagnosis of unexplained knee pain; also offers the possibility of obtaining a synovial biopsy
- Tibial plateau fractures; allows intraoperative assessment of the articular surface while fixing these difficult fractures

Osteotomies about the knee

Degenerative arthritis can lead to varus or valgus deformities in the knee joint. This leads to an imbalance in the stresses exerted on the affected compartment, which further predisposes to acceleration of degenerative changes in that compartment. In this situation, the goal of an osteotomy is to redistribute the forces equally, thereby unloading the involved compartment by correcting the deformity.

The ideal patient for an osteotomy is a well-motivated young adult who is not overweight, who has disease limited to a single compartment and who has a good preoperative range of movement.

The osteotomies commonly performed are a closing-wedge high tibial osteotomy on the lateral side or an opening-wedge tibial osteotomy on the medial side for a varus knee. For the valgus knee, if the deformity is mild, correction can be achieved

by a varus-producing osteotomy on the tibial side; if the deformity is larger, e.g. more than 12–15°, a supracondylar osteotomy is essential on the femoral side.

Arthrodesis of the knee

Arthrodesis of the knee is reserved for a neuropathic joint; as a salvage procedure for an infected joint following a total knee replacement or septic arthritis; for traumatic arthritis in a young patient; or for malignant lesions affecting the knee joint. However, in clinical practice the most common indication is a failed total knee replacement.

Arthrodesis can be achieved by the intramedullary method using a long intramedullary nail or via an extramedullary method using external fixation and compression. The final preferred position of an arthrodesed knee is about 5–8° of valgus, 0–10° of external rotation and 10–15° of flexion to allow clearance of the foot while walking.

Total knee replacement

The rapid rise in the number of total hip replacements has been followed by a similar rise in the number of total knee replacements as this operation is now found to have a similar success rate to that of a total hip replacement. In the knee, the medial compartment (the load-bearing part of the joint) seems to be particularly susceptible to osteoarthritis in old age. In rheumatoid arthritis the lateral compartment of the knee is more commonly affected. In all cases, the patellofemoral and the opposite tibiofemoral compartment eventually become involved, producing the end-stage of tricompartmental disease.

The goals of a total knee replacement are to alleviate pain and correct deformity. The principles of an ideal joint replacement remain the same as in the hip; however, the design features are significantly different in the knee compared with the hip.

In its simplest form, the knee replacement can be considered as a resurfacing procedure, in which the articular surfaces of the tibia and the femur are replaced with metal and the menisci are replaced by a polyethylene insert (Fig. 35.14). The natural knee joint is not congruent (one surface does not fit within the other). Therefore, to obtain stability the artificial knee joint needs to be restrained. If an artificial knee is completely restrained, e.g. a hinge knee, then the translational loads that occur within the knee on movement are transmitted directly to the implant–bone interface and this results in early loosening. On the other hand, if the artificial knee is only partially restrained by making the tibial component slightly concave, then the femoral component slides as well as rolls on the tibial component. This allows the normal movements to occur within the joint but creates point loading (high stresses at a specific point) at the tibiofemoral joint surface. Most of the condylar knee replacements on the market are currently of the latter design; however, it is a compromise in trying to create as much congruency as possible (to spread the load) with as much freedom of movement as possible (to minimise implant–bone interface loading).

Technically, the goals of a knee replacement are to achieve the correct mechanical alignment, a good balance of the collateral ligaments and the correct position of the joint line, and to ensure that the patella tracks appropriately over the femoral condyle. In the context of the balancing of the collateral ligaments it is essential to understand the concept behind the development of contractures and deformity. Degenerative changes in the knee joint lead to constant overloading of one compartment and this in turn

Figure 35.14 Total knee replacement.

causes the collateral ligament on that side to contract and on the other side to stretch. This eventually leads to the production of a varus or a valgus deformity. Therefore, the collateral ligaments need to be preserved and then released on the contracted side to allow balancing so that both the ligaments are in equal tension and length throughout the range of movement (Summary box 35.14).

Summary box 35.14

Technical goals of a total knee replacement

- Correct mechanical alignment
- Correct positioning of the joint line
- Accurate collateral ligament balancing
- Good patellar tracking over the femoral condyle

Surgical exposure involves a midline vertical incision centred over the knee and, subsequently, a medial parapatellar incision to expose the joint. Rarely, a subvastus approach is used because it offers the advantage of preserving the quadriceps and theoretically the possibility of a quicker recovery. However, as in the hip, whichever approach is used it is essential to be able to perform a knee replacement safely and achieve the technical goals of a well-positioned and a well-aligned knee.

The postoperative period is centred on building up the quadriceps and in the early phase the patient is encouraged to do an

active straight leg raise. This is followed by an intensive course of physiotherapy for 6 weeks to 3 months to strengthen the quadriceps and achieve full extension. The patient should be assessed at 6 weeks, 3 months, 6 months, 1 year and yearly thereafter following surgery.

Complications

Complications following a total knee replacement can be related to the patient, the operation or the rehabilitation period. As in the hip they can be divided into intraoperative and postoperative complications (Summary box 35.15).

Summary box 35.15

Complications of total knee replacement

Intraoperative complications

- Neurovascular injury
- Tibial or femoral fracture
- Malalignment
- Tourniquet injury – neurovascular

Postoperative complications

- Infection
- Thromboembolism
- Osteolysis and loosening
- Instability due to inappropriate ligament balancing
- Stiffness
- Chronic pain – complex regional pain syndrome

Unicompartmental knee replacement

The natural history of osteoarthritis of the knee shows that the disease starts in the medial compartment in 92% of cases and then progresses into the other compartments. This was the basis for the development of the unicompartmental knee replacement. In its current form, both the fixed- and mobile-bearing options are available and the results reported in most series are good at 10 years (Fig. 35.15).

The ideal candidate for a unicompartmental knee replacement is a patient who is over 60 years of age, not physically active, not obese and who has disease limited to one compartment with not more than 15° of deformity (which is correctable) and no instability.

The operation is performed via a 5–7 cm incision and the quadriceps is preserved. The patient is usually discharged earlier than with a total knee replacement. It is a conservative procedure as it allows bone stock to be preserved and, should it fail, a total knee replacement can still be performed with good results.

Revision total knee replacement

The main causes for revision in the knee are implant loosening secondary to infection or polyethylene wear leading to osteolysis. Other causes include a periprosthetic fracture, maltracking of the patella, malalignment (Fig. 35.16a) and ligament instability. Tibial component loosening is more common than femoral component.

The patient should be assessed thoroughly for ligament instability as the choice of implant depends upon the integrity of the collateral ligaments. If the collateral ligaments are non-functional a constrained implant is necessary. Also, as in the hip, it is of paramount importance to investigate whether the loosening is secondary to infection because a two-staged approach may

Figure 35.15 Unicompartmental knee replacement.

be warranted in such cases. Finally, like the primary total knee replacement, the goals of a revision total knee replacement are to implant a well-aligned, well-balanced and stable knee (Fig. 35.16b and c).

Foot and ankle

LEARNING OBJECTIVES

To understand:

- The common problems affecting the foot and ankle in each age group
- The basic anatomy and biomechanics of the foot and ankle
- The principles behind the treatment of each condition, be it conservative or surgical
- The significance of progressive neurological diseases
- The advances in the management of disorders of the foot and ankle and that modern surgical practice is still evolving

INTRODUCTION

All foot conditions are congenital, developmental or acquired. Foot and ankle disorders fall into two broad categories: those that affect the paediatric population and those that affect adults.

ANATOMY

There are 26 main bones in the foot (seven tarsal bones, five metatarsals and 14 phalanges) plus the two sesamoids of the hallux and a variable number of other sesamoid and accessory bones.

Movements at the ankle joint are mainly dorsiflexion and plantarflexion but, because the talus is wider anteriorly than posteriorly, dorsiflexion of the ankle leads to external rotation of the fibula at the syndesmosis. This means that the foot externally rotates with dorsiflexion and internally rotates with plantarflexion.

Stability is conferred upon the ankle by the shape of the medial, lateral and posterior malleoli and the integrity of the medial and lateral ligaments and the inferior tibiofibular ligaments.

The subtalar joint is divided into anterior, middle and posterior facets and, along with the talonavicular and calcaneocuboid joints, makes up the triple joint complex. These joints are responsible for inversion and eversion of the hind and midfoot with most of the movement occurring at the talonavicular joint.

The second tarsometatarsal joint is recessed relative to the first and third and acts as a 'keystone'. Disruption of this joint (Lisfranc's injury) leads to loss of the transverse arch and an acquired flat foot.

Jacques Lisfranc, 1790–1847, Professor of Surgery and Operative Medicine, Paris, France.

The lower leg is divided into four compartments:

- the superficial posterior – gastrocnemius, soleus and plantaris;
- the deep posterior – tibialis posterior, flexor digitorum longus and flexor hallucis longus;
- the lateral – peroneus brevis and peroneus longus;
- the anterior – tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius.

There is only one muscle on the dorsum of the foot, the extensor digitorum brevis. The muscles on the plantar aspect of the foot are divided into four layers, the first being the most superficial. The plantar fascia is a very important structure that takes its origin from the heel and inserts into the bases of the proximal phalanges of the toes. At toe-off, the fascia tightens and accentuates the medial plantar arch and helps provide a rigid lever arm, the so-called 'windlass mechanism'.

The blood supply of the foot is from the anterior tibial, the posterior tibial and the peroneal arteries. The following nerves supply sensation to the foot: posterior tibial, saphenous, sural, superficial and deep peroneal (Fig. 36.1) (Summary box 36.1).

Summary box 36.1

Anatomy of the foot

- There are 26 major bones in the foot
- There are four layers of muscles in the sole of the foot
- The blood supply of the foot is from the anterior and posterior tibial arteries plus the peroneal artery

BIOMECHANICS

The human foot has evolved to allow orthograde bipedal locomotion (upright walking); it is adapted for walking, running and jumping as well as standing. During walking there are vertical,

Figure 36.1 Cutaneous nerve supply of the foot. Courtesy of Bartleby.com.

horizontal and lateral body displacements. The forces that act on the human body are those created by muscular activity and gravity.

During walking the centre of pressure moves from the heel to the metatarsal area and then the great toe and the pressure pattern can be measured using a force plate.

The walking cycle is divided into the stance (62%) and swing (38%) phases. The stance phase is divided into three intervals: (1) heel strike to foot flat; (2) foot flat until the body passes over the ankle; and (3) ankle joint plantarflexion to toe-off. During walking up to 12% of the gait cycle is spent with both feet in the stance phase but with running there is a period when neither foot is in contact with the ground, the 'float' phase. During running the cycle time is shortened but the forces generated are very much increased.

Some confusion surrounds the terminology used to describe foot motion. Plantar- and dorsiflexion are movements in the sagittal plane. Inversion is tilting of the plantar surface of the foot towards the midline and eversion is the opposite movement. Adduction is movement of the foot towards the midline in the transverse plane and abduction is away from the midline. Supination is a combination of adduction, inversion and plantarflexion and pronation is the opposite movement, i.e. abduction, eversion and dorsiflexion. The subtalar joint moves around a single inclined axis. The flatter the foot the more horizontal the axis and the greater the supinatory/pronatory forces applied to the foot. In such individuals the forces on the tibialis posterior tendon are increased and the tendon is prone to dysfunction. The transverse tarsal (talonavicular and calcaneocuboid) joints are parallel and therefore more flexible with the heel everted, and non-parallel and therefore 'locked' when inverted. At heel strike the heel is everted thus allowing the foot to accommodate to the terrain encountered but, at toe-off, the heel is inverted, thereby providing a rigid lever for propulsion. It is worth remembering that isolated fusion of the talonavicular joint leads to loss of 90% of motion in the triple joint complex whereas a calcaneocuboid joint fusion only abolishes 30% of inversion/eversion (Summary box 36.2).

Summary box 36.2

Biomechanics

- Human walking is known as orthograde bipedal locomotion
- The gait cycle is divided into swing and stance phases
- Running generates increased forces, shortens the gait cycle and has a float phase when neither foot touches the ground

PAEDIATRIC CONDITIONS

Congenital talipes equinovarus (Fig. 36.2)

This deformity (clubfoot), with characteristic equinus and varus positioning of the foot, is apparent at birth. Associated conditions (e.g. arthrogryposis, myelomeningocele) must be excluded. The condition is more prevalent in boys and affects 1:1000 live births. Both limbs are affected in up to 50% of cases. The relationship of the talus to the calcaneus is abnormal and, in addition, the talus is smaller than usual.

It is essential that both treating physician and parents understand that the limb will never be normal – even after successful treatment the foot remains small with underdeveloped calf musculature. The aim of treatment is to achieve a plantigrade foot that is both stable and painless. Better understanding of the pathology has allowed manipulative techniques, combined with appropriate Achilles tendon lengthening, to achieve these goals

Figure 36.2 Clubfoot.

Achilles, the Greek hero, was the son of Peleus and Thetis. When he was a child his mother dipped him in the Styx, one of the rivers of the Underworld, so that he should be invulnerable in battle. The heel by which she held him did not get wet, and was, therefore, not protected. Achilles died from a wound in the heel, which he received at the siege of Troy.

without the need for major soft tissue release (the Ponseti technique). Surgery is best undertaken before 1 year of age. Sequential release of tendons, ligaments and joint capsules allows reduction of the deformity. A long posteromedial (Turco) or circumferential (Cincinnati) incision can be used. Talonavicular reduction is held with temporary K-wire fixation and serial below-knee casts.

Undercorrected residual or relapsed clubfoot

In older children who may or may not already have had surgery, a combination of osteotomies, tendon transfers and soft-tissue release is required. Some centres report encouraging results using circular external fixation.

Metatarsus adductus

The forefoot is medially deviated on the hindfoot. A variety of other terms (metatarsus varus, skewfoot) are used to describe the spectrum of this condition.

In most cases manipulative treatment taught to the parents is sufficient. Splintage at night with straight-last shoes aids the maintenance of correction. Only rarely is surgery required. Soft-tissue release of the abductor hallucis muscle and shortening osteotomy of the cuboid is one of several surgical techniques described.

Calcaneovalgus foot

This positional deformity in which the ankle joint is excessively dorsiflexed will correct with manipulative treatment. Splintage with serial casting may be required for more rigid cases, but consideration should first be given to alternative diagnoses, such as congenital vertical talus or a neurological abnormality.

Cavus foot

See Pes cavus.

Flat foot

The key to successful management is to differentiate between idiopathic flexible flat foot (requiring no treatment) and flat foot associated with an underlying abnormality.

Rigid flat foot

Congenital vertical talus gives the foot a characteristic rocker-bottom shape. The head of the talus is palpable in the sole of the foot. There is dorsolateral dislocation of the navicular. Treatment options include serial casting or surgery. The latter often needs to include more than a soft-tissue release to achieve reduction of the joint.

Tarsal coalition

In this condition there is incomplete separation of the developing bones in the hindfoot. The most common coalitions are talocalcaneal and calcaneonavicular (Fig. 36.3). The coalition may be bony, cartilaginous or fibrous. Pain with activity is the usual presenting complaint.

Martin Kirschner, 1879–1942, Professor of Surgery, Heidelberg, Germany introduced the use of skeletal wires in 1909.

Figure 36.3 Tarsal coalition (talocalcaneal).

Commonly, the medial longitudinal arch is of low height and the heel is in valgus. If these features do not correct when the child stands on tiptoe then the deformity is not correctable (i.e. the Windlass test is negative). Plain radiographs and axial imaging determine the pathology.

Activity modification or casting may allow symptoms to settle. Surgery to excise the coalition has better results in children than in young adults. Fusion of the affected joint reliably relieves pain in older patients or if excision is not successful.

Other causes

The subtalar joint may be the first joint involved in rheumatoid arthritis (RA). Rare causes of hindfoot pain include osteomyelitis, fracture or bone tumour. All may present with pain and a flat foot deformity.

Flexible flat foot

Most flexible flat feet are painless and require no treatment. Orthotics have been shown to be of no long-term benefit. In rare painful cases the synchondrosis between the secondary ossification centre of the navicular and the main body of the bone may be the cause. Treatment should be symptomatic for as long as possible, in the expectation that the pain will resolve at skeletal maturity. Surgical treatment for recalcitrant cases aims to fuse the synchondrosis or remove the accessory ossicle.

Hallux valgus

Surgical treatment is best reserved until skeletal maturity. Congruent joints must be identified and the distal metatarsal articular angle corrected without producing joint subluxation (see Pathology in the adult, Hallux valgus, below).

Cerebral palsy

Ankle and foot disorders in patients with cerebral palsy evolve as the muscle balance changes, even though the central nervous system lesion is non-progressive. For non-ambulatory patients, splintage using an ankle/foot orthosis (AFO) to maintain the foot in a plantigrade position and stretch the tight calf is a safe and helpful treatment. In ambulatory patients, surgery to lengthen the Achilles tendon should not be undertaken in isolation without assessment of the knees and hips because of the possibility of causing a deterioration in the ability to walk.

Traumatic conditions

Transitional fractures of the ankle

Paediatric ankle fractures include a small sub-group that requires careful assessment and treatment. The distal tibial growth plate closes in a predictable pattern and children who injure their ankles during this period of maturation may have either a Tillaux fracture or a Triplane fracture (Fig. 36.4). In the former injury the anterior tibiofibular ligament causes avulsion of the anterolateral tibial epiphysis. The fracture is intra-articular. In a Triplane injury the fracture line forms a complex appearance, best appreciated with computerised tomography (CT). Treatment of displaced fractures is by accurate reduction and internal fixation.

PATHOLOGY IN THE ADULT

The forefoot

Hallux valgus

Hallux valgus is deviation of the big toe away from the midline, i.e. towards the lesser toes, and is usually associated with a bunion, an erythematous swelling on the medial aspect of the first metatarsal head (Fig. 36.5). It is a common condition that affects mainly shod populations, women more than men, and which is often bilateral. It is believed that the tendency to hallux valgus is inherited and that closed-in shoes accelerate the development of the condition. Other factors that predispose to the development of hallux valgus include:

- metatarsus primus varus;
- hypermobility of the first metatarsocuneiform joint (less common);
- a round metatarsal head as opposed to a flat head.

Paul Jules Tillaux, 1834–1904, Professor of Surgery, Paris, France.

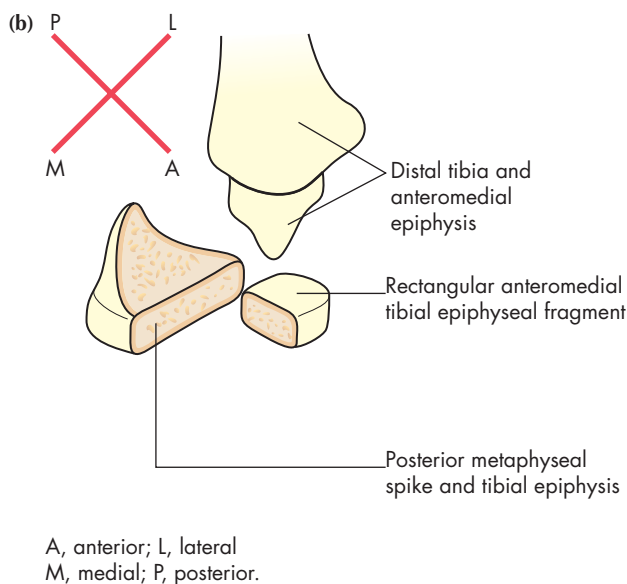

Figure 36.4 Triplane fracture.

Hallux valgus can occur as a result of trauma and will often follow amputation of the second toe. Joint hyperelasticity (e.g. Ehlers–Danlos syndrome) and anything that leads to attenuation of the medial capsule can give rise to the deformity. With increasing deformity the first ray becomes defunctioned, and overload of the second metatarsophalangeal (MTP) joint results in pain and swelling and eventually hammering of the second toe.

When examining a patient the following should be documented:

- extent of valgus deformity;
- range of motion;
- pronation of hallux;
- second toe deformity/MTP joint tenderness;
- medial arch height;
- any other foot deformity.

Edvard Ehlers, 1863–1937, Professor of Clinical Dermatology, Copenhagen, Denmark, described this condition in 1901.
Henri Alexandre Danlos, 1844–1912, Dermatologist, Hôpital St. Louis, Paris, France, gave his account of this condition in 1908.

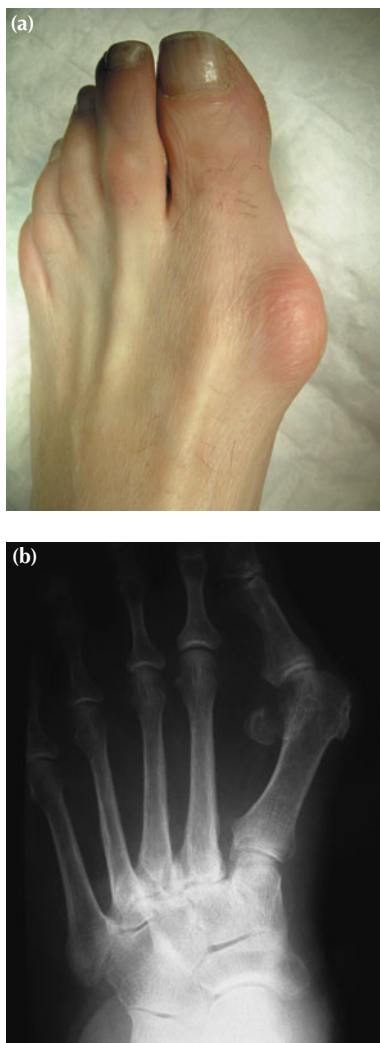

Figure 36.5 Hallux valgus and bunion.

Hallux valgus is classified as follows:

- mild [hallux valgus angle (HVA) $< 20^\circ$];
- moderate (HVA $20\text{--}40^\circ$);
- severe (HVA $> 40^\circ$) (Fig. 36.6).

The only investigations required are weight-bearing anteroposterior and lateral radiographs of the foot and a non-weight-bearing oblique radiograph if there are lesser toe issues.

The decision-making process regarding management is not straightforward. The options are, however, simple: do nothing, modify footwear or carry out surgery. The problem with footwear modification is that it often involves providing a shoe with a wide and deep toe box, which is unacceptable to many. Operating for purely cosmetic reasons is difficult to justify but, if a young patient has a significant deformity, it is likely that the deformity will worsen. Surgery is therefore recommended for those patients with significant pain and/or significant deformity, providing that they understand the risks involved, the importance of following post-operative instructions and the fact that it takes 6–12 months to make a full recovery.

The more deformed the foot, the more technically demanding the surgery. For mild deformities a distal osteotomy (e.g. chevron) is usually adequate. For moderate deformities the surgeon is more

Figure 36.6 Diagram of hallux valgus angles.

likely to use a shaft (e.g. Scarf, Fig. 36.7) or a basal (proximal chevron or crescentic) osteotomy. Severe deformities can be corrected by shaft and basal osteotomies but sometimes a fusion of the first tarsometatarsal joint (modified Lapidus) or a first MTP joint fusion can be effective. Operations such as a Keller's excision arthroplasty should no longer be performed now that more 'anatomical' procedures are available.

The prognosis without surgery is usually a slow progression of the deformity over many years. Surgery should produce 90% satisfaction rates, especially if patients are properly informed as to what they might expect. The complications of surgery are infection, cutaneous nerve damage, recurrence/overcorrection of deformity, stiffness and overload of the second MTP joint (transfer lesion) (Summary box 36.3).

Summary box 36.3

Hallux valgus

- Bunions affect women more than men
- Patients with hallux valgus have inherited a tendency to develop the condition
- Not all patients need surgery
- The choice of operation is determined by the severity of the deformity

William Lordan Keller, 1874–1959, Head of the Department of Surgery, the Walter Reed Hospital, Washington, DC, USA, described this operation in 1904.

Figure 36.7 Pre- (a) and postoperative (b) radiographs of a Scarf osteotomy.

Hallux rigidus

Hallux rigidus is a painful condition of the hallux MTP joint characterised by loss of motion and osteophyte formation (Fig. 36.8). Hallux limitus is a term that is synonymous with this condition but which implies restriction in terms of movement. It is a common condition in adults. There is also a juvenile form that is associated with excessive length of the first metatarsal and/or an osteochondral lesion of the first metatarsal head and possibly elevation of the metatarsal head (metatarsus elevatus). In adults there is often a history of trauma or repetitive microtrauma (sport) but, occasionally, there is a strong family history of the condition. It is also said to be associated with a flat metatarsal head. Patients complain of stiffness and pain on weight-bearing and certain shoes will be a lot more uncomfortable than others. Clinical examination will often reveal a dorsal swelling (dorsal bunion), joint-line tenderness and a restricted range of motion. Pain at the extreme of dorsiflexion often implies impingement of the synovium between osteophytes.

There are three grades of hallux rigidus based on subjective, objective and radiological findings. Grade I is mild and there may only be some stiffness and some dorsal spurring. Grade II is

Figure 36.8 Clinical (a) and radiographic (b) appearances of hallux rigidus.

moderate and is associated with significant pain, stiffness and moderate joint-space narrowing, whereas in Grade III there is severe pain, profound stiffness and almost complete obliteration of the joint space.

Non-operative treatment involves analgesics and/or non-steroidal anti-inflammatory drugs (NSAIDs), footwear and activity modification. A steroid injection may give short-term pain relief and physiotherapy may help a small percentage of sufferers. The most effective non-operative treatment is provision of a stiff-soled shoe with a deep toe box. This combination splints the joint and protects it from pressure.

The mainstays of surgical management are cheilectomy (from the Greek *cheilos*, for 'lip') and fusion. A cheilectomy is a radical joint debridement and resection of the dorsal 30% of the metatarsal head. It is the procedure of choice if pain is only at the extremes of motion and at least 50% of the articular cartilage remains. Fusion is for the severely affected and is an effective means of abolishing pain. It does, however, restrict the height of heel that can be worn. A fusion will still allow sports participation. Joint replacement has yet to be proven as a successful form of treatment (Summary box 36.4).

Summary box 36.4

Hallux rigidus

- Hallux rigidus can affect adolescents as well as adults
- Stiff-soled shoes with a deep toe box are the most comfortable type of shoe
- Cheilectomy and fusion are the mainstays of surgical treatment

Lesser toe deformities

Lesser toes can be the source of great misery. There are four types of lesser toe deformity (Table 36.1). Hammer toes (Fig. 36.9) result from mechanical overload whereas mallet and curly toes occur as a result of soft-tissue/muscle imbalance of non-neurological origin. These three types often affect a single digit. The fourth type, clawing, has a neurological cause, often affects all the lesser toes and needs to be appropriately investigated (Fig. 36.10).

These deformities may be flexible or fixed and symptomatic or asymptomatic. For symptomatic flexible deformities soft-tissue surgery is usually adequate but for fixed deformities bony procedures are required. Non-operative treatment involves appropriate padding and footwear modification.

Freiberg's disease (Fig. 36.11)

This condition is uncommon but affects the second metatarsal head in teenagers (girls more than boys). It is thought that it is caused by ischaemic necrosis of the epiphysis, resulting in pain and swelling of the joint. It will often settle with rest but sometimes surgery is required to tidy up the joint. Rarely, a closing wedge osteotomy of the metatarsal head is required but excision of the whole head should never be performed.

Morton's neuroma and metatarsalgia

Metatarsalgia means 'pain in the region of the metatarsals' and is as non-specific a term as 'headache'. It usually occurs secondary to joint problems or irritation of a nerve. Morton's neuroma is a painful condition that arises from compression of the common digital nerve between the third and fourth metatarsal heads (90% of cases). In 10% of cases the nerve between the second and third metatarsal heads is affected. Characteristically, the patient will only experience pain when wearing shoes and the tighter the shoe the greater the problem. The affected toes often go numb and the patient will remove the shoe and rub the foot to gain relief. Non-

Figure 36.9 Hammer toe.

Figure 36.10 Claw toes.

operative treatments include advice about footwear, an orthosis (pre-metatarsal dome) to splay the metatarsal heads or an injection of steroids for short-term relief. Surgery involves resection or transposition of the neuroma and is usually highly successful; however, the neuroma can regrow and the affected toes will

Table 36.1 Types of lesser toe deformity

Deformity	MTPJ	PIPJ	DIPJ	Comments
Hammer toe	Extended	Flexed	Extended or flexed	Associated with hallux valgus. Second toe most common
Mallet toe	Normal	Normal	Flexed	
Curly toe	Medial deviation and rotated	Medial deviation and rotated	Medial deviation and rotated	Affects third, fourth or fifth toes
Claw toe	Extended	Flexed	Flexed	Look for underlying neurological diagnosis

DIPJ, distal interphalangeal joint; MTPJ, metatarsophalangeal joint; PIPJ, proximal interphalangeal joint.

Albert Henry Freiberg, Professor of Orthopaedic Surgery, University of Cincinnati, Cincinnati, OH, USA, gave his account of this condition in 1926. Thomas George Morton, 1835–1903, Surgeon, the Pennsylvania Hospital, Philadelphia, PA, USA, described this condition in 1876.

Figure 36.11 Freiberg's disease.

be permanently numb if the nerve is removed. It is essential to distinguish between a second MTP joint synovitis (often seen in hallux valgus) and a second space neuroma (Summary box 36.5).

Summary box 36.5

Morton's neuroma

- Morton's neuroma most commonly affects the third web space
- It is important to distinguish a second space neuroma from a second MTP synovitis
- Surgical excision of a neuroma is often successful

Midfoot and hindfoot

The hindfoot comprises the ankle joint and the calcaneus. The midfoot comprises the remaining tarsal bones as far as the tarsometatarsal joints. The majority of problems affecting this part of the body relate to joint and tendon disorders. These problems can be broadly divided into mechanical/degenerative disorders and inflammatory conditions. Osteoarthritis (OA) can affect any of the joints as can inflammatory arthritides such as RA.

Degenerative joint conditions

Degenerate joints may be asymptomatic but usually present with pain, swelling and/or deformity. There may or may not be a history of trauma or repeated microtrauma. If a foot is swollen and deformed but without pain there is likely to be an underlying neuropathy. In the majority of cases pain will be the reason for the patient seeking help. On examination there is usually joint-line tenderness and it is therefore very important to be familiar with the surface anatomy of the joints of the foot. The diagnosis and the extent of any deformity are usually confirmed by plain weight-bearing radiography. Before recommending treatment it is important to assess the level of a patient's symptoms.

Non-operative treatments include analgesics, non-steroidal medication, footwear modification (including bracing), activity modification, physiotherapy and judicious usage of intra-articular steroids. One should never forget that a walking stick can also be helpful. Surgery is reserved for those patients who fail non-operative treatment.

Operative treatment for OA will usually be in the form of arthrodesis (fusion). This is normally carried out via an open approach but arthroscopic ankle arthrodesis is now an established procedure. When there is significant osteophyte formation and impingement without significant OA, osteophyte removal can be extremely effective. Osteophytes that cause impingement tend to be anterior whereas posterior impingement tends to be caused by an os trigonum. In severe OA of the ankle debridement has no role but joint replacement of the ankle (Fig. 36.12) is finally becoming a viable alternative to fusion in selected cases (low-demand patients without significant deformity).

In the past it was felt that a triple fusion should be performed when any of the joints of the triple joint complex needed fusing but it is now deemed preferable to fuse only the affected symptomatic joints.

Inflammatory joint conditions

The treatment of conditions such as RA is very similar in principle to that outlined above for OA. In RA, however, it is essential that the medical management of the condition is optimised before considering surgery. It is also important to realise that these patients often have multiple joint involvement and the postoperative period can pose major problems in terms of

Figure 36.12 Total ankle arthroplasty.

mobility. It is essential to remember that knee deformity must be addressed before corrective hindfoot surgery is undertaken (Summary box 36.6).

Summary box 36.6

Midfoot and hindfoot

- Joint disorders are degenerative or inflammatory
- The mainstay of surgical treatment remains fusion although ankle replacements are becoming more successful
- Rheumatoid arthritis must be medically controlled as well as possible before surgery

Tendon disorders

Tenosynovitis occurs as a result of injury or overuse or is secondary to inflammatory joint conditions. Rest, anti-inflammatory medication and physiotherapy are often helpful but, in inflammatory conditions, tenosynovectomy may be required.

The tendons most commonly affected by degeneration are the Achilles, tibialis posterior and peroneii (brevis more than longus). Achilles 'tendinitis' is either mid-substance or insertional (Fig. 36.13). The former will often settle with non-operative strategies and time but the insertional type often requires debridement and resection of the prominent calcaneal tuberosity. The peroneus brevis is prone to longitudinal tears and splitting, particularly in patients with high-arched feet (Fig. 36.14). Surgical repair is often necessary and quite effective.

The tibialis posterior tendon tends to fail in overweight individuals and those who have flat feet. Often, after unaccustomed exercise, the tendon swells and is painful. The diagnosis is rarely made early. Rest, splinting and anti-inflammatory medication can help in the early stages but, with time, the foot becomes flatter and the tendon ceases to work. Many individuals will require surgical treatment in the form of a medial displacement calcaneal osteotomy, flexor digitorum longus or flexor hallucis longus tendon transfer and spring ligament repair. Failure to treat this condition can lead to spectacular deformity (Fig. 36.15).

Ankle instability

Most people who sustain an ankle sprain will recover, particularly if they receive prompt physiotherapy. However, some individuals

Figure 36.13 Insertional Achilles tendinitis.

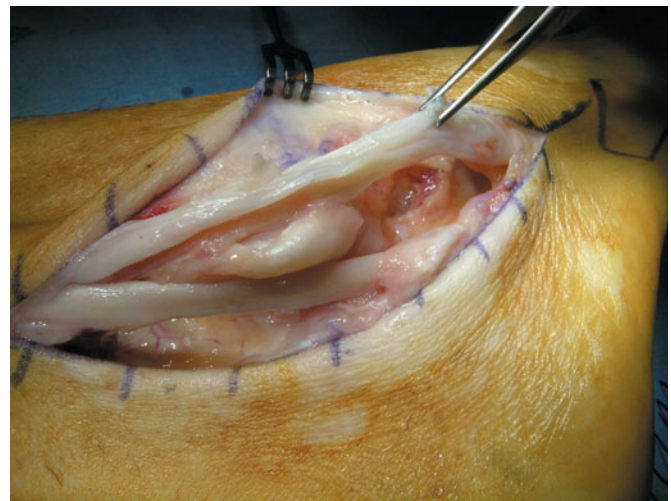

Figure 36.14 Split and degenerate peroneus brevis.

Figure 36.15 A tibialis posterior tendon-deficient foot.

develop significant instability. The frequency of episodes of giving way varies enormously with some patients suffering daily sprains. If physiotherapy is unsuccessful at resolving the problem, an anatomical reconstruction using the Brostrom method is usually curative.

Osteochondral lesions of the talus

Nearly all lateral and 70% of medial osteochondral lesions of the talus (OLTs) follow a traumatic episode. They can vary from a chondral flap to a large loose OLT (Fig. 36.16). If progress appears slow following an ankle sprain and the patient complains of a poorly localised ache within the ankle an OLT should be suspected. Diagnosis is confirmed on magnetic resonance imaging (MRI). Arthroscopic debridement is often required but is not always successful. Osteochondral autologous transplantation (OATS) from the knee, or cartilage culture and transplantation, may be considered for such cases.

Figure 36.16 Magnetic resonance imaging of an osteochondral lesion of the talus.

Pes cavus

Pes cavus sometimes presents in adults (Fig. 36.17). It is usually bilateral and most cases will be associated with an underlying neurological condition, the most common being Charcot–Marie–Tooth disease. These patients may present with recurrent ankle sprains or fifth metatarsal stress fractures. Precise diagnosis is confirmed with nerve conduction studies. Surgical correction of deformity is often required but not curative in this progressive disease. If a teenager presents with a unilateral pes cavus an underlying tethering of the spinal cord (diastematomyelia) should be suspected (Summary box 36.7).

Figure 36.17 Pes cavus.

Jean Martin Charcot, 1825–1893, Physician, La Salpêtrière, Paris, France.

Pierre Marie, 1853–1940, Neurologist, Hospice de Bicêtre, Paris, France, later becoming Professor of Pathological Anatomy in the Faculty of Medicine, and finally, in 1918, Professor of Neurology.

Howard Henry Tooth, 1856–1925, Physician, St Bartholomew's Hospital, and the National Hospital for Nervous Diseases, Queen Square, London, England, described peroneal muscular atrophy in 1886 independently of Charcot and Marie.

Summary box 36.7

Pes cavus

- Pes cavus needs neurological investigation
- About 80% of cases of pes cavus are associated with a neurological disease
- The commonest cause is Charcot–Marie–Tooth disease
- Unilateral pes cavus – think diastematomyelia

Acquired flat foot

In adults there are a number of conditions that should be considered when a foot becomes flat. Often, it is a flat foot that becomes even flatter. The causes are:

- tibialis posterior tendon dysfunction;
- tarsometatarsal arthritis/injury (Fig. 36.18);
- Charcot neuroarthropathy, e.g. diabetes;
- inflammatory/degenerative arthritis of the subtalar/talonavicular joints;
- spring ligament rupture.

Non-operative treatment is appropriate except in the acute trauma situation. Surgical intervention may be required in other cases but is rarely required in the Charcot foot unless unacceptable deformity or ulceration occurs. Patients with tibialis posterior tendon dysfunction have medial ankle pain and swelling and often have considerable difficulty performing a single heel raise (Summary box 36.8).

Summary box 36.8

Acquired flat foot

- Tibialis posterior tendon dysfunction and tarsometatarsal OA are common causes of an acquired flat foot
- Orthoses, rest and NSAIDs can help with symptomatic relief
- Surgery is a major undertaking but often highly successful at achieving symptomatic relief

Figure 36.18 Tarsometatarsal arthritis.

Tumours

Tumours can be benign or malignant. Malignant tumours of the foot are vanishingly rare but do occur. The two most common benign tumours of the foot are ganglia and angioleiomyomas (Fig. 36.19); these tumours may need surgical excision.

Infection

Septic arthritis in the foot or ankle is rare; when it occurs it usually follows a surgical procedure but it can also arise as a result of haematogenous spread. Treatment is immediate surgical drainage and administration of appropriate high-dosage antibiotics. The most common causative organism is *Staphylococcus aureus* with methicillin-resistant *S. aureus* (MRSA) becoming more prevalent. Even with prompt treatment chondrolysis often occurs and subsequent degenerative changes develop rapidly.

Osteomyelitis can be equally devastating. Prompt and appropriate management with rest and high-dosage antibiotics can successfully treat the condition. Treatment continues until the patient is afebrile, the foot quiescent and the inflammatory markers normal. Chronic osteomyelitis is treated using similar principles when a flare-up occurs but cure can only be achieved by surgical excision of the infected bone.

Foot infections are either acute or chronic and arise as a result of direct inoculation or haematogenous spread. Treatment is with rest, elevation and appropriate antibiotics but surgical debridement may be required, especially with conditions such as necrotising fasciitis (*Streptococcus pyogenes*).

In immunocompromised patients opportunistic infections can arise and, in diabetics, failure to treat with debridement can lead to amputation. It is important to realise that radiographs in the early stages of infection are usually normal and that diagnosis is made on clinical suspicion and with blood tests and more sophisticated imaging such as MRI or bone scanning.

Tuberculosis can affect the foot and is associated with major bony damage; it responds surprisingly well to debridement and appropriate anti-tuberculous therapy (Fig. 36.20).

Diabetes

Diabetics have foot problems secondary to neuropathy and microvascular changes. They are at increased risk of infection

Figure 36.19 Angioleiomyoma of the hallux.

Figure 36.20 Tuberculosis of the foot.

and ulceration, and trauma (sometimes trivial) can lead to collapse of the foot, also known as Charcot neuroarthropathy (Fig. 36.21). There are three stages (Eichenholtz) to the process of Charcot neuroarthropathy, which takes up to 18 months to run its course: stage I, fragmentation; stage II, coalescence; and stage III, bone consolidation. It is essential to distinguish between infection and neuroarthropathy; however, in the acute situation this can be difficult. Infection requires appropriate antibiotic therapy and/or surgical debridement whereas the acute Charcot foot requires appropriate splintage in a Charcot retaining orthotic walker (CROW) or a total contact cast (TCC). If there is no history of skin damage, infection is unlikely, but inflammatory markers and MRI can help differentiate between the two conditions.

Ulceration can lead to major morbidity and amputation (Fig. 36.22). Ulcers need to be treated and when ulcer healing has occurred the aim should be to keep the foot ulcer free (Summary box 36.9).

Summary box 36.9

Diabetes

Diabetics are prone to infection because of:

- Peripheral neuropathy
- Peripheral vascular disease
- Impaired resistance to infection

Entrapment neuropathies

Any nerve supplying the foot can become entrapped and result in pain, and treatment often requires surgical decompression. Tarsal tunnel syndrome is much rarer than carpal tunnel syndrome in the hand.

Heel pain

The commonest cause of heel pain is plantar fasciitis. Pain is located inferomedially within the heel and is worst first thing in the morning and after periods of rest. It often, but not always, follows unaccustomed activity in a middle-aged overweight

Figure 36.21 Charcot foot. Radiographs taken at the time of a trivial injury (a) and 6 weeks later (b).

individual. Treatment includes cortisone injection, physiotherapy, analgesics and orthoses. The majority of cases settle within 18 months and surgery is rarely required or successful.

Amputation

In orthopaedics, amputation is usually carried out for uncontrolled infection, trauma or tumour. The level of amputation is

Figure 36.22 Diabetic foot ulcer.

chosen to allow optimal wound healing and prosthetic fitting. It is carried out when the patient is clearly going to be better off without the foot (or leg).

CONCLUSION

Major advances have occurred and will continue to emerge in the subspeciality of foot and ankle surgery. As a general rule, non-operative measures should be tried before surgery is considered. Modern foot and ankle surgery has a lot to offer sufferers and most patients will do well and be satisfied if treatment is tailored to their needs and they are informed about what to reasonably expect from the treatment.

Inflammation and infection and musculoskeletal tumours

LEARNING OBJECTIVES

Inflammation and infection in bones and joints

To understand:

- Common diseases causing inflammation of the musculoskeletal system with their characteristic features in terms of history, examination, pathogenesis, investigation, treatment and prognosis
- Characteristic features in the history and examination of infection of bone and joint
- Treatment of infection of bone and joint

Musculoskeletal tumours

To understand:

- Symptoms and signs that suggest the presence of a benign or malignant musculoskeletal tumour
- Action to be taken with suspicious lesions
- Value of centres of excellence for staging, biopsy and multidisciplinary assessment
- Staging before biopsy
- Diagnosis before treatment
- Taking a biopsy
- Surgical treatment of musculoskeletal tumours
- Surgical treatment in metastatic disease, pathological fracture or impending fracture

INFLAMMATION AND INFECTION IN BONES AND JOINTS

RHEUMATOID ARTHRITIS

The commonest type of inflammatory arthritis is rheumatoid arthritis, which affects approximately 3% of women and 1% of men in Northern Europe. The prevalence is less in other areas of the world but tends to rise with urbanisation. Patients with rheumatoid arthritis are not seen represented in historical western art and literature. This suggests that it is a modern disease in Europe. However, changes characteristic of the disease are recognised in ancient Native American skeletons, leading to speculation that it originated in the New World. The disease appears to arise from a cell-mediated (T-cell) autoimmune response, but there may be an underlying infectious aetiology. Once the T-cell response is triggered, there is a release of cytokines, including interleukins IL-1 and IL-6, and tumour necrosis factor (TNF), which cause the inflammatory reaction. The disease has a predilection for small joints in the hands and feet and is usually symmetrical. However, it can involve any joint, and also affects tissues elsewhere in the body. There is inflammation of the soft tissues and synovial hyperplasia, containing lymphocytes and plasma cells. A layer of inflammatory tissue called a 'pannus' spreads over the joint surfaces and erodes the subchondral bone, denuding articular cartilage. There

is chronic mononuclear cell infiltration and neovascularisation. Rheumatoid factor (RF) is found in approximately 80% of cases of the disease (and in 1–5% of the unaffected population). The extra-articular manifestations are found in the skin, eyes, lungs, heart and kidneys. Amyloid may also arise, as well as neuritis secondary to vasculitis (Summary boxes 37.1 and 37.2).

Summary box 37.1

Rheumatoid arthritis

- Occurs in around 3% of women and 1% of men
- Caused by a cell-mediated (T-cell) autoimmune response
- Rheumatoid factor positive in 80%
- Often starts with symmetrical disease affecting small joints of the hands and feet

Summary box 37.2

Extra-articular manifestations of rheumatoid arthritis

- Skin – subcutaneous nodules
- Eyes – scleritis, iritis
- Lungs – interstitial lung disease, pleural effusion
- Heart – myocarditis
- Kidneys – nephritis
- Amyloid – lungs, kidneys, heart, bowel
- Compression and vascular neuritis

The diagnostic criteria for rheumatoid arthritis were devised by the American College of Rheumatology (1987). This involves the patient having four of the seven criteria listed in Table 37.1.

The onset is often insidious with joint stiffness and polyarthritis but may be acute in approximately 30% of patients, presenting with malaise and low-grade fever. Hands and feet are commonly affected early in the disease. On examination there are joint effusions and synovitis. These cause swelling, warmth, erythema and stiffness of the affected joints with pain on movement.

There are very characteristic patterns of disease and deformity seen in the hand and wrist. Inflammation of the tendons (tenosynovitis) commonly affects flexor and extensor tendons of the hand and wrist, producing swelling and crepitus. Eventually tendons may rupture, so that passive range of movement exceeds active. Rupture is especially common in the extensor tendons of the little finger (Figs 37.1–37.3). It is usual for the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) to be elevated (Summary box 37.3).

Summary box 37.3

Problems in the hand and wrist caused by rheumatoid arthritis

- Radial deviation of the wrist
- Extensor tendon ruptures
- Ulnar deviation metacarpophalangeal joints
- Z-deformity of the thumb
- Boutonnière deformity of the fingers
- Swan neck deformities
- Carpal tunnel syndrome

Longstanding, stable, mild cases of rheumatoid arthritis can be treated with analgesics and non-steroidal anti-inflammatory drugs (NSAIDs). However, it is now believed that the disease is best treated aggressively in its early phase before erosions and extra-articular pathology can occur. This may prevent long-term recruitment of the autoimmune cascade. The treatment is with disease-modifying anti-rheumatic drugs (DMARDs) such as methotrexate, gold, sulphasalazine/Salazopyrin, leflunomide, penicillamine and ciclosporin. The most recent development of anti-TNF drugs such as etanercept and infliximab may revolutionise treatment. Corticosteroid therapy continues to be useful,

Table 37.1 American College of Rheumatology criteria for diagnosis of rheumatoid arthritis

Morning stiffness lasting at least 1 hour
Active arthritis of three or more joints simultaneously
Active arthritis of at least one hand joint (wrist, MCPJ or PIPJ)
Symmetrical arthritis
Subcutaneous rheumatoid nodules on extensor surfaces, juxta-articular or over bony prominences
Rheumatoid factor
Radiographic changes of periarticular erosions or osteopenia in affected joints, not osteoarthritis

MCPJ, metacarpophalangeal joint; PIPJ, proximal interphalangeal joint.

Figure 37.1 Flexor pollicis longus tenosynovitis.

Figure 37.2 Swan neck deformity.

Figure 37.3 Rheumatoid wrist and hand radiograph, showing arthritis of the distal radioulnar joint, wrist with radial deviation, dislocated ulnar, deviated metacarpophalangeal joints, screw arthrodesis of the thumb interphalangeal joint and wired arthrodesis of the finger proximal interphalangeal joints.

Figure 37.4 Silvis ring worn to prevent proximal interphalangeal joints hyperextension (swan neck deformity) but allow flexion.

systemically, topically and by local injection into joints or around tendons.

Splints can be helpful to reduce pain and improve function (e.g. unstable wrist, swan neck deformity (Fig. 37.4)). They probably do not often prevent deformity. Orthotics are useful for the foot and ankle.

For the moment surgery is still very important for rheumatoid arthritis. Surgical options for joints include arthrodesis [especially for cervical spine, finger proximal interphalangeal joints (PIPJ), the wrist, ankle and hindfoot], and joint replacement (for major joints including the elbow, metacarpophalangeal joints and even the wrist). There are a few sites where excision arthroplasty is used such as the distal ulna and radial head (Figs 37.5 and 37.6).

If tenosynovitis is resistant to medical treatment, it should be treated with tenosynovectomy to prevent tendon rupture. If rupture occurs, it is treated with tendon transfer (e.g. extensor indicis proprius to ruptured extensor pollicis longus). An alternative is interposition grafting (often using palmaris longus) or arthrodesis in a functional position of the joint previously controlled by the tendon (e.g. of the thumb IPJ after flexor pollicis longus rupture; see Fig. 37.3) (Summary box 37.4).

Summary box 37.4

Surgery for rheumatoid arthritis

- Synovectomy – for inflamed joints
- Tenosynovectomy for inflamed tendon sheaths
- Arthrodesis (fusion) – finger joints (IPJs), wrist, spine, ankle and hindfoot
- Joint replacement (hip, knee, elbow, shoulder, metacarpophalangeal joints)

GOUT AND PSEUDOGOUT

Gout was first described in the fourth century by Hippocrates. Gout affects approximately 1% of the UK population, mostly men

Hippocrates was a Greek Physician, and by common consent 'The Father of Medicine'. He was born on the Greek island of Cos off Turkey about 460 BC, and probably died in 375 BC.

Figure 37.5 Anteroposterior and lateral radiographs of a rheumatoid elbow. There is significant erosion and bone loss of elbow with rheumatoid arthritis.

Figure 37.6 Radiograph of elbow with total elbow replacement.

over 40. Pseudogout affects the elderly, both men and women. There is excess urate in the blood and tissues. Over time, crystals of urate form in and around joints, causing inflammation (Fig 37.7). Renal calculi may also form.

The initial presentation is usually with a single joint affected in an acute attack. The first metatarsophalangeal joint is affected in half of first attacks. Other common sites are the small joints of the hand, wrist, elbow, mid-tarsal joints, ankle and knee. The

Figure 37.7 Gouty tophus.

larger joints and axial skeleton are rarely affected, and certainly never in the first attack. The pain develops over a few hours, often overnight. There is intense inflammation of the affected joint, with erythema, swelling and extreme tenderness; even bedclothes touching the joint cannot be tolerated. There may be fever and malaise.

Investigations should include serum urate; however, this may be lowered during an acute attack and should be measured between attacks, using two separate fasting samples. There may be a neutrophilia, and raised CRP during an acute attack. Renal function should be checked.

Definitive diagnosis rests upon demonstration under polarised light of negatively birefringent monosodium urate monohydrate crystals within the synovial fluid, obtained by joint aspiration. The synovial fluid will be turbid with a high neutrophil count.

The main differential diagnoses of acute gout are pseudogout and septic arthritis. These may co-exist, so the aspirate should also be examined with a Gram stain and cultured for organisms.

A radiograph of the affected joint is usually normal during an initial attack, but may show punched-out eccentric, asymmetrical juxta-articular erosions after repeated attacks. (Fig. 37.8) These have normal bone density around the cysts, contrasting with the ill-defined, symmetrical, marginal erosions with osteopenia seen in rheumatoid arthritis. The higher the hyperuricaemia, the worse the destruction in most cases (Fig 37.9).

Treatment of the acute attack involves pain relief with anti-inflammatories, and/or aspiration. Attempting to lower the serum urate may conversely prolong the attack – and should be avoided.

Pseudogout [calcium pyrophosphate deposition disease – (CPPD)] leads to pyrophosphate deposition within the joints. It is the most common cause of acute mono-arthropathy in the elderly and is most likely to affect the knee, wrist, shoulder or ankle. Calcium pyrophosphate shows positively birefringent crystals under polarised light. The radiograph in pyrophosphate arthropathy may show changes of osteoarthritis and calcification within the menisci of the knee, the triangular fibrocartilage on the ulnar side of the wrist, or the symphysis pubis. More rarely, there is calcification within hyaline cartilage.

Figure 37.8 Radiograph of hand and wrist with changes characteristic of gout.

Figure 37.9 Characteristic radiographic features of neglected gout in index finger (left) and thumb (right), same patient as in Fig 37.7.

THE SPONDYLOARTHROPATHIES

The spondyloarthropathies are a heterogeneous group or spectrum of disorders, including ankylosing spondylitis, reactive arthritis and psoriatic arthritis. They are associated with HLA-B27 and a negative rheumatoid factor.

Ankylosing spondylitis

Ankylosing spondylitis affects approximately 0.5% of men and 0.2% of women in the UK. This most commonly starts in the late teens, twenties or thirties. There is a strong genetic component, being associated with HLA-B27.

The disease principally affects the sacroiliac joints, axial skeleton and peripheral joints, starting with sacroiliitis. The sacroiliac

Figure 37.10 Radiograph showing sacroiliitis in ankylosing spondylitis.

Table 37.2 Radiological changes in the sacroiliac joint in ankylosing spondylitis

0	Normal
I	Minimal changes
II	Sclerosis, some erosions
III	Severe erosions, pseudodilatation of joint space, limited ankylosis
IV	Ankylosis

joint changes are classified on plain radiographs as shown in Table 37.2 and Fig. 37.10. Patients usually present with inflammatory low back and buttock pain. Over time, increasing stiffness of the spine is seen, with a flattening of the normal lumbar lordosis, and then a thoracic kyphosis. The rib cage stiffens and so lung capacity becomes limited (Figs 37.11 and 37.12). A fixed flexion deformity of the hips is common. This is compensated for by flexion of the knees, so that the patient adopts a 'question mark' posture. Enthesitis (inflammation at the insertion of tendon or ligament to bone) commonly occurs at the insertion of the Achilles tendon or the plantar fascia on the calcaneus.

Sacroiliitis can be seen very early in the disease process on magnetic resonance imaging (MRI). Ultrasound can be useful in the diagnosis of enthesitis. Plain radiography shows characteristic changes, as described above, commonly known as 'bamboo spine'.

Medical treatment with regular physiotherapy is important to maintain range of movement. Around 10% of patients require total hip replacement. Occasionally a corrective osteotomy of the kyphosis is needed to allow forward vision. The stiff spine makes patients susceptible to unstable spinal fractures.

REACTIVE ARTHRITIS (REITER'S DISEASE)

Stoll described this triad of urethritis, uveitis and arthritis in 1776, Reiter redescribing the condition much later. The condition starts

Hans Conrad Julius Reiter, 1881–1968, President of the Health Service, and Honorary Professor of Hygiene at the University of Berlin, Germany, described this disease in 1916.
Maximilian Stoll, 1742–1787, Physician, Vienna, Austria.

Figure 37.11 Lumbar spine radiographs showing 'bamboo spine' changes in ankylosing spondylitis.

with an infection as the gastrointestinal or genitourinary systems with a triggering organism, such as *Shigella* or *Chlamydia*. This is followed by a reactive synovitis and arthritis with effusion (Table 37.3). The precipitating infection may be asymptomatic, especially *Chlamydia* in women. *Yersinia* causes arthritis inversely proportional to the severity of the gastrointestinal symptoms. Patients have either an oligoarthritis or a monoarthritis, and the lower limb joints are most commonly affected. The joint is acutely inflamed with erythema, swelling/synovitis and effusion. Enthesitis is usually present in addition to the arthritis, affecting the Achilles tendon and plantar fascia insertions on the calcaneus. Sacroiliitis and dactylitis are also seen. Ocular manifestations include conjunctivitis (which has often settled

Kiyoshi Shiga, 1870–1957, a Japanese Bacteriologist, who was Dean of the Medical Faculty of the Keijo Imperial University, Chosen, Japan.

Figure 37.12 Radiograph of cervical spine in ankylosing spondylitis.

Table 37.3 Features and causes of reactive arthritis

Classic clinical features	Classic infective organisms
Asymmetrical oligoarthritis, especially lower limb	<i>Salmonella</i> <i>Campylobacter</i>
Enthesitis	<i>Yersinia</i>
Extra-articular signs, e.g. uveitis	<i>Shigella</i> <i>Chlamydia</i>

when the arthritis presents) or acute anterior uveitis. Abnormal investigations include raised ESR and particularly CRP ($> 100 \text{ mg l}^{-1}$). Assays for antinuclear antibodies and RF are negative.

Affected joints require rest and occasionally splintage. Joint aspiration is also useful for symptomatic relief. This may be followed by corticosteroid injection once septic arthritis has been excluded.

ARTHRITIS ASSOCIATED WITH PSORIASIS OR COLITIS

Psoriatic arthritis affects 5–40% of the 1–3% of people with skin psoriasis. There is a similar association with ulcerative colitis and Crohn's disease in 10–20% of patients. Radiographs show an inflammatory type of arthritis, with 'whiskering': erosive changes at the margins of joints with adjacent new bone. When severe, erosion often produces a 'pencil-in-cup' radiographic appearance (Fig 37.13). Changes in the axial skeleton are similar to those seen in ankylosing spondylitis. Appearances may resemble

Daniel Elmer Salmon, 1840–1914, Veterinary Pathologist, Chief of the Bureau of Animal Industry, Washington, DC, USA.
Alexandre Emile Jean Yersin, 1863–1943, Bacteriologist, Institute Pasteur, Paris, France.
Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Figure 37.13 'Pencil-in-cup' appearance of metacarpophalangeal joints in psoriatic arthritis.

Forestier's disease (diffuse idiopathic spinal hyperostosis; Fig 37.14). Skin therapy has no effect on arthritis. Treatment options include NSAIDs, intra-articular or paratendinous steroid injection, DMARDs (sulphasalazine, methotrexate, ciclosporin). Surgical options are similar to those described for rheumatoid arthritis.

Figure 37.14 Lumbar spine radiograph showing changes of psoriatic arthropathy.

JUVENILE RHEUMATOID ARTHRITIS

This affects mostly girls under 5. The late-onset pauciarticular type affects more boys. The systemic type often starts in children

Jacques Forestier, 1890–1978, a French Rheumatologist, described this condition in 1950.

under 5 and affects boys and girls equally. The pathophysiology is similar to that of rheumatoid arthritis but the effects are different because the bones and joints are growing. Hyperaemia can increase growth in the short term, but chronic disease may result in very small bones. Severe and longstanding disease may cause ankylosis and soft-tissue contractures. The most frequently affected joint is the knee. Other commonly affected joints are the ankle, wrist, hip and cervical spine. The pauciarticular type affects younger children. The polyarticular cases may involve several joints simultaneously or sequentially and also include tenosynovitis. While the arthritis is active, the child may feel unwell and have a low-grade pyrexia. The temporomandibular joints are very frequently extremely stiff, making anaesthesia difficult and fiberoptic intubation may be required. Surgery is generally restricted to soft-tissue releases and occasional synovectomy until cessation of growth, but joint replacement is increasingly indicated in early adult life as prostheses have become more reliable.

SYSTEMIC LUPUS ERYTHEMATOSUS

This is an autoimmune disorder that can present with symptoms and signs in almost any part of the body. The aetiology is multifactorial, including genetic, hormonal and environmental factors. There is often an effusion, but rarely synovitis. Hip pain raises suspicion of avascular necrosis (AVN) of the femoral head, a complication of systemic corticosteroid therapy. MRI gives early diagnosis. Investigations should include antinuclear antibody assay. An increase in anti-dsDNA antibody or anti-Sm antibody level is virtually specific for systemic lupus erythematosus (SLE). Surgery for SLE is less often indicated than for rheumatoid arthritis. Metacarpophalangeal joint subluxation is treated with silicone arthroplasty and soft-tissue reconstruction. Some patients benefit from interphalangeal joint arthrodesis in a functional position for severe deformities. Femoral head AVN may indicate total hip replacement (Summary box 37.5).

Summary box 37.5

Other causes of inflammatory joint disease

- Gout – deposition of urate crystals – commonly affects big toe
- Pseudo-gout – calcium pyrophosphate (birefringent crystals) – larger joints
- Ankylosing spondylitis – HLA-B27-positive – sacroiliac joints affected first
- Reactive arthritis – urethritis, uveitis and arthritis; triggered by bowel infection
- Associated arthritis – psoriasis and ulcerative colitis
- Juvenile rheumatoid arthritis – commonly starts in girls under 5
- SLE – anti-Sm antibodies diagnostic

SEPTIC ARTHRITIS

Septic arthritis occurs at any age, most commonly at the extremes of age. In adults, the immunocompromised are most at risk, including intravenous drug abusers, diabetics and sufferers of rheumatoid arthritis. Infection can arise from contamination of the joint following trauma, but it also appears possible that

bacteria can settle in the joint from a transient bacteraemia in the blood (which occurs regularly in us all) as well as from a full-blown septicaemia (blood poisoning).

The most commonly affected joints are the hip in neonates and the knee in children and adults. In around 10% of cases more than one joint is involved. The patient with acute septic arthritis usually has a short history and is sometimes very unwell, with a high pyrexia (if septicaemic). However, septic arthritis may present only with severe joint pain, and the patient may be afebrile much of the time, and then only develop a low-grade pyrexia from time to time. A high index of suspicion is required if the diagnosis is to be made quickly. One cardinal sign is that the joint is held immobile in the 'position of comfort', and there is severe pain if any attempt is made to move the affected joint actively or passively. Radiographs show no change for 7–10 days. Ultrasound scanning and guided aspiration is useful, especially for the hip in small children. Treatment of the septic joint consists of removal of pus and reduction of joint pressure as soon as possible. Intravenous antibiotics should be started immediately after samples and blood cultures have been taken. Cefuroxime is a good empirical choice until organism and/or sensitivities are identified, as it covers staphylococci and gram-negative organisms. Repeated aspiration may be needed, but if the effusion re-accumulates a safer option is to perform open arthrotomy and wash-out. The capsule is left open, and skin sutured. In the knee or shoulder an arthroscopic washout can be performed. Common infective organisms are shown in Table 37.4.

TUBERCULOUS ARTHRITIS

This had become uncommon in the UK, but was still prevalent in the developing world. There is now a resurgence in the developed world from travel, immigration, more immunocompromised/elderly patients and drug addicts. The usual organism is *Mycobacterium tuberculosis*, 3–5% of cases affect the skeleton, half in the spine. It presents with a chronic history, usually from haematogenous spread. Osseous tuberculosis affects the metaphysis or subchondral bone. If host resistance is poor, destruction extends along and out of the bone. A 'cold abscess' (not inflamed) or fistula may form. Spinal involvement is commonly paradiscal, but vertebral, anterior or posterior infections or 'skip

Table 37.4 Organisms most commonly involved in bone and joint infections

<i>Staphylococcus aureus</i>	Overall the commonest in all sites and age groups
β-Haemolytic streptococci and anaerobes	Also cause acute infection
<i>Escherichia coli</i> , group B streptococci	Neonates
<i>Haemophilus influenzae</i>	Non-immunised toddlers
Aerobic gram-negative rods	Discitis in the elderly

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology, (1891–1900), and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

lesions' affecting non-adjacent vertebrae are seen. Diagnosis is based on joint aspirate or biopsy. MRI can delineate disease extent within bone and soft tissues, especially spine. Tuberculin skin testing and blood tests are usually unhelpful. Treatment is anti-tuberculous chemotherapy; early surgery is required only for cord compression with paraplegia. Debridement is occasionally indicated (Summary box 37.6).

Summary box 37.6

Septic arthritis

- Commonest in babies and the elderly
- Extreme pain on moving the joint
- Diagnosis by ultrasound-guided aspiration of effusion
- Commonest organism is *Staphylococcus aureus* but *Escherichia coli* and others can occur in neonates
- Needs early decompression and high-dose antibiotics
- Tuberculous arthritis often affects the spine

INFECTION IN JOINT REPLACEMENTS

In a prosthetic infection the ulcer is more indolent, and the patient is rarely unwell. Occasionally, acute infection can present in the early postoperative phase (less than 1% of cases in good units). Others develop later but most almost certainly began from contamination at the time of surgery. Low-virulence organisms, particularly skin commensals such as *Staphylococcus epidermidis* and also methicillin-resistant *Staphylococcus aureus* (MRSA) are frequently the cause. If bacteria introduced at the time of surgery survive, they appear to get buried in a protein layer (biofilm) associated with the interface between the healing bone and the implant. In this position they cannot replicate quickly but they are also immune to antibiotics. However, they produce a low-grade inflammatory response which causes pain and rapid loosening of the implant; CRP will rise rather than fall. If infection is suspected, treatment should be started as soon as possible if the implant is to be saved. A firm diagnosis is best made by opening the joint and taking multiple biopsy specimens of the synovium and membrane around the implant. If there is no sign of infection then nothing further need be done until the culture results return, but if there is felt to be excessive inflammation but no gross infection, an aggressive clearance of all soft tissues and a washout of the wound is performed. This is followed by high-dose intravenous antibiotics. If infection is obvious (frank pus in the joint), the joint replacement needs removing with all the cement as well. Some surgeons immediately replace the prosthesis with a new one (one-stage revision), others leave the patient without a joint for a minimum of 3 months and treat with high-dose antibiotics while they wait for the infection to clear. Then they put in a new implant (two-stage revision). If the infection does not settle, then the patient may need to be left without a joint. This is called the Girdlestone operation in the hip (Summary box 37.7).

Gathorne Robert Girdlestone, 1881–1950, Nuffield Professor of Orthopaedics, The University of Oxford, Oxford, England.

Summary box 37.7

Infected joint replacement

- Most are avoidable with good theatre technique and prophylactic antibiotics
- Indolent onset with pain, weakness and failure to improve after surgery
- Persistent raised ESR and CRP; positive culture at biopsy
- One- or two-stage revision needed with long-term antibiotics

OSTEOMYELITIS

This is commonest in children (decreasing), and the elderly or immunocompromised (increasing). The elderly most commonly have vertebral osteomyelitis, whereas children develop infection in a long bone metaphysis. The commonest organism is *Staphylococcus aureus*, despite the infrequency of staphylococcal bacteraemia, presumably because of that organism's particular ability to infect bone. Acute osteomyelitis is usually regarded as that which occurs before there is actual bone death, while chronic osteomyelitis involves infection both within and around bone that has died.

Osteomyelitis is classified according to cause:

- haematogenous;
- post-traumatic;
- contiguous (from neighbouring tissue – e.g. diabetic foot ulcer).

The history is usually short, 48 hours or less. Initially, there is bone pain and marked tenderness without visible inflammation. When infection spreads subperiosteally, local and systemic signs of infection appear. Pus then forms in bone and soft tissues. The appearance of the bone does not change for 10–14 days so radiographs are a baseline for future change and to exclude differential diagnoses (Ewing's sarcoma, leukaemia). Softening of soft-tissue planes may be seen. Ultrasound gives an early diagnosis and if fluid or oedema can be seen aspiration provides an organism in 70% of cases. MRI is useful for visualising deeper bones, e.g. pelvis. Full blood count (FBC), ESR, CRP and blood cultures are all useful indicators. When repeated they can give a guide to the success of treatment. Treatment with empirical intravenous antibiotics should start immediately after cultures have been taken. Likely organisms are those also listed for septic arthritis. A definitive choice is directed by sensitivities once available. Antibiotic treatment should be continued for several weeks. Surgery (or interventional radiology) is indicated to evacuate abscesses. Bone drilling is not routinely required. With modern antibiotic therapy, the high mortality and permanent disability caused by osteomyelitis have dramatically improved. Now, only 5% of cases develop long-term sequelae. Chronic osteomyelitis is typically seen in elderly patients who developed acute osteomyelitis in the pre-antibiotic era. This is rarely 'cured', and reactivates at times of poor health or trauma. Pathology shows necrotic bone, new bone formation and chronic inflammation. Antibiotics (or natural host defences) cannot reach organisms within dead tissues, and disease continues. Necrotic cortical bone is extruded. This is called a 'sequestrum'. The encasing live bone, the 'involucrum', may be perforated by openings which can lead to the skin as a sinus. Treatment combines clearance of all dead

and contaminated tissues, bone de-roofing, intramedullary reaming and intravenous antibiotics. Wound closure, often with local or free flaps is preferred (Summary box 37.8).

Summary box 37.8

Osteomyelitis

- Children, the elderly and the immunocompromised
- Radiographs may be normal for up to 10 days
- Diagnosis is by aspiration and culture
- Treatment: immediate high-dose antibiotics (chosen on best guess)
- Correct antibiotics (if necessary) when culture results available

INFECTIONS OF SOFT TISSUE

See the section on necrotising fasciitis in Chapter 30.

MUSCULOSKELETAL TUMOURS

The most common malignant bone tumours are metastases (Fig. 37.15). As a result of advances in oncological treatment, the number of patients presenting with skeletal failure due to metastatic disease is increasing. The most common tumours that metastasise to bone are breast, prostate, lung, kidney and thyroid carcinomas (Fig. 37.16).

Multiple myeloma (Fig. 37.17) is a malignant neoplasm arising from the plasma cells in the bone marrow. It is usually multicentric. If the condition is solitary it is called a plasmacytoma. Malignant primary sarcomas of bone are very rare. The most common of these is osteosarcoma (Fig. 37.18). Osteosarcoma has two peaks in incidence, one in adolescence, the other later in life, arising in patients with Paget's disease and those who have had previous radiotherapy (Fig. 37.19). Chondrosarcoma (Figs 37.20–37.22) and Ewing's sarcoma (Fig. 37.23, p. 550) make up most of the rest. Ewing's sarcoma occurs in adolescence, while the incidence of chondrosarcoma increases from middle age onwards. Some conditions are associated with an increased likelihood of developing malignant disease in bone and/or cartilage (Table 37.5). Soft-tissue tumours are also quite rare and most are benign, with only one in a hundred being malignant (Fig. 37.24, p. 551).

Malignant tumours usually metastasise to bone by means of haematogenous spread. The spine is the third most common site for metastases, after the lung and liver. Although most patients with systemic cancer will have metastatic disease in the spine before they die, only 10% are symptomatic. Tumour cells metastasise to the spine via Batson's venous plexus. These retroperitoneal veins have no valves and allow retrograde spread by embolisation to the spine and proximal long bones (Fig. 37.25,

Figure 37.15 (a) Pathological fracture of the proximal femur through metastatic breast carcinoma. (b) Radiographs of the whole femur show a further, more distal metastatic deposit.

p. 551). Metastases can be lytic, sclerotic or mixed. Lytic metastases usually arise from tumours that are vascular. However, they can also occur in very aggressive, destructive tumours with no healing response from the bone. Sclerotic lesions are commonly from the prostate.

BONE TUMOURS

Bone tumours are classified according to the tissue of origin. These include:

- metastases – may show histological features of their tissue of origin;
- haematopoietic tumours – e.g. myeloma;
- osteogenic tumours – e.g. osteosarcoma;
- chondrogenic tumours – e.g. chondrosarcoma;
- others – e.g. Ewing's sarcoma.

Sir James Paget, 1814–1899, Surgeon, St. Bartholomew's Hospital, London, England, described osteitis deformans in 1877.

James Ewing, 1866–1943, Professor of Pathology, The Cornell University Medical College, New York, NY, USA, described this type of sarcoma in 1921.

Oscar V. Batson, 1894–1979, an American Otolaryngologist.

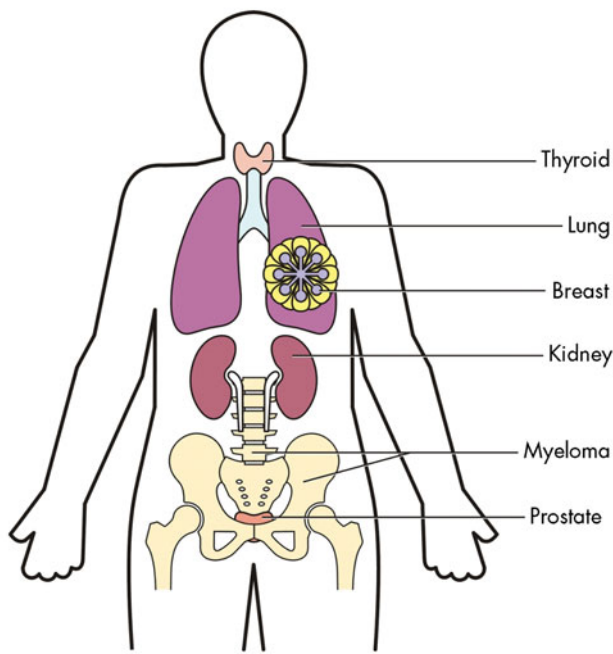

Figure 37.16 Malignant tumours commonly metastasising to bone.

Figure 37.17 (a) Multiple myeloma with a large deposit in the left proximal femur. (b) Multiple myeloma with multiple deposits in the skull.

METASTASES

The vast majority of tumours spreading to the skeleton are carcinomas; but not infrequently the primary tumour is never found. Metastases are rare in children, but can occur from neuroblastoma, rhabdomyosarcoma and clear cell carcinoma of the kidney (Summary boxes 37.9 and 37.10).

Summary box 37.9

Most common bone metastases (93%)

- Breast
- Prostate
- Lung
- Renal
- Thyroid

Summary box 37.10

Commonest sites of bone metastases

- Spine
- Proximal femur
- Proximal humerus

Table 37.5 Conditions associated with an increased risk of malignant disease in bone and cartilage

High risk	Moderate risk	Low risk
Maffucci's syndrome (enchondromatosis and angiomas of soft tissue)	Diaphyseal aclasia (multiple osteochondromas)	Chronic osteomyelitis
Ollier's disease (enchondromatosis)	Polyostotic Paget's disease	Osteonecrosis
Familial retinoblastoma syndrome	Radiation osteitis	Fibrous dysplasia, osteogenesis imperfecta, osteoblastoma and chondroblastoma

Angelo Maffuci, 1845–1903, Professor of Pathological Anatomy, Pisa, Italy.

Louis Xavier Eduard Leopold Ollier, 1830–1900, Professor of Surgery, Lyons, France, described enchondromatosis in 1899.

Figure 37.18 Sclerotic osteosarcoma of the proximal tibia.

Figure 37.19 Radiation-induced osteosarcoma of the proximal humerus (following treatment for breast carcinoma).

HAEMATOPOETIC TUMOURS

There are no benign neoplasms of the haematopoetic system. Malignant tumours can be divided into two groups:

- solitary plasmacytoma/multiple myeloma (see Fig. 37.17 p. 548);
- lymphomas – malignant neoplasm of the lymphoid cells (Summary box 37.11).

Summary box 37.11

Malignant bone tumours

- Plasmacytoma – solitary form of multiple myeloma
- Osteosarcoma – could be secondary to Paget's disease and radiotherapy
- Chondrosarcoma
- Ewing's sarcoma

Figure 37.21 (a) Chondrosarcoma of the foot. (b) Computerised tomography scan reconstruction showing multiple calcifications. (c) T2-weighted magnetic resonance imaging scan shows high signal in chondrosarcoma. (d) Excised chondrosarcoma of the foot.

OSTEOGENIC TUMOURS

These tumours produce osteoid or bony matrix.

Osteoid osteoma (Figs 37.26 and 37.27) is a benign bone-forming lesion which is small but very painful. Usually, symptoms

occur at night and are typically relieved by anti-inflammatories. Children and adolescents are frequently affected. Osteomas can occur in any bone but are common in the proximal femur.

Figure 37.22 Pathological fracture through a primary chondrosarcoma of the proximal humerus.

Figure 37.23 Ewing's sarcoma of the proximal fibula.

Figure 37.24 (a) Large, fungating soft-tissue sarcoma of the buttock. (b) Magnetic resonance imaging scan showing a large fungating sarcoma of the buttock.

Figure 37.25 Common sites of metastatic bone disease.

Figure 37.26 Radiograph showing osteoid osteoma of the proximal femur with reactive bone formation.

Figure 37.27 (a) Axial computerised tomography (CT) scan showing an osteoid osteoma nidus in the distal tibia. (b) CT-guided radio-frequency thermocoagulation of an osteoid osteoma of the distal tibia. The scan shows the electrode *in situ*.

Osteoid osteomas are usually diaphyseal in location and give rise to a dense cortical reaction (Fig. 37.26). Osteoblastoma is the larger more aggressive counterpart of osteoid osteoma that commonly occurs in the spine.

Osteosarcoma (see Figs 37.18 and 37.19, p. 549) is most common in the distal femur, followed by proximal tibia, proximal humerus and distal tibia. Radiologically and histologically the tumour can be sclerotic (Fig. 37.18), chondroblastic, teleangiectic and of other more unusual histological forms. Usually, osteosarcomas are intraosseous, but they can also arise from the surface of the bone. Paraosteal osteosarcoma (Fig. 37.28) is a low-grade osteosarcoma that arises from the surface of the bone. It frequently affects the distal femur and proximal tibia. The clinical symptoms are often mild and longstanding (Summary box 37.12).

Summary box 37.12

Tumours producing bone

- Osteoid osteoma – small and painful; produce a dense cortical reaction
- Osteoblastoma – larger and more aggressive than osteoid osteoma
- Osteosarcoma – malignant; commonest in lower femur and upper tibia

CHONDROGENIC TUMOURS

These tumours produce chondroid matrix. The biological spectrum of these tumours ranges from very benign to highly malignant.

Osteochondroma (Figs 37.29 and 37.30) is a benign cartilage-capped bony projection. It is thought to originate from the physis. The bony projection is always growing away from the joint towards the diaphyseal region of the bone. It has no structures attached to it. Osteochondromas can be pedunculated or sessile. The stalk or base is always continuous with the intramedullary cavity of the bone. They are usually solitary, but can be multiple (Fig. 37.31) in diaphyseal aclasia (autosomal dominant inheritance). Complications include mechanical symptoms, nerve impingement, vascular pseudo-aneurysm, fracture and infarction. Increasing size or pain, particularly after skeletal maturity, is concerning and may indicate malignant transformation. The incidence of malignant transformation is less than 1% in solitary osteochondromas and 1–3% in diaphyseal aclasia.

Figure 37.28 Paraosteal osteosarcoma of the distal femur in an unusually young patient. There is no continuity with the intramedullary cavity of the femur.

Figure 37.29 Pedunculated osteochondromas of the proximal fibula with pseudarthrosis. Osteochondromas always grow away from the physis.

Figure 37.30 Excised pedunculated osteochondroma showing cartilage cap.

Figure 37.31 Multiple osteochondromas in diaphyseal aclasia.

Enchondroma (Fig. 37.32) is a benign cartilaginous neoplasm within the intramedullary cavity of bone. Approximately 50% are in the hands and feet. Enchondroma is the most common bone tumour in the hand. A large proportion of these tumours are entirely asymptomatic, and diagnosis is often incidental. They can present with pain, swelling or pathological fracture. Patchy calcification, expansion and scalloping can be visible on the radiographs, but some are only diagnosed on MRI scan. Ollier's disease is a developmental condition characterised by multiple enchondromas. In Maffucci syndrome, the multiple enchondromas are associated with multiple angiomas. Malignant transformation to chondrosarcoma can occur in approximately 20% of patients with Ollier's disease and is almost inevitable in patients with Maffucci syndrome.

Chondroblastoma (Fig. 37.33) is a benign cartilage-producing tumour that occurs in the epiphyses of children. It is most common around the knee. Pain is often severe with associated inflammation and possibly joint effusion. Radiologically, there is an often barely visible lytic lesion in the centre of the epiphysis. The diagnosis is often missed, and bone scan can aid in the localisation of the lesion.

Chondrosarcoma (see Figs 37.20–37.22, pp. 549–50) is a malignant tumour with cartilage differentiation. The biological spectrum is very wide; it ranges from very low-grade lesions to highly aggressive dedifferentiated tumours. Clinically, the presenting symptom is pain and or swelling. Symptoms are often longstanding. Radiological and pathological correlation is particularly important in the evaluation of this condition. Clear cell chondrosarcoma is a rare form of chondrosarcoma that occurs in the epiphysis (Fig. 37.34 and Summary box 37.13).

Summary box 37.13

Tumours producing cartilage

- Osteochondroma – cartilage capped; grows away from the physis
- Enchondroma – inside bone; commonest in the hands and feet
- Chondroblastoma – in the epiphyses of adolescents
- Chondrosarcoma – of varying malignancy

Figure 37.32 Calcification in benign enchondroma of the proximal humerus.

OTHER BONE TUMOURS

Simple bone cyst, or unicameral bone cyst (Fig. 37.35), is a membrane-lined cavity filled with serous fluid. It usually occurs in the proximal long bones of children.

Aneurysmal bone cyst (Fig. 37.36a) is a benign cystic lesion of bone consisting of blood-filled spaces separated by fibrous septa. The lesion is much more aggressive than a simple bone cyst and often presents with pain and swelling. Plain radiographs show commonly aggressive features with eccentric expansion of the cortex and an open physis. Scans often show multiple fluid levels (Fig. 37.36b).

Giant cell tumour of bone (Fig. 37.37) is a benign aggressive tumour with large osteoclast-like giant cells. It usually occurs between ages 20 and 45, when the physes have closed. Giant cell tumour typically affects the epiphysis of long bones, especially around the knee, proximal humerus and distal radius.

Eosinophilic granuloma (Fig. 37.38) is a rare neoplastic proliferation of Langerhans cells. It can be unifocal, multifocal or disseminated (respectively: eosinophilic granuloma, Hand-Schuller-Christian disease, Letterer-Siwe disease). There is a predilection for the skull and diaphyses of long bones. In the spine it can present with vertebral collapse (vertebra plana). Radiographs can appear aggressive with punched-out lesions and periosteal reaction.

Fibrous dysplasia (Fig. 37.39) is a benign fibro-osseous lesion that can be monostotic or polyostotic. It usually affects the long bones, ribs and skull. Patients can present with pain, swelling and/or fracture. Hip fractures can produce a shepherd's crook deformity. Radiologically there is often expansion and a ground glass appearance. Cysts may well be present.

Ewing's sarcoma (see Fig. 37.23, p. 550) is a round cell sarcoma of bone. It tends to arise in the diaphyses of long bones or the pelvis. Patients usually present with a painful mass and may have general symptoms with fever, anaemia and increased ESR. Radiologically the bone appears moth-eaten and may show an

Figure 37.35 Pathological fracture through a simple bone cyst with the pathognomonic fallen leaf sign. The fracture healed and the cyst consolidated without operative intervention.

Figure 37.36 (a) Aneurysmal bone cyst with pathological fracture of the proximal tibia. (b) Magnetic resonance imaging scan shows multiple fluid levels.

Figure 37.37 Giant cell tumour of the medial malleolus.

Figure 37.38 (a) Eosinophilic granuloma of the scapula. (b) Computerised tomography scan shows a 'punched-out' lesion. (c) Spontaneous resolution.

'onion-skin' periosteal reaction. There is often significant inflammation with oedema on the MRI scan.

Bone tumours can also be classified according to their site (Tables 37.6 and 37.7). Epiphyseal tumours are likely to be benign. Bone tumours are usually staged using the Enneking staging system.

Figure 37.39 Fibrous dysplasia affecting the proximal femur.

Benign tumours are staged as:

- latent, i.e. osteochondroma;
- active, i.e. osteoid osteoma;
- aggressive, i.e. giant cell tumour.

Latent lesions are usually asymptomatic and often discovered incidentally. Active lesions, such as osteoid osteoma, do present with mild symptoms and continue to grow. A giant cell tumour is an example of an aggressive lesion. Aggressive lesions tend to grow rapidly. For malignant tumours, the Enneking system combines stage and grade of a tumour (Table 37.8). The compartment is the bone that is involved with the tumour. A tumour is extra-compartmental when the tumour has breached the cortex of the bone as visible on the plain radiographs. Most bone tumours are Enneking stage 2B at diagnosis (Summary boxes 37.14 and 37.15).

Table 37.6 Classification of bone tumours by site

Tumour and site	Diaphyseal	Metaphyseal	Epiphyseal
Eosinophilic granuloma	Most		Chondroblastoma
Osteoid osteoma			Intra-articular osteoid osteoma
Fibrous dysplasia			Giant cell tumour (physis closed)
Adamantinoma			Clear cell chondrosarcoma
Ewing's sarcoma			

Table 37.7 Common diaphyseal bone tumours according to age

Age	Most common diaphyseal tumour
< 10	Eosinophil granuloma
Teenage	Ewing's sarcoma
Adult	Lymphoma
> 60	Metastasis? Myeloma?

Table 37.8 The Enneking staging system for bone tumours

Low-grade	Intracompartmental	1A
	Extracompartmental	1B
High-grade	Intracompartmental	2A
	Extracompartmental	2B
Any grade	Metastases	3

Summary box 37.14

Other bone tumours

- Simple bone cyst – proximal long bones of children
- Aneurysmal bone cyst – more aggressive, expanding
- Giant cell tumour – found in the epiphyses around the knee
- Fibrous dysplasia – may be multiple; found in long bones, ribs and skull
- Ewing's – round cell sarcoma; patients may have fever and anaemia

Summary box 37.15

Warning signs of bone tumour

- Non-mechanical bone pain
- Especially common around the knee in young adolescents
- Radiographs raise concern

SOFT-TISSUE TUMOURS

These tumours are also classified according to the cell of origin. Most types have a benign and a malignant counterpart [i.e. lipoma (Fig. 37.40) and liposarcoma]. The biological spectrum of these tumours is wide and full multidisciplinary assessment is essential to make a correct diagnosis. The Trojani system, based on tumour differentiation, mitotic count and tumour necrosis, is often used to grade soft tissue tumours. The tumour–node–metastasis (TNM) system is used for staging (Summary box 37.16).

Summary box 37.16

Warning signs of soft tissue tumour

- Larger than 5 cm
- Increasing in size
- Painful
- Deep to the fascia
- Recurrence after previous excision

HISTORY AND EXAMINATION, INVESTIGATION AND DIAGNOSIS

In the assessment of musculoskeletal tumours, a multidisciplinary approach that allows clinical, radiological and pathological correlation is essential to establish a correct diagnosis. Treatment of primary bone and soft-tissue tumours should only take place in an institution that has a full multidisciplinary team (centre of excellence).

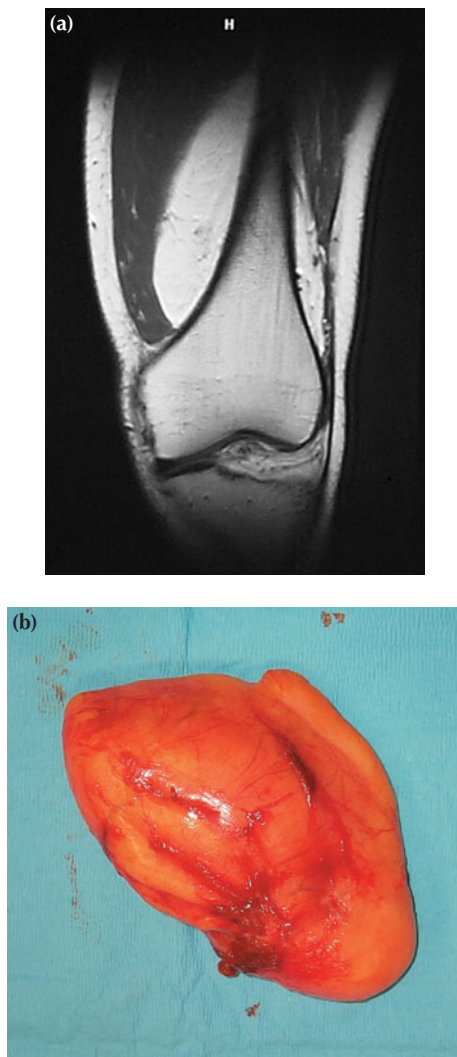

Figure 37.40 (a) Coronal T1-weighted magnetic resonance imaging scan showing a benign lipoma deep to the quadriceps muscle. (b) Excised benign lipoma.

When a musculoskeletal tumour is suspected:

- Stop
- Think
- Stage.

History and examination

Bone tumours

Non-mechanical and/or night pain, particularly in the young adolescent, is a concerning symptom and a primary bone tumour should be suspected. Symptoms that resolve with aspirin are suggestive of an osteoid osteoma.

The principles of management of primary bone tumours are:

- a high index of suspicion;
- early referral to a tumour centre;
- careful imaging studies;
- biopsy after completion of imaging investigations;
- minimally invasive technique for biopsy;
- a multidisciplinary approach to management.

Patients with a past medical history of malignancy who present with back pain should be considered to have metastatic disease until proved otherwise. Plain radiographs of the spine and routine blood tests are the minimum that is required. For metastatic disease of bone:

- the extent of metastases is best demonstrated on a bone scan;
- prophylactic treatment of any impending fracture should be considered;
- radiotherapy and internal fixation improve pain and quality of life;
- beware the 'solitary' metastasis (Fig. 37.41). This could be a primary bone tumour and *full staging, including biopsy*, is required.

Figure 37.41 (a) A patient with a previous history of breast carcinoma presented with a solitary lesion in the femur. Biopsy showed primary bone sarcoma and the lesion was excised. (b) *En bloc* excision, including the biopsy track. (c) Reconstruction with endoprosthetic replacement.

Multiple myeloma (see Fig. 37.17, p. 548) is the most common primary malignancy of bone in adults:

- It should be considered in all patients with back pain over 65 years of age.
- Back pain with an ESR $> 100 \text{ mm h}^{-1}$ is multiple myeloma until proved otherwise.
- Monoclonal gammopathy is diagnostic.
- Elevated urinary and serum Bence Jones proteins are diagnostic.

Soft-tissue tumours

Soft-tissue swellings are common and the vast majority are benign. Symptoms and signs that suggest malignant disease are:

- *pain*;
- *size*: larger than 5 cm and/or increasing;
- *position*: deep to fascia;
- *behaviour*: recurrence after previous excision (whatever the pathology).

Each of these factors has a 25% risk of malignancy.

Staging

Primary musculoskeletal tumours should be staged according to local and distant features:

- Local
 - plain radiographs of the whole affected bone or soft tissue lesion (see Fig. 37.15, p. 547);
 - MRI of the whole affected bone or soft-tissue lesion;
 - computerised tomography (CT) scan;
 - ultrasound scan (for soft-tissue tumours only).
- Distant
 - blood tests; including FBC, ESR, profile, calcium and myeloma screen;
 - plain radiographs of the chest;
 - CT scan of the lungs;
 - bone scan (for bone tumours only);
 - ultrasound scan of the abdomen (if renal metastasis is a possibility).

For bone tumours, plain film radiographs are the most informative, but appropriate scans are required for further confirmation and staging. Imaging should always include the whole of the affected bone to look for satellite lesions and skip metastases. Satellite lesions occur within, whereas skip lesions occur beyond the reactive zone of the tumour. Both primary bone sarcomas and soft-tissue sarcomas commonly metastasise to the lungs and a CT scan is an essential part of the staging. Patients who present with a lytic bone lesion could have a renal primary and an ultrasound scan of the kidneys is advised. Biopsy without this could result in unexpected massive blood loss (Summary box 37.17).

Summary box 37.17

Staging

- Plain radiography is most informative for bone tumours
- Always image the whole bone in case of skip lesions
- CT of the lung detects lung metastases
- Lytic lesions require ultrasound of the abdomen to check for a renal primary

Henry Bence Jones, 1813–1873, Physician, St. George's Hospital, London, England.

Biopsy

A biopsy is performed only when the staging process is completed. This should be done in the centre performing the definitive surgical procedure. Image-guided biopsies have a higher diagnostic accuracy as areas of radiological concern can be targeted. If image-guided biopsy is performed, close discussion between radiologist and surgeon is required to ascertain that the correct biopsy route is used. It is essential that the biopsy track is excised at the time of definitive surgery (Figs 37.41–37.43). Biopsies for bone tumours are usually taken using a Jamshidi needle (Fig. 37.44), whereas Trucut needles are preferred for soft-tissue tumours.

The principles of biopsy are as follows:

- A tourniquet can be used, but exsanguination should be avoided as this can release tumour cells in the circulation.
- Use longitudinal incisions that are part of an extensile approach.
- Do not cross compartments.
- The biopsy track will have to be excised at the time of definitive surgery (Summary box 37.18).

Figure 37.42 Poorly placed biopsies, making subsequent surgical excision of the track impossible.

Figure 37.43 *En bloc* excised tumour and biopsy track.

Figure 37.44 Bone biopsy instruments.

Summary box 37.18

Biopsy

- Only biopsy once staging is completed
- Biopsy should be performed at the centre undertaking the main surgery
- Image-guided biopsy is more reliable
- The biopsy track must be excised at definitive surgery
- Jamshidi needles for bone; Trucut needles for soft tissues

Assessment

The assessment of any bone or soft-tissue lesion can be divided into three phases. The first two phases can be performed in a district general hospital, but the third phase is best done in a tumour treatment centre (Table 37.9). Patients with metastatic disease often require resuscitation for electrolyte imbalance, anaemia, cardiorespiratory problems or hypercalcaemia before surgical treatment can be considered. Hypercalcaemia can be treated effectively with fluid resuscitation and pamidronates (Fig. 37.45). The risk of pathological fracture needs to be assessed. This is best assessed using the Mirels score (Table 37.10).

TREATMENT, PROGNOSIS AND COMPLICATIONS

Primary bone tumours

Most latent and active benign bone tumours are treated by intralesional curettage. Packing of the cavity with graft of bone

substitutes is usually not required. Simple bone cysts can heal following pathological fracture and an initial observant approach following fracture is best. If the cyst persists following union of the fracture, a variety of treatments, including injection with steroid or bone marrow and surgical curettage, have been described. Osteoid osteomas can resolve spontaneously. However, symptoms are often pronounced and most patients are treated by CT-guided thermocoagulation. Large or more rapidly growing benign bone tumours might require more extensive surgical excision and reconstruction. Malignant primary bone tumours require a more

Figure 37.45 (a) Multiple deposits of metastatic breast carcinoma and lytic deposit in the right proximal femur. (b) Consolidation following treatment with pamidronate.

Table 37.9 The three phases of assessment of lesions

Phase 1 (within 24 hours)	Phase 2 (within first week)	Phase 3 (at tumour centre)
History and examination	Bone scan	CT scan of lesion
Blood assays	Ultrasound scan of the abdomen	MRI scan of lesion
Radiograph of whole bone	CT scan of chest	Biopsy
Chest radiograph		

CT, computerised tomography, MRI, magnetic resonance imaging.

Table 37.10 The Mirels scoring system for risk of pathological fracture

	Score		
	1	2	3
Site	Upper limb	Lower limb	Peritrochanter
Pain	Mild	Moderate	Functional
Size	< 1/3	1/3–2/3	> 1/3
Lesion	Blastic	Mixed	Lytic

Score > 8, high risk of fracture – urgent prophylactic treatment needed; score < 7 low risk of fracture – stabilisation of the bone not immediately needed.

aggressive approach. Osteosarcoma and Ewing's sarcoma are treated with neoadjuvant chemotherapy and surgery. Chondrosarcomas are not sensitive to chemotherapy or radiotherapy and treatment is surgical.

The surgical options for malignant primary bone tumours are:

- amputation or van Ness rotationplasty;
- excision alone (for dispensable bones);
- excision and replacement with a graft or prosthesis.

If surgical excision is undertaken it is important for the biopsy track to be excised *en bloc* with the surgical specimen to avoid local recurrence through the biopsy track (see Figs 37.41 and 37.43, p. 557 and 558). Following excision the resection margins can be classed as shown in Table 37.11.

In most cases, limb salvage with excision and reconstruction is possible (Fig. 37.46). Only a minority of cases have neurovascular invasion and require amputation. Limb salvage, compared with amputation, has a slightly higher rate of local recurrence. However, no difference in overall survival has been demonstrated (Summary boxes 37.19 and 37.20).

Summary box 37.19

Treatment – benign bone tumours

- Benign lesions can be simply curetted
- CT-guided thermocoagulation is used for osteoid osteoma
- Large benign tumours may require reconstruction

Figure 37.46 Endoprosthetic replacement of the distal femur.

en bloc is French for 'in a block'.

Table 37.11 Classification of surgical resection margins

Intralesional	Resection through the lesion
Marginal	Resection through the reactive zone of the tumour
Wide	Resection outside the reactive zone of the tumour
Radical	Excising the whole affected compartment

Summary box 37.20

Treatment of malignant bone tumours

- Osteosarcomas and Ewing's sarcoma require neoadjuvant chemotherapy
- Chondrosarcomas are insensitive to radiotherapy or chemotherapy
- Most malignant tumours can be treated with limb salvage.
- There is no difference in survival between amputation and limb salvage

Metastatic bone tumours

Surgical treatment in patients with metastatic bone disease is palliative. This should be kept in mind when planning treatment. Surgery is unable to lengthen life in patients with metastatic bone disease, but it can shorten it. Spinal surgery may be required for stabilisation of the spine and/or decompression in patients with (impending) cord compression. Surgery in the peripheral skeleton is mainly for treatment of (impending) pathological fracture.

Renal metastases tend to be very vascular and massive blood loss can be encountered during surgery. Therefore, preoperative embolisation should be considered just before surgery to prevent blood loss (Fig. 37.47). Treatment of myeloma is mainly haematological. Surgical treatment is only required for complications such as fracture and spinal cord compression. Solitary plasmacytoma is an exception and surgical excision is usually advised.

Patients with a previous history of malignancy may present with a (solitary) bony lesion or pathological fracture. It should not be assumed that this is a metastatic lesion (see Fig. 37.41, p. 557). Prior to planning surgical treatment it is important to ascertain that the diagnosis is correct. Staging including biopsy will be required to exclude a malignant primary bone tumour. Prior to planning surgical treatment for patients with metastatic bone disease it is important to have an assessment of:

- survival: prognosis of the primary tumour (Fig. 37.48);
- quality of life;
- medical fitness;
- biomechanical/risk of fracture;
- single or multiple bone lesions;
- response to adjuvant treatment such as radiotherapy and hormonal treatment;
- radiotherapy – before or after surgery?

It is difficult to give strict guidelines for the surgical management of patients with metastatic bone disease. However, when a prolonged disease-free interval is expected, prosthetic replacement is usually preferred to intramedullary nailing. A high failure rate is associated with internal fixation of pathological fractures (Fig. 37.49). Prior to surgical treatment it is essential to stabilise the patient's medical condition. Pamidronate can have a dramatic effect and might make surgery unnecessary (see Fig. 37.45, p. 559). Epiphyseal and metaphyseal lesions are best treated with

Figure 37.47 (a) Lytic metastasis of renal cell carcinoma. (b) Angiogram shows increased vascularity. (c) Following embolisation.

prosthetic replacement, whereas diaphyseal lesions are usually best treated with an intramedullary nail. In the shoulder, prosthetic replacements have poor function and internal fixation usually gives the best results. However, in hip lesions the best treatment is joint replacement.

Solitary breast and renal metastases can have a prolonged disease-free survival so excision and replacement rather than fixation should be the treatment of choice (Summary box 37.21).

Figure 37.48 Survival curves of patients who present with bony metastasis.

Figure 37.49 Failed metalwork following fixation of a metastatic fracture.

Summary box 37.21

Treatment of bone metastases

- Surgery cannot lengthen life but may shorten it
- Spines may need stabilising and nerves or the spinal cord decompressing
- Long bones will need stabilising if a pathological fracture is imminent
- Patients who have a possibility of long survival may need a prosthesis
- Radiotherapy relieves pain

Soft-tissue tumours

Malignant soft-tissue tumours are preferably excised with as wide a margin as possible. As in bone tumours, it is important for the biopsy track to be excised *en bloc* with the surgical specimen (see Fig. 37.43, p. 558). The skin might require reconstruction with a split-skin graft (Fig. 37.50) or skin flap (Fig. 37.51). In general, skin flaps are preferred as they allow for early administration of radiotherapy. Following surgical excision of high-grade soft-tissue sarcomas, adjuvant radiotherapy should be considered. Preoperative radiotherapy can also have good results, but there is a risk of wound healing problems following surgery. Chemotherapy has a limited role in the treatment of soft tissue sarcomas.

Figure 37.50 Excised soft tissue sarcoma and reconstruction with a split-skin graft.

Figure 37.51 (a) Excised soft-tissue sarcoma and reconstruction with skin flap. (b) Final result following radiotherapy.

ACKNOWLEDGEMENTS

Parts of this chapter were previously published in the 24th edition of this volume under the title 'Diseases of bones and joints',

authored by Tony Berendt and Martin McNally. Their material has been added to and updated by the current authors.

Paediatric orthopaedics

LEARNING OBJECTIVES

To be familiar with:

- The normal development of the musculoskeletal system and understand how deformity can arise through failure of normal development
- The difference between normal variants and pathological deformity
- The diagnosis and treatment of developmental hip dysplasia
- The presentation and management of other conditions affecting the hip in childhood
- The management of clubfoot
- The need to consider, diagnose and treat appropriately musculoskeletal infection in childhood

INTRODUCTION

Young skeletons have the potential to heal rapidly and remodel but growth plate injury or muscle imbalance may lead to progressive deformity. The conservative treatment of common conditions, such as developmental dysplasia of the hip (DDH) and clubfoot, combines the remodelling ability of the growing skeleton with an understanding of the Heuter–Volkman principle and Wolff's law (Summary box 38.1): by improving the biomechanical environment, abnormal growth patterns may be reversed. In contrast, in conditions such as Blount's disease and physeal trauma, growth plate damage leads to asymmetrical growth and deformity.

Summary box 38.1

Laws governing the remodelling of bone

Heuter–Volkman principle

- Compressive forces inhibit growth
- Tensile forces stimulate growth

Wolff's Law

- Bone is deposited and resorbed in accordance to the stresses placed upon it

Recently, the molecular and genetic bases of some congenital musculoskeletal conditions have been established, which may lead to new avenues of prevention and treatment. In other

childhood conditions, such as Perthes' disease, the aetiology remains a matter of speculation, reflected in the variety of controversial treatment methods available.

DEVELOPMENT OF THE MUSCULOSKELETAL SYSTEM

Embryogenesis of the limbs starts with formation of the upper limb bud on the lateral wall of the embryo 4 weeks after fertilisation, followed promptly by the lower limb bud. By 2 months, differentiation of the limb elements is complete. The majority of congenital limb anomalies arise during this interim period.

Three intercoordinated signalling centres control different aspects of limb development. The *apical ectodermal ridge* (AER) is a thickened layer of ectoderm that condenses over the limb bud. It acts as a signalling centre to guide differentiation of the mesoderm into appropriate structures in a proximal-to-distal direction and is responsible for interdigital necrosis and, hence, separation of the webbed digits. The *zone of polarising activity* (ZPA), within the posterior margin of the limb bud, functions as a signalling centre for anterior-to-posterior limb development via the sonic hedgehog protein. The *wingless-type* (Wnt) signalling centre, in the dorsal ectoderm, secretes factors that induce the underlying mesoderm to adopt dorsal characteristics, developing dorsal-to-ventral axis configuration and alignment of the limb.

Certain limb anomalies are directly related to alterations in these centres. For example, removal of the AER during embryogenesis yields a truncated limb similar to a congenital amputation, and prohibits interdigital necrosis, causing syndactyly.

Richard von Volkman, 1830–1889, Professor of Surgery, Halle, Germany.
Julius Wolff, 1836–1902, Professor of Orthopaedic Surgery, Berlin, Germany.
Walter Putnam Blount, 1900–1992, Professor of Orthopaedic Surgery, Marquette University, Milwaukee, WI, USA, described this condition in 1937.

Georg Clemens Perthes, 1869–1927, Professor of Surgery, Tübingen, Germany.

An error during limb development may disturb other organ systems that are developing simultaneously; therefore, some limb anomalies are associated with systemic disorders whereas others are not. Many of the systemic conditions are more important than the limb anomaly and accurate identification allows treatment of life-threatening problems, such as cardiac anomalies. Conversely, an extensive work-up for an isolated anomaly (e.g. a transverse deficiency) is unnecessary (Summary box 38.2).

Summary box 38.2

Development of the musculoskeletal system

- Occurs between 4 and 8 weeks after fertilisation
- AER controls proximal-to-distal differentiation and interdigital necrosis
- ZPA controls posterior-to-anterior differentiation
- Wnt controls dorsal-to-ventral differentiation

NORMAL VARIANTS

Normal variants require no intervention. The most common causes of concern are intoeing, bowlegs, knock-knees and flat foot. If the child fails to follow the normal development pattern or there are functional problems help may be required.

Normal variants are usually symmetrical, symptom free and without stiffness or systemic problems. There is often a family history of similar complaints. The child should have had no significant perinatal problems and should have achieved all developmental milestones normally.

Intoeing gait

Intoeing, defined as a negative foot progression angle, can originate from anywhere in the lower limb and may result from a combination of torsional components (Fig. 38.1 and Table 38.1).

Figure 38.1 Foot progression angle: a positive angle is caused by an extoeing gait, a negative angle by an intoeing gait.

Table 38.1 Common sites and causes of intoeing gait in childhood

Site	Cause
Femur/hip	Persistent femoral neck anteversion
Tibia	Internal tibial torsion
Foot	Metatarsus varus

Persistent femoral anteversion

All femurs have an anteverted neck at birth. As the femur lengthens it also rotates, reducing this anteversion to around 7° in the adult; however, if the anteversion persists, the child intoes. Clinically, there will be excessive internal rotation at the hip joint. Spontaneous correction usually occurs but if a significant deformity is still present by 12–13 years of age and function is impaired then a corrective osteotomy may be justified. Development of external tibial torsion (a normal process) may compensate for persistent femoral anteversion.

Internal tibial torsion

This is assessed by the foot/thigh angle and is commonly associated with physiological tibia vara in infants. Spontaneous correction can be expected by age 4.

Metatarsus varus

This foot deformity is often mobile and spontaneous correction occurs in 90% of patients by the age of 2–4 years. If the deformity is not easily correctable then stretching, corrective plasters or straight-last shoes may be helpful. Surgical release is rarely indicated.

Other abnormalities of gait

Toe walking

Toe walking is a phase in normal gait development. If the gait does not mature to a heel-toe pattern by the age of 3 years, conservative treatment with physiotherapy and casting may be used. Surgical lengthening of a contracted gastrosoleus complex may become necessary in the older child. If toe walking starts after walking age a spinal or neuromuscular aetiology such as a tethered cord or a muscular dystrophy must be considered.

Extoeing

Extoeing is less common than intoeing but may result from relative femoral retroversion, external tibial torsion or flexible flat feet. The young child may be late walking because of poor balance associated with the externally rotated foot posture. This condition improves as the child grows.

Knock-knees and bowlegs

Normal children change their leg shape dramatically as they grow. All children start life with bowlegs, often accompanied by tibial torsion. By the age of 2–3 years they have developed knock-knees, which regress towards the normal adult tibiofemoral angle of 7° valgus by the age of 7 (Fig. 38.2).

Traditionally, deformity is quantified by measuring the intercondylar or intermalleolar distance although this is not very accurate. Further investigation is needed when the deformity is severe, asymmetrical or symptomatic. The most common pathological causes are previous trauma, rickets or a skeletal dysplasia.

Figure 38.2 Graph to show the normal tendency of limb alignment to change from varus to valgus with growth.

Flat foot

All children under 3 years have flat feet because the medial longitudinal arch has not yet developed. Most adults do not have flat feet and, thus, the natural history of flat feet is for improvement, although genetic factors (both family and racial) may influence this.

The painless, flexible flat foot needs no treatment. Orthoses do not alter the natural history of the condition but can alleviate symptoms if they arise.

The symptomatic, rigid flat foot is usually the result of a tarsal coalition or inflammation and requires appropriate medical or surgical treatment (Fig. 38.3 and Table 38.2) (Summary box 38.3).

Summary box 38.3

Normal variants

- Intoeing or extoeing may be caused by extremes of femoral torsion, tibial torsion or foot deformity
- It is essential to look for neurological abnormalities in toe walkers
- Children's legs are often bowed until the age of 2 years and then knock-kneed until the age of 6 or 7
- Flat feet that are flexible and painless do not need treatment

Postural abnormalities

Many babies are subjected to moulding pressures while *in utero*. At birth they have 'postural abnormalities' such as torticollis, calcaneovalgus feet and plagiocephaly. A careful examination will exclude significant abnormalities and postural problems improve with time and some stretching exercises.

Table 38.2 All flat feet have a flattened medial arch with a valgus heel but the two major types of flat feet should be distinguished from each other

Type	Characteristics
Flexible	On tiptoe the arch is restored and the heel corrects into varus; subtalar joint movements are full and pain free
Rigid	On tiptoe the arch fails to return; subtalar joint movements are restricted and often painful

Figure 38.3 Oblique radiograph of the foot that shows the most common form of tarsal coalition, a calcaneonavicular bar.

CONGENITAL AND DEVELOPMENTAL ABNORMALITIES OF THE SKELETON

Although many generalised or focal skeletal abnormalities are identified on antenatal ultrasound scans or at birth, others only become apparent with growth. Skeletal disorders are often linked to soft-tissue abnormalities; the presence of a skin dimple or vascular malformation should make the clinician look for a more generalised condition.

Congenital limb malformations usually arise from failure of differentiation but may result from inadequate or excessive growth of all or part of a limb. Most congenital malformations fit the classification shown in Table 38.3.

Many congenital anomalies require surprisingly little treatment and cause minimal functional disability whereas others, such as proximal femoral focal deficiency and radial club hand, pose considerable management challenges in which the functional and cosmetic needs of the child and the family must be balanced with the available resources and expertise. Despite advances in limb reconstruction techniques there is relatively little high-quality evidence-based data from skeletally mature patients to support their widespread use. In the meantime, considerable advances are also being made in the field of amputation prosthetics and rehabilitation.

Generalised skeletal dysplasias

This chapter cannot discuss all forms of skeletal dysplasia but the following more common conditions are representative of the challenges posed.

Table 38.3 Classification of congenital limb malformations

Category	Example
Failure of formation of parts	
Transverse	Congenital amputation
Longitudinal	Fibular hemimelia
Failure of differentiation	Vertebral body fusion; syndactyly
Duplication	Extra digits
Overgrowth	Gigantism; macrodactyly
Undergrowth	
Congenital constriction band syndrome	Often affects hands/feet with poor formation of the digits
Generalised skeletal abnormalities	Skeletal dysplasia, e.g. achondroplasia

Achondroplasia

This is the most common skeletal dysplasia that doctors see. The cause is a defect in the *FGFR3* gene on chromosome 4 that codes for fibroblast growth factor receptor 3. Enchondral bone formation is most affected and thus the patient presents with disproportionate short stature and classic clinical and radiographic features. The most characteristic feature is that the limbs are disproportionately short compared with the trunk (Fig. 38.4).

Relative underdevelopment of the foramen magnum and spinal stenosis can cause significant neurological difficulties.

Figure 38.4 Achondroplasia. (a) Clinical photograph of a child with achondroplasia. (b) Radiograph of the lower limb of a child with achondroplasia showing short limbs, widened metaphyses and a varus deformity of the distal tibia.

Correction of limb alignment may be necessary and the use of limb lengthening techniques is popular in some countries.

Hereditary multiple exostoses – diaphyseal aclasis

Exostoses grow as the child grows and may cause cosmetic or functional difficulties that justify excision. The later the excision is performed, the less the risk of recurrence and/or physal damage. Differential growth between the paired bones of the lower arm and leg can lead to joint deformity and loss of function. Distortion of the physis secondary to altered mechanical forces may exacerbate this problem. Growth abnormalities should be predicted and aggressive treatment designed to prevent deformity may be necessary (Fig. 38.5).

Enchondromas

An abnormality in the ossification of the cartilage columns of the physis may be the precursor of these cartilaginous masses. They are discussed in Chapter 37.

Fibrous dysplasia

This common disorder often presents as a chance finding on radiography and probably results from a somatic mutation causing defective bone formation (Fig. 38.6). This is discussed in Chapter 37 (Summary box 38.4).

Summary box 38.4

Congenital and developmental abnormalities of the skeleton

- Achondroplasia most affects endochondral ossification and presents with disproportionate dwarfism
- Exostoses may cause cosmetic or functional problems secondary to growth disturbance
- Enchondromas mostly occur in the hands and feet – multiple enchondromas occur in Ollier's disease and Maffucci's syndrome

METABOLIC BONE DISEASE

Rickets

There are various causes of the clinical condition described as rickets but in all cases the primary problem can be described as inadequate mineralisation of growing bone (Table 38.4).

In severe cases skeletal deformities along with classic radiographic features may surround every physis (Fig. 38.7).

The mainstay of treatment is medical to improve mineralisation. Deformity correction occurs with growth. Surgery may be necessary for the management of pathological fractures or to correct mechanical alignment associated with residual deformity when the medical condition has been controlled.

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) or 'brittle bone disease' represents a spectrum of conditions linked by a qualitative and/or quantitative

Louis Xavier Edouard Léopold Ollier, 1830–1900, Professor of Surgery, Lyons, France, described enchondromatosis in 1899.
Angelo Maffucci, 1845–1903, Professor of Pathological Anatomy, Pisa, Italy, described this syndrome in 1881.

Figure 38.5 Radiograph of the knee showing multiple broad-based osteochondromas.

Figure 38.6 The diaphyseal lesions of fibrous dysplasia classically have a 'ground glass' appearance and, if extensive, may be associated with angular deformity or pathological fracture.

malfunction of collagen production. Many specific genetic defects have been identified; most are caused by mutations in the collagen *1A1* or *1A2* gene on chromosome 17q or 7q respectively. The bone may break easily but it usually heals promptly and well. All structures that contain collagen may be affected, which accounts for the ligamentous laxity, blue sclerae and poor teeth found in some forms of this disease.

Cyclical bisphosphonate treatment has become popular in the management of severe OI. Its use decreases bone resorption and

Figure 38.7 Radiographs demonstrate widened physes with cupped, flared metaphyses.

bone turnover. This reduces bone pain and fracture rate, which in turn improves weight-bearing mobility and, subsequently, bone strength (Fig. 38.8).

When a bone fractures care must be taken to minimise disuse osteoporosis and maintain normal bone alignment. Treatment options range from simple casting techniques to more specialised procedures that include intramedullary nailing to correct/maintain limb alignment while allowing growth (Fig. 38.9) (Summary box 38.5).

Summary box 38.5

Metabolic bone disease

- Rickets, resulting from nutritional or other causes, is characterised by failure of bone mineralisation
- In osteogenesis imperfecta there is a defect in type I collagen production
- In severe forms of osteogenesis imperfecta, frequent fractures lead to progressive deformity and treatment with bisphosphonates may reduce the fracture rate

ABNORMALITIES OF THE HIP

Developmental dysplasia of the hip

This term describes the spectrum of hip instability ranging from the irreducibly dislocated hip to the hip that is correctly located but associated with a shallow ('dysplastic') acetabulum.

Table 38.4 Common causes of rickets

Nutritional	Reduced intake of vitamin D and calcium (high intake of phytates or oxalates may be contributory)
Environmental	Inadequate exposure to sunlight
Gastrointestinal disease	e.g. Crohn's disease, gluten-sensitive enteropathy
Genetic	e.g. X-linked hypophosphataemia
Renal disease	e.g. end-stage renal failure, renal tubular anomalies. Secondary hyperparathyroidism changes may be present

Figure 38.8 Radiograph of a child with osteogenesis imperfecta who has been treated with cyclical bisphosphonates. Multiple growth lines are visible in addition to an intramedullary device.

Figure 38.9 Radiograph of two adolescent femora showing different types of intramedullary alignment device *in situ*.

Reflecting the spectrum of pathology there is a spectrum of presentation of DDH from birth to adult life: in a neonate there may be instability, a toddler may limp, an adolescent may experience exercise-induced pain and, in an adult, there may be pain as a result of degenerative arthritis.

Incidence

The incidence of neonatal instability may be as high as 20 cases per 1000 births whereas the incidence of dislocated hips is about 2 cases per 1000 live births; this is because many hips that are unstable at birth will stabilise spontaneously.

Aetiology (Table 38.5)

- **Gender.** DDH is five times more common in girls than boys, possibly related to hormonal factors causing temporary joint laxity.
- **Breech presentation.** Up to 20% of breech babies, particularly with the extended breech (hips and knees extended), have DDH.

Table 38.5 Risk factors associated with an increased incidence of hip dislocation

DDH	Female gender Breech position Family history and/or ethnic origin Oligohydramnios and/or associated moulding abnormalities
Teratologic hip dislocation	Associated syndromic features Neuromuscular conditions

- **Birth order.** DDH is more common in firstborns because the primigravid uterus is tighter, restricting movement, and in the left hip, as a result of the common fetal position.
- **Oligohydramnios.** This restricts fetal movement and may also increase the risk of other postural deformities such as torticollis and metatarsus adductus; the presence of these factors raises the possibility of DDH.
- **Family history.** The incidence of DDH is increased significantly with a positive family history. This may reflect faulty acetabular development or excessive ligamentous laxity. When there is joint laxity the clinical diagnosis of DDH can be difficult as there may be no limitation of hip abduction.
- **Racial and seasonal variations.** DDH is more common in certain regions and in certain races. The incidence is low among African but high in Navaho Indian populations, perhaps because of a combination of genetic and environmental factors; swaddling the legs together will exacerbate an unstable hip whereas carrying the baby astride the carer's hip encourages a position of hip flexion and abduction that will help stability. DDH is more common in babies born in winter.

DDH is often found in association with generalised syndromes or neuromuscular conditions such as spina bifida and arthrogryposis. Sometimes these conditions are occult and can lead to unexplained problems during treatment. These teratologic hips are often resistant to surgical intervention and the results are poor. The overall condition and prognosis of the child must also be considered.

Diagnosis

Neonates

All newborn babies should be screened clinically for instability and limitation of hip abduction. The hips should be examined again at 6 weeks.

Clinical instability The knees and hips are flexed and the thigh held by the examiner with the thumb along the medial aspect and the ring or middle finger behind the greater trochanter. The hips are gently abducted while lifting the greater trochanter upwards with the finger. A dislocated hip may reduce during this manoeuvre with a soft clunk – the Ortolani test (Fig. 38.10a). The examiner should note if both hips abduct fully. If the hip does abduct fully, then, as a continuous movement, the hip is adducted while pressing gently downwards on the knee with the palm and inside of the thumb. An unstable hip may dislocate or

The Navaho Indians are an American Indian people from New Mexico and Arizona, USA.

(a) Ortolani

(b) Barlow

Figure 38.10 Line diagram illustrating the Ortolani and Barlow tests for developmental dysplasia of the hip.

sublux with a soft clunk – the Barlow test (Fig. 38.10b). With an irreducible hip there is no clunk of reduction but there will usually be limitation of abduction. Bilateral dislocation may be missed as abduction is symmetrical, and abduction may be normal when there is ligamentous laxity.

Ultrasound Ultrasound can confirm clinical suspicion of dislocation or instability and be used to monitor the early treatment (Fig. 38.11). It can also be used as a screening tool, either universally or in 'at-risk' groups. As the sonographic appearance of most hips matures (becomes less dysplastic) spontaneously there is a risk of overtreatment if scans are performed too early. If delayed, the best opportunity for acetabular remodelling may be lost. Ideally, therefore, screening scans should be performed between 4 and 6 weeks after birth and treatment instigated promptly.

X-ray Plain radiographs can also be used to evaluate dysplasia from about 12 weeks. The appearance of the femoral ossific nucleus is often delayed in the presence of dysplasia (Fig. 38.12).

Infant

The hips should be checked as part of routine developmental monitoring, looking in particular for limitation of abduction in flexion, limb asymmetry, such as an extra thigh crease, or limb shortening.

Marius Ortolani, Orthopaedic Surgeon, Istituto Provinciale Per L'Infanzia di Ferrara, Italy, described this test in 1937.
Thomas Geoffrey Barlow, 1915–1975, Orthopaedic Surgeon, The Salford Royal Hospital, Salford, England.

Child

Children present with a limp. The affected leg tends to be short and externally rotated and there may be unilateral tiptoe walking. There is an extra thigh crease and limited abduction. However, the signs may be subtle and easily misinterpreted as normal development in an unsteady toddler. If both hips are affected there will be a waddling gait.

Adolescent

Discomfort after exercise is the usual feature but the pain may be in the knee. Typically, a radiograph shows dysplasia and possibly subluxation.

Adult

Pain is the usual complaint and radiographs may show degenerative change as well as dysplasia (Summary box 38.6).

Summary box 38.6

Diagnosis of DDH

- All neonates are screened clinically using the Barlow and Ortolani tests, at birth and then again at 6 weeks
- Ultrasound is used to confirm and monitor hip stability and as a screening test, particularly in 'at-risk' babies
- Radiography can be carried out from 3 months onwards
- Older children may present with a limp

Management

When diagnosed early, conservative treatment is likely to be successful, but after walking age, surgery is usually required. However, the principles are the same; the objective is to obtain a stable, congruous reduction and to avoid damage to the capital epiphysis [avascular necrosis (AVN)] or growth plate. Such damage is a major complication, causing stiffness, coxa vara and shortening.

Neonate

Some normal hips are unstable at first because of ligamentous laxity, but these stabilise within the first couple of weeks of life and do *not* need treatment. Ultrasound will confirm whether the acetabulum is normal.

Hips that remain unstable or are dislocated at rest are treated with harnesses or splints devised to maintain the hip safely in the reduced position of abduction and flexion. A harness (e.g. Pavlik harness) allows controlled movement and may be safer but it requires close supervision (Fig. 38.13). It is also possible to ultrasound hips in the harness to check on progress. A splint (e.g. von Rosen) holds the hips more rigidly but carries a greater risk of AVN. Excessive abduction should be avoided with either type of device. If the hips fail to relocate or stabilise or can only be held reduced in excessive abduction then treatment should be discontinued.

Infant

Successful treatment with a harness is unusual after 4–6 months of age. For the late-presenting hip or the hip that fails conservative treatment, an examination under anaesthetic may allow a

Sophus von Rosen, Orthopaedic Surgeon, Malmo General Hospital, Malmo, Sweden.

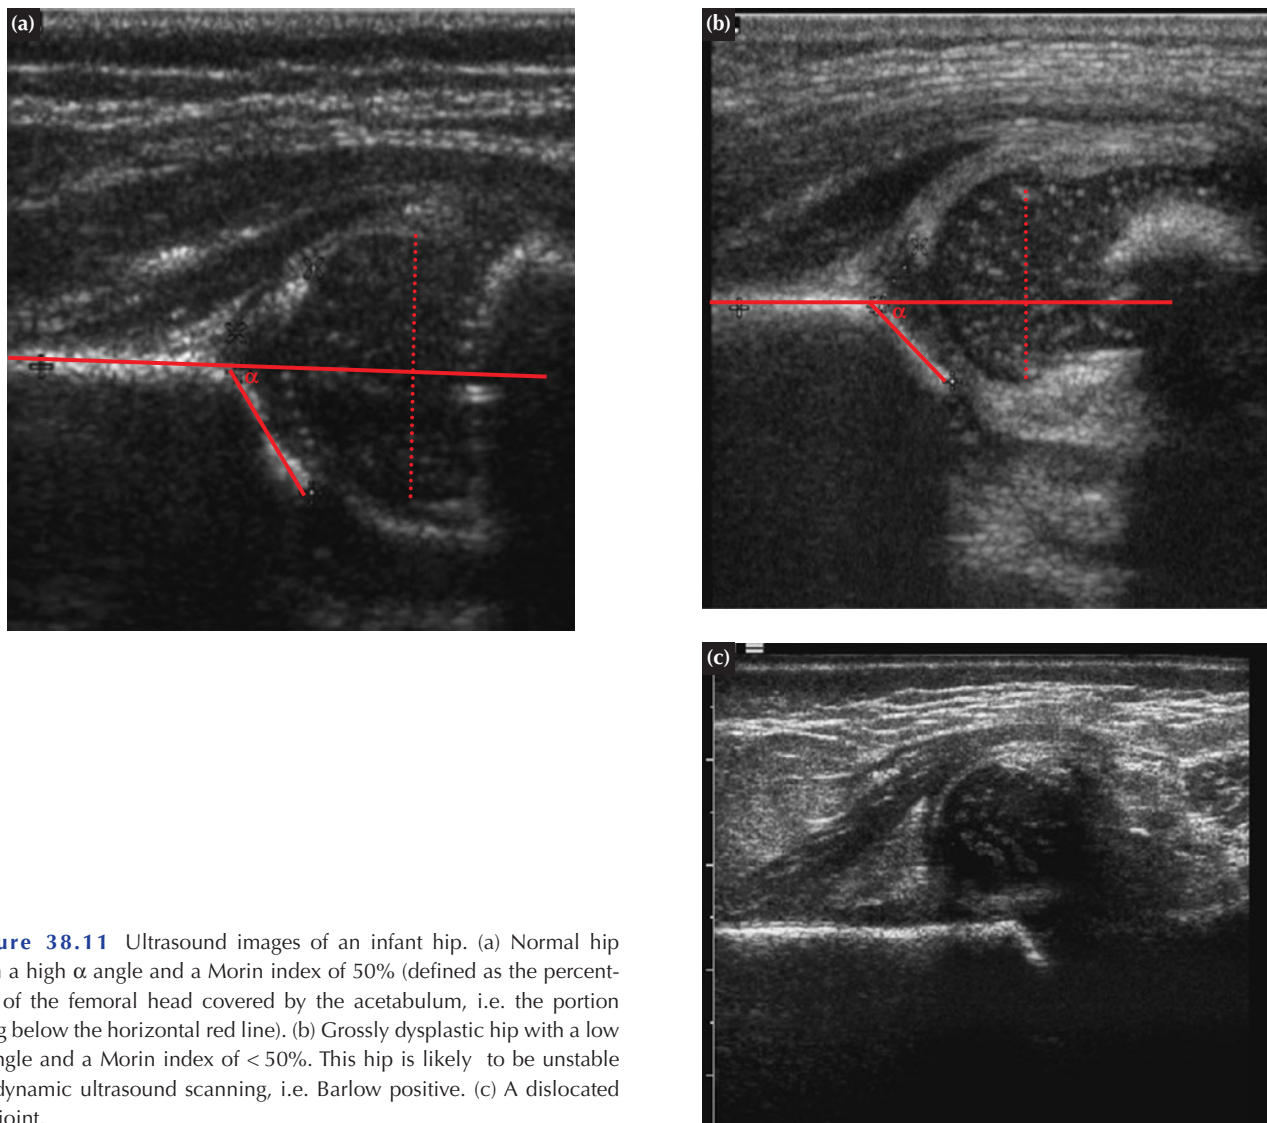

Figure 38.11 Ultrasound images of an infant hip. (a) Normal hip with a high α angle and a Morin index of 50% (defined as the percentage of the femoral head covered by the acetabulum, i.e. the portion lying below the horizontal red line). (b) Grossly dysplastic hip with a low α angle and a Morin index of < 50%. This hip is likely to be unstable on dynamic ultrasound scanning, i.e. Barlow positive. (c) A dislocated hip joint.

Figure 38.12 Anteroposterior pelvic radiograph showing Hilgenreiner's line (a) and Perkins' line (b). The femoral head (ossific nucleus) of a normal hip lies in the inner lower quadrant. The right hip is normal, the left hip has developmental dysplasia of the hip.

closed reduction to be attempted. The arthrogram shows whether a concentric reduction is present and, if not, it will indicate which structures are blocking reduction and a psoas/adductor release can be performed as necessary. A closed reduction must be held with a short- or long-leg hip spica cast for some months.

If the hip is irreducible or can only be held in an extreme position with a small safe zone then this treatment method must be abandoned and an open reduction considered via a medial approach or, in an older infant, via an anterior approach (Summary box 38.7).

Summary box 38.7

Management of early DDH

- Many hips that are unstable in the first few days of life do not need treatment
- Until the age of 4–6 months, a harness or splint is usually effective
- In older babies, closed reduction is still sometimes possible
- For failed closed treatment, open surgical reduction may be required

Figure 38.13 The anterior strap of the Pavlik harness controls hip flexion whereas the posterior strap limits adduction and encourages abduction.

Toddler and young child

The older the child, the less likely that reduction by closed methods will succeed (Fig. 38.14). Open reduction together with bony realignment is necessary. The traditional approach is to carry out open reduction via an anterior approach after the age of 1 year. Earlier surgery via the medial approach can be considered but access is limited and no additional surgery such as capsulorrhaphy or bony realignment can be performed through the same incision. The anterior approach offers excellent access. A pelvic osteotomy may be required to reorient or close down the acetabulum, and

Figure 38.14 Anteroposterior pelvic radiograph showing acetabular dysplasia with subluxation (developmental dysplasia of the hip) of the left hip. This child presented at the age of 4.

femoral shortening or derotation osteotomies are often used to improve stability.

Older child

In the older child a similar approach can be used. Acetabuloplasty is frequently required. The older the child, the more difficult and unrewarding surgery becomes. In bilateral cases surgery is often not undertaken in children aged over 6–8 years and in unilateral cases over age 8–10 years.

Adolescent and young adult

These hips are often subluxed. Investigations are required to see if the hip can be reduced and, if so, if that position can be recreated with a combination of pelvic and femoral osteotomies. For the hip that cannot be reduced, some form of acetabular augmentation may reduce symptoms and delay the onset of degenerative change requiring hip arthroplasty (Summary box 38.8).

Summary box 38.8

Management of late-presenting DDH

- The older the child, the more likely it is that they will need surgery
- Femoral osteotomy can stabilise the hip and reduce pressure on the femoral head
- Pelvic osteotomy can redirect or reshape the acetabulum
- Acetabular remodelling ceases at the age of 6 years
- Avascular necrosis is a risk of treatment of DDH at any stage

Secondary procedures and complications

Regular follow-up is required to ensure that the hip remains concentrically reduced and that the acetabulum continues to develop. Acetabular remodelling continues up until the age of 6 years and may be assessed objectively by measuring the acetabular index or, in children over 5 years, the centre–edge angle (Fig. 38.15).

If the acetabulum does not improve then a variety of operations are available. For example, the innominate osteotomy or shelf procedures both improve cover. Significant AVN with relative overgrowth of the greater trochanter can cause a Trendelenburg limp and distal transfer of the trochanter may help. Occasionally, a leg length difference needs treatment. In the long term there is an increased risk of osteoarthritis necessitating hip replacement or resurfacing.

Legg–Calvé–Perthes' disease

This condition is characterised by the development of AVN of the proximal femoral epiphysis and is probably one of the most controversial topics in paediatric orthopaedics.

Incidence and aetiology

The condition is rare and affects boys predominantly, most commonly between the ages of 4 and 8 years. The aetiology is

Arthur Thornton Legg, 1874–1939, Orthopaedic Surgeon, The Children's Hospital, Boston, MA, USA.

Jacques Calvé, 1875–1927, Orthopaedic Surgeon, La Fondation Franco-Americaine, Berck Plage, Pas-de-Calais, France.

Legg, Calvé and Perthes all described osteochondritis of the head of the femur independently in 1910.

Figure 38.15 Anteroposterior pelvic radiographs demonstrating the acetabular index (AI) and the centre-edge (CE) angle. (a) Normal hips; (b) the left hip shows residual dysplasia. The AI is increased compared with the normal right hip. The left CE angle would be smaller than the right too but is not measured on this radiograph.

unknown although a variety of factors have been implicated. Up to 10% of patients may develop bilateral disease.

Recently, thrombophilia secondary to protein deficiencies has been cited as an aetiological factor but there is little supporting evidence for this (Summary box 38.9).

Summary box 38.9

Factors implicated in the pathogenesis of Perthes' disease

- Low birthweight
- High birth order
- Abnormalities in anthropometric measurements
- Delayed bone age
- Low socio-economic status

Pathology

Once established the process follows a relatively well-defined course. The avascular change may affect the whole of the femoral head or only part of it. The avascular bone may collapse and this is followed by fragmentation of the ossific nucleus and subsequent healing with revascularisation and regeneration of the bony epiphysis; in this respect Perthes' disease is a self-limiting condition but, during the collapse and fragmentation phases, femoral head deformity occurs.

Diagnosis

The history, clinical examination and anteroposterior and 'frog' lateral radiographs of the pelvis make the diagnosis. An intermittently painful hip (or knee) with a limp and restriction of hip movements requires investigation. The radiographic features will vary with the stage of the disease and may not correlate with the clinical condition (Fig. 38.16).

AVN of the femoral head may be due to other causes and a differential diagnosis should be considered, particularly if the radiographic changes are bilateral (Summary box 38.10).

Figure 38.16 Anteroposterior pelvic radiographs of Perthes' disease demonstrating whole head involvement. (a) Right-sided disease; the process is in an early phase. The area of dense necrotic bone is visible (b). There has been collapse and fragmentation.

Summary box 38.10

Causes of avascular necrosis of the femoral head

- Steroids
- Infection
- Perthes' disease
- Sickle cell disease
- Hypothyroidism
- Skeletal dysplasia – classically multiple epiphyseal dysplasia

Management (Table 38.6)

The aim of treatment is to minimise femoral head deformity and, hence, reduce the likelihood of secondary acetabular dysplasia. To encourage sphericity of the head it is important to maintain a good range of movement with regular analgesia and physiotherapy and avoid joint contractures developing. Some restriction of sporting activity is advisable but the routine use of crutches and/or wheelchairs is to be discouraged because of the flexion/adduction posture that they promote. Brace management on its own seems ineffective in maintaining movement or head sphericity, perhaps because the 'good' hip moves more readily than the affected hip.

The role of operative treatment is controversial. Surgery can be performed early to prevent deformity secondary to femoral head collapse or late to 'salvage' a poor mechanical situation, such as hinge abduction occurring because of deformity. In this case the surgery must be performed after the stage of collapse when the head is no longer vulnerable to loading pressures, otherwise recurrent deformity develops.

Joint distraction (arthrodiastasis) via an articulated external fixator to preserve some joint movement may maintain femoral head height but there are no long-term results available yet.

Not all hips with deformity require 'salvage' surgery. With time, remodelling of deformity does occur, with secondary acetabular changes leaving an aspherical but congruent hip joint. Thus, young children, with more time to remodel, have a better prognosis. Long-term follow-up may be required to deal with

sequelae such as mechanical symptoms caused by loose osteochondral fragments, a Trendelenburg gait secondary to trochanteric overgrowth or a short-leg gait. A leg length discrepancy may exacerbate the poor mechanical situation associated with coxa breva and trochanteric overgrowth. Degenerative change may occur in adult life.

There are other conditions (all eponymous) in which there are radiographic changes of AVN (Table 38.7). Again, the radiographic changes 'heal' but the change in shape of the affected bone may lead to secondary joint stiffness and loss of function (Summary box 38.11).

Summary box 38.11

Legg–Calvé–Perthes' disease

- Most common in boys aged between 4 and 8 years
- AVN of the femoral head leads to softening and collapse; healing occurs with the return of the blood supply
- Management tries to contain the head within the acetabulum and maintain its sphericity
- Treatment may be non-surgical, to maximise range of movement, or surgical, for containment or 'salvage'
- The prognosis is better in younger children who have more remodelling potential

Slip of the upper (capital) femoral epiphysis

The physis links the proximal femoral epiphysis (the femoral head) to the metaphysis of the femoral neck. In certain physiological or pathological conditions a 'complete fracture' or a 'stress fracture' through the physis allows the epiphysis to displace on the femoral neck in a manner similar to that which occurs with an intracapsular femoral neck fracture. The leg comes to lie in a shortened, externally rotated position. There is usually painful limitation of hip joint movement. Hilton's law, which states that a joint is supplied by the same nerves as the muscles that move the joint, explains why so many children present with knee pain although the pathology is in the hip.

Table 38.6 A guide to some of the surgical options available for the management of Perthes' disease

Timing	Type of procedure	Comments	Aim
Early	Femoral osteotomy Innominate osteotomy Shelf acetabuloplasty	Varus and derotation	To cover ('contain') the vulnerable femoral head
Intermediate	Arthrodiastasis	Hinged distraction to allow movement	To reduce deforming pressures on the femoral head
Late	Femoral osteotomy Cheilectomy Arthrotomy Trochanteric epiphyseodesis	Valgus and extension; to remove osteochondral fragments	To improve joint congruity and hence function; to improve joint mechanics
Contralateral limb	Distal femoral epiphyseodesis		To improve leg length discrepancy and reduce effects on hip joint mechanics

John Hilton, 1805–1878, Surgeon, Guy's Hospital, London, England.

Table 38.7 Other conditions (commonly classified as osteochondroses) in which the radiographic appearance is of avascular necrosis

Condition	Affected bone
Keinbock's disease	Lunate
Panner's disease	Capitellum of the humerus
Freiberg's disease	Metatarsal head – usually the second
Köhler's disease	Navicular

Incidence and aetiology

Slip of the upper (capital) femoral epiphysis (SUFE or SCFE) is rare, with an incidence of around 5 cases per 100 000 population. Boys are affected most commonly: the peak incidence is related to the start of puberty and, hence, is earlier in girls than in boys. At this stage, secondary to hormonal changes, the strength of the growth plate, its resistance to shear and its orientation are changing. The hip is therefore 'at risk' and normal forces, exacerbated by obesity and repetitive minor trauma, may precipitate a slip.

Other conditions such as hypothyroidism and renal failure also increase the risk of a slip. Patients who have undergone radiotherapy treatment may be at increased risk if the treatment has weakened the physis and/or been responsible for pituitary hormonal changes.

Diagnosis

The diagnosis is suggested by the history and examination and confirmed on plain radiography (Fig. 38.17). Displacement is

Figure 38.17 Anteroposterior pelvic radiograph demonstrating a mild slip of the upper (capital) femoral epiphysis on the right side. A line drawn along the upper margin of the femoral neck should transect the femoral head (left side) – if it does not do so (right side) a slip is present. There are many other radiographic features that help confirm the diagnosis but the changes are often subtle.

Robert Kienbock, 1871–1953, Professor of Radiology, Vienna, Austria, described this condition in 1910.

Hans Jessen Panner, 1871–1930, Radiologist of Copenhagen, Denmark, described this condition in 1927.

Albert Henry Freiberg, 1869–1940, Professor of Orthopaedic Surgery, The University of Cincinnati, Cincinnati, OH, USA, described this disease in 1926.

Alban Köhler, 1874–1947, Radiologist of Wiesbaden, Germany, described this disease in 1908.

sometimes difficult to identify on an anteroposterior radiograph but more obvious on a lateral view.

Classification

The severity of the slip can be graded on the lateral radiograph by how much of the metaphysis is uncovered (Table 38.8).

The condition can also be classified according to its timing. Epiphyseal displacement can occur slowly with the patient presenting with *chronic* symptoms or suddenly with an *acute* onset of symptoms or there may be an acute episode on the background of chronic symptoms (*acute-on-chronic*).

Management

Following an *acute* episode the patient is often unable to bear weight through the leg and the slip is considered to be *unstable* by the Loder classification. Displacement is often *moderate* or *severe*. This situation is very similar to a displaced intracapsular femoral neck fracture in a child or young adult. An acute severe unstable SUFE is an emergency: poor treatment will result in death of the femoral head. The risk of AVN is considerable and is reduced by prompt screw fixation to stabilise the 'fracture' (Fig. 38.18). A gentle repositioning of the femoral head may be acceptable and often occurs inadvertently with the reduction of muscle spasm that accompanies the general anaesthetic. Current evidence suggests that to be effective such treatment must take place within 24 hours of injury. If delayed the outcome of treatment may be worse than the natural history of the condition, and the rate of AVN increases.

With *chronic* slips the patient is usually able to weight bear, albeit with pain, and the slip is considered stable. Screw or pin fixation *in situ* will relieve pain and often improve the range of movement but permanent reduction in abduction, flexion and internal rotation will be present (Fig. 38.19). The leg is slightly short.

In the *acute-on-chronic* case, repositioning of the acute element of the slip may be feasible. Full correction is impossible and must not be attempted.

If the slip is severe it may be impossible to place a screw in a satisfactory position in the epiphysis, even by starting anteriorly on the metaphyseal neck. In addition, despite fixation *in situ*, there may be significant, persistent malalignment leading to restriction of joint movement. In such cases a realignment osteotomy must be considered. As with all osteotomies, the closer the correction is to the site of deformity, the better the outcome; however, in this situation, the risks of AVN or chondrolysis complicating correction at the level of the physis may be unacceptably high, in which case a more distal osteotomy, for example in the intertrochanteric region, could be considered.

Bilateral slips do occur and the reported incidence is variable.

Table 38.8 Grading of the severity of slip of the upper (capital) femoral epiphysis

Slip severity	Metaphysis uncovered (%)
Mild	< 33
Moderate	33–66
Severe	> 66

Randall Loder, Professor of Orthopaedic Surgery, Philadelphia, PA, USA.

Figure 38.18 Anteroposterior pelvic radiograph showing a left-sided acute severe unstable slip of the upper (capital) femoral epiphysis. (a) At presentation; (b) following partial repositioning and fixation with a cannulated screw.

Prophylactic pinning of the normal but ‘at-risk’ hip may be considered (Summary box 38.12).

Summary box 38.12

Slip of the upper (capital) femoral epiphysis

- Occurs in prepubertal children, mainly boys
- Often presents with knee pain and the leg may be shortened and externally rotated
- Classification may be according to the severity of slip, whether acute or chronic, or whether stable or unstable – all may affect the prognosis
- Most slips are pinned *in situ* with a single screw in the centre of the epiphysis
- Avascular necrosis is the most feared complication of both the condition and its treatment

ABNORMALITIES OF THE KNEE AND LOWER LEG

Many knee problems are self-limiting. Others require surgical consideration to reduce the risk of degenerative change in the longer term.

Figure 38.19 Anteroposterior radiograph showing screw fixation *in situ* of a case of bilateral chronic slip of the upper (capital) femoral epiphysis. Note the position of the screw entry point on the anterior femoral neck.

Osteochondritis dissecans

Osteochondritis dissecans (OCD) is found most commonly in the knee although it does affect other joints. An osteochondral fragment becomes partially or completely separated from the joint surface. Magnetic resonance imaging (MRI) is usually diagnostic. In mild cases, or those treated early with rest and activity modification, the fragment may remain attached and heal. If it detaches, partially or completely, mechanical symptoms may require treatment. Treatment aims to encourage bone healing via fixation of the fragment but, in certain cases, the loose body must simply be removed. Younger children have a better prognosis.

Discoid meniscus

This invariably affects the lateral meniscus, which is abnormally thick, covering much of the tibial surface. The knee may snap or clunk when extended and there is often pain, especially when the menisiofemoral ligament is torn. MRI is usually diagnostic. Surgery is only required for pain or mechanical symptoms.

Anterior knee pain

In children, the extensor mechanism is the commonest site of knee pain.

Osgood–Schlatter disease is a traction apophysitis of the patellar tendon insertion, probably caused by the high biomechanical strain as the mobile ligament inserts via a bone/cartilage ‘sandwich’ onto the apophysis. Pain, tenderness and swelling at the tibial tubercle, exacerbated by exercise, are diagnostic and radiographs are unnecessary. (The normal apophysis often appears fragmented.) Treatment is rest and analgesia, and the condition resolves once the apophysis has fused.

Patellofemoral pain is common in adolescents and often attributed to a degree of patellar maltracking. Treatment, as with

Robert Bailey Osgood, 1873–1956, Professor of Orthopaedic Surgery, Harvard University Medical School, Boston, MA, USA.

Carl Schlatter, 1864–1934, Professor of Surgery, Zurich Switzerland. Osgood and Schlatter described osteochondritis of the tibial tubercle independently in 1903.

more extreme degrees of patellar instability, starts with physiotherapy to develop the quadriceps muscles, particularly vastus medialis. Surgery is rarely appropriate.

Fibular hemimelia

In this longitudinal deficiency there is failure of formation of the lateral 'column' of the lower leg (Fig. 38.20 and Table 38.9). Management varies with the severity of the deficiency and treatment options range from the use of a shoe raise, through multiple episodes of limb equalisation surgery to amputation. An early prediction of the leg length discrepancy at maturity allows a realistic treatment plan to be devised for the patient that includes an honest assessment of final outcome and the time required to achieve this.

Blount's disease

In this condition there is disordered growth in the posteromedial tibial physis. The aetiology is unknown but the infantile form is more common in those of Afro-Caribbean origin. The adolescent-onset disease affects all ethnic origins. Risk factors include early walking and obesity. The child presents with progressive and often severe tibia vara with significant intoeing. There are classical features on radiography (Fig. 38.21).

Treatment is surgical and, following correction of limb alignment via an osteotomy, an epiphyseodesis of the remaining physis may be necessary to prevent recurrence of deformity.

Congenital pseudarthrosis of the tibia

This rare condition presents clinically with an anterolateral bow of the tibia with or without a fracture. Classic radiographic

Table 38.9 Classical radiographic features of fibula hemimelia

Foot and ankle	Absent lateral rays; tarsal coalition; ball and socket ankle joint
Lower leg	Absent or deficient fibula; tibial bow
Knee	Absent cruciate ligaments; deficient lateral femoral condyle
Femur	Relative hypoplasia
Limb length and alignment	Short; external rotation \pm valgus

Figure 38.20 Anteroposterior (a) and lateral (b) radiographs of two lower limbs showing some of the features of a fibular hemimelia: absent 5th ray in the foot, absent fibula and deformed tibia.

Figure 38.21 Anteroposterior radiograph of the left knee demonstrating changes compatible with Blount's disease affecting the posteromedial tibial physis with changes in both the epiphysis and the metaphysis.

changes are noted and up to 50% of cases are thought to be associated with neurofibromatosis. Once fractured the tibia is reluctant to heal and long-term orthotic treatment may be necessary, with subsequent surgical procedures designed to obtain bony union and restore leg length (Summary box 38.13).

Summary box 38.13

Abnormalities of the knee and lower leg

- *Osteochondritis dissecans* – better prognosis in children than adults
- *Discoid meniscus* – usually lateral, may require surgery
- *Anterior knee pain* – treatment almost always conservative
- *Fibular hemimelia* – associated with abnormality from the hip distally
- *Blount's disease* – clinically, a sharp proximal tibial angulation
- *Congenital pseudarthrosis of the tibia* – anterolateral bowing

ABNORMALITIES OF THE FOOT AND ANKLE

Parents are often concerned that minor foot abnormalities will cause their child to be clumsy or slow. This is rarely the case. A careful examination excludes significant pathology and explanation reassures parents.

Club foot

In this condition, more correctly called congenital talipes equinovarus (CTEV), the foot is deformed in three planes (Fig. 38.22). In true CTEV the deformity is fixed. Intrauterine moulding can cause an identical pattern of deformity that is postural and correctable.

Incidence and aetiology

The overall incidence varies from one to six cases per 1000 live births, depending on racial differences. It is more common in boys and bilateral in approximately 50% of cases. A family history is

Figure 38.22 Anteroposterior photograph of a foot showing the classic deformities associated with a clubfoot. The hindfoot is in equinus and varus, there is midfoot cavus and the forefoot lies adducted and apparently supinated, although actually pronated relative to the hind-foot.

common but inheritance is likely to be multifactorial. Most cases are idiopathic but as the outcome varies with the aetiology it is important to consider the cause when planning treatment (Table 38.10).

Pathology

The talonavicular joint is subluxed with the navicular displaced medially and plantarwards with respect to a deformed talar head and neck. Ligaments, particularly the calcaneofibular ligament, and tendon sheaths, such as the posterior tibial tendon sheath, are shortened and thickened and have been shown to contain contractile myofibroblasts. Conversely, gastrosoleus and posterior tibial muscles are smaller and thinner than normal, with reduced myofibrils and increased connective tissue, possibly because of a regional nerve abnormality. The vascular supply via the dorsalis pedis may be altered. Theories abound but it is not known which abnormalities are primary and which occur as the deformity develops.

Clinical assessment

It is usually possible to distinguish the postural clubfoot from the structural (rigid) foot, although not always immediately after birth.

The postural clubfoot may need some physiotherapist input via stretching or casting but can soon be manipulated into a 'normal' position of 45° of abduction and full dorsiflexion with the calcaneus well down in the heel pad. Medial creases are minimal and posterior creases shallow and multiple. Some studies suggest that

Table 38.10 Several different types of clubfoot are recognised

Type	Example
Postural	
Idiopathic	
Neuromuscular	Spina bifida; arthrogryposis; spinal cord anomalies – must be considered in feet that resist treatment or relapse
Syndromic	Trisomy 15

intrauterine moulding is important in the development of both DDH and the postural clubfoot and recommend neonatal hip screening for these 'at-risk' infants.

The structural clubfoot has fixed deformity with elements of equinus, varus and supination and cannot be corrected beyond neutral. Cavus is often marked. The heel feels 'empty' as the calcaneus is held up by the shortened tendo Achilles. There is a deep medial and single posterior crease.

All children with structural clubfoot deformity have an associated small calf and a small foot. Some tibial shortening may become apparent with growth. They should be examined carefully for abnormal neurological signs of intraspinal pathology.

Both Pirani and Dimeglio have developed scoring systems based on the appearance of the foot in the position of maximal correction. These can be used to predict response to treatment and to monitor progress (Summary box 38.14).

Summary box 38.14

Clubfoot

- Triplanar deformity, with hindfoot equinus and varus, midfoot cavus and forefoot adduction and supination
- Incidence is one to six cases per 1000 live births, more common in boys and with a familial tendency
- Most cases are idiopathic but neuromuscular causes include spina bifida and arthrogryposis
- Scoring systems, such as those of Pirani and Dimeglio, can be used to assess the severity

Family counselling

The diagnosis of CTEV may be made during an antenatal ultrasound, at which time counselling is limited by uncertainty as to the severity of the deformity. Antenatal counselling is a good opportunity to accustom the parents to the idea of a lengthy period of treatment. At the same time they can be reassured that the child with clubfoot will walk, run and play with his/her peers. The same advice applies if the first meeting is post-natally.

Treatment

Recently, there has been a major swing from operative to non-operative treatment of clubfoot.

Ponseti method

The method described by Ponseti is associated with successful correction of the foot deformity in 95% of cases without the need for a formal surgical release. The technique has been introduced successfully worldwide but a learning curve exists. Treatment commences within a few days of birth. A specific series of manoeuvres results in gradual correction of the deformity, using a series of well-moulded above-knee plaster casts (Fig. 38.23). The head of the talus is the fulcrum around which the rest of the foot swivels, using direct pressure on the first ray and counterpressure over the lateral aspect of the talar head with the distal femur supported. The first ray is elevated to remove the cavus by supinating the forefoot relative to the hindfoot. The varus, inversion and adduction are then gradually corrected by abducting the foot. The calcaneus rotates under the talus into a neutral position. After the forefoot has been corrected, most feet (about 80%)

Figure 38.23 A photograph of a series of casts documenting the stepwise correction of the foot deformity with the Ponseti method of serial manipulation and casting.

require a percutaneous Achilles tenotomy in order to dorsiflex the foot satisfactorily.

Once corrected the foot position is maintained by a foot abduction orthosis (FAO) that holds the feet in external rotation and slight dorsiflexion. The FAO is worn full-time for 3 months and at 'night and nap-time' for at least 18 months. Compliance may be difficult to achieve as the child gets older but failure to do so is associated with a higher relapse rate. Recurrent deformity can be treated with further plasters, even in older children, but a tibialis anterior tendon transfer may be required around the age of 2½–4 years for dynamic supination.

There is evidence that feet treated with the Ponseti method are less stiff, less likely to be painful and less subject to overcorrection than those treated surgically. It has the advantage that it can be performed successfully even when surgical facilities are limited. Other conservative regimes have been reported; some are variations on the Ponseti method and others are more resource-intensive. Overall, the results are not as good as with the true Ponseti method.

Surgical treatment

When conservative treatment fails, surgical intervention is required, ideally before walking age.

Surgical release is generally performed 'à la carte', with sequential release of the pathologically tight structures via either a Turco incision on the medial side of the foot or the Cincinnati incision, which runs circumferentially from the naviculo-cuneiform joint medially to the sinus tarsi laterally (Table 38.11).

This approach allows reduction of the subluxed joints but stabilisation may require the use of temporary Kirschner wires. Deformity correction should not be compromised by wound closure and the Cincinnati incision particularly can be left open to heal by secondary intention to preserve ankle position.

Postoperative casting is followed by splinting and physiotherapy as required. Good or excellent results are reported in 60–80% of children treated surgically, but stiffness and over- or undercorrection are common complications.

Martin Kirschner, 1879–1942, Professor of Surgery, Heidelberg, Germany, introduced the use of skeletal traction wires in 1909.

Table 38.11 The four stages of a peritalar release that might be required for the correction of a severe clubfoot deformity

Site	Structures requiring lengthening or release
Posterior	Tendo Achilles Ankle and subtalar joints Calcaneofibular ligament Posterior elements of the peroneal tendon sheaths
Medial	Abductor hallucis Tibialis posterior Talonavicular joint Toe flexors
Lateral	Calcaneocuboid joint
Plantar	Plantar ligaments Plantar fascia
Protect	Neurovascular bundle Talocalcaneal interosseous ligament (if possible)

Secondary surgery for such complications is often difficult and requires a careful assessment of the residual deformity in both the forefoot and hindfoot. Growth disturbance of the distal tibial physis must be considered. Surgical procedures may involve further soft-tissue releases or tendon transfers but, in the presence of fixed deformity, bony correction is often necessary. The foot becomes progressively stiffer with each surgical intervention (Summary box 38.15).

Summary box 38.15

Treatment of clubfoot

- The Ponseti method of serial casting is successful in 95% of feet, avoiding formal surgical release although percutaneous tenotomy is usually required
- The standard sequence is elevation of the first ray, gradual abduction to 60° and, finally, dorsiflexion, usually following Achilles tenotomy
- Tibialis anterior transfer can be used to correct dynamic supination in toddlers and older children
- Surgical release may need to address posterior, medial, plantar and lateral structures, and may result in a stiffer foot than one treated conservatively

Other foot and ankle conditions

Most postural deformities of metatarsus adductus and calcaneo-valgus feet improve spontaneously although in a small proportion minor residual deformity persists.

Congenital vertical talus (CVT) is rare and often associated with neuromuscular conditions such as arthrogryposis and spinal dysraphism. Clinically, there is a stiff 'rocker-bottom' foot and the underlying abnormality is dorsal dislocation of the navicular on the talus (Fig. 38.24). Correction is surgical.

In *tarsal coalition* there is failure of segmentation of adjacent tarsal bones. Presentation is usually in children of school age (up to teens) with hindfoot pain and recurrent ankle sprains. The stiff subtalar joint cannot accommodate uneven ground. The most common coalitions are talocalcaneal and calcaneonavicular (see Fig. 38.3, p. 565). Radiography, computerised tomography (CT) or bone scan may be required to confirm the diagnosis. Treatment

Figure 38.24 Congenital vertical talus. (a) Lateral photograph demonstrating a 'rocker-bottom foot'. (b) Lateral radiograph showing hindfoot equinus and suggesting dorsal subluxation of the non-ossified navicular and forefoot with respect to the head of the talus.

is initially conservative but, if the coalition requires surgical excision, this should be carried out before significant degenerative changes develop.

Curly toes that are flexed and medially deviated are common, often familial and rarely need treatment. They are caused by relative tightness of the toe flexors. Strapping is ineffective. Flexor tenotomy is used when there are symptoms such as rubbing, callosities and difficulty with shoe wear.

Table 38.12 Common minor congenital anomalies affecting the hand

Anomaly	Definition	Treatment
Extra/accessory digits		Excise/amputate when necessary
Syndactyly	Failure of separation of digits	Separation with/without skin grafting for functional or cosmetic reasons
Trigger thumb (digit)		Release of the A1 pulley of the flexor tendon sheath
Clinodactyly (usually the fifth digit)	Abnormal angulation of the digit in the radioulnar plane	Surgical treatment of the delta phalanx if deformity progressive or interfering with hand function
Camptodactyly (usually the fifth digit)	Fixed flexion deformity of proximal interphalangeal joint	Splinting/physiotherapy; surgery rarely indicated

James Warren Sever, 1878–1964, Orthopaedic Surgeon, The Children's Hospital, Boston, MA, USA, described apophysitis of the os calcis in 1912.

Other causes of foot pain in children include osteochondroses (see Table 38.7):

- *Köhler's disease*. This presents with dorsal forefoot pain and swelling in young children. The alarming radiological appearances resolve spontaneously and without sequelae.
- *Sever's disease* (enthesopathy of the calcaneal apophysis). This presents with heel pain related to activity. Tightness in the calf muscle complex may be a contributing factor.
- *Freiberg's osteochondrosis*. This presents with forefoot pain and avascular change in the second metatarsal head. It may be asymptomatic and can present at any age as an incidental finding on radiography. Occasionally it remains symptomatic because of changes within the joint. Bony spurs and osteochondral fragments may need excision (Summary box 38.16).

Summary box 38.16

Other foot and ankle conditions

- Congenital vertical talus – presents as 'rocker-bottom' foot
- Tarsal coalition – presents as a stiff, painful flat foot
- Curly toes are common – most do not need treatment
- Osteochondroses are almost always self-limiting

ABNORMALITIES OF THE UPPER LIMB

Minor abnormalities of the fingers are common (Table 38.12) and frequently require some surgical intervention; however, it must be remembered that, although hand appearance is important, comfort and function are more so.

Function must also be the most important consideration when managing other, more extensive, abnormalities of the upper limb. Treatment is delayed until hand dominance has been established and it is clear what problems a specific deformity are causing in a given child. Children are very adaptable and cope with certain disabilities much more readily than their parents or doctors expect.

Radial club hand

This longitudinal failure of formation is commonly associated with other malformations, for example as part of the VACTERL syndrome (abnormal vertebrae, anus, cardiovascular system, trachea, renal system and limb buds). The clinical presentation of

the upper limb problem depends on the severity of the malformation and, most specifically, whether the thumb is present and functional (Fig. 38.25). Treatment is a balance of conservative measures including physiotherapy and splinting and the judicious use of surgery to centralise and stabilise the hand and wrist on what is essentially a single bone forearm. Thumb reconstruction may be technically challenging. In later childhood, forearm lengthening may be considered.

An ulnar club hand is less common.

Radioulnar synostosis

This is a rare condition in which failure of separation of the embryonic radius and ulna proximally results in no forearm rotation with the hand held in a fixed position. The condition often presents in childhood when the fixed position, for example of full pronation, may become a functional problem. If it is, osteotomy of the forearm bones can change the fixed position but no surgical procedure can restore the range of movement.

Congenital radial head dislocation

The dislocation is usually posterolateral compared with the classic anterior dislocation that accompanies a Monteggia fracture–dislocation (Fig. 38.26). Some restriction of elbow joint movement and forearm rotation is noted and there may be some pain on activity. Excision of the prominent radial head may be required (Summary box 38.17).

Summary box 38.17

Upper limb abnormalities

- Radial club hand is highly associated with other congenital anomalies, for example as part of the VACTERL syndrome
- Radioulnar synostosis usually presents some time after birth with fixed forearm rotation
- Congenital radial head dislocation is usually posterolateral

Figure 38.25 Anteroposterior radiograph of a radial club hand demonstrating a short radius, a deformed ulna and an absent thumb.

Figure 38.26 Radial head dislocation. (a) Lateral radiograph of a forearm showing a proximal radioulnar synostosis with a posterolateral dislocation of the radial head. Note the underdeveloped radial head and neck. (b) Lateral radiograph of a traumatic anterior dislocation of the radial head with a normal appearance to the head and neck and a deformity in the proximal ulna.

SPINAL DEFORMITIES AND BACK PAIN

Congenital deformities

By definition these problems are present at birth and are either failures of formation or of segmentation of vertebral bodies. Failure of formation may result in a hemivertebra. Failure of segmentation may produce a unilateral bar or bilateral bar (i.e. fusion).

The clinical result is usually a scoliosis (Fig. 38.27), and treatment is based on the potential for curve progression. When a kyphosis results, progressive neurological deficit is common. Bracing is ineffective for congenital vertebral deformities.

Scoliosis

The term ‘scoliosis’ describes deviation and rotation of the spine such that the most obvious deformity is lateral curvature; the

Figure 38.27 Anteroposterior radiograph of the spine demonstrating multiple congenital vertebral anomalies including hemivertebrae.

rotational component is often most apparent in forward flexion (the forward bend or Adams test), when the rib asymmetry creates a 'rib hump' (Fig. 38.28).

The aetiology may be idiopathic, neuromuscular, syndrome-related or congenital, and this, as well as the age of onset, affects the natural history.

Idiopathic scoliosis is common and may be classified according to the age of onset (Table 38.13). In general, the earlier the onset, the more likely the deformity is to be progressive.

The adolescent idiopathic curve is the most common, affecting girls more commonly than boys, but careful assessment must exclude other diagnoses. Full neurological examination and exclusion of leg length discrepancy are essential. Idiopathic scoliosis is generally not painful and so the presence of significant pain requires exclusion of infection and, in particular, tumour. Radiological assessment is by measurement of the Cobb angle (Fig. 38.29). Curves with a Cobb angle of $< 20^\circ$ do not need treatment, progressive curves of $25\text{--}40^\circ$ are generally treated with bracing and those over 40° are considered for surgery (Summary box 38.18).

Figure 38.28 Clinical photograph of the Adams forward bend test that demonstrates the presence of a rib hump and the level of the curve.

Table 38.13 Classification of idiopathic scoliosis

Type	Age of onset
Infantile	0–3 years
Juvenile	4–10 years
Adolescent	11–18 years
Adult	Onset at maturity

Summary box 38.18

Scoliosis

- Deformity is multiplanar and includes a rotational component
- Aetiology may be congenital (underlying bony malformation), neuromuscular, syndromic or idiopathic
- Adolescent idiopathic scoliosis is the most common type
- Back pain associated with scoliosis may be associated with an acquired cause such as infection or tumour
- Treatment depends on the severity and likelihood of curve progression – it varies from observation, through bracing to surgery

Kyphosis

Normal kyphosis is $20\text{--}50^\circ$. When it exceeds this the cause may be postural or structural. Structural kyphosis is most commonly

Figure 38.29 Anteroposterior radiograph of a spine with a scoliosis (right thoracic), with a Cobb angle of 47° .

secondary to *Scheuermann's disease*, which presents as progressive kyphosis in adolescence and is characterised radiologically by vertebral wedging of 5° or more at three adjacent levels and vertebral end-plate changes. The aetiology is unknown. Treatment ranges from physiotherapy and bracing to surgery, depending on the degree of deformity, progression and symptoms.

Spondylolisthesis

Spondylolysis refers to a defect in the pars interarticularis of the vertebra. There are six types: congenital (dysplastic facet joints), isthmic (weak or elongated pars), degenerative, post-traumatic, pathological or post-surgical. *Spondylolisthesis* occurs when the upper vertebra slips forward on the lower; it is graded according to the percentage slip, measured by relating the slipped vertebra to the one below (Table 38.14).

Mild slips are often asymptomatic and do not require treatment. Treatment (physiotherapy, bracing and surgery) depends on the degree of slip and symptoms; mechanical back pain may respond to conservative methods but the development or threat of neurological involvement usually requires surgical intervention.

Torticollis

In torticollis the head is tilted toward and rotated away from the tight sternocleidomastoid muscle.

Congenital torticollis is usually secondary to intrauterine moulding but may present with fixed sternocleidomastoid contracture or with a palpable mass in the muscle. Plagiocephaly may develop and there is a strong correlation with DDH, requiring careful screening of the hips. Most cases resolve with stretching but, occasionally, surgical release of the sternocleidomastoid at one or both ends is needed.

Acquired torticollis is less common and may be caused by gastro-oesophageal reflux, posterior fossa tumour/other regional abnormality, inflammation/infection, ocular problems or atlanto-axial rotatory subluxation. A more comprehensive work-up is therefore required for torticollis presenting after the neonatal period.

Back pain

Children report back pain less frequently than adults although more than half will have had an episode by their late teenage years. Back pain that is mild, intermittent or occurs only on strenuous activity is usually self-limiting; however, back pain in a child is in itself a 'red flag' for serious spinal pathology (Summary box 38.19).

Table 38.14 Classification of spondylolisthesis according to severity of the slip

Grade	Percentage slip
0	No slip
1	< 25%
2	26–50%
3	51–75%
4	> 75%
Spondyloptosis	> 100% – complete translation

Holger Werfel Scheuermann, 1877–1960, Radiologist, The Municipal Hospital, Sundby, Copenhagen, Denmark, described juvenile kyphosis in 1920.

Summary box 38.19

'Red flag' symptoms and signs for spinal pathology

- Systemic illness, fever or weight loss
- Progressive neurological deficit
- Unrelenting or night pain
- Spinal deformity

All of these require urgent further investigation with a full blood count (FBC), measurement of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), plain radiography and MRI or other appropriate imaging. Other causes of back pain include intra-abdominal, renal and systemic pathology; all must be considered but, once excluded, physiotherapy should help improve symptoms (Summary box 38.20).

Summary box 38.20

Other spinal conditions

- Excessive kyphosis may be caused by Scheuermann's disease
- Spondylolisthesis is forward slip of one vertebra on another; it may cause mechanical and, rarely, neurological symptoms
- Torticollis may be congenital and usually responds to stretching of the fibrosed sternocleidomastoid muscle. Acquired torticollis requires elimination of a number of causes
- Back pain with red flag symptoms and signs requires urgent investigation

NEUROMUSCULAR CONDITIONS

Joint stability and limb function depend on the complex integration of a normal musculoskeletal system and a normal neurological system. Damage to either can lead to a variety of conditions linked only by the fact that they are never curable. Thus, management must be directed at helping the child cope with their disability, minimising further deterioration and maximising function. It is important to have an understanding of what the damage is and what the future holds. Several factors need to be considered (Summary box 38.21).

Summary box 38.21

Factors to be considered in the assessment of a neuromuscular disability

- Is the insult to the neurological system progressive or non-progressive?
- Is it located centrally or peripherally?
- Is it general or focal?
- Is it associated with other abnormalities or not?

Spina bifida and polio are classic lower motor neurone lesions whereas cerebral palsy and head injuries affect upper motor neurones and the higher centres and there may be other disabilities such as poor vision, epilepsy and intellectual difficulties to consider.

In children it must be remembered that, even if the initial insult to the neuromuscular system is not progressive, the effects of the insult will change with growth. Damage to any level of the neuromuscular system by whatever cause leads to an alteration in tone and muscle imbalance associated with decreased control of movement. Altered muscle pull, particularly in combination with the effects of gravity, alters bone growth leading to deformity and joint contracture. Muscles are almost always relatively weak and, thus, with body growth and an increase in weight, the muscle is no longer strong enough to control a heavier limb, particularly when deformity means it is working at a mechanical disadvantage.

A multidisciplinary approach to management is essential; therefore, although surgeons must have an understanding of both surgical and non-surgical options, they must *not* work alone. Good physiotherapists and orthotists will reduce the need for surgical intervention, and the results of surgery will be severely compromised if these practitioners are not available to help in the postoperative period.

In conditions such as Duchenne muscular dystrophy there is a substantial evidence base for the benefits of certain surgical procedures; however, in other conditions, such as cerebral palsy, there are fewer long-term validated studies that show significant benefits of surgery.

In general, it is important to maintain a full range of passive joint movement and thus maintain good muscle length and tendon excursion. This is easier to achieve in patients with a flaccid paralysis or low tone. The maintenance of muscle strength is also important. The use of splints, positioning techniques and seating and sleeping systems is essential in most cases. The aim is to prevent the development of a fixed contracture.

Surgery has a valuable role in the management of carefully selected patients (Table 38.15). The surgeon must anticipate the general effects of surgery on the patient, for example altering ankle posture may affect knee and hip posture/function, the patient must have the intellectual ability and motivation to recover from the surgical procedure (Summary box 38.22).

Summary box 38.22

Principles of treatment of neuromuscular conditions

- A neurological defect, whether progressive or not, may cause progressive deformity as the skeleton grows
- A multidisciplinary approach is essential
- Primary therapy aims to maintain range of movement and prevent fixed contractures, with an emphasis on managing tone and position
- Surgery has a limited role in the management of neuromuscular conditions

Cerebral palsy

Cerebral palsy is caused by a non-progressive insult to the developing brain in the perinatal period; in most cases only risk factors, such as prematurity, rather than specific causes, such as hypoxia, can be identified. The effects of cerebral palsy may only become apparent as the child grows and fails to reach the expected developmental milestones. Investigations at this stage may help with aetiology and may predict the pattern of the cerebral palsy, for example premature babies may show evidence of periventricular leucomalacia on a brain MRI, which is associated with the development of a spastic diplegia with relative preservation of intellectual function.

In general, the pattern of involvement can be classified according to the anatomical site involved and the effect on muscle tone (Table 38.16). The prognosis for walking can be predicted by identifying evidence of neurological development, i.e. the loss of primitive reflexes.

An important aspect of management is the control of high tone. Tone can be reduced with drugs such as diazepam and baclofen. Alternatively, neuromuscular blockers such as botulinum toxin can bring about a focal reduction in tone. This toxin prevents acetylcholine release at the neuromuscular junction and, hence, transmission at the motor end-plate. The effect is temporary, giving a window of opportunity in which the physiotherapists can work to stretch agonists and strengthen antagonists. It is important to differentiate between dynamic and fixed contractures; the latter will not respond to tone management or splinting.

Table 38.15 General types of surgical procedure that might be considered in the management of a patient with a neuromuscular condition

Surgical procedure	Aim of treatment
Lengthening of the muscle–tendon unit Tendon transfer	Restore joint range (but results in relative muscle weakness) Improve functional movement; rebalance muscle forces, after correction of the fixed deformity
Release of joint contracture; correction of bony deformity	Restore mechanical alignment, which may allow muscles to work in a more efficient manner
Fuse/stabilise/relocate joints	Improve posture/function Reduce pain
Neurological procedures, e.g. selective dorsal rhizotomy, intrathecal baclofen pumps	Reduce tone
Leg equalisation procedures	Improve lower limb mechanics

Guillaume Benjamin Amand Duchenne, (Duchenne de Boulogne), 1806–1875, a Neurologist who worked successively in Boulogne and Paris, France, but who never held a hospital appointment.

Table 38.16 Classification of cerebral palsy with respect to muscle tone and site of involvement

Characteristics	
Tone	
Low	Often low tone in trunk with high tone in the limbs
High	
Mixed	
Variable	High tone and low tone apparent in the same limb on different occasions
Site	
Hemiplegia	Arm more affected than leg
Diplegia	Legs more affected than arms
Total body involvement	Often significant intellectual impairment

The classic cerebral palsy gait patterns show spasticity with the flexors most obviously affected. The child with spastic diplegia has problems at all levels of the lower limb. Multilevel surgery is popular but knowing when to operate and what to operate on is difficult. Observational gait analysis is a skill that improves with practice; computerised gait analysis provides objective evidence of joint movement and mechanics in multiple planes (Fig. 38.30). Appropriate bone and soft-tissue procedures can then be planned. Botulinum toxin can help manage post-operative pain and spasm.

In the child with total body involvement (TBI) and high muscle tone, hip subluxation and eventual dislocation cause some ethical dilemmas (Fig. 38.31). How hard should you work to keep a hip in joint when the patient themselves may be unaware of any difficulty? Current thinking is that the hip should be kept in joint by the simplest means possible but surgical intervention should be performed early if necessary. Spinal involvement is also common and, again, aggressive

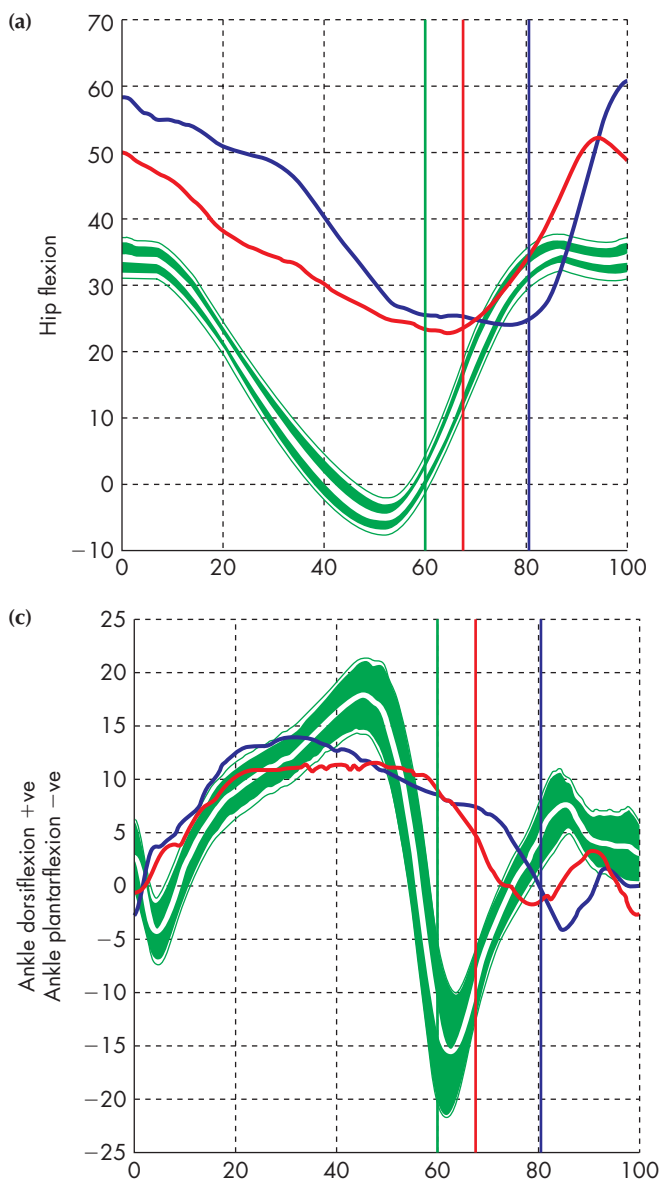

Figure 38.30 a-c Gait analysis graphs such as these demonstrate the normal range of joint movements (green band) at hip (a), knee (b) and ankle (c) during the stance and swing phases of gait. The abnormal joint ranges are shown in red (right leg) and blue (left leg) and demonstrate the excessive hip flexion and lack of knee extension and abnormal knee mechanics associated with the ‘crouch’ gait of a child with cerebral palsy.

Figure 38.31 Anteroposterior pelvic radiograph of a child with spastic cerebral palsy. Both hips are subluxed. Reimer's migration percentage ($a/a + b$ as a percentage) has been measured as approximately 60% on the right hip.

management may be required, with specific attention given initially to seating position and subsequently to spinal bracing or surgery.

Overall, it is important to remember what the child's needs will be once they reach adulthood. Independent mobility and effective means of communication are two of the most important requirements. Hence, it may not be appropriate to invest time and effort into gaining an upright posture if mobility will be achieved via an electric wheelchair and a hand-controlled car (Summary box 38.23).

Summary box 38.23

Cerebral palsy

- Brain injury is non-progressive
- Classified as hemiplegia, diplegia and TBI
- Tone may be high, low or variable but there is generalised, relative muscle weakness
- In ambulant children, gait analysis may be used to plan surgery or botulinum toxin injections given to improve gait
- In TBI, primary concerns are hip subluxation and spinal deformity

Polio

Although an effective polio vaccine has been available for many years the disease still occurs. About 1–2% of patients develop neurological problems when the virus affects the anterior horn cells. Muscle weakness is proportionate to the number of motor units destroyed. Patients often develop trick movements to cope with their muscle weakness and minor joint contractures might actually improve function. Careful assessment before surgery is essential and both the surgeon and the patient must understand the goals of treatment.

Spina bifida

The extent of the disability varies with the level of the lesion and there may be upper motor neurone involvement with spasticity as well as the more classic lower motor neurone lesion. Hydrocephalus may contribute to this. Muscle imbalance leads to secondary joint deformity but the accompanying sensory disturbance, which is often profound, may affect the choice of surgical and non-surgical options.

Muscular dystrophy

Many types of muscular dystrophy exist and the presentation in terms of severity and distribution of involvement is varied. Surgical intervention can be useful for improving quality of life. This is best achieved by operating early to release joint contractures and maintain walking ability and good spinal posture.

Brachial plexopathy

The obstetric brachial plexus injury is still common. It may have a devastating effect on upper limb function, particularly if anti-gravity motor activity has not recovered by the age of 6 months. Neural repair may be necessary in the first few months of life and, later, surgical interventions aim to prevent joint contractures and improve function.

INFECTION

Bone and joint infection remain frequent causes of significant morbidity throughout the world.

Septic arthritis

Joint infection is usually secondary to haematogenous spread but direct inoculation does occur, and sometimes surprisingly easily, for example during a neonatal venepuncture. Diagnosis can be difficult in the very young and in those presenting with overwhelming sepsis. Neonates, children who are immunocompromised and those with sickle cell disease are all at increased risk. At the other end of the clinical spectrum the differentiation between joint sepsis and transient synovitis of the hip can also cause concern.

Classically, the child presents with pain, fever and a reluctance to move or to use the joint; in the lower limb joints this translates to a reluctance to weight bear. On examination, local tenderness and painful restriction of movement are apparent and in superficial joints signs of inflammation may be obvious, with joint swelling and an effusion.

Investigations should include FBC, ESR, CRP and blood culture specimens. Plain radiographs help to exclude other diagnoses and may identify an area of osteomyelitis. Ultrasound scans of deep seated joints, such as the hip, are particularly useful to identify joint effusions (Fig. 38.32). Other investigations such as MRI may be useful on occasion but should not be regarded as a necessity. Good clinical skills, regular patient review and a high index of suspicion are more useful. Four clinical predictors have been identified that differentiate between septic arthritis and transient synovitis (Summary box 38.24 and Table 38.17).

Figure 38.32 Ultrasound scan of a hip joint. A large effusion is distending the joint capsule. The dotted line represents the distance between the femoral neck and the joint capsule.

Summary box 38.24

The clinical predictors of Kocher *et al.* for the diagnosis of a septic joint

- History of fever
- Non weight-bearing
- Erythrocyte sedimentation rate $> 40 \text{ mm h}^{-1}$
- White cell count $> 12 \times 10^9 \mu\text{l}^{-1}$

Pus in a joint is destructive because the proteases produced by leucocytes destroy both the collagen matrix of the articular cartilage and the bacteria. AVN may also occur secondary to pressure effects or ischaemic infarction. The treatment of a presumed septic arthritis is thus the prompt removal of pus from the joint and appropriate adequate antibiotic therapy. Pain relief and rest are also important. The general health and nutrition of the patient must also be considered and treated.

Joint fluid can be aspirated and if pus is confirmed then a formal washout must be performed; standard teaching states that the joint must be opened, irrigated thoroughly and free drainage encouraged via the capsulotomy (a section of joint capsule is often removed). Recently, some literature supports repeated aspiration/irrigation via a large-bore cannula or a small arthroscope. Antibiotic usage is guided by the local hospital policy, the source of the infection, the Gram stain and, in due course, the culture and sensitivity of the organism identified. The joint

Table 38.17 The value of the clinical predictors of Kocher *et al.* in determining the likelihood of the joint being septic

No of positive predictors	Predicted probability of joint sepsis
0	< 0.2%
1	3.0%
2	40.0%
3	93.1%
4	99.6%

Figure 38.33 Septic arthritis of the right hip. (a) Anteroposterior pelvic radiograph with subtle signs of right hip subluxation. (b) Anteroposterior pelvic radiograph 6 months later showing destruction of the femoral head secondary to late treatment of a septic joint.

capsule may have been distended by the presence of fluid and softened by the inflammatory process and this can lead to joint instability with subluxation or even frank dislocation, particularly in the hip joint (Fig. 38.33a). In such cases the joint must be splinted in the reduced position whilst the inflammatory process settles.

The most frequently identified organism is *Staphylococcus aureus*. Streptococcal infection is also common and other organisms are more prevalent in certain age groups, e.g. the neonate, in certain conditions, e.g. sickle cell disease, or in certain countries. The *Haemophilus influenzae* type B (Hib) vaccine has essentially eliminated *Haemophilus influenzae* as a cause of infection.

Improvement is judged clinically and by monitoring the inflammatory markers. Reaccumulation of pus does occur and must be suspected and treated promptly if the child fails to improve (Summary box 38.25).

Summary box 38.25

Septic arthritis

- Diagnosis is difficult in neonates and the immunocompromised
- Typical presentation is pain, fever and a reluctance to move the joint or weight-bear
- Investigations should include FBC, ESR, CRP, blood cultures and appropriate imaging studies, combined with astute clinical skills
- Pus in a joint can destroy articular cartilage and cause avascular necrosis
- Treatment is prompt removal of pus, appropriate antibiotic therapy, pain relief and splintage

Osteomyelitis

As with septic arthritis, bone infection is usually caused by haematogenous spread. Infection often occurs in long bones in which the slow vascular flow within the looped vessels of the metaphysis combined with microtrauma encourages seeding of infection during a bacteraemia (Fig. 38.34a).

Inflammation follows and, if purulent material develops, the pressure effects of the subsequent abscess will lead to progressive bony destruction. Pus can pass through cortical bone and will then elevate the strong periosteum, a process that may render the cortical bone avascular. As in cases of trauma or tumour, the periosteal elevation is a potent stimulus for new bone formation. In cases of untreated or chronic infection this new bone or involucrum may surround the dead bone, the sequestrum, leading to a 'bone-within-a-bone' appearance (Fig. 38.34b).

The presentation and investigation of osteomyelitis is similar to that for joint sepsis. The differentiation between the two may be difficult and a sympathetic joint effusion may occur with metaphyseal osteomyelitis. Thus, if there are no organisms seen on microscopy of a joint aspirate the possibility of a coexisting osteomyelitis must be considered. The metaphysis of a long bone may be intracapsular and infection may spread easily into the joint once the periosteum is breached. In the neonate, proximal femoral osteomyelitis and septic arthritis are essentially the same condition (Fig. 38.34c).

The general treatment principles for the management of infection must be adhered to. Pus needs to be drained but otherwise the treatment is medical. Debate continues over the duration of treatment and indeed whether antibiotics should be parenteral or oral during this time. Overtreatment probably does occur but each case deserves to be treated on its merits, remembering that the child may be immunocompromised and malnourished. The risks of undertreatment are considerable (Summary boxes 38.26 and 38.27).

Summary box 38.26

The general treatment principles for bone and soft tissue infection

- Rest/splintage of affected limb
- Analgesia
- Surgical drainage of pus
- Appropriate antibiotics via a suitable route and for the correct time
- Treatment of the underlying condition, e.g. nutritional deficiency, sickle cell disease

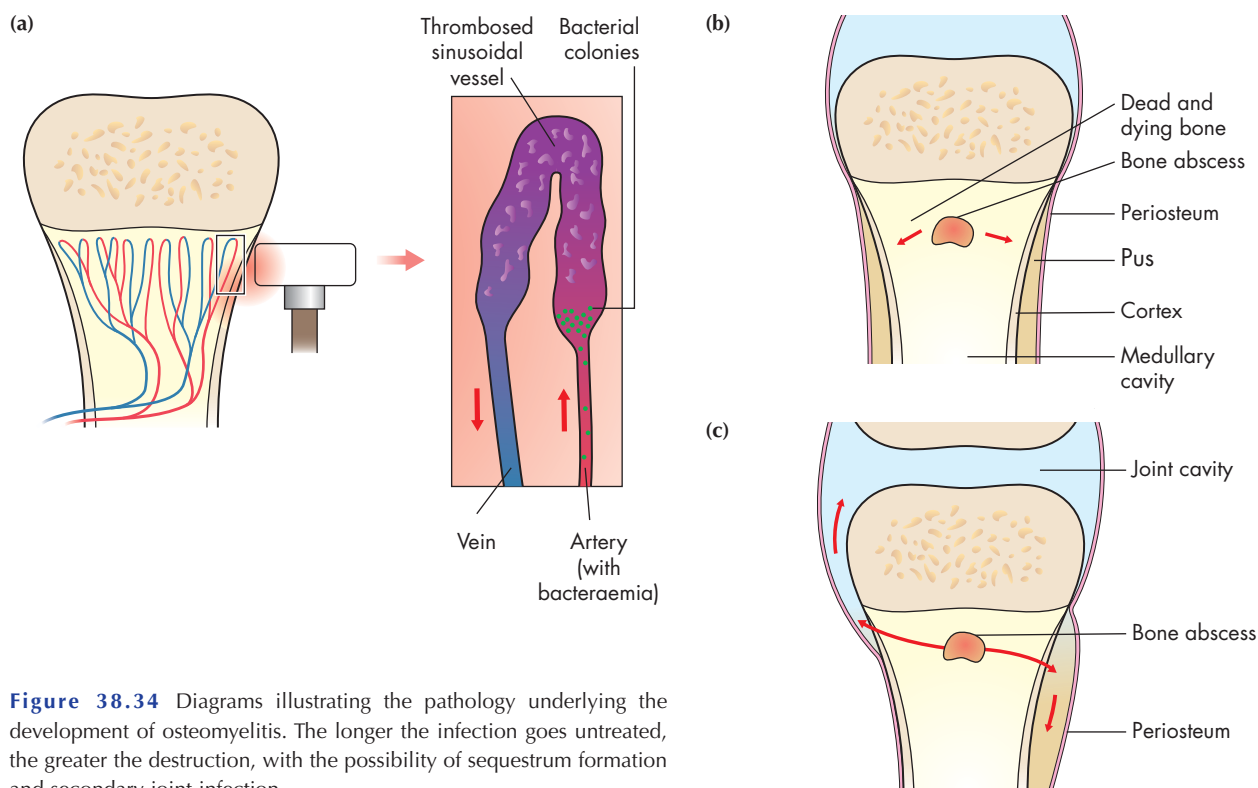

Figure 38.34 Diagrams illustrating the pathology underlying the development of osteomyelitis. The longer the infection goes untreated, the greater the destruction, with the possibility of sequestrum formation and secondary joint infection.

Summary box 38.27

Osteomyelitis

- Occurs by haematogenous spread, enhanced by microtrauma
- If untreated, new involucrum envelops the dead sequestrum
- A joint effusion may be sympathetic or caused by direct spread from the adjacent metaphysis
- Treatment is drainage of pus when present, appropriate and often prolonged antibiotic therapy, pain relief and splintage

Complications of bone and joint sepsis

Most cases of bone and joint sepsis, if treated appropriately, resolve with no sequelae. However, significant complications can occur, particularly in terms of chronic infection and in cases in which there has been damage to the joint and/or the physis and the secondary growth centre in the epiphysis. In the neonate, vascular channels pass through the physis, connecting the metaphysis with the epiphysis, and a poorer outcome may ensue (see Fig. 38.33b, p. 586). Orthopaedic follow-up should be continued until normal growth patterns are documented.

Meningococcal sepsis

The often debilitating, late orthopaedic sequelae of meningococcal septicaemia are secondary to endotoxin-induced microvascular injury and subsequent ischaemic physeal damage.

Tuberculosis

Tuberculosis is still common. The clinical presentation is often more insidious, with general features such as malaise and weight loss combined with a boggy joint swelling, muscle wasting and joint contractures. Spinal deformity and neurological symptoms are particular problems.

Chronic relapsing/recurrent multifocal osteomyelitis

Although radiographic features suggest subacute or chronic osteomyelitis, laboratory and histopathological findings in chronic relapsing/recurrent multifocal osteomyelitis are usually non-specific and microbiological culture is negative. This is probably an inflammatory rather than an infective condition.

Discitis

Children who refuse to weight-bear may also complain of back pain and may have a discitis. There is continued debate regarding the aetiology of this condition, which may be infective or inflammatory. If the vertebral bodies are involved, infection is assumed.

Brodie's abscess

Subacute or chronic infections may present with radiographic features of a cyst with a sclerotic wall.

Sir Benjamin Collins Brodie, 1783–1862, Surgeon, St. George's Hospital, London, England, described 'Brodie's Abscess' in 1828.

CLINICAL DILEMMAS**The limping child**

Children may limp because of pain, weakness, deformity or to gain attention, and the causes vary from sepsis to a spinal tumour and from a leg length discrepancy to a shoe that rubs. It is essential to exclude serious causes and the 'surgical sieve' helps to identify the most likely diagnoses (Summary box 38.28).

Summary box 38.28

A guide to the clinical assessment of the limping child

- Symptom onset: sudden or gradual?
- Symptom duration
- Concurrent events: recent viral infection, trauma, new shoes, new sport?
- General health: is the child well?

The examination must include all joints and soft tissues and, in addition, a brief neurological examination, measurement of leg length and an assessment of pain at rest or on weight bearing.

Many conditions, such as sepsis and juvenile arthritis, can present at any age but certain hip conditions are more likely in particular age groups (Table 38.18).

Plain radiographs should usually include both anteroposterior and 'frog' lateral views of the pelvis. Always bear in mind the possibility of a tumour; further imaging such as MRI may be required.

Non-accidental injury

No child is exempt but some children are at particular risk of non-accidental injury (NAI), including those under the age of 3 and those with disabilities. A careful clinical assessment is required (Fig. 38.35) (Summary boxes 38.29 and 38.30).

Summary box 38.29

Factors that raise concern in the clinical assessment of suspected non-accidental injury**History**

- Delay in seeking medical advice
- Inconsistent story
- Mechanism of injury inconsistent with pattern of injury

Examination

- Unexpected bruising to the buttocks/back of legs
- 'Finger-mark' bruises
- Bruising of various ages
- Burns, deep scratches, etc.

Table 38.18 Age at presentation of certain hip conditions

Age (years)	Diagnosis
1–3	Late presenting developmental dysplasia of the hip; sepsis
3–10	Transient synovitis; Perthes' disease
11–15	Slipped upper femoral epiphysis

Figure 38.35 Anteroposterior radiograph of a knee showing metaphyseal corner fractures that are often considered to be pathognomonic of non-accidental injury. Non-accidental injury must also be considered in any fracture that presents late or without an adequate explanation.

Summary box 38.30

Fracture patterns with a high specificity for non-accidental injury

- Corner or bucket-handle metaphyseal fractures
- Multiple fractures at different stages of healing/old fractures
- Scapular fractures
- Posterior rib fractures
- Any fracture in a child below walking age

Whenever there is suspicion of NAI, the case should be discussed with the relevant child protection team. All injuries should be documented carefully and photographed if appropriate. If there are concerns for the child's immediate safety it may be prudent to admit the child until further checks have been made. It is important to remember that child abuse occurs in different forms: emotional, physical, sexual and neglect.

Skin and subcutaneous tissue

LEARNING OBJECTIVES

To understand:

- The structure and functional properties of skin

To know:

- The classification and general management of benign skin tumours, malignant skin tumours and vascular skin lesions

- The common cutaneous manifestations of generalised disease that are seen in surgical practice

FUNCTIONAL ANATOMY AND PHYSIOLOGY OF SKIN

Skin can be divided into an outer layer, the *epidermis* and an inner layer, the *dermis*. Deep to the dermis is the *hypodermis*, which is composed of subcutaneous fat and remnants of the *panniculus carnosus*.

Epidermis

The epidermis is composed of keratinised, stratified, squamous epithelium and can be subdivided further into five layers: the *stratum basale* (deepest), the *stratum spinosum*, the *stratum granulosum*,

the *stratum lucidum* and the *stratum corneum* (superficial). It accounts for 5% of the total skin (Fig. 39.1)

The majority of epidermal cells are keratinocytes arranged in layers. The basal epidermis (*stratum basale*) also contains melanocytes. Keratinocytes are classified according to their depth in the epidermis and their degree of differentiation. Keratinocytes grow and are replaced via mitoses in the cells of the *stratum granulosum*. As they mature and die, they travel up and out from deep to superficial, losing their nuclei and organelles as they progress before forming the *stratum corneum*, which ultimately separates and sloughs off to form house dust! The other keratinocyte layers in the skin (the *strata lucidum*, *granulosum* and *spinosum*) are variably

Figure 39.1 Three-dimensional diagram of the structural layers of the skin and its adnexal structures. (Reproduced from Simonsen T, Aarbakke J, Kay I, Coleman I, Sinnott P and Lysaa R, *Illustrated Pharmacology for Nurses*, London: Hodder Arnold, 2006 with kind permission of the illustrator Roy Lysaa.)

present according to body site – for instance, all three are present in the glabrous skin of the palms and soles of the feet (Summary box 39.1).

Summary box 39.1

Layers of the skin

Epidermis

- Stratum corneum
- Stratum lucidum
- Stratum granulosum
- Stratum spinosum
- Stratum basale

Dermis

- Papillary layer
- Reticular layer

Melanocytes are dendritic cells of neural crest origin, which are usually located in the basal epidermis. Each melanocyte synthesises the brown-black pigment melanin, which is transferred via membrane processes to the keratinocytes in the strata granulosum and spinosum. Melanin is positioned within keratinocytes to shield the nuclei from ultraviolet radiation (UVR). Ethnic differences in skin colour are determined by variations in the amount, combination and distribution of melanin within the keratinocytes, rather than differences in the number of melanocytes.

Dermis

The dermis constitutes 95% of the skin and is structurally divided into two layers. The superficial papillary layer is composed of delicate collagen and elastin fibres in ground substance, into which a capillary and lymphatic network ramifies. The deeper reticular layer is composed of coarse branching collagen, layered parallel to the skin surface.

The epidermis and dermis meet at the dermo-epidermal junction in a three-dimensional, wave-like arrangement, in which epidermal rete pegs project down and interdigitate with upward-pointing dermal papillary ridges containing vascular and lymphatic plexi.

The skin also contains specialised cells such as Langerhans cells, the role of which is to engulf antigens and present them to T cells. Merkel cells and Meissner and Pacinian corpuscles have a role in mechanosensation.

Skin adnexa

Adnexal structures such as hair follicles and sebaceous and sweat glands span both the epidermal and dermal layers and contain some keratinocytes in their ducts. In injuries in which epidermis is lost, re-epithelialisation occurs from these structures as well as from the wound margins.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany.

Friedrich Sigmund Merkel, 1845–1919, Professor of Anatomy successively at Rostock, Königsberg (now Kaliningrad in Russia) and Göttingen, Germany.

George Meissner, 1829–1905, successively Professor of Anatomy and Physiology, Basle, Switzerland, Professor of Zoology and Physiology, Freiburg, Germany, and Professor of Physiology, Göttingen, Germany.

Filippo Pacini, 1812–1883, Professor of Anatomy and Physiology, Florence, Italy.

Hair follicles

The human body has two types of hair: *vellus hairs* are a fine, downy, non-pigmented hair that covers the body for 3 months *in utero*, then is eventually shed before birth, apart from the face. *Terminal hairs* are thicker, pigmented and long and are usually found on the scalp, face, axillae, groins, arms and legs and then variably elsewhere according to ethnic, hormonal and genetic predisposition. Hairs are keratinised shafts of tissue that grow out from the bulb at the base of each hair follicle. Each hair follicle has a growth cycle of three phases: during anagen phase the hair grows, then it regresses during catagen phase (during which the hair is shed), and then the follicle remains quiescent for several months during telogen phase before entering a new anagen phase. Hair follicles can only be killed during the anagen (growth) phase. Strips of smooth muscle (erector pili) are inserted into the wall of the hair follicle and lead to hair elevation in times of stress and cold.

Sebaceous glands

Most are hair follicle appendages situated between each hair follicle and its erector pili muscle. When the erector pili muscle contracts to elevate the hair, it compresses the gland and sebum is released (an example of holocrine secretion). The function of the sebum is to act as a skin lubricant and physical protective barrier.

Sweat glands

Eccrine and apocrine glands are simple sweat glands that open into pores in hair follicles. Eccrine glands are distributed throughout the entire body surface except on the lips. These glands secrete sweat in response to emotion or during thermoregulation. Apocrine glands are found in the axillary and groin areas and become active at puberty. Their secretion, which becomes characteristically malodorous after degradation by bacteria, varies in response to emotion and hormone secretion.

Skin thickness

Skin thickness varies with age and body area. It is thinner in children than in adults in any given region. The dermis is between 15 and 40 times thicker than the epidermis, but starts to thin during the fourth decade as part of the ageing process. The epidermis is thickest on the palms, soles, back and buttocks, and is thinnest on the eyelids (0.5–1 mm on sole of the foot, 0.05–0.09 mm on the eyelid).

Blood supply of the skin

In the last 25 years, the ‘angiosome model’ has furthered our understanding of the anatomical blood supply of the skin and therefore the ability to reconstruct soft-tissue defects using vascularised flaps of various tissue compositions. With respect to its blood supply, the body can be envisaged as three-dimensional segments of tissue called angiosomes, each with an arterial supply and a venous drainage. Blood equilibrates and flows between neighbouring angiosomes via ‘choke’ vessels, which tend to be situated within muscles. Cutaneous arteries, which are direct branches of segmental arteries (concentrated at the dorsoventral axes and intermuscular septae), perforate the underlying muscles or run directly within fascial layers to the skin from the deep tissues (Fig. 39.2).

The blood supply to the skin anastomoses in subfascial, fascial,

Figure 39.2 Schematic showing two neighbouring angiosomes. Note the choke vessels within the muscle spanning the two cutaneous territories of angiosome A and B – two common examples of myocutaneous flaps which utilise this physiology include the rectus abdominus and the latissimus dorsi flaps.

subdermal, dermal and subepidermal plexi. The epidermis contains no blood vessels so epidermal cells derive nourishment by diffusion.

The venous drainage of the skin is via both valved and unvalved veins. The unvalved veins allow an oscillating flow between cutaneous territories within the subdermal plexus, equilibrating flow and pressure. The valved cutaneous veins drain via plexi to the deep veins.

Anomalies of skin metabolism

Blood flow to the skin can vary between 5 and 100 ml 100 g⁻¹ min⁻¹ in the temperature range 20–40°C. Therefore, the skin has a potential blood supply that is 20–100 times greater than its metabolic and thermoregulatory requirements. Despite this, the blood supply is inadequate to support wound healing alone, as evidenced by the fact that either primary closure or granulation tissue is required for healing to occur.

A teleological explanation for this apparent excess blood supply is in the restitution of mechanical integrity after the myriad of injuries (such as scratching, stretching, compressing, heating and cooling) to which our skin is constantly subjected.

Skin functions optimally at temperatures below body core temperature and can tolerate long periods of ischaemia (allowing it both to be grafted and to be expanded and used in reconstructive surgery – see Chapter 29).

FUNCTION OF THE SKIN

Human skin and subcutaneous tissue have several important functions:

- barrier to the environment: trauma, radiation, pathogens;
- temperature and water homeostasis;

- excretion (e.g. urea, sodium chloride, potassium, water);
- endocrine and metabolic functions;
- sensory organ for pain, pressure and movement.

Skin grafts

Grafts of the skin can be used to reconstruct wounds having been harvested as a split- (leaving some epidermal components) or full-thickness graft. The process by which a skin graft adheres to and heals a wound is a unique and unnatural process, in which normal wound healing at the recipient site is altered by the presence of the graft. The survival of a skin graft is largely dependent on how fast the graft derives a new blood supply from the wound on which it is placed. Until the graft establishes a new blood supply, nutrition is derived by diffusion through the fibrin layer formed between it and the wound bed. After 48–72 hours, a fine capillary network grows into the graft and anastomoses with the native vasculature of the graft. Factors that inhibit this process (formation of haematoma, seroma or bacterial exudate between graft and wound bed) will decrease the likelihood that the graft will ‘take’ successfully (see Chapter 29).

Ulcers

An ulcer is a discontinuity of an epithelial surface. It is characterised by progressive destruction of the surface epithelium and a base which may be necrotic granulating or malignant. Ulcers can be classified as non-specific, specific and malignant (Table 39.1 and Fig. 39.3).

Sinuses

A sinus is a blind-ending tract that connects a cavity lined with granulation tissue (often an abscess cavity) with an epithelial

Table 39.1 Classification of common types of ulcer

Ulcer	Type
Peptic	Non-specific
Pressure sores (decubitus ulcers) and ischaemic ulcers	Non-specific
Gravitational ulcers – venous insufficiency	Non-specific
Secondary infective – wound infection and abscess drainage	Non-specific
Traumatic ulcers	Non-specific
Neuropathic ulcers – diabetes, tabes dorsalis, leprosy	Non-specific
Iatrogenic – intravenous fluid extravasation	Non-specific
Dermatitis artefacta – self-mutilation	Non-specific
Aphthous	Non-specific
Primary infective – herpes simplex, tuberculosis, fungal, syphilis	Specific
Gastrointestinal tract and skin	Malignant

surface. Sinuses may be congenital or acquired. Congenital sinuses arise from the remnants of embryonic ducts that persist instead of being obliterated after involution during embryonic development. Acquired sinuses occur as result of the presence of a retained foreign body (e.g. suture material), specific chronic infection (e.g. tuberculosis, actinomycosis or a dental abscess), inflammation (e.g. Crohn's disease), malignancy or inadequate drainage of the cavity (Fig. 39.4).

Treatment of a sinus is directed at removing the underlying cause. Biopsies should always be taken from the wall of the sinus to exclude malignancy or specific infection. For specific management of the disease conditions, please refer to the appropriate chapter.

Fistulas

A fistula is an abnormal communication between two epithelially lined surfaces. This communication or tract may be lined by granulation tissue but may become epithelialised in chronic cases. Fistulas may be congenital or acquired. Examples of congenital fistulas include tracheo-oesophageal and branchial fistulas. Acquired fistulas include fistula-*in-ano*, enterocutaneous fistula following Crohn's disease or postoperative anastomotic

Figure 39.3 Some characteristic shapes of the edges of ulcers. (a) Non-specific ulcer: note the shelving edge. (b) Tuberculous ulcer: note the undermined edge. (c) Basal cell carcinoma (rodent ulcer): note the rolled edge, which may exhibit small blood vessels. (d) Epithelioma: note the heaped-up, everted edge and irregular thickened base. (e) Syphilis: note the punched-out edge and thin base, which may be covered with a 'wash-leather' slough.

Figure 39.4 A sinus (a) and a fistula (b); both usually arise from a preceding abscess. (a) This is a blind track, in this case a pilonidal abscess. (b) This is a track connecting two epithelium-lined surfaces, in this case a colocolocutaneous fistula from colon to skin.

complications and arteriovenous fistula, which may be traumatic or iatrogenic (for haemodialysis).

Again, management of the fistula is directed to treating the underlying aetiology (see appropriate chapter).

PATHOPHYSIOLOGY OF THE SKIN AND SUBCUTANEOUS TISSUES

Radiation damage

UVR and ionising radiation (IR) damage cellular DNA via the tumour suppressor gene *p53*, inhibiting cellular repair and apoptotic mechanisms. There is also evidence that efferent immune responses are impaired after skin exposure to UVR, so facilitating neoplasia.

Ultraviolet radiation

UVR is divisible into types A, B and C according to wavelength. UVR is the principal cause of all types of skin cancer. Its effects are attenuated by melanin and there is an inverse relationship between melanin content and skin susceptibility to UV-induced neoplasia. Some protection is afforded by the stratum corneum, which reflects and refracts UVR, and by clothing, protective creams, cloud cover and buildings.

Ionising radiation

The effects of IR are dose and time dependent. The skin with its rapid cellular turnover exhibits signs soon after exposure. High-frequency rays cause electron coupling at the molecular level damaging proteins, polysaccharides and lipids.

Infrared radiation

Infrared radiation generates heat with cumulative exposure posing the risk of thermal burns.

Cutaneous ageing

The natural process of cutaneous ageing is accelerated by exposure to UVR. The epidermis becomes thinner because and the dermo-epidermal papillae flatten. Numbers of melanocytes and Langerhans cells decrease.

In the dermis, the amount of glycosaminoglycans, proteoglycans and elastin decreases. Dermal collagen content decreases by 6% each decade and the proportion of type I collagen increases relative to that of type III. The rete pegs flatten and the dermis becomes less adherent to the hypodermis. Generally skin appendages decrease in number and function.

In total, these changes, in combination with gravity and life events, result in the characteristic sagging, stretched and wrinkled skin of the elderly and the prematurely aged skin characteristic of the sun exposed.

Congenital/genetic disorders

Neurofibromatosis (Fig. 39.5)

There are two distinct neurofibromatosis syndromes in which Schwann cells form tumours. Each is caused by different genes on different chromosomes; 70% are autosomal dominant and 30% arise from sporadic mutations. Neurofibromatosis (NF) 1 or von Recklinghausen's disease is the more common variant, affecting approximately 1:4000 births. It arises from a gene mutation on chromosome 17. Skin manifestations can appear in early life, with the development of more than five smooth-surfaced café au lait spots, subcutaneous neurofibromata, armpit or groin freckling, and Lisch nodules.

Naevoid basal cell carcinoma (Gorlin's) syndrome

This is an autosomal dominant inherited condition caused by an abnormality in the tumour suppressor gene on chromosome 9q22–31 that codes for the 'patched' protein; 90% of patients develop multiple basal cell carcinomas (BCCs). Patients may also exhibit specific phenotypical characteristics including overdeveloped supraorbital ridges, broad nasal roots, hypertelorism, bifid ribs, scoliosis, brachymetacarpalism, palmar pits and molar odontogenic cysts.

Xeroderma pigmentosum

Described by Kaposi in 1874, this syndrome is caused by an abnormality on the 'patched' gene of chromosome 9q, resulting in aberrant nucleotide repair during cellular DNA maintenance. It has an autosomal recessive inheritance conferring an > 2000-fold increase in skin cancer risk. Sufferers have an intolerance of UVR, which is

Figure 39.5 Neurofibromatosis (courtesy of St John's Institute for Dermatology, London, UK).

Theodor Schwann, 1810–1882, Professor of Anatomy successively at Louvain, (1839–1848), and Liege, Belgium (1849–1880).

Friedrich Daniel von Recklinghausen, 1833–1910, Professor of Pathology, Strasbourg, France, described generalised neurofibromatosis in 1882.

Karl Lisch, B. 1907, Ophthalmologist, Wörgl, Austria.

Robert J. Gorlin, 1923–2006, Professor of Oral Pathology, the University of Minnesota, Minneapolis, MN, USA.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria.

manifested as erythema, pigmentation and photophobia. This leads to premature skin ageing and the development of multiple neoplasms, with most affected individuals dying in early adulthood from metastatic disease (60% mortality by 20 years of age).

Gardner's syndrome

This is an autosomal dominant disease variant of familial adenomatous polyposis caused by an abnormal gene on chromosome 5. Gardner's syndrome can cause the development of cutaneous pathology, such as multiple epidermoid cysts and lipomata.

Ferguson–Smith's syndrome (Fig. 39.6)

A rare, autosomal dominant abnormality on chromosome 9q. This results in a syndrome that can be traced to a single familial line from western Scotland, with affected individuals developing multiple self-healing squamous cell carcinomas (SCCs).

Cutaneous manifestations of generalised disease

Many diseases have cutaneous manifestations that may present in surgical practice. These include necrobiosis lipoidica, granuloma annulare in diabetes mellitus and pyoderma gangrenosum in inflammatory bowel disease.

Hyperhidrosis

This condition involves excessive eccrine sweating of the palms, soles of the feet, axillae and groins. This can cause functional and social problems, but can be controlled, depending on severity, with anti-perspirants or periodic local injections with botulinum toxin A. More resistant cases are treated by endoscopic cervical sympathectomy.

Lipodystrophy

Lipodystrophy (lipoatrophy) is a localised or generalised loss of fatty tissue, which can have primary or secondary causes. It is most commonly seen as a complication of long-term administration of insulin, following treatment of HIV with protease inhibitors or in transplant recipients.

It can be treated in selected cases with local injections of poly-L-lactic acid, autologous fat grafting or free tissue transfer to fill out the contour defect that results.

Figure 39.6 Mid-face of a patient with Ferguson–Smith's syndrome. Note the two tumours at different stages of development: on the nose and the right cheek (courtesy of St John's Institute for Dermatology, London, UK).

Eldon J. Gardner, B. 1909, Professor of Zoology, Utah State University, Salt Lake City, UT, USA.

John Francis Ferguson-Smith, 1888–1978, Dermatologist, The Victoria Infirmary, Glasgow, Scotland.

Inflammatory conditions**Hidradenitis suppurativa (Fig. 39.7)**

This is a chronic inflammatory disease culminating in suppurative skin abscesses, sinus tracts and scarring. It most commonly occurs in the skin of the axillae and groins, which contains apocrine glands. Less common sites include the scalp, breast, chest and perineum.

Hidradenitis suppurativa appears to have a genetic predisposition with variable penetrance, and is strongly associated with obesity and smoking. Women are four times more likely to be affected than men.

The pathophysiology involves follicular occlusion followed by folliculitis and secondary infection with skin flora (usually *Staphylococcus aureus* and *Propionibacterium acnes*). Clinically, patients develop tender, subcutaneous nodules which may not point and discharge, but which usually progress to cause chronic inflammation and scarring.

This condition is managed by advising patients to stop smoking and lose weight where appropriate. Symptoms can be reduced by the use of antiseptic soaps, tea tree oil and non-compressive and aerated underwear. Medical treatments include topical and oral antibiotics and anti-androgen drugs.

In selected cases, patients may require radical excision of the affected skin and subcutaneous tissue with reconstruction. Healing by secondary intention more frequently leads to contracture and functional impairment than when plastic surgical techniques such as skin grafting or flap transposition are used.

Pyoderma gangrenosum (Fig. 39.8)

Pyoderma gangrenosum is characterised by cutaneous ulceration with purple undermined edges. It occurs secondary to heightened, immunological reactivity, usually from another

Figure 39.7 Hidradenitis suppurativa affecting the axilla (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.8 Pyoderma gangrenosum affecting the legs (a) and the breasts (b) (courtesy of St John's Institute for Dermatology, London, UK).

disease process such as inflammatory bowel disease, rheumatoid arthritis, non-Hodgkin's lymphoma or Wegener's granulomatosis.

Cultures from ulcers often grow Gram-negative streptococci. These skin lesions generally respond to steroids. Surgery is rarely indicated and may exacerbate the condition.

Inflammation and abnormal wounds after healing**Abnormal scars**

Ideally, a scar after trauma, and especially after a surgical incision with primary closure, will be thin and pigmented similarly to the surrounding skin after healing and inflammation are complete.

Scars that heal under tension between the two apposed skin edges in the first 9 weeks (while maximum scar strength is being achieved) are prone to stretching.

Scars that result from healing by secondary intention, or which are subject to tension in two dimensions after primary closure, may become hypertrophic. Hypertrophic scars are elevated but confined within the boundary of the initial injury or incision. They tend to form soon after the causal injury, and affect the young, rather than the elderly, and females more than males. The anterior chest, shoulders and deltoid regions are particularly

Thomas Hodgkin, 1798–1866, Curator of the Museum and Demonstrator of Morbid Anatomy, Guy's Hospital, London, England.

predisposed to hypertrophic scarring. They may regress spontaneously over several years (Fig. 39.9).

Keloid scars and hypertrophic scars are often confused, but it is important to be able to distinguish the two. Keloid scars resemble hypertrophic scars superficially in that they are elevated, but, unlike hypertrophic scars, they extend beyond the boundary of the original injury or incision. They can form, in some instances, within previously normal scars, months or years after injury – often apparently in response to hormonal stimuli at puberty or during pregnancy and diminishing sometimes after the menopause. Males and females are equally prone to keloid scars, but dark skin types, especially skins of African genetic origin, are 15 times more likely to form them. There is also a strong familial tendency, with both autosomal recessive and dominant inheritance described, and they are associated with Ehlers–Danlos syndrome and scleroderma. Wound tension does not play a role in their genesis and they have never been noted in albino skin.

There are some similarities between keloid and hypertrophic scars: both involve abnormal collagen metabolism resulting in a higher than usual proportion of type III collagen. They are more likely to form in wounds that undergo inflammation without resolution for more than 3 weeks, and both are associated with tissue hypoxia and sustained levels of transforming growth factor (TGF) β 1 and -2 (rather than TGF β 3), within the wound. However, they differ

histologically: keloid scars contain thick collagen and have increased levels of epidermal hyaluronic acid, whereas hypertrophic scars have a more nodular microscopic structure with fine collagen bundles and increased concentrations of α -actin.

Management of abnormal scars

Despite having different aetiologies, hypertrophic and keloid scars share several treatments in common, which only adds to the confusion that surrounds them.

Non-surgical treatments

Pressure from massage, compressive dressings or clip-on earrings increases collagenase activity and decreases collagen synthesis within either type of scar and, likewise, silicone applied as a dressing or oil diminishes both scars – possibly via an immune mechanism – with more effect on hypertrophic than keloid scars. Corticosteroids decrease collagen synthesis and so both types of scar may respond to intralesional injections, which should avoid the hypodermis so as not to cause hypodermal fat atrophy. Cryotherapy and intralesional steroids injections combined work well in treating keloid scars. Radiotherapy can be used for intractable keloid scars, but its use should be balanced against longer term side-effects as patients tend to be young and will live long enough to develop the long-term sequelae of radiation damage.

Figure 39.9 (a) Hypertrophic scar after a knife wound – it is raised and stretched, but confined to the boundary of the initial incision. (b) Keloid scar at the site of a bacille Calmette–Guérin vaccination: note how the scar has spread beyond the initial tiny puncture. (c) Keloid scar, following an ear piercing, which is dumbbell shaped, in three dimensions – this became keloid several years after the piercing. (d) Keloid scar in a white-skinned individual at the site of a mosquito bite (courtesy of Mr A.R. Greenbaum).

Surgical treatments

Surgery alone for keloid scars that are resistant to non-surgical treatments carries a 50–80% recurrence rate – less so for hypertrophic scars, especially if the resulting defect can be closed without tension using a local flap. Surgery is usually combined with intralesional steroid administration pre- and postoperatively and can also be combined with radiotherapy. Where possible, pressure should be applied postoperatively for 2 months. A very good compromise in treating keloid scars, which has a lower rate of recurrence but a suboptimal cosmetic result, is to perform an ‘intralesional’ excision, leaving the rim of the original scar behind – this seems to fool the scar into not realising it has been mostly removed.

Infections

Skin and soft-tissue infections can be localised or spreading and necrotising or non-necrotising. Localised or spreading non-necrotising infections usually respond to broad-spectrum antibiotics. Localised necrotising infections will need surgical debridement as well as antibiotic therapy. Spreading, necrotising soft-tissue infection constitutes a life-threatening surgical emergency, requiring immediate resuscitation, intravenous antibiotic therapy and urgent surgical intervention with radical debridement.

Impetigo (Fig. 39.10)

Impetigo is a superficial skin infection with staphylococci, streptococci or both. It is highly infectious and usually affects children. Impetigo is characterised by blisters that rupture and coalesce to become covered with a honey-coloured crust. Treatment is directed at washing the affected areas and applying topical anti-staphylococcal treatments, and broad-spectrum oral antibiotics if streptococcal infection is implicated.

Erysipelas (Fig. 39.11)

This is a sharply demarcated streptococcal infection of the superficial lymphatic vessels, usually associated with broken skin on the face. The area affected is erythematous and oedematous. The patient may be febrile and have a leucocytosis. Prompt administration of broad-spectrum antibiotics after swabbing the area for culture and sensitivity is usually all that is necessary.

Figure 39.10 Impetigo. Note the honey-coloured crust (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.11 Erysipelas (courtesy of St John's Institute for Dermatology, London, UK).

Cellulitis/ lymphangitis (Fig. 39.12)

Cellulitis is a bacterial infection of the skin and subcutaneous tissue that is more generalised than erysipelas. It is usually associated with previous skin trauma or ulceration. Cellulitis is characterised by an expanding area of erythematous, oedematous tissue that is painful and associated with a fever, malaise and leucocytosis. Erythema tracking along lymphatics may be visible (lymphangitis). The commonest causative organism is *Streptococcus*. Blood and skin cultures for sensitivity should be taken

Figure 39.12 Cellulitis affecting the left leg (courtesy of St John's Institute for Dermatology, London, UK).

before prompt administration of broad-spectrum intravenous antibiotics and elevation of the affected extremity.

Necrotising fasciitis (Fig. 39.13)

Necrotising fasciitis was first described by Paré in the sixteenth century. Meleney's synergistic gangrene and Fournier's gangrene are all variants of a similar disease process (Summary box 39.2).

Summary box 39.2

Necrotising fasciitis

- Surgical emergency
- Polymicrobial synergistic infection
- 80% have a history of previous trauma or infection
- Rapid progression to septic shock
- Urgent resuscitation, antibiotics and surgical debridement
- Mortality 30–50%

Necrotising fasciitis results from a polymicrobial, synergistic infection – most commonly a streptococcal species (group Aβ haemolytic) in combination with *Staphylococcus*, *Escherichia coli*, *Pseudomonas*, *Proteus*, *Bacteroides* or *Clostridium*; 80% have a history of previous trauma/infection and over 60% commence in the lower extremities. Predisposing conditions include:

- diabetes;
- smoking;

Figure 39.13 Necrotising fasciitis affecting the left orbit and facial skin (courtesy of St John's Institute for Dermatology, London, UK).

Ambroise Paré, 1510–1590, a French Military Surgeon, who also worked at the Hôtel Dieu, Paris, France.

Frank Lamont Meleney, 1889–1963, Professor of Clinical Surgery, Columbia University, New York, NY, USA.

Jean Alfred Fournier, 1832–1915, Syphilologist, Founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.

- penetrating trauma;
- pressure sores;
- immunocompromised states;
- intravenous drug abuse;
- skin damage/infection (abrasions, bites and boils).

Classical clinical signs include: oedema stretching beyond visible skin erythema, a woody hard texture to the subcutaneous tissues, an inability to distinguish fascial planes and muscle groups on palpation, disproportionate pain in relation to the affected area with associated skin vesicles and soft-tissue crepitus. Lymphangitis tends to be absent. Early on patients may be febrile and tachycardic, with a very rapid progression to septic shock. If radiographs have been taken, they may demonstrate air in the tissues, but ideally, the diagnosis will have been made promptly on the basis of symptoms and signs without recourse to 'screening radiography' because unnecessary delay may be lethal.

Management should commence with urgent fluid resuscitation, monitoring of haemodynamic status and administration of high-dose broad-spectrum intravenous antibiotics. This is a surgical emergency and the diseased area should be debrided as soon as possible, until viable, healthy, bleeding tissue is reached. Early review in the operating theatre and further debridement is advisable, together with the use vacuum-assisted dressings. Early skin grafting in selected cases may minimise protein and fluid losses. Mortality of between 30% and 50% can be expected even with prompt operative intervention.

Purpura fulminans

This is a rare condition in which intravascular thrombosis produces haemorrhagic skin infarction. This progresses rapidly to septic shock and disseminated intravascular coagulation. It is usually seen in children, but can occur in adults. It may be subdivided into three types based on aetiological mechanism.

Acute infectious purpura fulminans (Fig. 39.14)

This is the commonest form of purpura fulminans and is caused by either an acute bacterial or viral infection. *Neisseria*

Figure 39.14 Meningococcal septicaemia. Note the sharply demarcated necrotic areas distal to the affected end or perforating arteries with surrounding normal skin (courtesy of St John's Institute for Dermatology, London, UK).

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wrocław, Poland).

meningitidis and varicella are the most common causal organisms. Acute infectious purpura fulminans causes an acquired protein C deficiency as endotoxins produce an imbalance in the procoagulant and anticoagulant endothelial activity. Acute infectious purpura fulminans is most common in children under 7 years, following an upper respiratory tract infection or in asplenia. Clinically, an initial petechial rash is observed, which develops into confluent echymoses and haemorrhagic bullae, which, in turn, necrose to form well-demarcated lesions that form hard eschars. Extensive tissue loss is common, which often culminates in limb amputation. Acute infectious purpura fulminans is associated with a mortality rate of 40–50% usually a result of multiorgan failure.

Neonatal purpura fulminans

This is an inherited deficiency of protein C and protein S, primarily affecting children, causing extensive venous thrombosis of the skin and viscera in the first days of life.

Idiopathic purpura fulminans

Usually follows a viral illness after a latent period before the development of the clinical picture of purpura fulminans.

Skin and soft-tissue cysts

Milia (Fig. 39.15)

These are tiny hard keratin retention cysts seen both in babies and also in the elderly after chronic sun exposure damage.

Epidermal cysts (Fig. 39.16)

These are cysts lined with true stratified squamous epithelium derived from the infundibulum of the hair follicle or traumatic inclusion. They are commonly known as sebaceous cysts and are often found on hairy areas of the body such as the scalp, trunk and face. They are fixed to the skin and usually have a central punctum and are often indentable with pressure.

Treatment depends on the clinical state of the cyst. When they are inflamed or infected, they should be incised and drained initially, and removed later once the inflammation and induration has subsided. It is important to excise the cyst in its entirety as failure to do so usually results in recurrence.

Figure 39.15 Milia (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.16 Multiple scrotal epidermal cysts (courtesy of St John's Institute for Dermatology, London, UK).

Meibomian cysts are epidermal cysts found on the free edge of the eyelid. A chronic Meibomian cyst is called a chalazion. Tricholemmal (pilar/pilosebaceous) cysts can be confused with epidermal cysts, except that they are derived from the epidermis of the external root sheath of the hair follicle; 90% are found in the scalp and 70% are multiple.

SKIN TUMOURS

Benign lesions

Basal cell papilloma (seborrhoeic keratosis, senile keratosis, verruca senilis) (Fig. 39.17)

These are soft warty lesions, which are often pigmented and hyperkeratotic. They are formed from the basal layer of epidermal

Figure 39.17 Basal cell papilloma (courtesy of St John's Institute for Dermatology, London, UK).

Heinrich Meibom, (Meibomius), 1638–1700, Professor of Medicine, History and Poetry, Helmstadt, Germany, described these glands in 1666.

cells and contain melanocytes. They are one of the most common benign skin tumours in the elderly.

Papillary wart (*verruca vulgaris*)

This is a benign skin tumour arising from infection with the human papillomavirus (HPV), which is also responsible for plantar warts and condylomata acuminata.

Freckle (*ephelis*)

A freckle is an area of skin that contains a normal number of melanocytes, producing an abnormally large number of melanin granules.

Lentigo

Lentigenes are small, sharply circumscribed pigmented macules that are a marker for sun damage and some systemic syndromes. Solar lentigenes are commoner in fairer skins. An example of a systemic syndrome associated with lentigenes is Peutz–Jeghers syndrome.

Moles/naevi

Melanocytes migrate from the neural crest to the basal epidermis during embryogenesis. When these melanocytes layer in the epidermis they form a simple mole. Melanocytes that aggregate in the dermis or at the dermo-epidermal junction are called naevus cells.

Junctional naevus (Fig. 39.18)

A junctional naevus is a deeply pigmented macule or papule that occurs commonly in childhood or adolescence. It represents a dermo-epidermal proliferation of naevus cells, and usually progresses to form a compound or intradermal naevus with advancing age. It may be found on any part of the body but has no malignant potential. Benign mucosal lesions tend to be junctional naevi.

Compound naevus (Fig. 39.19)

This is a maculopapular, pigmented lesion that becomes most prominent during adolescence. It represents a junctional proliferation of naevus cells with nests and columns in the dermis.

Figure 39.18 Junctional naevus (courtesy of St John's Institute for Dermatology, London, UK).

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St John's Hospital, The Hague, The Netherlands.
Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.

Figure 39.19 Compound naevus (courtesy of St John's Institute for Dermatology, London, UK).

Intradermal naevus (Fig. 39.20)

Intradermal naevi are faintly pigmented papules in adults showing no junctional proliferation but a cluster of dermal melanocytes. These commonly occur on the face.

Spitz naevus (Fig. 39.21)

These are reddish brown (occasionally deeply pigmented) nodules previously termed 'juvenile melanoma'. They most commonly occur on the face and legs, growing rapidly initially and then remaining static. The differential diagnosis is melanoma, and excision biopsy is warranted if there is doubt as to the diagnosis.

Spindle cell naevus

Spindle cell naevi are densely, black lesions that contain spindle cells and atypical melanocytes at the dermo-epidermal junction. They are commonly seen on the thighs and affect women more frequently. They may have malignant potential.

Figure 39.20 Intra-dermal naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.21 Spitz naevus (courtesy of St John's Institute for Dermatology, London, UK).

Halo naevus (Fig. 39.22)

The halo of depigmentation around any benign naevus represents an antibody response to melanocytes. The importance of this depigmentation is that it may also appear around a malignant melanoma (MM). Halo naevi are associated with vitiligo.

Café au lait spots (Fig. 39.23)

These are coffee-coloured macules of variable size (from a few millimetres up to 10 cm). Multiple, smooth-bordered lesions are associated with neurofibromatosis type 1 and McCune–Albright syndrome. They are more common in dark-skinned races.

Naevus spilus (Fig. 39.24)

This is also known as speckled lentiginous naevus. It is similar in appearance to a café au lait spot but with hyperpigmented speckles throughout. It is a benign lesion that is associated with various cutaneous diseases. The mainstay of management is observation and serial photography as malignant transformation is possible but rare.

Figure 39.22 Halo naevus (courtesy of St John's Institute for Dermatology, London, UK).

Sophie Spitz, B. 1910, American Pathologist.
 Donovan James McCune, 1902–1976, American Paediatrician.
 Fuller Albright, 1900–1969, Physician, Massachusetts General Hospital, Boston, MA, USA.

Figure 39.23 Café au lait spots. Note the two topographical variants: in (a) the spot has a smooth 'coast of California' border, whereas the upper spot in (b) has an irregular 'coast of Maine' border. Multiple smooth bordered lesions are commonly associated with syndromes (courtesy of St John's Institute for Dermatology, London, UK).

Mongolian spot (Fig. 39.25)

A Mongolian spot is a congenital, blue-grey macule found over the sacral skin area. Pigmentation initially deepens and then regresses completely by age 7 years.

Blue naevus (Fig. 39.26)

A blue naevus is a benign skin lesion that is four times commoner in children, typically affecting the extremities and face.

Figure 39.24 Naevus spilus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.26 Blue naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.25 Mongolian spot (courtesy of St John's Institute for Dermatology, London, UK).

Naevi of Ota and Ito (Figs 39.27 and 39.28)

The naevus of Ota is a dermal, melanocytic hamartoma presenting as a characteristically blue or grey macule in the ophthalmic and maxillary dermatomes of the trigeminal nerve. It is four times more common in women, with peaks of incidence in infancy and adolescence, suggesting a hormonal influence. It is most frequently seen in Oriental and African races.

Minoru Ito, 1892–1986, Professor of Dermatology, Tohoku University, Sendai, Honshu, Japan.

Figure 39.27 Naevus of Ota (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.28 Naevus of Ito (courtesy of St John's Institute for Dermatology, London, UK).

The naevus of Ito is characterised by dermal melanocytosis in the shoulder region and can occur simultaneously in a patient with naevus of Ota. It is most frequently seen in Oriental and African races.

Hair follicles

Trichoepithelioma

Trichoepitheliomas are small skin-coloured nodules most often found in the nasolabial fold. Clinically and histologically, they look similar to BCC.

Pilomatrixoma (calcifying epithelioma of Malherbe)

These are benign tumours of hair matrix cells characterised by basaloid and eosinophilic ghost cells. They commonly calcify and 40% are found in the under-10 age group.

Tricholemmoma (naevus sebaceous of Jadassohn) (Fig. 39.29)

Tricholemmoma is a congenital hamartoma with the appearance of a linear verrucous naevus. These were believed to form BCCs in up to 10% of cases after puberty, but reviewed histology casts doubt on the frequency with which this occurs, although it is recognised that they have an increased potential for malignant change.

Adenoma sebaceum (tuberous sclerosis, Bourneville's disease) (Fig. 39.30)

Typically these are red facial papules (angiofibromas) that are found usually on the nasolabial folds, cheek and chin. They form part of the disease process in tuberous sclerosis. Skin lesions

Figure 39.30 Adenoma sebaceum (courtesy of St John's Institute for Dermatology, London, UK).

usually appear in children under 10 years of age and increase in size and number until adolescence. Cosmetic removal with carbon dioxide or pulse-dye lasers or scalpel is possible.

Rhinophyma (Fig. 39.31)

Rhinophyma is an end-stage sequela of acne rosacea. It is hypertrophy and hyperplasia of the sebaceous glands and tends to affect elderly men (male to female ratio 12:1). Up to 3% of cases may have an occult BCC. Treatment by dermabrasion or laser resurfacing produces good results.

Sweat glands

Cystadenoma (hydrocystadenomas, hidradenomas)

These are 1- to 3-cm translucent blue cystic nodules.

Eccrine poroma (papillary syringoma)

These are single raised or pedicled lesions found most often on the palm or sole.

Figure 39.29 Naevus sebaceous of Jadassohn (courtesy of St John's Institute for Dermatology, London, UK).

Josef Jadassohn, 1863–1936, a Dermatologist of Breslau, Germany (now Wrocław, Poland).
Desire M. Bourneville, 1840–1909, Physician, Le Bicêtre, Paris, France.

Figure 39.31 Rhinophyma (courtesy of St John's Institute for Dermatology, London, UK).

Cylindroma (turban tumour)

A variant of eccrine spiradenoma, which can be multiple on the scalp and can coalesce to form a 'turban tumour'.

Pre-malignant lesions

Actinic/solar keratoses (Fig. 39.32)

These are areas of dyskeratosis and cellular atypia, with sub-epidermal inflammation, but a normal dermo-epidermal junction. Up to 20% go on to form SCCs.

Cutaneous horn (Fig. 39.33)

A cutaneous, keratin accumulation, which, by definition, has a height greater than its base diameter; 10% will have an underlying SCC.

Figure 39.32 Actinic keratosis (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.33 Cutaneous horn (courtesy of St John's Institute for Dermatology, London, UK).

Keratoacanthoma (Fig. 39.34)

Classically, this is a cup-shaped growth that exhibits symmetry about its middle. The central crater is filled with a plug of keratin. It is twice as common in men and is usually found on the face of 50- to 70-year-olds. Keratoacanthoma has an unclear aetiology; it may be caused by papilloma virus infecting a hair follicle during the anagen phase of the growth cycle, but it has also been associated with smoking and chemical carcinogen exposure. Lesions can grow to between 1 and 3 cm over 6 weeks and then they typically resolve spontaneously over the subsequent 6 months. Removal of the central keratin plug may speed resolution. However, excision is recommended as the differential diagnosis includes anaplastic SCC and the excision scar is often better than that which remains after resolution.

Bowen's disease (Fig. 39.35)

This is an SCC *in situ*, of which 3–11% progress to SCC. It is currently not thought to be a paraneoplastic condition. Chronic solar damage and inorganic arsenic compounds have been implicated as aetiological factors in the development of Bowen's disease and HPV16 has also been documented as a cause.

Bowen's disease often presents as a slowly enlarging, erythematous, scaly patch or plaque. It may occur anywhere on the mucocutaneous surface of the body. On the glans penis, it is often called erythroplasia of Queyrat, although somewhat unfairly because the condition was described 50 years earlier by Paget (Fig. 39.36).

Topical therapy with 5-fluorouracil or imiquimod is an effective treatment. Alternatives include surgical excision with a 4-mm margin or Mohs' micrographic surgery for larger or recurrent lesions.

Extramammary Paget's disease (Fig. 39.37)

This is a form of intra-epidermal adenocarcinoma, which may occur in the genital or perianal regions or in cutaneous sites that

Figure 39.34 Keratoacanthoma (courtesy of St John's Institute for Dermatology, London, UK).

John Templeton Bowen, 1857–1941, Professor of Dermatology, Harvard University Medical School, Boston, MA, USA, described this intradermal precancerous skin lesion in 1912.

Auguste Queyrat, 1856–1933, Dermatologist, Paris, France, described this condition in 1911.

Frederic E. Mohs, a twentieth century American Surgeon.

Figure 39.35 Bowen's disease – Squamous cell carcinoma *in situ* (courtesy of St John's Institute for Dermatology)

Figure 39.37 Extramammary Paget's disease (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.36 Erythroplasia of Queyrat – Squamous cell carcinoma *in situ* on the glans penis; also called Paget's disease of the penis (courtesy of St John's Institute for Dermatology, London, UK).

are rich in apocrine glands, such as the axilla. Approximately 25% of extramammary Paget's disease is associated with an underlying *in situ* or invasive neoplasm. The early skin changes are subtle and may mimic an eczematous lesion or intertrigo. Surgical excision forms the basis of treatment.

Giant congenital pigmented naevus (GCPN) or giant hairy naevus (Fig. 39.38)

This naevus causes a great deal of confusion as its definition and management are contentious. It is a hamartoma of naevomelanocytes that has a tendency to dermatomal distribution. It has a similar histology to compound naevi, but the naevus cells are distributed variably from the epidermis throughout all layers

and into the subdermal fat and muscle. There is general agreement that GCPNs are precursors of MM but the magnitude of this risk is unclear, largely due to the lack of well-conducted studies and poor classification. A 3–5% lifetime risk of melanoma is quoted. In total, 1:3 childhood MM arise in patients with GCPN but the risk decreases with advancing age: 15% present at birth, 62% present by puberty and 99% by 45 years of age. MM arising

Figure 39.38 Giant congenital pigmented naevus (courtesy of St John's Institute for Dermatology, London, UK).

within GCPN is more likely in axial rather than extremity lesions. Retroperitoneal or intracranial melanosis in association with GCPN of the back or scalp respectively is associated with MM presenting before the age of 3 or in the third decade.

A multidisciplinary management approach is advocated for these birthmarks, with initial investigations directed towards discovering neurocutaneous melanosis, as leptomeningeal involvement may necessitate a shunt to avoid raised intracranial pressure.

Removal of GCPN can be considered for both aesthetic and oncological reasons but the evidence to support complete excision to avoid developing MM is poor. Various possibilities for partial or complete removal exist – none is completely successful. They include perinatal curettage, dermabrasion, laser resurfacing and surgical excision with reconstruction using a split-skin graft or after neighbouring skin has been expanded to allow coverage of the defect.

Dysplastic (atypical) naevus (Fig. 39.39)

Dysplastic naevi are irregular proliferations of atypical melanocytes at the basal layer of the epidermis. They have variegated pigmentation with irregular borders, measuring more than 5 mm in size. Dysplastic naevi can have a familial inheritance and carry a 5–10% risk of forming superficial spreading melanoma.

Malignant lesions

Basal cell carcinoma

Usually a slow-growing, locally invasive malignant tumour of pluripotential epithelial cells arising from basal epidermis and hair follicles, hence affecting the pilosebaceous skin (Summary box 39.3).

Summary box 39.3

BCC

- Slow growing
- Caused by UV light
- 90% nodular/nodular cystic
- High- and low-risk BCC

Epidemiology

The strongest predisposing factor to BCC is UVR. The incidence of BCC therefore increases with proximity to the equator,

Figure 39.39 Dysplastic naevus (courtesy of St John's Institute for Dermatology, London, UK).

although, interestingly, 33% arise in parts of the body that are not typically sun exposed. It occurs in the middle-aged or elderly, with 90% of lesions found on the face above a line from the lobe of the ear to the corner of the mouth. Other predisposing factors include exposure to arsenical compounds, coal tar, aromatic hydrocarbons, IR and genetic skin cancer syndromes. White-skinned people are almost exclusively affected. Overall, 95% occur between the ages of 40 and 80 years and they are more common in men.

Pathogenesis

BCCs have no apparent precursor lesions and their development is proportional to the initial dose of the carcinogen, but not duration of exposure. BCCs rarely metastasise, are hard to culture and resist transplantation. All of this suggests that a multistep mechanism for their development is unlikely, and that mesodermal factors acting as intrinsic promoters coupled with an initiation step is the most likely explanation for their development.

Macroscopic appearance (Fig. 39.40)

BCC can be divided into localised (nodular, nodulocystic, cystic, pigmented and naevoid) and generalised lesions, which can be superficial (multifocal or superficial spreading) or infiltrative (morphoeic, ice pick and cicatrising). Nodular and nodulocystic variants account for 90% of BCCs.

Microscopic appearance (Fig. 39.41)

In total, 26 histological types have been described. The characteristic finding is of ovoid cells in nests with a single, outer 'palisading' layer. It is only the outer layer of cells that actively divide. This may explain why tumour growth rates are slower than the cell cycle speed would suggest, and why incompletely excised lesions are more aggressive. Morphoeic BCCs synthesise type IV collagenase and so spread rapidly.

Prognosis

There are 'high-risk' and 'low-risk' BCCs. High-risk BCCs are those which are large (> 2 cm), are located at specific sites (near the eye, nose, ear) or which have ill-defined margins. Recurrent tumours and those forming in the presence of immunosuppression are also higher risk.

Management

Treatment can be surgical or non-surgical. Margins should always be assessed and marked under loupe magnification and vary between 2 and 15 mm depending on the macroscopic variant. When margins are ill defined or tissue is at a premium (nose, eyes), either Mohs' micrographic surgery or a two-stage surgical approach with subsequent reconstruction after confirmation of clear margins is advisable. The histological sample must be orientated and marked for pathological examination.

Mohs' micrographic surgery is a method used by dermatological surgeons (dermatologists who have undergone extra training in techniques of cutaneous surgery and histopathology) to excise skin cancer under microscopic control. It has been demonstrated to minimise recurrence rates and maximise conservation of surrounding normal tissue when treating suitable skin tumours. The technique is, therefore, considered the optimal treatment for poorly demarcated, recurrent or incompletely excised BCCs (including BCCs around the nose, eyes and ears, where clearance may be uncertain, significant morbidity may be associated with

Figure 39.40 (a) A nodulocystic basal cell carcinoma (BCC). Note the characteristic pearly surface with telangiectasia. (b) An ulcerating BCC on the lower eyelid. (c) A recurrent morphoeic BCC ((a) and (b) courtesy of Mr A.R. Greenbaum; (c) courtesy of St John's Institute for Dermatology, London, UK).

incomplete excision and where reconstruction with a flap is preferable cosmetically). It can also be used for excision of SCCs, dermatofibrosarcoma protuberans and lentigo maligna (using either frozen section and immunohistochemistry or horizontal paraffin-embedded sections).

Mohs' micrographic surgery is performed under local anaesthesia (which is one of its limitations) and involves an initial

Figure 39.41 A basaloid, epithelial tumour with palisading cells on the periphery of the tumour that sits within a mucinous stroma (courtesy of Dr Catherine di Stefanato, Consultant Dermatopathologist, St John's Institute for Dermatology, London, UK).

'saucerising excision' of the primary tumour's visible extent. The sample and the defect are then marked and orientated. A map of the specimen is drawn and characterised using different coloured stains in different quadrants. A histotechnician and a Mohs' surgeon work together: the histotechnician receives a tissue sample from the Mohs' surgeon, which is then sectioned horizontally (including lateral and deep margins in the same slide) and stained with haematoxylin and eosin. The Mohs' surgeon then examines the slides for the presence of residual tumour and excises more tissue from the relevant parts of the mapped defect as necessary. In theory, the technique offers complete evaluation of the lateral and deep margins of tumour excision and so should be dependable. Complete excision rates exceeding 99% are the rule in trained and experienced hands.

In elderly or infirm patients, radiotherapy produces similar recurrence rates to surgery. Superficial tumours can also be treated with topical treatments (5-fluorouracil, imiquimod) or cryotherapy. Cosmetically, radiotherapy scars age badly so plastic surgery is always likely to be the better option if possible for patients who are likely to live longer than 10 years.

Excision must be complete as there is a 67% recurrence rate if margins are grossly involved and a 33% recurrence rate within 2 years with microscopic involvement or when reported 'close'. Patients with uncomplicated, completely excised lesions can be discharged, with follow-up reserved for patients with tumours in high-risk areas, globally sun-damaged skin, syndromes (e.g. naevoid BCC syndrome) and incompletely excised tumours if further surgery is declined.

Cutaneous squamous cell carcinoma

SCC is a malignant tumour of keratinising cells of the epidermis or its appendages. It also arises from the stratum basale of the epidermis but, unlike BCC, it expresses cytokeratins 1 and 10.

Epidemiology

SCC is the second most common form of skin cancer. It is four times less common than BCC and usually affects the elderly. It is strongly related to cumulative sun exposure and damage, and is twice as common in men and in white-skinned individuals living nearer the

equator. SCC is also associated with chronic inflammation (chronic sinus tracts, pre-existing scars, osteomyelitis, burns, vaccination points) and immunosuppression (organ-transplant recipients). When a SCC appears in a scar it is known as a Marjolin's ulcer.

The time taken to develop a SCC after radiation exposure is proportional to the wavelength of the radiation. SCC is also caused by chemical carcinogens (arsenicals, tar) and infection with HPV5 and HPV16. There is also evidence that current and previous tobacco use doubles the relative risk of cutaneous SCC (Summary box 39.4).

Summary box 39.4

SCC

- Associated with UV light exposure, chronic inflammation and viral infection
- Ulcerated lesions
- Metastasis in 2% of cases

Macroscopic appearance (Fig. 39.42)

The early appearance of SCC may vary from smooth nodular to verrucous, papillomatous and ulcerating lesions. However, all variants will eventually ulcerate as they grow. The ulcers have a characteristically everted edge and are surrounded by inflamed, indurated skin. The main differential diagnoses of SCC are actinic keratosis, BCC, keratoacanthoma, pyoderma gangrenosum and warts.

Microscopic appearance (Fig. 39.43)

Characteristic irregular masses of squamous epithelium are noted to proliferate and invade the dermis from the germinal layer. This tumour stains positive for cytokeratins 1 and 10. SCC can be histologically graded according to Broder's histological grading. This system describes the proportion of de-differentiated cells (i.e. the ratio of pleomorphic and anaplastic to normal cells).

The histopathology report on an SCC should include information on the pathological pattern (e.g. adenoid), the cellular morphology (e.g. spindle), the Broder's grade, the depth of invasion,

Figure 39.42 (a) A squamous cell carcinoma (SCC) on the face. (b) A recurrent SCC arising in a previously skin-grafted area of the scalp. (c) An SCC arising on the dorsum of the hand in a renal transplant recipient on immunosuppressive therapy. (d) An SCC arising on the lip of a smoker who worked outside on a farm ((a–c) courtesy of Mr A.R. Greenbaum; (d) courtesy of St John's Institute for Dermatology, London, UK).

Jean-Nicholas Marjolin, 1780–1850, Surgeon, Paris, France, described the development of carcinomatous ulcers in scars in 1828.
Albert Compton Broders, 1885–1964, an American Pathologist of Minnesota, USA.

Figure 39.43 An invasive, epidermal keratinising tumour characterised by proliferation of atypical squamous cells with 'horn pearls' (courtesy of Dr Catherine di Stefanato, Consultant Dermatopathologist, St John's Institute for Dermatology, London, UK).

the presence of any perineural or vascular invasion and the deep and peripheral margin clearance (Table 39.2).

Prognosis

There are several independent prognostic variables for SCC:

- Invasion:**
 - Depth:** the deeper the lesion, the worse the prognosis. For SCC < 2 mm, metastasis is highly unlikely, whereas if > 6 mm, 15% of SCCs will have metastasised;
 - Surface size:** lesions > 2 cm have a worse prognosis than smaller ones.
- Histological grade:** the higher the Broder's grade, the worse the prognosis.
- Site:** SCCs on the lips and ears have higher local recurrence rates than lesions elsewhere, and tumours at the extremities fare worse than those on the trunk.
- Aetiology:** SCC that arises in burn scars, osteomyelitic skin sinuses, chronic ulcers and areas of skin that have been irradiated has a higher metastatic potential.
- Immunosuppression:** SCC will invade further in those with impaired immune response.
- Prognosis:** Tumours with perineural involvement have a worse prognosis and require a wider than usual clearance.

The overall rate of metastasis is 2% for SCC – usually to regional nodes – with a local recurrence rate of 20%.

Management

SCC is a heterogeneous tumour with a malignant behaviour that varies between subtypes. Management must therefore address the need for definitive treatment, the possibility of in-transit metastasis and the tumour's tendency for lymphatic metastasis.

Table 39.2 TNM classification and staging of squamous cell carcinoma

Size	Nodes	Metastases	Grade
T1 = < 2 cm	N0 = no regional nodes	M0 = no metastases	G1 = low grade
T2 = 2–5 cm	N1 = regional nodes	M1 = distant metastases	G2 = moderately differentiated
T3 > 5 cm			G3 = high grade or highly anaplastic
T4 = muscle or bony invasion			

Stage I = T1, N0, M0; stage II = T2–3, N0, M0; stage III = T4, N0, M0 and any T, N1, M0; stage IV = any T, any N1, M1(+).

Surgical excision is the only means of providing accurate histology. The margins for primary excision should be tailored to surface size in the first instance. This should ideally be assessed using surgical loupe magnification. A 4-mm clearance margin should be achieved if the SCC measures < 2 cm across, and a 1-cm clearance margin if it measures > 2 cm.

Overall, 95% of local recurrence and regional metastases occur within 5 years, so follow-up beyond this period is not indicated.

Cutaneous malignant melanoma

MM is a cancer of melanocytes. It usually arises in skin but can form anywhere that melanocytes exist, such as in the bowel mucosa, the retina and the leptomeninges.

Epidemiology

Cutaneous melanoma is caused largely by exposure to UVR. Its rise in incidence reflects social behaviour and increased recreational activity in the sun amongst white-skinned races that are not suited to sun exposure. Although it accounts for less than 5% of skin malignancy generally it is responsible for over 75% of deaths related to skin malignancy.

Worldwide, MM accounts for 3% of all malignancy. It is the commonest cancer in young adults (20–39 years) and is the most likely cause of cancer-related death.

Distribution between the sexes varies around the world and reflects occupational and recreational exposure to sunlight. Likewise, geographical distribution reflects exposure of white-skinned individuals to sunlight: Auckland, New Zealand, currently reports the highest incidence per capita, and before that Brisbane, Australia, held that distinction.

Of all patients with MM, 5% will develop a second primary melanoma. Overall, 7% of all MMs present as occult metastasis from an unknown primary.

Pathophysiology

Exposure to UVR is the major causal factor for developing MM. Cumulative exposure favours the development of lentigo maligna melanoma, whereas 'flash fry' exposure – typical of rapidly acquired holiday tans – favours the other morphological variants (Summary box 39.5).

Summary box 39.5

MM

- Rising incidence
- Caused by UV exposure
- Superficial spreading form is the most common
- Breslow thickness is the most important prognostic indicator until there is lymph node involvement
- Sentinel node biopsy is useful for staging disease

A small proportion of MM is genetically mediated, as in xeroderma pigmentosum, which increases the relative risk of developing MM to 1000. Immunosuppression secondary to drugs or HIV infection will increase the incidence of MM by 20- to 30-fold.

The risk factors for developing MM are summarised below:

- 1 xeroderma pigmentosum (relative risk = 1000);
- 2 past medical or family history of MM with dysplastic naevi (relative risk = 33–1269);
- 3 previous melanoma (relative risk = 84);
- 4 high total number of naevi (relative risk = 3.4, if > 20 naevi);
- 5 dysplastic naevi (10% lifetime risk);
- 6 red hair (relative risk = 3);
- 7 tendency to freckle (relative risk = 1.9);
- 8 immune compromised conditions: HIV infection, Hodgkin's disease, ciclosporin A therapy;
- 9 GCPN (increased risk);
- 10 history of sunburn – especially in childhood.

Macroscopic appearance

Only 10–20% of MMs form in pre-existing naevi, with the remainder arising *de novo* in previously normally pigmented skin. The most likely naevi to form MMs are the junctional and compound types. Macroscopic features in a pre-existing naevus that suggest malignant change are listed in Summary box 39.6.

Summary box 39.6

Macroscopic features in naevi suggestive of MM

- Change in *size* – any adult naevus > 6 mm is suspect (for reference a lead pencil diameter is 7 mm) and anything changing to > 10mm is more likely to be malignant than benign
- Shape
- Colour
- Surface (nodularity or ulceration)
- Satellite lesions (discrete pigmented areas spreading away from the primary)
- Tingling/itching/serosanguinous discharge (usually late signs)
- Blood supply: melanomas > 1 mm thick have a blood supply that can be found with a hand-held Doppler monitor, so 'Doppler-positive' pigmented lesions should be excised

There are four common macroscopic variants of MM. In addition, there are several other notable, but rarer forms.

Superficial spreading melanoma (Fig. 39.44)

This is the commonest type (70%) and the most likely to arise in a pre-existing naevus; classically, after several years of slow change, there follows a rapid growth of a darker pigmented area in a junctional naevus in the preceding months before presentation. Nodularity within superficial spreading melanoma heralds the onset of the vertical growth phase.

Nodular melanoma (Fig. 39.45)

This accounts for 15% of all MMs and tends to be more aggressive than superficial spreading melanomas, with a shorter clinical onset. These lesions typically arise *de novo* in skin and are more

Figure 39.44 Superficial spreading melanoma (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.45 Nodular melanoma (courtesy of St John's Institute for Dermatology, London, UK).

common in men than women, often presenting in middle age and usually on the trunk, head or neck. They typically appear as blue-black papules, 1–2 cm in diameter and, because they lack the horizontal growth phase, they tend to be sharply demarcated. Up to 5% are amelanotic.

Lentigo maligna melanoma (Fig. 39.46)

This was previously also known as Hutchinson's melanotic freckle. This variant presents as a slow-growing, variegated, brown macule (a lentigo) on the face, neck or hands of the elderly. They are positively correlated with prolonged, intense sun exposure, affecting women more than men. They account for between 5% and 10% of MMs. *In situ* melanoma in this variant is called lentigo maligna.

Sir Jonathan Hutchinson, 1828–1913, Surgeon, St Bartholomew's Hospital, London, UK.

Figure 39.46 Lentigo maligna melanoma (courtesy of St John's Institute for Dermatology, London, UK).

Lentigo maligna melanomas are thought to have less metastatic potential than other variants as they take longer to enter a vertical growth phase. Nonetheless, when they have entered the vertical growth phase their metastatic potential is the same as any other melanoma.

Acral lentiginous melanoma (Fig. 39.47)

Acral lentiginous melanoma affects the soles of feet and palms of hands. It is rare in white-skinned individuals (2–8% of MMs) but more common in the Afro-Caribbean, Hispanic and Asian populations (35–60%). It usually presents as a flat, irregular macule in later life; 25% are amelanotic and may mimic a fungal infection or pyogenic granuloma.

MMs under the fingernail are usually superficial spreading melanomas rather than acral lentiginous melanomas. For finger- or toenail lesions it is vital to biopsy the nail matrix rather than just the pigment on the nail plate. A classical feature of a

Figure 39.47 (a) Acral lentiginous melanoma on the sole of the foot (courtesy of Mr A.R. Greenbaum). (b) Subungual melanoma – probably a superficial spreading melanoma. Note the swelling proximal to the nail fold. (c) Benign racial melanonychia ((b) and (c) courtesy of St John's Institute for Dermatology, London, UK).

subungual melanoma is Hutchinson's sign: nail-fold pigmentation then widens progressively to produce a triangular pigmented macule with associated nail dystrophy. The differential diagnosis is 'benign racial melanonychia', which produces a linear dark streak under a nail in a dark-skinned individual. Malignancy is unlikely if the nail fold is uninvolved.

Miscellaneous

Amelanotic melanoma is, as the name suggests, not pigmented. It often arises in the gastrointestinal tract, presenting with obstruction or as a metastasis from an unknown primary.

Desmoplastic melanoma is mostly found on the head and neck region. It has a propensity for perineural infiltration and often recurs locally if not widely excised. It may be amelanotic clinically.

Microscopic appearance

Malignant change occurs in the melanocytes in the basal epidermis; while *in situ*, atypical melanocytes are limited to the dermo-epidermal junction and show no evidence of dermal involvement. During the horizontal growth phase, cells spread along the dermo-epidermal junction, and although they may breach the dermis their migration is predominantly radial. During the vertical growth phase, the dermis may be invaded; the greater the depth of invasion, the greater is the metastatic potential of the tumour.

Management

History and clinical examination should be directed at discovering the primary lesion and identifying local, regional or distant spread. Clinical photography is useful when choosing to observe a lesion rather than perform excision biopsy for definitive histo-

pathological diagnosis. An excision biopsy with a 2-mm margin of skin and a cuff of subdermal fat is acceptable in the first instance. Incision biopsy is occasionally indicated – for instance, in large lesions on the face where an excision biopsy of the whole lesion would be disfiguring.

Biopsy and pathological examination provide the first step towards staging melanoma. The Breslow thickness of a melanoma (measured to nearest 0.1 mm from the granular layer to the base of the tumour) is the most important prognostic indicator in the absence of lymph node metastases. The American Joint Committee on Cancer (AJCC) staging system then takes lymph node and distant metastases into account (Table 39.3).

Investigations

Guidelines for staging are contentious – published UK guidelines for investigating MM seem currently to be aimed at detecting stage IV disease, whereas one could and arguably should, aim investigations towards detecting occult stage II disease in order to upstage patients and then treat them accurately and appropriately. Thus, offering sentinel node biopsy (SNB) to patients with clinical stage II disease seems prudent (and follows the AJCC staging system used in the USA and the UK guidelines), and investigations for stage III disease should be directed to individual clinical presentation.

Local treatment

The treatment for melanoma is surgery. Lentigo maligna (melanoma *in situ*) should be excised completely in most clinical situations because of the risk of it entering the vertical growth phase to become lentigo maligna melanoma. A complete excision with a clinical 5-mm margin requires no further treatment.

Table 39.3 American Joint Committee on Cancer 2001 staging for malignant melanoma

Stage	Primary tumour	Lymph node	Metastases
0	<i>In situ</i>	No nodal involvement	No distant metastases
IA	< 1 mm, no ulceration		
IB	< 1 mm, with ulceration > 1 but < 2 mm, no ulceration		
IIA	> 1 but < 2 mm, with ulceration > 2 but < 4 mm, no ulceration		
IIB	> 2 but < 4 mm, with ulceration > 4 mm, no ulceration		
IIC	> 4 mm, with ulceration		
IIIA	Any Breslow, no ulceration	Micrometastasis	
IIIB	Any Breslow, with ulceration Any Breslow, no ulceration Any Breslow, with or without ulceration	Micrometastasis ≤ 3 palpable nodes In transit metastases/satellites	
IIIC	Any Breslow, with ulceration Any Breslow, with or without ulceration	≤ 3 palpable nodes ≥ 4 palpable or matted nodes or nodes plus in transit metastases	
IV			M1: skin, subcutaneous or distant M2: lung M3 all other sites/ or any site plus ↑ [LDH]

[LDH], concentration of lactate dehydrogenase.

For melanoma < 1 mm deep, wide local excision with a 1-cm margin is sufficient. For deeper lesions, a 2-cm margin is recommended, as there is no evidence that wider margins make a difference.

Regional lymph nodes

The likelihood of metastatic spread to regional lymph nodes is proportional to the Breslow thickness of the melanoma. The management of regional lymph nodes has been a contentious topic for well over a century. Historically, some advocated simultaneous elective lymph node clearance at the time of wide excision of the primary melanoma, whereas others favoured a later, therapeutic lymphadenectomy only if regional metastases became clinically evident.

Certainly evidence from retrospective studies suggested that patients with thick melanomas had better survival after elective lymphadenectomy, whereas data from prospective randomised studies were less convincing except in specific sub-groups. However, electively clearing regional nodes in those patients whose melanomas have not metastasised derives them no benefit and exposes them unnecessarily to the morbidity and complications of a major surgical procedure. Ideally, therefore, one would like to be able to select the group of patients in whom melanoma has spread to regional lymph nodes and treat only these patients. This goal underpins SNB, which is based on the hypothesis that lymphatic metastasis proceeds as an orderly process that can be predicted by mapping the lymphatic drainage from a primary tumour to the first or 'sentinel' node in the regional lymphatic basin, a hypothesis that has been borne out in both animal and human studies. When SNB is performed according to consensus standards, it is predictive of the regional nodal status in 99% of cases. There is negligible benefit in performing SNB in patients whose primary melanoma is thinner than 1 mm – only 4% of sentinel nodes would be expected to be positive for tumours with a Breslow thickness of < 1.25 mm. In practice, 70–80% of patients with metastases in the sentinel nodes will have no other involved regional nodes so, although the current standard approach is to proceed to completion lymphadenectomy, this will overtreat a significant number of sentinel node-positive patients, which appears to be a better option than potentially undertreating 20–30% of patients with positive sentinel nodes. Evidence of objective survival benefit from SNB is currently unavailable but several large prospective clinical trials are in progress to investigate this; meanwhile, SNB remains part of the AJCC staging system.

Current treatment for biopsy positive nodal disease is block dissection of the regional lymph nodes to remove all the lymph nodes in that regional basin.

Adjuvant therapy

None is of proven benefit, with clinical trials currently looking at vaccine and interferon treatments.

Prognosis

The Breslow thickness of the primary tumour offers the best correlation with survival in stage I disease. The higher the mitotic index, the poorer the prognosis of the primary tumour; this has greater significance than the presence or absence of ulceration.

The presence of lymph node metastases is the single most important prognostic index in melanoma, outweighing both tumour and host factors. The number of affected nodes and the presence of extranodal extension are also significant outcome predictors. Once regional nodes are involved clinically, 70–85% of patients will have occult distant metastases.

Merkel cell (dermal mechanoreceptor) tumour (Fig. 39.48)

This is an aggressive malignant tumour of Merkel cells. It usually affects the elderly and is four times more common in women than men. Treatment is with wide local excision, aiming for a 25- to 30-mm margin, followed by radiotherapy.

VASCULAR LESIONS

Congenital: haemangiomas and vascular malformations

These can be subclassified *biologically* into vascular tumours or vascular malformations based on their endothelial characteristics or *radiologically* into haemangiomas and vascular and lymphatic malformations based on their vascular dynamics.

Haemangiomas

These are benign endothelial tumours that affect three girls for every boy. They may go unnoticed at birth or be evident as a faint 'herald' patch. Haemangiomas grow rapidly in the first year of life, then slowly involute over several years, with 70% having resolved by 7 years of age.

The clinical appearance of a haemangioma depends on its depth relative to the dermis and the growth phase in which it is observed. Early proliferating lesions are bright red, irregularly surfaced, papular lesions reminiscent of strawberries; deeper lesions may be blue or skin coloured. Involution typically begins with the

Figure 39.48 Merkel cell tumour (courtesy of St John's Institute for Dermatology, London, UK).

fading of colour, leaving greyish areas, and the lesion softens and shrinks at the same time. When involution is complete, often all that remains is the 'crêpe paper'-textured area of skin which may be redundant and stretched locally.

Haemangiomas may occur anywhere in the body, but the majority are central rather than peripheral and 60% are on the head. The majority of haemangiomas require no specific treatment. Most clinical problems needing intervention occur during the early proliferative growth phase. Periorbital lesions may obstruct the visual fields and cause deprivation amblyopia. Total obstruction of one visual field for more than a week during the first year of life may result in permanent visual impairment. Pressure on the globe from a large lesion near the eye can cause astigmatism and an ophthalmologist should be involved with all such patients immediately.

Neonates are obligate nasal breathers, so large haemangiomas that obstruct the nose pose a serious risk. Rarely, skin ulceration over a haemangioma can cause haemorrhage but this usually settles acutely with localised compression. Blood-borne bacteria can lodge in haemangiomas and produce a nidus for septicaemia and localised necrosis. Large haemangiomas can trap platelets leading to thrombocytopenia (Kasabach–Merritt syndrome) and large visceral or multiple lesions can cause congestive heart failure secondary to shunting of blood.

The management of most clinical problems is primarily non-surgical. Systemic corticosteroids induce involution in up to 60% (2 mg kg^{-1} for 3 weeks, then a tapering dose). The primary role of surgery is in the management of abnormally textured or redundant skin left behind after involution.

Vascular malformations

Vascular malformations affect boys and girls equally. They arise secondary to errors in development of the vascular elements during the eighth week *in utero* and are associated with numerous congenital syndromes. They are invariably present at birth but may be missed if deep to the skin. Vascular malformations subsequently grow in proportion to a child's growth (other than in response to sepsis or hormonal stimulation). Stasis can lead to a localised, consumptive coagulopathy in large venous malformations. Low-flow malformations may cause skeletal hypoplasia, whereas high-flow malformations can cause hypertrophy.

Common vascular birthmarks

Salmon patch (Fig. 39.49)

A haemangioma that presents as a pink macule, usually at the nape of the neck, in 50% of infants. It is caused by an area of persistent fetal dermal circulation and usually disappears within a year.

Capillary haemangioma (strawberry naevus) (Fig. 39.50)

The commonest birthmark, which is found most commonly on the head and neck; 90% appear at birth and, as a consequence of intravascular thrombosis, fibrosis and mast cell infiltration, 10% resolve each subsequent year, with 70% resolved by the age of 7 years. White-skinned individuals are affected most commonly and girls are affected three times more than boys.

Haig H. Kasabach, 1898–1943, Radiologist, the Presbyterian Hospital, New York, NY, USA.
Katharine K. Merritt, B. 1886, American Paediatrician.

Figure 39.49 Salmon patch (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.50 Capillary haemangioma (courtesy of St John's Institute for Dermatology, London, UK).

'Port-wine' stains (Fig. 39.51)

These arise from capillary malformations and are 20 times less common than capillary haemangiomas; they result from defective maturation of cutaneous sympathetic innervation during embryogenesis, leading to localised intradermal capillary vasodilatation. At birth, they appear as flat, smooth, intensely purple-stained areas, most frequently on the head and neck, often within the maxillary and mandibular dermatomes of the trigeminal nerve; with age their surfaces become more keratotic and nodular.

Treatment with intense pulsed light and pulse-dye laser are

Figure 39.51 'Port-wine' stain (courtesy of St John's Institute for Dermatology, London, UK).

successful. Port-wine stain (PWS) is associated with several syndromes:

- *Sturge–Weber syndrome*. PWS affecting trigeminal dermatomes; associated with epilepsy and glaucoma (secondary to ipsilateral, leptomeningeal angiomas), cortical atrophy and visual field defects.
- *Klippel–Trenaunay–Weber syndrome*. PWS on a limb with associated bone and soft tissue hypertrophy and lateral varicose veins when the lower limb is involved. It is called Parkes–Weber syndrome if there is an associated arteriovenous malformation.
- *Proteus syndrome*. PWS and regional gigantism in association with lymphatic (lymphaticovenous) malformation. Hypertrophy is always asymmetrical.

Acquired

Campbell de Morgan spots (Fig. 39.52)

These are arteriovenous fistulae at the dermal capillary level that usually, although not exclusively, occur in skin on the trunk of older patients. Multiple lesions are associated with liver disease.

Spider naevi (Fig. 39.53)

These are angiomas that appear (and may disappear) spontaneously at puberty or in two-thirds of pregnant women, usually disappearing in the puerperium. Spider naevi are also associated with chronic liver disease. They can be treated with intense pulsed-light or pulse–dye laser.

William Allen Sturge, 1850–1919, Physician, the Royal Free Hospital, London, UK.

Figure 39.52 Campbell de Morgan spot (courtesy of Mr A.R. Greenbaum).

Figure 39.53 Spider naevus (courtesy of St John's Institute for Dermatology, London, UK).

Pyogenic granuloma (Fig. 39.54)

These share many histological characteristics of haemangiomas and are probably a subtype thereof. Most are small (0.5–1.5 cm), raised, pedunculated, soft, red nodular lesions showing superficial ulceration and a tendency to bleed after trivial trauma. They should be excised with a minimal margin.

Glomus tumour (Fig. 39.55)

These arise from subcutaneous arteriovenous shunts (Sucquet–Hoyer canals) especially in the corium of the nail bed. Typically, they are small, purple nodules measuring a few millimetres in size, which are disproportionately painful in response to insignificant stimuli (including cold exposure). Subungual varieties may be invisible causing paroxysmal digital pain.

Angiosarcoma ('malignant angioendothelioma') (Fig. 39.56)

Angiosarcoma is a rare, highly malignant tumour arising from vascular endothelial cells. The *lymphangiosarcoma* variant arises

J.P. Sucquet, fl 1840–1870, an Anatomist of Paris, France.
Heinrich Hoyer, 1834–1907, Professor of Histology, Embryology and Anatomy, the Central Medical School, the Polish University, Warsaw, Poland.

Figure 39.55 Glomus tumour (courtesy of St John's Institute for Dermatology).

from lymphatic endothelium and can develop in lymphoedematous tissue, particularly on an extremity. Proliferation is rapid, with early systemic spread.

Kaposi's sarcoma (Fig. 39.57)

This is a malignant, proliferative tumour of vascular endothelial cells, which was first described as a rare tumour in elderly Jewish men but is now usually associated with immune compromise after

Figure 39.56 Angiosarcoma (courtesy of St John's Institute for Dermatology, London, UK).

Figure 39.57 Kaposi's sarcoma (courtesy of St John's Institute for Dermatology, London, UK).

transplantation or human immunodeficiency virus (HIV) infection. There appears to be a causal link with infection by human herpesvirus 8 and immune dysfunction. Kaposi's sarcoma usually starts as a red-brown, indurated, plaque-like skin lesion that becomes nodular and then ulcerates. Treatment is with radiotherapy.

WOUNDS: CONGENITAL

Cutis aplasia congenita

This is a rare condition characterised by congenital absence of the epidermis, dermis and, in some cases, subcutaneous tissues, with underlying bony defects in 20%. Lesions may occur on any body surface, but localised scalp agenesis is most frequent. Treatment depends on the severity of the presentation but usually involves plastic surgery.

Parry–Romberg disease

This is an uncommon and poorly understood progressive, hemifacial atrophy of skin, soft tissue and bone. Its incidence is

Caleb Hillier Parry, 1755–1822, Physician, the General Hospital, Bath, UK.
Moritz Heinrich Romberg, 1795–1873, a German Neurologist who was Director of the University Hospital, Berlin, Germany.

unknown and its inheritance uncertain but it affects women more commonly than men.

It usually starts when a patient is in his or her late twenties but can present in childhood when the resulting deformity is worse because it is magnified by differential growth elsewhere. The commonest presentation is confined to lipodystrophy, but mixed atrophy of skin, fat, muscle, cartilage and bone combined result in the classic *coup de sabre* deformity.

The condition is self limiting, usually by 5–10 years after onset. Once the condition is stable, plastic surgical techniques can be employed alone or in combination to reconstruct an aesthetic contour.

Spina bifida

Failure of closure of the caudal neuropore during the fourth week *in utero* results in the incomplete development of some or all of the structural elements posterior to the spinal cord. This can occur anywhere, but is most common in lumbar vertebrae and presents as two gross variants: *spina bifida occulta*, in which there is a variable bony defect without neural protrusion (and which is, therefore, asymptomatic) and *spina bifida cystica*, in which there is herniation of the meninges (meningocele), spinal cord (myelocoele) or, most commonly, both (meningomyelocoele). Management ideally involves a multidisciplinary approach and is directed towards protecting the spinal cord, preventing cerebrospinal fluid contamination and secondary hydrocephalus and meningitis.

WOUNDS: ACQUIRED

Pressure sores

These begin with tissue necrosis at a pressure point (next to a bony prominence) and develop into a cone-shaped volume of

Coup de Sabre is French for 'a sabre cut', a vertical cut across the shoulder from the front to the back.

necrotic loss (with the cone's tip superficial). As many as 10% of acute hospital in-patients will suffer some degree of pressure sore; the majority affect the elderly and patients with spinal injury or decreased sensibility. Overall, 80% of paraplegics will get a pressure sore and 8% will die as a result.

The pathogenesis of pressure sores revolves around unrelieved pressure: an increase in local tissue pressure above that of perfusion pressure produces ischaemic necrosis that is directly proportional to the duration and degree of pressure and inversely proportional to the area over which it is applied. Muscle and fat are more susceptible to pressure than skin.

In a patient who has no predisposing factors (who developed a sore while unable to move but who normally can move), management is aimed at debridement and repair of the defect as necessary on the assumption that recurrence will not occur once normal function and sensibility returns. In the paraplegic, recurrence is likely, so management should involve a multidisciplinary approach with surgery used sparingly once all other predisposing factors have been addressed. Primary treatment involves relieving pressure (special mattress, nursing care, relief of muscle spasm and contractures), optimising nutrition, correcting anaemia, preventing infection and using dressings. Surgery involves thorough debridement to promote healing and plastic surgery to reconstruct the defect if vacuum-assisted closure is unable to heal it.

Elective neurosurgery

LEARNING OBJECTIVES

To understand and know:

- The pathophysiology of raised intracranial pressure and hydrocephalus
- The common causes, presentations, investigation and treatment options for intracranial infection

To be able to:

- Describe the presenting features, investigation and treatment of intracranial tumours

- Understand the diagnosis and management of intracranial haemorrhage
- Define the role of surgery in the management of epilepsy, pain and movement disorders
- Recognise the common compressive peripheral neuropathies
- Understand the principles involved in defining brain death

RAISED INTRACRANIAL PRESSURE

An understanding of raised intracranial pressure (ICP) pathophysiology is crucial to understanding the presentation and treatment of the common neurosurgical conditions (Summary box 40.1).

Summary box 40.1

Raised intracranial pressure

- Results in reduced cerebral perfusion and brain herniation
- The major causes of raised ICP are haematomas, tumours and hydrocephalus

Pathophysiology

Normal intracranial pressure

Normal ICP varies from 5 to 15 mmHg in the adult at rest. ICP varies with venous pressure and is thus affected by factors such as gravitational drainage and manoeuvres that raise intrathoracic pressure (coughing, Valsalva, positive pressure ventilation) or lower it (normal inspiration). Normal values in small children and infants are lower than for adults.

Aetiology of raised intracranial pressure

The principle causes of raised ICP are mass lesions, hydrocephalus and cerebral oedema.

The Monro–Kellie doctrine describes the skull as a rigid container that encloses the brain, cerebrospinal fluid (CSF) and

arterial/venous blood. The addition of a new mass lesion such as a growing tumour or haematoma can initially be compensated for by the egress of CSF and venous blood from the skull. During this compensation phase, there is only a small increase in ICP. When compensation is maximal, there is then a rapid rise in ICP for relatively small increases in volume. This increased pressure causes compression and herniation of the brain (see figures in Chapter 23).

Cerebral oedema may be cytotoxic or vasogenic. Cytotoxic oedema refers to cerebral swelling as a result of cellular engorgement and can occur in both neurones and glia in response to insults such as ischaemia. Vasogenic oedema results from an accumulation of extracellular cerebral fluid, usually as a result of breakdown of the blood–brain barrier and leakage of fluid through ‘leaky’ capillaries. Vasogenic oedema is commonly seen with tumours such as metastases, malignant gliomas and meningiomas.

Hydrocephalus is discussed later in this chapter.

Raised intracranial pressure and cerebrovascular physiology

The brain does not store much energy and is unable to utilise anaerobic metabolism. The brain is therefore critically dependent on a constant flow of oxygen and glucose via the cerebral arterial vasculature. In the absence of arterial blood flow, brain tissue will be viable for only a few minutes.

In normal circumstances, cerebral blood flow is maintained at a constant rate despite fluctuations in mean arterial pressure (MAP) of between 50 and 150 mmHg via mechanisms termed cerebral autoregulation (Fig. 40.1). These mechanisms include neural regulation via aortic and carotid baroreceptors, and local factors such as arteriolar responsiveness to oxygen and carbon dioxide.

Alexander Monro, (Secundus), 1733–1817, Professor of Anatomy, Edinburgh, Scotland.

Figure 40.1 Autoregulation of cerebral blood flow (CBF): CBF remains constant over a wide range of mean arterial pressure. The curve is shifted to the right in patients with hypertension.

In the injured brain, cerebral autoregulation may be impaired either locally or globally. Cerebral blood flow is then dependent on MAP with a fall in MAP leaving the brain susceptible to ischaemia, and a rise in MAP resulting in hyperaemia, increased cerebral blood volume and thus raised ICP. Cerebral perfusion can be estimated by the following formula: cerebral perfusion pressure (CPP) = MAP – ICP. Studies of patients in traumatic coma have shown that poor prognostic factors include an ICP of > 20–25 mmHg or a CPP of < 60 mmHg.

Cerebral herniation

Sub-falcine herniation refers to shift of the cingulate gyrus of one hemisphere under the falx cerebri (a tough vertical dural fold between the two hemispheres) and across to the contralateral side. The thin wall dividing the lateral ventricles (septum pellucidum) may shift from the midline.

Uncal herniation refers to shift of the medial temporal lobe (uncus) medially towards the tentorial hiatus. As this occurs, the nearby oculomotor (third) nerve is stretched, causing dilatation and fixation of the ipsilateral pupil. This is usually accompanied by a rapidly progressive contralateral hemiparesis as pressure is exerted on the ipsilateral cerebral peduncle. Unusually, compression of the contralateral cerebral peduncle against the free edge of the tentorium (Kernohan's notch) causes an ipsilateral hemiparesis in association with an ipsilateral third nerve palsy.

Tentorial herniation refers to a downwards shift of midbrain structures through the tentorial hiatus. Tonsillar herniation refers to a downwards shift of the cerebellar tonsils and medulla through the foramen magnum. This type of herniation is associated with death due to compression and/or ischaemia of the cardiorespiratory centres.

Clinical features

Symptoms of raised ICP in a patient include headaches that tend to be worse in the early morning or on lying down and may improve with ambulation. Associated symptoms include nausea, vomiting or visual disturbance, particularly double vision or blurred vision. The headache may be exacerbated by coughing, straining or bending. In addition there may be symptoms relevant to the location of the pathology, for example, cognitive and personality change, unsteadiness of gait and incontinence of urine in frontal lobe pathology or right-sided weakness and garbled speech

James Watson Kernohan, 1896–1981, Pathologist, the Mayo Clinic, Rochester, MN, USA.

in dominant temporal lobe pathology. As ICP increases further, relatives may report lethargy or drowsiness followed by unconsciousness and coma (Table 40.1).

Raised ICP may be associated with papilloedema on fundoscopy (Fig. 40.2). There may also be diplopia due to a sixth nerve palsy; this nerve is vulnerable to downwards cerebral shift of any cause due to its long intracranial course, sometimes called a *false localising sign*. There may be abnormalities of conjugate gaze. In particular, impaired upgaze or sun-setting may be seen as part of Parinaud's syndrome, caused by pressure on the dorsal midbrain (Fig. 40.3).

Raised ICP is associated with impaired consciousness and coma as measured by the Glasgow Coma Score (see Chapter 23).

Table 40.1 Symptoms of raised intracranial pressure

Headache	Early morning Worse on lying down
Nausea and vomiting	
Visual blurring or double vision	
Drowsiness	

Figure 40.2 Papilloedema showing a swollen optic disc with blurred margins.

Figure 40.3 Child with 'sun-setting' eye sign due to hydrocephalus.

In infants, raised ICP causes a bulging fontanelle, progressive macrocephaly with sutural diastasis, and dilatation of scalp veins rather than papilloedema (Table 40.2).

Treatment

Appropriate treatment of raised ICP depends on identifying the cause.

Medical

For a review of the medical management of raised ICP in head injury, see Chapter 23.

Mannitol is an osmotic diuretic that can be used in emergency settings to reduce ICP: the dose is 0.5–1.0 g kg⁻¹.

Vasogenic oedema is often treated with the administration of high-dose steroids in the form of dexamethasone, for example 8 mg twice daily. Steroids reduce the permeability of the blood–brain barrier and are useful in reducing cerebral swelling prior to definitive treatment of the underlying cause of the vasogenic oedema.

A carbonic anhydrase inhibitor such as acetazolamide can play a role in control of raised ICP in idiopathic intracranial hypertension and acts by reducing CSF production.

Surgical

A variety of mass lesions can cause raised ICP and are amenable to surgical treatment via craniotomy: in trauma, acute extradural and subdural haematomas, intracerebral contusions and chronic subdural haematomas; in cerebrovascular pathology, superficial lobar haematomas, haematomas associated with ruptured aneurysms; in neuro-oncology, a variety of primary and secondary tumours. Occasionally, surgical control of ICP will involve a large bony decompression (craniectomy), such as in traumatic brain injury or extensive middle cerebral artery (MCA) infarction.

HYDROCEPHALUS

Hydrocephalus is a condition in which there is disequilibrium between CSF production and absorption, leading to raised ICP, and is often associated with dilated ventricles. Not all patients with ventriculomegaly have hydrocephalus and not all patients with hydrocephalus necessarily have enlarged ventricles (Summary box 40.2).

Summary box 40.2

Hydrocephalus

- Hydrocephalus may be obstructive or communicating
- Treatment is with removal of the causative lesion or by CSF diversion procedures

Table 40.2 Signs of raised intracranial pressure

Papilloedema

Sun-setting eyes

Cerebrospinal fluid physiology

The total CSF volume in an adult is about 150 ml and it is distributed between the cerebral ventricles (approximately 35 ml), the cerebral subarachnoid space and the spinal thecal sac. CSF production occurs at a rate of approximately 0.33 ml min⁻¹ or 450 ml day⁻¹, resulting in a turnover of three volumes per day (Table 40.3).

CSF production is primarily by the choroid plexus of the ventricles and is an active process independent of ICP. Some CSF production occurs by transependymal spread through the ventricular walls from the cerebral extracellular fluid, and from the spinal dural nerve root sheaths. CSF flows from the lateral ventricles, through the foramen of Munro, into the third ventricle and then into the cerebral aqueduct and fourth ventricle before exiting into the subarachnoid space via the midline foramen of Magendie and lateral foramina of Lushka. CSF absorption is a pressure-dependent passive process involving filtration across the arachnoid villi, which are abundant along the superior sagittal sinus into which the CSF is absorbed.

Relative to plasma, CSF has a lower potassium and calcium content but is richer in chloride and magnesium. Normal protein content is 0.15–0.45 g l⁻¹. CSF is slightly acidic relative to plasma (pH 7.33–7.35).

Aetiology of hydrocephalus

Hydrocephalus can be obstructive or communicating (Table 40.4 and Fig. 40.4). *Obstructive hydrocephalus* can be caused by any lesion blocking the CSF pathways from the lateral ventricles to

Table 40.3 Cerebrospinal fluid physiology

Volume	150 ml
Production	20 ml h ⁻¹ 80% by choroid plexus Active process

CSF, cerebrospinal fluid.

Francois Magendie, 1783–1855, Professor of Pathology and Physiology, at the College of France, and Physician, Hôtel Dieu, Paris, France.
Hubert von Luschka, 1820–1875, Professor of Anatomy, Tubingen, Germany.

Figure 40.4 Pathological specimen of a hydrocephalic brain.

the fourth ventricle (Fig. 40.5). Susceptible sites include the foramen of Munro (colloid cyst of the third ventricle) and cerebral aqueduct (congenital aqueduct stenosis, tectal plate glioma). Lesions may be within the ventricle, in the ventricular wall or distant from the ventricle but exerting mass effect on it. Posterior fossa mass lesions are more likely than supratentorial lesions to present with obstructive hydrocephalus because the fourth ventricle is easily compressed within the relatively small posterior fossa. *Communicating hydrocephalus* refers to circumstances in which the intracerebral CSF pathways are patent but there is accumulation of CSF, usually due to impaired CSF absorption.

Figure 40.5 Pineal region tumour causing obstructive hydrocephalus.

This may be because the CSF constituents have altered such as in cases of meningitis or subarachnoid haemorrhage (SAH).

Normal-pressure hydrocephalus is a specific form of communicating hydrocephalus that tends to affect the elderly. The clinical triad is ataxia, cognitive decline and urinary incontinence, and there is ventriculomegaly on imaging. Although one-off measurements of CSF pressure may be normal the syndrome is thought to arise from impaired CSF absorption, resulting in intermittent high pressure, and some patients respond clinically to CSF diversion with ventriculoperitoneal shunting.

Investigation

Lumbar puncture is contraindicated in *obstructive hydrocephalus* because of the risk of causing tonsillar herniation and death.

Ventricular size can be assessed with a computerised tomography (CT) scan of the brain (Fig. 40.6). The ventricles may be enlarged as a result of generalised cerebral atrophy or localised neuronal cell loss (*ex vacuo* dilatation) as well as by hydrocephalus. In children, chronic raised ICP can result in copper-beating of the skull (Fig. 40.7).

A magnetic resonance imaging (MRI) scan of the brain can provide better anatomical detail of lesions causing hydrocephalus and is particularly useful in the diagnosis of aqueduct stenosis. A midline T2-weighted MRI scan can be used to assess the suitability of a patient for a third ventriculostomy by identifying the relationships of the floor of the third ventricle, basilar artery and clivus.

ICP monitoring with a parenchymal probe placed into the frontal lobe via a twistdrill burrhole is a useful diagnostic tool for patients in whom hydrocephalus or CSF shunt dysfunction is suspected.

Figure 40.6 Axial computerised tomography scan, showing a neonate with hydrocephalus and markedly dilated ventricles. The temporal horns, normally just visible, are particularly enlarged.

Figure 40.7 Lateral skull radiograph showing copper-beating, which is indicative of chronic raised intracranial pressure.

In *communicating hydrocephalus*, a lumbar puncture may be both diagnostic, by measurement of opening pressure, and therapeutic, by draining a volume of CSF that allows the closing pressure to be within normal limits.

In the diagnosis of normal pressure hydrocephalus, other diagnostic procedures include the CSF tap test (clinical evaluation before and after withdrawal of 20–30 ml of CSF via lumbar puncture) and CSF infusion studies. These involve infusing saline into the thecal sac while measuring the pressure to obtain an estimate of resistance to CSF outflow. Values of CSF outflow of $> 14 \text{ mmHg ml}^{-1} \text{ min}^{-1}$ have a positive predictive value for responsiveness to ventriculoperitoneal shunt insertion.

Management

Management of hydrocephalus will depend on the underlying cause. Options include removing a causative mass lesion, ventricular shunting or third ventriculostomy.

Removing a causative mass lesion

Intracranial mass lesions may present with obstructive hydrocephalus. In some circumstances it may be appropriate to treat the hydrocephalus by tumour removal and decompression of the CSF pathways, perhaps with the insertion of an external ventricular drain (EVD) to cover the early postoperative period. In other cases, such as a patient who presents with an impaired conscious level secondary to obstructive hydrocephalus, it may be appropriate to treat the hydrocephalus with an EVD or ventriculoperitoneal shunt and allow the patient to recover before undertaking tumour surgery.

Ventriculoperitoneal shunt

A ventriculoperitoneal shunt involves the insertion of a catheter into the lateral ventricle (usually right frontal or occipital) (Fig. 40.8). The catheter is then connected to a shunt valve under the scalp and finally to a distal catheter, which is tunneled subcutaneously down to the abdomen and inserted into the peritoneal cavity. If the CSF pressure exceeds the shunt valve pressure, then CSF will flow out of the distal catheter and be absorbed by the peritoneal lining.

Figure 40.8 Various types of cerebrospinal fluid shunt.

Other options for distal catheter placement include the right atrium via the deep facial and jugular vein (ventriculo-atrial shunt) or the pleural cavity (ventriculopleural shunt).

Shunt valves have a variety of mechanisms of action, which include diaphragm and ball-in-cone systems. These valves are pressure regulated but others are flow regulated. Pressure-regulated valves are susceptible to *siphoning*, a term that describes increased shunt flow when gravity acts on a column of fluid such as the distal shunt tubing in an upright patient. Most shunt valves are available in two or three different performance settings (such as high, medium and low pressure). For patients in whom the correct valve setting is difficult to determine, a programmable valve can be inserted. This allows the valve pressure to be adjusted by the application of an external magnet without the need for surgery. Shunt valves usually have an in-built CSF reservoir on the ventricular side of the valve, which may be useful for shunt tapping to obtain a CSF sample.

Shunt complications

The most common complications include shunt blockage and infection. Approximately 15–20% of shunts are revised within the first 3 years.

Shunt blockage may affect the ventricular catheter, shunt valve or distal catheter. Causes of blockage include choroid plexus adhesion, blood, cellular debris or misplacement of the distal catheter in the pre-peritoneal space. More than one-half of cases of shunt blockage are subsequently shown to be infected.

Shunt infection affects between 1% and 7% of shunt insertions and is usually caused by skin commensals, such as *Staphylococcus epidermidis*. Neonates are susceptible to *Escherichia coli* and haemolytic streptococcal infections. Risk factors for infection include very young children, open myelomeningocele, longer operative time and excessive staff movement into and out of theatre. Most infections become apparent clinically by 6 weeks and over 90% are apparent within 6 months. Treatment is by removal of the shunt, external CSF drainage and treatment of infection prior to re-insertion of the shunt at a different site. The introduction of antibiotic-impregnated catheters has resulted in a reduction in shunt infection rates.

Shunt systems may overdrain leading to subdural haemorrhage or slit ventricle syndrome. Other complications are common to intracranial surgery and include seizures (5%), CSF leak, stroke and intracerebral haemorrhage (< 1%).

Endoscopic third ventriculostomy

An endoscopic third ventriculostomy (ETV) involves the insertion of a neuroendoscope into the frontal horn of the lateral ventricle and then into the third ventricle through the foramen of Munro. A stoma can be created in the floor of the third ventricle in between the mamillary bodies and infundibular (pituitary) recess. CSF can then communicate freely between the ventricular system and interpeduncular subarachnoid space. The technique is particularly useful when there is obstruction of the CSF pathways below the third ventricle such as with aqueduct stenosis or posterior fossa mass lesions.

It has an advantage over shunting in that no tubing is left in the patient and therefore infection rates are lower. ETVs may block off, however, with about one-half of these patients ending up with a shunt. Rare, but serious, complications include basilar artery rupture or memory impairment from injury to the fornix. The procedure is less useful for communicating types of hydrocephalus or in infants of less than 6 months of age, but has a success rate of over 70% for accepted indications.

External drains

External drains can be placed within the ventricle (EVD) or the lumbar thecal sac (lumbar drain). These are useful for temporary CSF drainage and can be used to administer intrathecal antibiotics to treat CSF infection.

INTRACRANIAL INFECTION (SUMMARY BOX 40.3 AND TABLE 40.5)

Summary box 40.3

Intracranial infection

- Cerebral abscess can be caused by local or haematogenous spread
- Subdural empyema can be difficult to diagnose and requires urgent surgical drainage
- Common cerebral mass lesions in human immunodeficiency virus – acquired immunodeficiency syndrome (HIV-AIDS) include toxoplasmosis and lymphoma

Meningitis

Meningitis is a life-threatening infection that, if left untreated, will progress through meningeal inflammation, subpial encephalopathy, cortical venous thrombosis, cerebral oedema and death. The causative pathogens are age dependent (Table 40.6). Presentation is with fever, neck stiffness, photophobia and altered conscious level. Investigation is via CT and lumbar puncture, and treatment is by prompt administration of intravenous antibiotics such as cefotaxime. Aciclovir is usually added empirically to cover herpes simplex virus infection. Neurosurgical

Table 40.5 Types of intracranial infection

Meningitis
Extradural empyema
Subdural empyema
Cerebral abscess

Table 40.6 Organisms causing meningitis

Neonate	Group B <i>Streptococcus</i> <i>Listeria</i> Enterobacteriae
Infant	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Haemophilus influenzae</i>
Young child/adult	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i>
Immunocompromised patient	<i>Cryptococcus</i> <i>Mycobacterium tuberculosis</i> <i>Listeria</i>

intervention is seldom required but some patients require shunting for post-meningitic communicating hydrocephalus. Subdural effusions are common in infants with hydrocephalus but rarely need surgical intervention except to rule out subdural empyema.

Cerebral abscess

Pathology

Intracerebral abscess may occur as a result of direct spread from air sinus infection, following surgery or from haematogenous spread especially associated with respiratory infection, endocarditis or dental infection. In around 25% of cases no cause is found. Patients at increased risk of cerebral abscess formation include those with cyanotic heart disease and those who are immunocompromised: patients with diabetes, solid organ transplant, haematological malignancy or long-term steroids.

A 2- to 3-day period of early cerebritis with inflammatory cell inflammation is followed by late cerebritis over days 4–9, with the formation of a necrotic core and increasing numbers of macrophages and fibroblasts (Fig. 40.9). After 10 days, a capsule begins to form and is firm and mature by day 14 (Fig. 40.10).

In a non-compromised host the causative organisms include anaerobic and micro-aerophilic streptococci, staphylococci, enterobacteria and anaerobes. Immunocompromised hosts are also susceptible to other infections including *Nocardia*, *Listeria*, *Aspergillus*, *Candida*, *Cryptococcus* and *Toxoplasma*.

Diagnosis

Presentation is with focal signs, seizures and raised ICP, as with other mass lesions, but the time course is often short. Patients may be febrile or have a raised peripheral white cell count or inflammatory markers. However, many patients with cerebral abscess show no markers of systemic infection. An intracerebral abscess appears as a ring-enhancing mass lesion on CT (Fig. 40.10) or MRI and the lesions may be multiple in the case of haematogenous spread. Differential diagnosis includes primary brain tumour and cerebral metastasis. A diffusion-weighted MRI may help differentiate between a tumour and an abscess because the latter will show restricted diffusion, but false negatives and positives occur. Where there is doubt, a ring-enhancing lesion should be treated as a cerebral abscess until proven otherwise.

Treatment

Cerebral abscess is usually treated by surgical drainage followed by administration of intravenous antibiotics for at least 6 weeks.

Figure 40.9 Axial computerised tomography scan with contrast of a patient with frontal sinusitis and epilepsy, showing a hypodense area of cerebritis in the left frontal region.

Surgical drainage is often by image-guided aspiration, which may need to be repeated several times during the course of the illness. Excision of the abscess wall is an option and may be required for lesions that fail to resolve and multilocular or posterior fossa abscesses. Antibiotic therapy is rationalised according to microbiological culture and sensitivity, and regular surveillance scanning is recommended during therapy and for some months after therapy to pick up recurrences. Multiple small abscesses may be treated medically with antibiotics targeted against organisms isolated from systemic sources but rigorous surveillance is essential. Stereotactic aspiration of one of the lesions to confirm the organism is often desirable.

Steroids are reserved for cases with significant oedema or mass effect and their routine use is discouraged because of their negative impact on antibiotic therapy. Owing to the high risk of seizures, patients should also be treated with anticonvulsants.

Outcome

The overall mortality for cerebral abscess has fallen with the advent of CT and image-guided surgery to around 4% from 40% in earlier decades. It remains the case that a delay in diagnosis and treatment is highly dangerous. If a cerebral abscess is allowed to progress and ruptures into the ventricle, then the rate of mortality is over 80%.

Subdural empyema

Subdural empyema is less common than cerebral abscess but carries a high mortality (5–10%). Infection usually spreads locally from sinusitis and the pus collects over the cerebral convexity and in the parafalcine space (Fig. 40.11). Location in the

Figure 40.10 Axial computerised tomography scan with contrast of the same patient as in Fig. 40.9 but 2 weeks later. A ring-enhancing lesion has developed, typical of a pyogenic abscess.

subdural space encourages cortical venous thrombophlebitis with consequent venous infarction. Causative organisms are usually streptococci such as *Streptococcus viridans* or *Streptococcus milleri*.

Presentation is with headache, fever and meningism. Seizures are common and focal neurological deficits may progress quickly to altered mental state and coma. Diagnosis by non-contrast CT can be difficult and a high index of suspicion must be used – a small parafalcine collection of fluid may be all that is visible. MRI is useful when the diagnosis is doubtful.

Treatment is by craniotomy and thorough drainage of the pus, followed by intravenous antibiotic treatment, anticonvulsants and radiological surveillance as for cerebral abscess.

Tuberculosis

Tuberculosis may affect the central nervous system (CNS) by causing meningoencephalitis or small tumour-like masses of granulomatous tissue called tuberculomas that tend to appear at the base of the cerebral hemispheres. Tuberculoma is a very common cause of intracerebral mass lesion in India. True cerebral abscess in tuberculosis is rare except in patients with AIDS.

Diagnosis of tuberculosis is usually by lumbar puncture. There will be an increased opening pressure with increased CSF white cell count, mainly lymphocytes. Protein is elevated and glucose reduced but not as much as in bacterial meningitis. CSF culture may take several weeks but polymerase chain reaction (PCR) detection is more rapid.

The management of tuberculosis is with drug therapy except

Figure 40.11 Axial computerised tomography scan with contrast showing a right hemisphere subdural empyema and a right frontal Pott's puffy tumour.

in cases when hydrocephalus requires shunt insertion or diagnostic doubt necessitates biopsy.

Parasitic central nervous system infections

Neurocysticercosis

Infection with the pork tapeworm is endemic in areas of Eastern Europe, Asia, South America and Africa. Ingestion of the larval form via contaminated human faeces results in cysticercosis. The larvae burrow through the duodenum and gain access to the systemic circulation, including to the brain. In the brain, larval infection stimulates cyst formation with intense inflammation. They show on CT as ring-enhancing cysts. Presentation may be with seizures, raised pressure or cranial nerve deficits from basal arachnoiditis.

Treatment is with anti-helminthic drugs such as praziquantel or albendazole. The only role for surgery is to treat hydrocephalus or when there is diagnostic doubt.

Toxoplasmosis

Toxoplasma species are obligate intracellular parasites that can be ingested from contact with raw beef, lamb or cat faeces. Infection is more common in the immunocompromised host, especially in the context of AIDS.

Percivall Pott, 1714–1788, Surgeon, St Bartholomew's Hospital, London, UK, described the 'Puffy Tumour' in 1760.

Neurosurgery and human immunodeficiency

Patients with HIV-AIDS may present with a variety of CNS manifestations including HIV-related meningitis and opportunistic infections. The most common focal brain lesions, in descending order of frequency, are: toxoplasmosis, primary CNS lymphoma, progressive multifocal leucoencephalopathy and cryptococcal abscess. Surgical biopsy is reserved for cases of diagnostic doubt.

Toxoplasmosis

Toxoplasmosis occurs in 15–30% of patients with AIDS and usually occurs late in the course of the disease when the CD4 count is less than 400 cells/mm³. The resulting abscesses represent over 70% of the cerebral mass lesions in AIDS. They are usually multiple (> 5), prefer a basal ganglia or subcortical location and demonstrate ring enhancement. Treatment is with pyrimethamine and sulphadiazine.

Primary central nervous system lymphoma

Primary CNS lymphoma occurs in about 10% of AIDS patients, is associated with Epstein–Barr virus infection and carries a worse prognosis than in the normal population. Unlike in the normal population, ring enhancement on CT or MRI is common, thus sometimes making a differentiation from toxoplasmosis on imaging criteria difficult. CSF cytology may be positive on lumbar puncture. It may be reasonable to treat for toxoplasmosis and reserve biopsy for those patients who do not respond.

Progressive multifocal leucoencephalopathy

This condition is caused by JC virus (a human polyoma virus) infection, with AIDS being the most common underlying disorder. The pathology is oligodendrocyte destruction and presentation is with progressive focal deficits and altered cognition. On imaging, the lesions are located in the white matter and may be multiple, but do not demonstrate enhancement or a mass effect. There is no specific treatment other than that of the underlying disorder and death usually occurs within a few months.

Cryptococcal abscess

Cryptococcus is a fungal infection that causes meningitis but also cerebral abscess in AIDS patients. The organism or its antigens may be detected in the CSF. Treatment is with amphotericin B and fluconazole.

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is a transmissible spongiform encephalopathy caused by an abnormal prion protein. It has a variant form (vCJD), which was described in 1996 after an epidemic of bovine spongiform encephalopathy in the UK.

The neurosurgeon may become involved by performing a brain biopsy when diagnosis of CJD is suspected. CJD is transmissible and standard sterilisation methods are inadequate. Disposable instruments must be used in cases in the UK for which a diagnosis of CJD is a possibility. Any non-disposable equipment must be quarantined until a final diagnosis is known and is then destroyed if CJD is confirmed. Because of the risk of vCJD transmission, neuroendoscopes used on those patients born before 1 January 1997 must be kept separate from those used on other patients. All neuroendoscopy accessories must be single use and disposable.

INTRACRANIAL TUMOURS

Intracranial tumours is a term encompassing a great variety of pathological entities ranging from developmental to benign, low-grade and frankly malignant mass lesions. An abridged version of the World Health Organization (WHO) classification of intracranial tumours is shown in Table 40.7. The cells of origin that form the majority of intracranial tumours include meningotheial cells, glial cells, metastatic deposits and pituitary cells. Any mass lesion within the skull is a threat to the integrity of brain function and therefore even histologically benign tumours can threaten life (Summary box 40.4).

Summary box 40.4

Intracranial tumours

- Intracranial tumours may present with seizures, focal neurological deficit, raised ICP or endocrine disturbance
- Cerebral metastases are the most common intracranial tumours
- Benign tumours may cause life-threatening intracranial complications
- For aggressive tumours, management options include steroids, surgery, radiotherapy and chemotherapy

Aetiology

The majority of primary brain tumours are sporadic. Various possible environmental risk factors such as smoking, diet, occupation and mobile phone use have been studied with no causative link proven. Some brain tumours are linked with known genetic abnormalities and this list is enlarging on an annual basis. Neurofibromatosis type 1 is caused by a mutation on chromosome 17, which encodes the protein neurofibromin and is associated with astrocytomas as well as neurofibromas. Neurofibromatosis type 2 is caused by a mutation on chromosome 22, which encodes the protein schwannomin, and is characterised by bilateral

vestibular Schwannomas (acoustic neuromas) as well as an increased incidence of meningiomas. Li–Fraumeni syndrome is caused a mutation of the gene encoding p53 protein on chromosome 17 and is associated with astrocytomas, as is the *PTEN* gene mutation of Cowden’s disease and also hereditary non-polyposis colorectal cancer syndrome. Familial adenomatous polyposis syndrome (*APC* gene mutation) and basal cell naevus syndrome (*PTCH* gene mutation) are associated with medulloblastoma.

Clinical features

Intracranial tumours can present with seizures, focal neurological deficits, raised ICP, seizures or endocrine dysfunction, or can be incidental findings.

Focal deficits

The type of focal neurological deficit will depend on the location of the lesion. With regard to the time-course of neurological symptoms, a steady progression of symptoms over time suggests a structural lesion more than the acute deficit of vascular pathology. An exception to this may be the acute deficit produced by haemorrhage into a malignant glioma, a melanoma metastasis or pituitary apoplexy (see the section on pituitary tumours).

Frontal lobe lesions tend to present with personality change, gait ataxia and urinary incontinence, contralateral hemiparesis if posterior frontal and dysphasia if involving the left inferior frontal gyrus. Parietal lesions are associated with sensory inattention, dressing apraxia, astereognosis and, if on the dominant side, acalculia, agraphia, left–right disorientation and finger agnosia (Gerstmann’s syndrome). Temporal lobe lesions may be associated with disturbance of memory, contralateral superior quadrantanopia or hemiparesis and, if on the dominant side, dysphasia. Occipital lesions are often associated with visual field deficits, most commonly an incomplete contralateral homonymous hemianopia.

Other classical focal deficits associated with tumours include: bitemporal hemianopia with a pituitary macroadenoma; anosmia, ipsilateral optic atrophy and contralateral papilloedema with an

Metastatic tumours		
Contiguous extension from regional tumours, e.g. glomus tumour		

anterior skull base meningioma (Foster–Kennedy syndrome); and ipsilateral hearing loss, tinnitus and dysequilibrium with a vestibular Schwannoma.

Raised intracranial pressure

Intracranial tumours may be associated with raised ICP by a variety of mechanisms, including direct mass effect, vasogenic oedema and obstructive hydrocephalus.

Seizures

The type of seizure may give a clue as to the location of the tumour: for example, parietal lesions causing simple partial seizures, which may become secondarily generalised, medial temporal lesions causing complex partial seizures and so on.

Gliomas

Gliomas include astrocytomas, oligodendrogliomas and mixed tumours. They are graded according to the WHO classification from I to IV according to histological criteria including cellularity, nuclear pleomorphism, mitoses, vascular proliferation and necrosis. A grade I tumour, such as a pilocytic astrocytoma, is the least aggressive; a grade IV tumour, such as a glioblastoma multiforme, is the most aggressive (Fig. 40.12).

Pilocytic astrocytoma is most common in children and young adults, with a peak incidence at the age of 10 years. Common sites include the cerebellum, optic nerve and chiasma, hypothalamus and brainstem. It may be possible to cure posterior fossa tumours by complete surgical excision.

Diffuse astrocytomas (WHO grade II) are most common in the fourth decade of life and often present with seizures or are incidental findings. Optimum treatment remains controversial. Options include surveillance scanning only, biopsy to confirm diagnosis or maximal resection. Radiotherapy may be given early or, more usually, after clinical or radiological progression. Diffuse astrocytomas cannot be cured by any treatment modality and tumour progression is likely, often to a higher grade, within 3–5 years.

Figure 40.12 Axial T1-weighted magnetic resonance imaging scan with gadolinium, showing a glioblastoma multiforme.

High-grade gliomas, including anaplastic astrocytomas (WHO grade III) and glioblastoma (WHO grade IV) are most common in the fifth and sixth decades of life respectively. Glioblastoma is the most common adult glial tumour. Treatment includes surgery to confirm the diagnosis and achieve a macroscopic excision when possible. Surgery is usually followed by high-dose (60 Gy) focused irradiation for those patients with a good performance status. Chemotherapy options include oral temozolomide, either concurrently or after radiotherapy. Chemotherapy wafers impregnated with carmustine may be inserted into the surgical cavity at the time of resection. Despite recent advances, the prognosis for a glioblastoma remains poor with a median survival of 12 months and 2-year survival of only 26% (Fig. 40.13).

The prognosis for a patient with a glioma depends on the histological grade, cell type, tumour size and patient factors such as age and performance status.

Cerebral metastases

Cerebral metastases are by far the most common intracranial tumours and will affect approximately one in every four cancer sufferers. They tend to occur in the fifth to seventh decades. The tumours of origin and their relative frequency are shown in Table 40.8.

The majority of patients with cerebral metastases have multiple lesions and are not suitable candidates for surgery. Palliation with steroids and whole-brain irradiation remain options. Occasionally, the diagnosis is unclear and a biopsy is required.

Patients with a solitary cerebral metastasis may be candidates for excision via a craniotomy if they are in good clinical condition and the primary disease is well controlled. In these circumstances surgery and radiotherapy prolongs life compared with radiotherapy

Table 40.8 Origin of cerebral metastases

Origin	Percentage
Lung	40
Breast	10–30
Melanoma	5–15
Colon, renal	–
Unknown	15

Figure 40.13 Pathological specimen of a glioblastoma multiforme.

alone. Some studies suggest that if two or even three metastases are present and all lesions can be safely removed, then the prognosis is similar to those with a solitary metastasis. Focused radiation therapy is an alternative to craniotomy.

Meningiomas

Meningiomas arise from meningotheial cells and represent around 15–20% of all intracranial tumours (Fig. 40.14). Meningiomas are usually benign although atypical and malignant forms can occur. Around 80% are supratentorial occurring in sites such as the convexity (20%), parafalcine area (20%), sphenoid ridge (10%), tuberculum sellae (10%) and olfactory groove (10%). They may occur within the ventricle (2–5%).

Meningiomas disturb brain function by mass effect, stimulation of vasogenic oedema, direct brain invasion or obstructive hydrocephalus. The tumours may grow slowly over many years and a decision to undertake surgery must consider the patient's neurological status, age and comorbidity. A course of steroids to reduce oedema preoperatively is often desirable.

The chance of recurrence of a benign meningioma depends on the extent of resection those that are completely excised have a 10-year recurrence rate of 10%, increasing to 20% if the dural origin is diathermied but not excised and 30% for subtotal excision.

Radiotherapy is reserved for more aggressive tumour types or difficult surgical locations such as the cavernous sinus.

Pituitary tumours

These account for 10–15% of all intracranial tumours. The majority are benign adenomas that are classified according to size, local invasiveness, the patient's endocrine status, ultrastructure and immunohistochemical staining. Metastases may occur, usually in elderly patients in the posterior pituitary. The differential

Figure 40.14 Axial T1-weighted magnetic resonance imaging scan with gadolinium, showing a large right parietal convexity meningioma.

diagnosis of a sellar region mass includes craniopharyngioma, meningioma, aneurysm and Rathke's cleft cyst.

The most common pituitary adenomas are prolactinoma (30%), non-functioning adenoma (20%), growth hormone-secreting adenoma (15%) and adrenocorticotrophic hormone (ACTH)-secreting adenoma (10%).

Clinical features

Pituitary adenomas may present with mass effect or endocrine disturbance. Mass effect may cause a bitemporal hemianopia due to pressure on the optic chiasma or cause dysfunction of cranial nerves III, IV and VI (Fig. 40.15). Endocrine dysfunction will depend on the secretory properties of the tumour if any: galactorrhoea and primary/secondary amenorrhoea in a prolactinoma, Cushing syndrome in an ACTH-producing tumour (Cushing's disease) and acromegaly or gigantism in a growth hormone-secreting tumour (Table 40.9).

Pituitary apoplexy results in the sudden onset of headache, visual loss, ophthalmoplegia and possibly altered conscious level. It is caused by haemorrhagic infarction of a pituitary tumour. The sudden headache and meningism is similar to the presentation of aneurysmal SAH. Preoperative resuscitation should include steroid cover, and urgent decompression is usually required.

Figure 40.15 Pituitary non-functioning macroadenoma with suprasellar extension and right cavernous sinus invasion.

Harvey Williams Cushing, 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA.

Table 40.9 Clinical syndromes for secretory pituitary tumours

Prolactin	Galactorrhoea Primary or secondary amenorrhoea Impotence
Growth hormone	Acromegaly Gigantism if prepubertal
Adrenocorticotrophic hormone	Cushing's disease

Investigation

A patient with a suspected pituitary tumour should undergo formal visual field and acuity testing, MRI scan of the pituitary region and baseline assessment of pituitary function including prolactin, fasting serum and urinary free cortisol, growth hormone and insulin-like growth factor-1, follicle-stimulating hormone, luteinising hormone and thyroid function.

It is essential that the patient's endocrine status is established particularly with regards to the ACTH–cortisol axis and prolactin. Cortisol deficiency must be corrected, especially in the perioperative period. A high prolactin level may indicate a prolactinoma and preclude the need for surgery (see below) but it is important to be aware that pituitary stalk compression from other tumours can moderately elevate the prolactin level. Diagnosis of an ACTH-secreting tumour can be difficult and will often involve the use of specialised tests such as petrosal sinus sampling as well as a dexamethasone suppression test.

Treatment

The aim of treatment of pituitary tumours is to alleviate mass effect, restore or replace normal endocrine function and prevent recurrence. Management requires close cooperation between neurosurgeon and endocrinologist.

Prolactinomas should be initially treated medically with dopamine agonists such as cabergoline or bromocriptine. Growth hormone-secreting tumours may be amenable to medical treatment with somatostatin analogues such as octreotide or dopamine agonists.

Surgical management of pituitary tumours requires trans-sphenoidal surgery either with an operating microscope or endoscope assisted. Large tumours with suprasellar extension may need to be managed by craniotomy as well. Surgical success as determined by normalisation of endocrine dysfunction and lack of recurrence varies according to the condition being treated and the size of the tumour. Complications of trans-sphenoidal surgery include CSF leak (3%), visual deterioration (1%), major vessel injury (1%) and panhypopituitarism (1%). Diabetes insipidus occurs following manipulation of the pituitary stalk and is usually transient.

Vestibular Schwannoma (acoustic neuroma)

Vestibular Schwannoma is the most common intracranial nerve sheath tumour and is benign. It may occur sporadically or in association with neurofibromatosis type 2 (bilateral vestibular Schwannomas being diagnostic of this condition).

Presentation is usually with a combination of hearing loss, tinnitus and dysequilibrium. Facial numbness and weakness are less common. Large tumours may present with symptoms of brainstem compression or hydrocephalus.

Imaging with MRI will demonstrate a tumour that may be in the internal auditory canal (intracanalicular) or extend through the meatus into the cerebellopontine angle (Fig. 40.16). Differential diagnosis includes meningioma, metastasis and epidermoid tumour.

Management depends on the size of the tumour and the presentation. Small intracanalicular tumours may be treated by radiological surveillance. Larger tumours could be considered for radiosurgery or craniotomy and excision. Open surgery is the favoured option for large tumours with brainstem compression. Hydrocephalus may need to be relieved via a ventriculoperitoneal shunt.

Preservation of facial nerve and hearing function will depend on preoperative function as well as the size of the tumour. Facial nerve preservation is possible in about 90% of tumours that are < 4 cm but in only 70% of those that are > 4 cm. Hearing preservation (retrosigmoid or middle fossa approach) is possible in around 50% of tumours that are < 1 cm but very unlikely in tumours that are > 2 cm.

Intracranial tumours in children

Intracranial tumours are the most common solid tumours in children.

In neonates, tumours tend to be of neuroectodermal origin and most are supratentorial. Tumour types include:

- teratoma;
- primitive neuroectodermal tumour;
- high-grade astrocytoma;
- choroid plexus papilloma/carcinoma.

Figure 40.16 Axial T1-weighted magnetic resonance imaging scan with gadolinium, showing a left vestibular Schwannoma.

Theodor Schwann, 1810–1882, Professor of Anatomy, successively at Louvain, (1839–1848), and Liege, Belgium (1849–1880).

In older children, the majority of tumours are infratentorial and one of three types:

- medulloblastoma;
- ependymoma;
- pilocytic astrocytoma.

Other tumours include supratentorial low-grade gliomas, craniopharyngioma and brainstem gliomas.

VASCULAR NEUROSURGERY (SUMMARY BOX 40.5)

Summary box 40.5

Vascular neurosurgery

- Aneurysmal SAH should be suspected in a patient with a sudden, severe headache
- Complications of aneurysmal SAH include re-bleeding, delayed ischaemic neurological deficit and hydrocephalus
- Patients with symptomatic carotid stenosis may benefit from carotid endarterectomy
- Arteriovenous malformations may present with seizures, focal neurological deficit or haemorrhage

Aneurysmal subarachnoid haemorrhage

The most common cause of SAH by far is trauma. On the other hand, non-traumatic SAH is caused by:

- aneurysms (75%);
- arteriovenous malformations (AVMs; 10%);
- idiopathic causes (10%);
- tumours.

Epidemiology

Aneurysmal SAH most commonly occurs in the sixth decade of life and has an incidence of about 10–15:100 000 population per year (Fig. 40.17). Risk factors include hypertension, a positive family history of SAH and, particularly in younger patients, cocaine abuse. Those with two first-degree relatives who have had aneurysmal SAH have a 15% chance of harbouring an intracranial aneurysm themselves. Other associated conditions include polycystic kidney disease (15% chance of aneurysm, increased risk of aneurysm rupture), fibromuscular dysplasia (7–20%) and other connective tissue disorders.

Clinical features

SAH can be difficult to diagnose clinically and missing the diagnosis often ends in a disastrous outcome for the patient. A high index of suspicion is therefore required in patients with a normal physical examination.

The typical presentation is the sudden onset of an unusual headache. This is often described as the worst headache of a patient's life or like being struck forcefully on the back of the head. The location of the headache is often occipital or cervical. There may be associated nausea, vomiting and photophobia. It is not uncommon for patients to experience transient loss of consciousness and collapse. There may be a history of less severe headache some days prior to the ictus – the warning or sentinel headache. Post-coital SAH may occur. Differential diagnosis includes migraine and post-coital cephalgia.

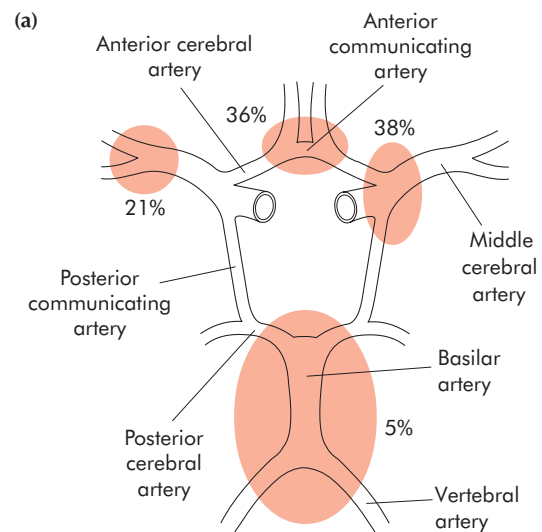

Figure 40.17 (a) Main sites of intracranial supraclinoid aneurysms. (b) Axial computerised tomography scan demonstrating a diffuse subarachnoid haemorrhage with hydrocephalus.

Physical examination may be entirely normal. Meningism with neck stiffness and photophobia should be sought. The development of a third nerve palsy in the context of a sudden severe headache should put in mind SAH from a ruptured posterior communicating artery aneurysm, because of the proximity of this nerve and artery. Patients may have an altered level of consciousness and clinically SAH is graded according to the World Federation of Neurological Surgeons system (Table 40.10). Focal neurological deficits in the limbs at presentation suggest a focal intracerebral haematoma or vascular dissection. Patients in the more severe grades are more likely to exhibit the systemic complication of SAH: cardiac tachyarrhythmias and neurogenic pulmonary oedema. A Cushing's response (hypertension and bradycardia) may be seen in patients with altered consciousness secondary to raised ICP.

Table 40.10 World Federation of Neurological Surgeons Grading of subarachnoid haemorrhage

Grade	Glasgow Coma Scale	Focal deficits*
I	15	–
II	13–14	–
III	13–14	+
IV	7–12	±
V	3–9	±

*Focal deficit = dysphasia or limb weakness.

Investigation

CT scan is positive in aneurysmal SAH in 95% of cases if performed within 48 hours but the sensitivity falls off rapidly with increased time from ictus as blood is cleared from the subarachnoid space. A positive CT scan precludes a lumbar puncture.

A lumbar puncture is indicated in those patients with a suspicious history for SAH but a negative CT scan (Fig. 40.18). These

Figure 40.18 Cerebrospinal fluid (CSF) sample for a patient presenting with subarachnoid haemorrhage. (a) Test tube showing blood-stained CSF. (b) Test tube showing the sample after having been spun down and demonstrating xanthochromia in the supernatant. Spectrophotometry should be used to test for pigments.

patients are likely to be in a good clinical state with no neurological deficit. The CSF should be spun down and the supernatant analysed with a spectrophotometer between wavelengths of 350 and 650 nm. The first breakdown product in blood to be seen is oxyhaemoglobin (413–415 nm), which appears from around 2–12 hours. Bilirubin (450–460 nm) appears later and a bilirubin peak is diagnostic of SAH. False negatives may occur if the lumbar puncture is performed within 12 hours of the ictus. False positives may occur in the presence of a traumatic tap or increased serum bilirubin. Remember that a traumatic tap (fresh procedure-related blood in the sample) does not exclude an SAH – it merely means that the lumbar puncture may not give a useful result.

In patients with a highly suspicious history and an unrevealing lumbar puncture result, a CT angiogram or formal cerebral angiogram is required (Fig. 40.19).

Management

Once a diagnosis of SAH has been made, and the patient has been resuscitated, the management priorities are:

- confirm the presence or absence of an aneurysm;
- prevent the main complications of aneurysmal rupture:
 - rebleeding;
 - delayed ischaemic neurological deficit;
 - hydrocephalus;
 - hyponatraemia.

The presence of an aneurysm can be confirmed by diagnostic cerebral digital subtraction angiography (DSA) or CT angiogram. Treatment of a ruptured aneurysm to prevent rebleeding is either by endovascular coiling or surgical clipping via a craniotomy (Figs 40.20 and 40.21). There is evidence that for small anterior circulation aneurysms a poor outcome is less likely (relative risk reduction 23.9%) with endovascular coiling and this is one of the factors that has led to a dramatic increase in aneurysm coiling in

Figure 40.19 Cerebral angiogram demonstrating a middle cerebral artery aneurysm.

Figure 40.20 The middle cerebral artery aneurysm in Fig. 40.19 undergoing embolisation with Guglielmi detachable coils.

Figure 40.21 Microscope picture of a clipped aneurysm.

recent years. There is still a role for surgery, and the decision about best treatment modality is based on characteristics of the aneurysm (size, dome to neck ratio, incorporation of branching vessels), operator experience and patient preference.

Delayed ischaemic neurological deficit (DIND) is the occurrence of focal neurological deficits, usually between 4 and 10 days after the SAH and often attributed to cerebral 'vasospasm'. DIND is a major cause of morbidity and mortality following subarachnoid haemorrhage, resulting in death in 7% and permanent morbidity in another 7%. Cerebral vasospasm may affect any of the cerebral arteries and occurs in response to blood in the subarachnoid space via uncertain mechanisms. Patients with a larger blood load are at higher risk of vasospasm. The diagnosis of DIND is made after exclusion of other complications such as

rebleeding, hydrocephalus and electrolyte disturbance, particularly hyponatraemia. A cerebral angiogram if performed may demonstrate cerebral artery narrowing. Treatment is with hypertension (inotropes may be required), hypervolaemia and haemodilution. The deficits of DIND are often reversible if diagnosed and treated in a timely fashion. Angioplasty, either chemical or with a balloon, plays a role in the treatment of short-segment large artery spasm. The incidence of DIND can be lowered (30% fewer cerebral infarctions) by prophylaxis with nimodipine (60 mg, 4-hourly) and hypervolaemia (8-hourly normal saline).

Hydrocephalus affects about 20% of patients who have a SAH, and around one-half of those with hydrocephalus will go on to require a ventriculoperitoneal shunt. Hydrocephalus early in the course of the disease is often treated by external ventricular drainage: acute blood clot in the ventricles may act as an obstructive mass lesion rendering lumbar puncture unsafe. Continuous CSF drainage is desirable and an EVD can be used to monitor ICP in the comatose patient. A ventriculoperitoneal shunt can be inserted if the patient requires it, once the red blood cell count in the CSF has fallen to $< 500 \text{ mm}^{-3}$.

Hyponatraemia is common after SAH and is often caused by cerebral salt wasting (CSW) rather than the syndrome of inappropriate antidiuretic hormone secretion (SIADH). The distinction is an important one as in CSW the problem is excessive salt loss, probably due to a natriuretic factor, with relative dehydration. The treatment is with volume loading and salt replacement. In SIADH the problem is retention of water and is treated by fluid restriction. In SAH, incorrectly diagnosing a patient with SIADH when in fact they have CSW is potentially dangerous, as inappropriate fluid restriction will lead to hypovolaemia and an increased incidence of DIND. Biochemical tests (plasma and urine sodium and osmolality) do not help distinguish between the two conditions. Estimating the fluid status of the patient prior to treatment is the best way of distinguishing the two conditions, but in SAH the patients are usually already being filled with intravenous fluids as part of DIND prophylaxis. Expert endocrinological advice may be required.

Prognosis

Aneurysmal SAH is not a benign condition. If only the grade I patients are considered, approximately one-half will go back to equivalent full-time employment. Neuropsychological sequelae are common. One-year mortality rates are about 10% for grade I patients, rising to over 40% for patients in grades IV–V. Moderate to severe disability is likely to affect at least 30% of survivors.

Arteriovenous malformations

Cerebral AVMs are lesions containing abnormal vessels with arteries feeding directly into veins without the normal interposed capillary bed, resulting in a high-pressure and high-flow vascular shunt. They may be congenital or acquired.

AVMs may present with headache, seizures, focal deficits or bleeding. Once an AVM has bled, then it has an approximately 2–4% per year risk of rebleeding although this risk may be much higher in the first 6 weeks. Bleeding can occur from intranidal aneurysms or flow aneurysms on feeding arteries, in which case the urgency of treatment is greater.

The diagnosis, suspected by vessels and calcification within a lesion seen on CT or MRI can be confirmed by cerebral angiography (Figs 40.22 and 40.23). Treatment can be endovascular (often using tissue glue), by stereotactic radiosurgery or surgical via craniotomy with factors such as AVM nidal size, functional

Figure 40.22 Sagittal T1-weighted magnetic resonance imaging scan of a young man presenting with a seizure. This demonstrates a serpiginous lesion (arrow) with low-signal flow voids that are typical of an arteriovenous malformation.

Figure 40.23 Lateral cerebral angiogram of the same patient as in Fig. 40.22. This demonstrates the arteriovenous malformation being filled by a branch of the middle cerebral artery and draining into the superior sagittal sinus.

importance of surrounding brain, number and type of feeding arteries, and superficial or deep venous drainage being taken into account (Fig. 40.24).

Figure 40.24 Intraoperative picture of the same patient as in Figs 40.22 and 40.23. The large superficial draining vein can be seen.

Cavernomas

A cavernoma is a benign angiographically occult cluster of abnormal sinusoidal blood vessels that may be associated with a developmental venous anomaly. They are more common in the supratentorial than infratentorial compartment and may be multiple. Cavernomas can present with seizures, focal signs and haemorrhage or they may be discovered incidentally. Surgery is recommended if seizures are refractory to medical therapy or to prevent rebleeding although the annual risk of haemorrhage is low.

Moyamoya disease

Moyamoya means 'puff of smoke' in Japanese. The condition, occurring in young patients, involves progressive occlusion of both internal carotid arteries in the region of the carotid siphon. The subsequent development of small capillary-like vessels followed by collateralisation from the external carotid artery underlies the angiographic findings. Presentation is with ischaemia or haemorrhage.

Surgical treatment options include:

- encephalosynangiosis (temporalis muscle to pia-arachnoid);
- superficial temporal artery (STA)–MCA bypass (STA to MCA);
- encephalodurarteriosynangiosis (STA to dura);
- omental pedicle transposition.

Surgery for stroke

Spontaneous intracerebral haemorrhage

When considering a patient for surgery for a spontaneous intracranial haemorrhage, one must always consider the possibility of an underlying lesion such as a tumour, vascular malformation or aneurysm.

In general terms, craniotomy and haematoma evacuation will do little to improve focal deficits from haemorrhagic cerebrovascular accidents. The role of surgery is to reduce raised ICP due to mass effect and therefore prevent brain herniation and perhaps improve the recovery of brain tissue in the surrounding ischaemic penumbra. A recent international trial centred in the UK (STICH), showed no benefit for surgery over conservative management in cases where the surgeon was uncertain whether or not to operate. Those likely to benefit from surgery are young patients with superficial haematomas and a falling Glasgow Coma Score.

Carotid endarterectomy

Carotid endarterectomy is indicated for symptomatic (recent transient ischaemic attack or stroke) patients with severe carotid artery stenosis. A North American trial demonstrated a 2-year ipsilateral stroke absolute risk reduction of 17% (26 vs. 9%) for surgery versus conservative management, with a number-needed-to-treat of six. These results were backed up by a similar European trial. The benefits of surgery for symptomatic patients with moderate stenosis or asymptomatic patients with severe stenosis are less clear-cut.

Posterior fossa infarction

Patients with posterior fossa infarction (haemorrhagic or ischaemic) are susceptible to brainstem compression and obstructive hydrocephalus from cerebral swelling. In selected patients, it is appropriate to offer decompressive craniectomy and infarct/clot evacuation.

Middle cerebral artery infarction

Infarction encompassing all or much of the MCA territory is associated with a high morbidity and mortality. In young patients in particular it is associated with malignant cerebral swelling. Recent trials have sought to address the question of whether there is overall benefit to a large decompressive craniectomy. As this operation will prevent herniation and coning, there was a concern that widespread use of the technique might result in a large increase in the number of survivors with severe disability. There is now evidence that surgery reduces mortality and increases those survivors with a modified Rankin score (mRS) of 1–4 but does not increase the number of patients with a mRS of 5 (bed-bound).

EPILEPSY SURGERY

Epilepsy is the most common neurological disorder but only a small fraction of epilepsy patients are considered suitable candidates for epilepsy surgery. All cerebral mass lesions may present with seizures, but epilepsy surgery as a subspecialty deals primarily with non-lesional or at least non-tumour-related seizures (Summary box 40.6).

Summary box 40.6

Epilepsy surgery

- Epilepsy surgery candidates are identified through extensive preoperative work-up
- Epilepsy surgery procedures include invasive monitoring, resective operations and disconnection operations

History and examination

For a patient to be considered for resective epilepsy surgery there must be concordance between clinical, radiological and electrophysiological data. In addition the patient should be under the care of a neurologist with a special interest in epilepsy and it should have been demonstrated that the seizures are refractory to best medical therapy. The seizures must adversely affect quality of life. Detailed information about seizure frequency, type, severity and location is required. Patients with mesial temporal sclerosis may give a history of complicated febrile seizures at a young age.

Electroencephalography

Scalp surface electrode recording can give valuable information about seizure localisation, particularly in the complex partial seizures of temporal epilepsy. Complex software analysis is used to compare ictal with interictal recordings. Video telemetry, accessed on an in-patient basis, is used to capture a run of seizures with synchronous clinical and electroencephalogram data collection.

Occasionally additional information about localisation is desirable. Surgical diagnostic procedures include the insertion of subdural grid or strip electrodes and, occasionally, depth electrodes.

Neuropsychology

Neuropsychological evaluation is important for two reasons: to assess the patient's baseline functional state and to evaluate the likely chance of postoperative language and memory deficits in temporal lobe epilepsy surgery. The latter assessment is made during the sodium amytal or Wada test.

Imaging

In mesial temporal sclerosis, an MRI scan will demonstrate loss of hippocampal volume and internal architecture and altered signal. MRI may also show lesions such as cortical dysplasia, low-grade tumours or gliosis.

An ictal SPECT (single-photon emission CT) scan can identify a seizure-onset zone by measurement of regional cerebral perfusion. A radioactive compound (^{99m}Tc HMPAO) is injected soon after seizure onset and is fixed in the brain for around 6 hours, during which time the scan is performed.

Interictal positron emission tomography (PET) scans using radiolabelled fluorodeoxyglucose (^{18}F FDG) may localise a seizure focus by demonstrating a region of hypometabolism.

Surgery: resective procedures

Surgery for mesial temporal sclerosis includes temporal lobectomy and selective amygdalo-hippocampectomy. With correct patient selection, seizure cure rates of 70% can be achieved. Anatomical or functional hemispherectomy is used for conditions such as Rasmussen's encephalitis (Fig. 40.25).

Surgery: disconnection and modulation procedures

Corpus callosotomy may improve quality of life for patients with drop attacks. Multiple subpial transactions may be used to disconnect a seizure focus from the surrounding cortex. The mode of action of a vagal nerve stimulator is uncertain but the device may improve seizures in idiopathic epilepsy.

FUNCTIONAL NEUROSURGERY (SUMMARY BOX 40.7)

Summary box 40.7

Functional neurosurgery modulates the nervous system to alleviate symptoms from movement disorders, pain syndromes and spasticity

John A. Wada, a twentieth century Japanese–Canadian Neurologist.

Figure 40.25 Coronal T2-weighted magnetic resonance imaging scan image following an anatomical hemispherectomy.

Movement disorder surgery

Deep brain stimulation (DBS) involves the stereotactic implantation of an electrode into the deep grey matter to alter brain function. The electrodes are connected to a pulse generator, the settings of which can be adjusted by an external programmer. DBS is generally preferred to lesion surgery as its effects are reversible and adjustable.

Parkinson's disease

DBS for Parkinson's disease targets either the subthalamic nucleus or globus pallidus interna. Surgery is reserved for those experiencing intolerable side-effects of medical therapy, such as dyskinesias. Tremor, rigidity and dyskinesia are the symptoms most likely to improve.

Dystonia

Options for focal dystonia include botulinum toxin injection and focal denervation surgery. Generalised dystonia may be treated with levodopa. For refractory cases, the target for DBS for dystonia is the globus pallidus interna bilaterally.

Tremor

The DBS target for tremor is the Vim nucleus of the thalamus.

James Parkinson, 1755–1824, a General Practitioner of Shoreditch, London, UK.

Surgery for pain

Painful conditions can often be managed by treatment of the underlying cause, medication of escalating strength, physical therapy and local injections when appropriate. Some patients have pain syndromes that are severe and refractory to conventional management; for these, a variety of functional neurosurgical procedures can be considered.

Spinal cord stimulators

Spinal cord stimulation (SCS) involves the insertion of electrodes onto the dura of the spine either by open laminotomy or percutaneously (Fig. 40.26). The electrodes are connected to a pulse generator implanted subcutaneously. Candidates for SCS include those with chronic leg pain following failed spinal decompressive surgery or those with arachnoiditis, peripheral vascular disease or angina.

Deep brain stimulation

Some patients with chronic pain syndromes such as from thalamic stroke are candidates for DBS. Targets include periaqueductal grey and the sensory thalamic nuclei.

Cordotomy/rhizotomy

In selected pain syndromes symptomatic improvement may be gained by dorsal root rhizolysis or surgical interruption of the spinothalamic tract (cordotomy).

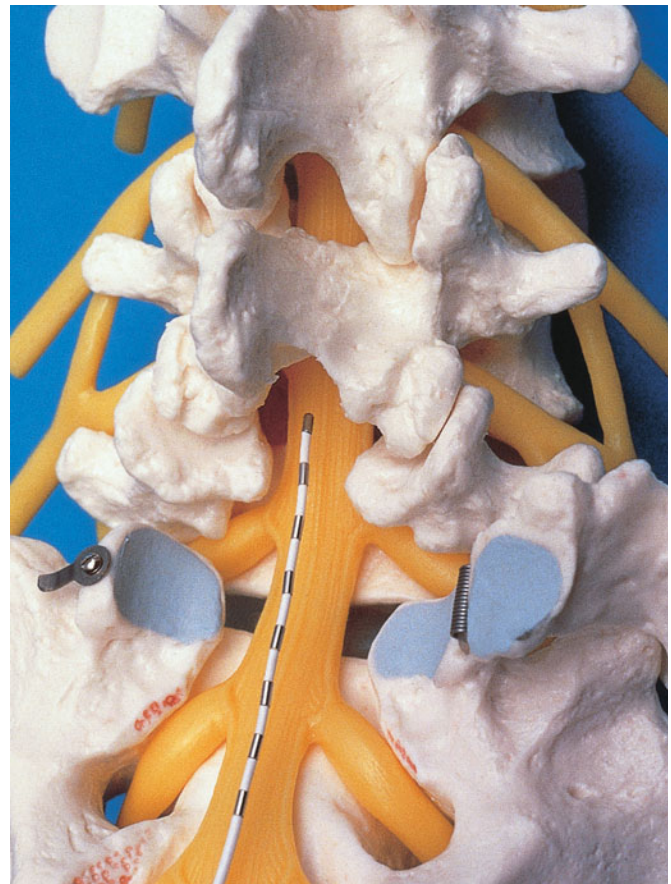

Figure 40.26 A spine model demonstrating the position of an epidural electrode.

Trigeminal neuralgia

Trigeminal neuralgia is a condition of severe episodic lancinating facial pain occurring in the distribution of the trigeminal nerve. The aetiology of the condition is unclear but vascular compression of the trigeminal nerve near the root entry zone seems to play a part. Bilateral trigeminal neuralgia should raise the suspicion of multiple sclerosis. Structural causes should be excluded by MRI.

Treatment is initially with medication such as carbamazepine or gabapentin. Refractory cases are considered for surgical treatments, which include:

- percutaneous treatments:
 - trigeminal ganglion techniques:
 - glycerol injection;
 - radiofrequency thermocoagulation;
 - balloon compression;
 - local nerve block;
- microvascular decompression via craniotomy;
- stereotactic radiosurgery.

Intrathecal drug delivery

An intrathecal catheter can be introduced into the lumbar spine region and connected to a subcutaneous pump containing either opiates for pain relief or baclofen to treat spasticity (Fig. 40.27).

DEVELOPMENTAL ABNORMALITIES (SUMMARY BOX 40.8 AND TABLE 40.11)

Summary box 40.8

Developmental abnormalities

- Spinal dysraphism is a term that encompasses a wide range of conditions resulting from abnormal CNS development
- Premature fusion of skull sutures causes abnormalities of skull shape

Arachnoid cysts

Arachnoid cysts are benign fluid-filled intracranial mass lesions, possibly formed by splitting of the arachnoid membrane. Around

Figure 40.27 A Medtronic synchronised programmable intrathecal drug delivery system.

Table 40.11 Developmental abnormalities

Arachnoid cysts	Spina bifida occulta

Chiari malformations	
Craniosynostosis	

one-half of them are located in the Sylvian fissure, whereas others occur in the cerebellopontine angle and the suprasellar and posterior fossa regions. They often present in the paediatric age group: some remain asymptomatic, others enlarge in size, causing a mass effect, and others may present with haemorrhage. Surgery is reserved only for symptomatic lesions and options include endoscopy and fenestration into a cistern or ventricle, or shunting.

Spinal dysraphism

Myelomeningocele

Myelomeningocele is a developmental abnormality of the caudal thoracodorsal spine and results from a failure of primary neuralisation (neural tube defect). The incidence has decreased in recent times to about 0.5:1000 births. Aetiology is multifactorial but is associated with folate deficiency, some anticonvulsant medications and family history. Diagnosis may be made prenatally using ultrasound and predicted using maternal alpha-fetoprotein levels or amniocentesis.

Surgical repair of an open myelomeningocele is recommended within 72 hours of birth to prevent infection. The majority of patients have hydrocephalus and will require a ventriculoperitoneal shunt. All patients with a myelomeningocele will have a Chiari II malformation (see next page).

Tethered cord syndrome

Associated with myelomeningocele and spina bifida occulta, this condition involves a low-lying conus medullaris and thickened filum terminale. Presentation may be with progressive neurological deficit, spasticity, bladder dysfunction or scoliosis. Surgical treatment involves untethering of the cord to prevent further neurological deterioration.

Spinal lipoma and lipomomyelomeningocele

Lipomas may occur within the normally located conus (lower cord) or be associated with distraction of neural tissue out of the spinal canal. Presentation is with a back mass or lower limb and bladder dysfunction. Surgery aims to preserve neural function and prevent the development of a tethered cord.

Encephaloceles

Encephaloceles, the developmental herniation of cerebral tissue through a cranial defect, occur with a frequency of approximately 1–4:1000 births (Fig. 40.28). They may be occipital, nasofrontal (more common in South-east Asia), frontoethmoidal or basal. Surgical repair is required to prevent infection, especially if skin covering is absent, and to reconstruct the skull.

Figure 40.28 An occipital encephalocele.

Chiari malformation

Chiari malformation is used to describe herniation of the posterior fossa contents (e.g. cerebellar tonsils) through the foramen magnum:

- normal: up to 5 mm of tonsillar descent through the foramen magnum;
- Chiari I: > 5 mm of tonsillar descent;
- Chiari II: descent of the tonsils and cerebellar vermis.

Chiari I malformation tends to present in young adults, with headaches that are exacerbated by coughing and straining. There may be signs associated with brainstem compression or spinal cord fluid cavity (syrinx).

Chiari II malformations tend to present in infancy, with signs of brainstem compression such as poor feeding, stridor and apnoeic spells.

Treatment of Chiari malformations is directed first towards associated hydrocephalus followed by consideration of foramen magnum decompression.

Craniosynostosis

Craniosynostosis, or premature fusion of the cranial sutures, may affect single or multiple sutures. Premature fusion leads to restricted growth in a plane at 90° to the suture, resulting in presentation with an abnormal head shape (Figs 40.29 and 40.30). Sagittal synostosis causes a narrow boat-shaped head with frontal and occipital bossing (scaphocephaly); bicoronal synostosis causes a shortened forehead (brachycephaly); metopic synostosis causes trigonocephaly. Unicoronal and unilambdoid synostosis must be differentiated from the much more common anterior and posterior plagiocephaly (positional flattening of the head).

There are rare genetic conditions associated with craniosynostosis, some of which are caused by abnormalities of the fibroblast growth factor receptor genes, such as the following syndromes:

- Crouzon;
- Apert;
- Pfeiffer;
- Saethre–Chotzen.

Hans Chiari, 1851–1916, Professor of Pathology, the German University, Prague, Czech Republic.
 Octave Crouzon, 1874–1938, Neurologist, La Salpêtrière, Paris, France.
 Eugene Apert, 1868–1940, Physician, L'Hôpital des Enfants-Malades, Paris, France.

Surgery aims to correct deformity and prevent the development of raised ICP.

PERIPHERAL NERVE DISORDERS

Carpal tunnel syndrome

This is entrapment of the median nerve at the wrist. Risk factors include diabetes, obesity, thyroid disorders and acromegaly. The patient complains of numbness and pins and needles in the median 3½ digits, worse at night and relieved by handshaking. Symptoms can progress to weakness and loss of hand function. Examination reveals altered sensation in the median 3½ digits (but not the palm), wasting of the thenar eminence and weakness of abductor pollicis brevis. Symptoms may be elicited by tapping over the carpal tunnel (Tinel's sign) or wrist flexion (Phalen's test).

The diagnosis can be confirmed by nerve conduction studies and treatment is with wrist splinting, steroid injection or carpal tunnel decompression.

Ulnar nerve entrapment at the elbow

Ulnar nerve entrapment at the elbow can cause pain, numbness and tingling in the ulnar 1½ digits of the hand, progressing to loss of hand function. Signs include wasting and weakness of the small muscles of the hand and the hypothenar eminence. Froment's sign, elicited by asking the patient to hold a piece of paper in the first web space while the examiner tries to slide it out, is flexion of the thumb on attempted thumb adduction. Nerve conduction studies confirm the diagnosis, which is treated by surgical decompression.

Meralgia parasthetica

Compression of the lateral nerve of the thigh as it passes beneath the inguinal ligament can cause pain, tingling and numbness in the lateral thigh. Treatment may be by weight loss if appropriate, steroid injection or surgical decompression.

Thoracic outlet syndrome

Thoracic outlet syndrome can be caused by a cervical rib or a fibrous band from the C7 transverse process to the first rib. Compression of the lower brachial plexus roots (C8, T1) and subclavian artery explains the symptoms and signs: neural compression causes radicular arm pain with wasting, weakness and numbness in a C8/T1 distribution.

Investigation may include plain cervical radiograph, nerve conduction studies and brachial plexus MRI. Treatment is by surgical decompression, dividing the fibrous band or removing the cervical rib.

BRAINSTEM DEATH

Brainstem death is defined by irreversible loss of consciousness, loss of brainstem reflexes and apnoea (absence of respiratory drive) and these patients are therefore mechanically ventilated in an intensive care setting. Brainstem death is equivalent to death and is one of the criteria for the harvesting of organs for transplant from a heart-beating donor.

George S. Phalen, Orthopaedic Surgeon, the Cleveland Clinic, Cleveland, OH, USA.
 Jules Froment, 1878–1946, Professor of Clinical Medicine, Lyons, France.

Figure 40.29 Characteristic appearance of scaphocephaly due to sagittal suture synostosis.

Diagnosis of brainstem death is in three stages:

- identification of the cause of irreversible coma (Fig. 40.31);
- exclusion of reversible causes of coma;
- clinical demonstration of absence of brainstem reflexes.

The brainstem reflexes tested for are:

- pupillary reaction to light;
- corneal reflex;
- vestibulo-ocular reflex;
- cough reflex;
- gag reflex;
- motor response to central pain;
- apnoea test: apnoea despite a carbon dioxide increase to > 6.65 kPa.

All reflexes must be absent and are tested for twice by two doctors.

Figure 40.30 Axial computerised tomography scan showing severe trigonocephaly due to premature fusion of the metopic suture.

Figure 40.31 Axial computerised tomography scan showing a fatal posterior fossa haematoma.

The eye and orbit

LEARNING OBJECTIVES

To understand and appreciate:

- The common ocular disorders and recognise ophthalmic symptoms and specific signs
- The value of special investigations
- When specialist referral is appropriate

OCULAR ANATOMY

Adnexae

The lids comprise skin, connective tissue, the orbicularis oculi (VIIth nerve) and the tarsal plate, with multiple meibomian glands opening posterior to the lashes and lined with conjunctiva, which is reflected onto the sclera. The upper lid is elevated by the levator muscle (IIIrd nerve) and has a horizontal strip of sympathetically innervated Müller's muscle, giving rise to 2 mm of ptosis in Horner's syndrome. Both lids are attached to the orbital rim by the medial and lateral canthal tendons. Both have a rich vascular supply and are innervated by V1 above and V2 below.

Lacrimal system

The almond-shaped lacrimal gland lies under the upper outer orbital rim and opens into the upper conjunctival fornix through 10–15 ducts. Tears are swept across the globe by the lids and evaporate or pass into the upper and lower lid puncta, and then into the canaliculi to join the common canaliculus, which passes into the lacrimal sac under the medial canthal tendon. The sac is drained by the nasolacrimal duct into the nose, opening in the inferior meatus under the inferior turbinate.

The globe (Fig. 41.1)

The cornea is the 12 mm-diameter window of the eye, 0.5 mm thick centrally; its clarity is due to the regular arrangement of collagen bundles and relative dehydration. It merges into the sclera at the corneoscleral junction (the limbus), the insertion of the bulbar conjunctiva. The sclera, which is 1 mm thick, comprises four-fifths of the wall of the eye, and gives attachment to the extraocular muscles. It is perforated by the long and short posterior ciliary arteries and the vortex veins and is contiguous with the optic nerve sheath. The uvea comprises iris, ciliary body and vascular choroid. The optic nerve is continuous with the retina and retinal pigment epithelium. The most sensitive part of the retina, the macula, lies

at the posterior pole within the vascular arcade. The biconvex lens and capsule are suspended by the suspensory ligament, over 300 tiny fibres attached to the ciliary muscle. Aqueous humour arises from the ciliary processes, hydrates the vitreous gel, passes through the pupil into the anterior chamber between the iris and the cornea and then drains out through Schlemm's canal in the drainage angle. The inner retina is supplied by the central retinal artery and drained by the central retinal vein.

Orbit

The orbit is four-sided and pyramidal in structure, housing the globe, optic nerve, the four rectus and two oblique muscles, the

Figure 41.1 Anatomy of the eye.

Friedrich Schlemm, 1795–1858, Professor of Anatomy, Berlin, Germany.

Johannes Peter Müller, 1801–1858, Professor of Anatomy and Physiology, Berlin, Germany.

Johan Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.

lacrimal gland, orbital fat, the IIIrd, IVth, Vth and VIth cranial nerves, the ophthalmic artery with its tributaries and the ophthalmic veins, which anastomose anteriorly with the face and posteriorly with the cranial cavity. Above is the frontal lobe of the brain, temporally the temporal fossa, inferiorly the maxillary sinus and nasally the lacrimal sac and ethmoidal and sphenoidal air sinuses. The optic nerve passes through the optic canal to the chiasm, with other nerves and vessels passing through the superior or orbital fissure.

PERIORBITAL AND ORBITAL SWELLINGS

Swellings related to the supraorbital margin

Dermoid cysts

Dermoid cysts are usually external angular cysts although they may occur medially (Fig. 41.2). They often cause a bony depression by their pressure and they may have a dumbbell extension into the orbit. They can also erode the orbital plate of the frontal bone to become attached to dura and for this reason it is important to image the area by computerised tomography (CT) before excision.

Neurofibromatosis

Neurofibromatosis may also produce swellings above the eye. The diagnosis can usually be confirmed by an examination of the whole body, as there are often multiple lesions. Proptosis can also result (Fig. 41.3). Other ophthalmic features may be present.

Swellings of the lids

Meibomian cysts (chalazion)

These are the most common lid swellings (Fig. 41.4). A meibomian cyst is a chronic granulomatous inflammation of a meibomian gland. It may occur on either upper or lower lids and presents as a smooth, painless swelling. It can be felt by rolling the cyst on the tarsal plate. It can be distinguished from a sty (hordeolum), which is an infection of a hair follicle and is usually painful. Persistent meibomian cysts are treated by incision and curettage from the conjunctival surface. Styes are treated by antibiotics and local heat.

Figure 41.2 External angular dermoid.

Heinrich Meibom (Meibomius), 1638–1700, Professor of Medicine, History and Poetry, Helmstadt, Germany, described these glands in 1666.

Figure 41.3 Neurofibroma in the orbit with proptosis, and also similar lesions in the forehead.

Figure 41.4 Meibomian cyst (courtesy of Mr D. Spalton, FRCS).

Basal cell carcinomas (rodent ulcers)

This is the most common malignant tumour of the eyelids (Fig. 41.5). It is locally malignant, is more common on the lower lids and usually starts as a small pimple that ulcerates and has raised edges. It is easily excised in the early stages. Histological confirmation that the excision is complete is required. More extensive lesions may require specialist techniques such as Mohs' micrographic surgical excision controlled by frozen section. Local radiotherapy or cryotherapy can be carried out; however, recurrence is more common, more aggressive and more difficult to detect (Summary box 41.1).

Frederic E. Mohs, a 20th century American Surgeon.

Figure 41.5 Rodent ulcers (courtesy of Mr J. Beare, FRCS).

Summary box 41.1

Basal cell carcinomas

- Basal cell carcinomas are the most common malignant eye tumour
- Treatment is by excision with care with histopathological margin control
- All unusual lesions should be biopsied

Other lid swellings

Other types of lid swelling can occur but they are less common. They include sebaceous cysts, papillomas, keratoacanthomas, cysts of Moll (sweat glands) (Fig. 41.6) or Zeis (sebaceous glands) and molluscum contagiosum. When molluscum contagiosum occurs on the lid margin, it can give rise to a mild chronic keratoconjunctivitis and should be curetted or excised.

Carcinoma of the meibomian glands and rhabdomyosarcomas are rare lesions; they need to be treated by radical excision. Atypical or meibomian cysts that recur should be biopsied.

Figure 41.6 Cyst of Moll.

Jacob Antonius Moll, 1832–1913, Ophthalmologist of The Hague, The Netherlands.
Edward Zeis, 1807–1868, Professor of Surgery, Marburg, (1844–1850), who later worked at Dresden, Germany, described these glands in 1835.

Swellings of the lacrimal system

Lacrimal sac mucocele

This occurs from obstruction of the lacrimal duct beyond the sac and results in a fluctuant swelling that bulges out just below the medial canthus. It can become infected to give rise to a painful tense swelling (acute dacryocystitis). If untreated it may give rise to a fistula. Treatment is by performing a bypass operation between the lacrimal sac and the nose [a dacryocystorrhinostomy (DCR)]. Watering of the eye can occur due to eversion of the lower lid (ectropion), which causes loss of contact between the lower punctum and the tear film, or from reflex hypersecretion as a result of irritation of inturning lashes in entropion, and these must be distinguished from a mucocele.

Lacrimal gland tumours

These are swellings of the lacrimal glands, which lie in the upper lateral aspect of the orbit. Eventually they lead to impairment of ocular movements and displacement of the globe forwards, downwards and inwards. Pathologically the tumours resemble parotid tumours and they can be pleomorphic adenomas with or without malignant change, carcinomas or muco-epidermoid tumours.

Orbital swellings

Orbital swellings result in displacement of the globe and limitation of movement. A full description of orbital swellings is outside the realm of this text but some of the most common causes include the following:

- *Pseudoproptosis*. This results from a large eyeball, as seen in congenital glaucoma or high myopia.
- *Orbital inflammatory conditions* that result in orbital cellulitis (Fig. 41.7).
- *Haemorrhage* after trauma or retrobulbar injection.
- *Neoplasia* affecting the lacrimal gland, the optic nerve, the orbital walls or the nasal sinuses, e.g. glioma (neurofibromatosis) (see Fig. 41.3, p. 646), meningioma and osteoma (Fig. 41.8).
- *Dysthyroid exophthalmos* (Figs 41.9–41.11). This may be unrelated to active thyroid disease but can start after thyroidectomy and may need urgent tarsorrhaphy, large doses of steroids or even orbital decompression if the eyeball is threatened by exposure or optic nerve compression. This is most easily done into the nasal sinuses. CT and magnetic resonance imaging (MRI) scans are useful in diagnosis.

Figure 41.7 Orbital cellulitis.

Figure 41.8 Radiograph showing an osteoma on the nasal side of the orbit giving rise to proptosis.

Figure 41.9 Computerised tomogram of the orbit in dysthyroid exophthalmos, showing swollen muscles (courtesy of Dr Glyn Lloyd).

Figure 41.10 Magnetic resonance imaging scan of a coronal view of the orbit, showing enlarged muscles in thyroid disease (courtesy of Dr Juliette Britton).

Figure 41.11 Exophthalmos in dysthyroid eye disease.

- *Pseudotumour*, or malignant lymphoma.
- *Haemangiomas* of the orbit (Fig. 41.12).
- *Tumour metastases*. These are rare. In children they usually arise from neuroblastomas of the adrenal gland, whereas in adults the oesophagus, stomach, breast and prostate can be sites of primary lesions.

Diagnostic aids

Diagnostic aids include radiography, CT, MRI, ultrasonography and, less commonly, tomography and orbital venography.

Treatment

Treatment is directed to the cause of the lesion if at all possible, taking care to prevent exposure of the eye, diplopia or visual impairment from optic nerve compression.

INTRAOCCULAR TUMOURS

Children

Retinoblastoma is a multicentric malignant tumour of the retina, which can be bilateral. Some are sporadic but many are hereditary. Children with a family history should be carefully monitored from birth. It is often not spotted until the tumour fills the globe and presents as a white reflex in the pupil or as a squint (Fig. 41.13). The differential diagnosis includes retinopathy of prematurity, primary hyperplastic vitreous and intraocular infections. If the tumour is large, enucleation may be required, but radiotherapy, cryotherapy or laser treatment can cure small lesions. Liaison with a paediatric oncologist is essential (Summary box 41.2).

Figure 41.12 Capillary haemangioma in a child. An orbital venogram demonstrates displacement of the second part of the superior ophthalmic vein (arrow) (courtesy of Dr Glyn Lloyd).

Figure 41.13 Retinoblastoma giving rise to a white pupillary reflex. This child was first seen with a convergent squint and discharged without a fundus examination. He was next seen many years later with a 'white reflex' and died soon after diagnosis (courtesy of M.A. Bedford, FRCS).

Summary box 41.2

Intraocular tumours

- All children with a squint should have a fundal examination to exclude a retinoblastoma
- A blind painful eye may hide a melanoma

Adults

Malignant melanoma is the most common tumour and it originates in the pigment cells of the choroid (Fig. 41.14), ciliary body or iris. It can present with a reduction in vision, a vitreous haemorrhage or by the chance finding of an elevated pigmented lesion in the eye. Tumour growth is variable but, as a general rule, the more posterior the lesion, the more rapidly progressive it is likely to be. Spread may be delayed for many years; however, the liver is frequently involved, hence the advice 'beware of the patient with a glass eye and an enlarged liver'. Treatment is by light or laser

Figure 41.14 Choroidal melanoma.

coagulation, radioactive plaque, radiotherapy, enucleation and, in selected cases, local excision using hypotensive anaesthesia. Diagnosis is made by direct observation and/or ultrasound, which shows a solid tumour (Fig. 41.15).

INJURIES INVOLVING THE EYE AND ADJACENT STRUCTURES

Corneal abrasions and ulceration

The cornea is frequently damaged by direct trauma or by foreign bodies (Fig. 41.16). Ulceration can occur with infection or after damage to the facial nerve. Post-herpetic ulceration is common and serious if not treated. Fluorescein instillation illuminated by blue light shows up corneal ulceration at an early stage (Summary box 41.3).

Summary box 41.3

Corneal abrasions

- A drop of fluorescein dye illuminated by a blue light reveals even the smallest corneal abrasion

Treatment is by protection (eye pads, tarsorrhaphy or a bandage contact lens) and antibiotics topically and rarely systemically:

Figure 41.15 B-scan showing choroidal melanoma (courtesy of Dr Marie Reston).

Figure 41.16 Corneal foreign body.

0.5% chloramphenicol or ofloxacin eye drops are commonly used. The eye is made more comfortable by the use of mydriatics such as homatropine or cyclopentolate. Herpes simplex ulcers are treated with aciclovir ointment. In countries in the Far and Middle East, chronic infection with trachoma can cause corneal opacification and blindness. Corneal grafting is the only cure for an opaque cornea. Rarely, osteo-odonto keratoprosthesis can be attempted in very severe cases of opaque corneas that are not suitable for grafting. Acanthamoeba is a rare serious cause of corneal infection. This infection usually follows the use of contact lenses. Specialist management and treatment is recommended.

Blunt injuries to the eye and orbit

The floor of the orbit is its weakest wall and in blunt trauma, such as a blow from a fist, it is often fractured without fractures of the other walls. This is called a blow-out fracture. Clinical signs are enophthalmos, bruising around the orbit, maxillary hypoesthesia, limitation of upward gaze and diplopia. This occurs when the extraocular muscles or orbital septa become trapped in the fracture and can be identified as a soft-tissue mass in the antrum on a radiograph (Fig. 41.17), although CT scans or tomograms may be necessary. Surgical repair of the orbital floor with freeing of the trapped contents may be necessary if troublesome diplopia persists or enophthalmos is marked. A child with an orbital floor fracture requires urgent assessment as a 'greenstick' fracture can result in ischaemia of a trapped inferior rectus muscle and may require urgent surgery. If an orbital haemorrhage is too extensive to examine the eye, it may be necessary to examine the eye under anaesthesia because there may be a hidden perforation of the globe. Injuries to the lids and lid margins must be repaired, and if the lacrimal canaliculi are damaged they should be repaired if possible, especially the lower canaliculus as 75% of tear drainage goes through it.

Blunt injuries can also cause damage to the optic nerve, which can result in blindness and a total afferent nerve defect (Figs 41.18 and 41.19).

Concussion injuries

Concussion injuries of the eye can give rise to several problems, which include the following:

- *Iritis*. Inflammation, treated with topical steroids.
- *Hyphaema* (blood in the anterior chamber) (Fig. 41.20). Rest and sedation, particularly in children, are advised because the

Figure 41.17 Radiograph showing a blow-out fracture of the orbit (left) with soft tissue in the antrum (courtesy of Dr Glyn Lloyd).

Figure 41.19 Scan of orbit from Fig. 41.18 showing a massive swelling of the medial rectus (courtesy of J. Beare, FRCS).

Figure 41.20 Hyphaema. Blood in the vitreous chamber after concussional injury.

main danger in this condition is secondary bleeding, resulting in an acute rise in intraocular pressure and blood staining of the cornea. The use of anti-fibrinolytic agents (ϵ -aminocaproic acid) has been advocated and, if the pressure rises, surgery to wash out the blood may be necessary.

- *Subluxation of the lens*. This is suspected if the iris, or part of the iris, 'wobbles' on movement (iridodonesis).
- *Secondary glaucoma*. This is often associated with recession of the drainage angle.
- *Retinal and macular haemorrhages and choroidal tears* (Fig. 41.21).

Figure 41.21 Retinal haemorrhage from a cricket bat injury (courtesy of J. Beare, FRCS).

- *Retinal dialysis*. This may lead to a retinal detachment and permanent damage to vision (Fig. 41.22).

Penetrating eye injuries

These occur when the globe is penetrated, often in road traffic and other major accidents (Fig. 41.23), and also in injuries from sharp instruments. The compulsory wearing of seatbelts in motor vehicles has substantially reduced the incidence of this type of eye injury, by up to 73% in the UK. The presence of an irregular pupil suggests prolapse of the iris and should arouse the suspicion of a penetrating injury. Treatment is prompt primary repair to restore the integrity of the globe. If a perforation is suspected, extensive eye examination should not be attempted before anaesthesia because this may lead to further extrusion of the intraocular contents. If the fundal view is poor, ultrasonography and orbital imaging are indicated. Secondary corneal grafting, lensectomy and vitrectomy have considerably improved the visual prognosis; these must be done by an experienced eye surgeon. Injuries to the optic nerves must also be excluded in severe accidents.

Figure 41.22 Retinal dialysis after concussional injury.

Figure 41.23 Facial lacerations from a windscreen injury. Beware of a perforating eye injury.

Intraocular foreign bodies

Intraocular foreign bodies must always be excluded when patients attend the accident and emergency department with an eye injury and a history of working with a hammer and chisel or a history of a potentially high-velocity injury. Radiography of the orbits should always be performed, and ferrous and copper foreign bodies should always be removed. B-scan ultrasonography can also assist in localising foreign bodies when a vitreous haemorrhage or cataract is present. CT can be used, but MRI is contraindicated (Summary box 41.4).

Summary box 41.4

Penetrating eye injuries

- A distorted and irregular pupil warrants the careful exclusion of a penetrating eye injury

Burns

Radiation burns

These occur after exposure to ultraviolet radiation after arc welding or excessive sunlight (snow blindness) and sun lamps. Such burns cause intense pain and photophobia as a result of keratitis, which starts some hours after exposure. Mydriatic and local steroids with antibiotic drops ease the condition, and healing usually occurs after 24 hours.

Thermal burns

If these involve the full thickness of the lids, corneal scarring may occur from exposure, and immediate corneal protection is necessary. A splash of molten metal may cause marked local necrosis and may lead to permanent corneal scarring. Treatment is to remove any debris by irrigation and to instill local atropine, antibiotics and steroids to prevent superadded infection and scarring. Lid reconstruction may be necessary.

Chemical burns

Chemical burns, and especially alkali burns, can be serious because ocular penetration occurs quickly and ischaemic necrosis can result (Fig. 41.24). Immediate irrigation until the pH is neutral will ensure that the chemical is diluted as much as possible, and all particles should be removed from the fornices. Treatment can then be continued as with thermal burns. Well-fitting goggles should prevent such injuries.

Figure 41.24 Chemical burn showing conjunctival necrosis.

DIFFERENTIAL DIAGNOSIS OF THE ACUTE RED EYE

This is important in the management of minor ocular complaints and the recognition of conditions that require expert attention. Possible causes of the acute red eye include:

- subconjunctival haemorrhage;
- conjunctivitis;
- keratitis;
- uveitis;
- episcleritis and scleritis;
- acute glaucoma.

Any condition with pain, visual impairment or a pupil abnormality suggests a more serious diagnosis.

Subconjunctival haemorrhage

This presents as a bright-red eye, often noticed incidentally with only minimal discomfort and normal vision. Causes include coughing, sneezing, minor trauma, hypertension and, rarely, a bleeding disorder. Reassurance and treatment of the underlying cause are required.

Conjunctivitis

Symptoms are grittiness, redness and discharge. Causes are infective, chemical, allergic or traumatic. In the newborn it can be serious; gonococcal and chlamydial infection must be excluded. Bacterial conjunctivitis is common, purulent, usually self-limiting and treated with topical broad-spectrum antibiotics. Chlamydial and adenovirus infections must be considered. Adenoviral infections usually affect one eye much more in severity and onset, tending to be more watery than sticky, and are often associated with a palpable preauricular gland.

Vernal conjunctivitis (Fig. 41.25) is a form of allergic conjunctivitis, usually worse in the spring and early summer and often associated with other allergic problems such as hay fever. Clinically, most signs are under the upper lid, which may have a cobblestone appearance instead of a smooth surface.

Giant pupillary conjunctivitis with large papillae under the upper lid may be seen in soft contact lens wearers. This is usually caused by an allergy to the sterilising solutions and may be helped by either using a preservative-free solution or using daily-wear disposable lenses.

Figure 41.25 Vernal conjunctivitis (spring catarrh) showing cobblestone appearance under the upper lid.

Kaposi's sarcoma can rarely present like a subconjunctival haemorrhage (Fig. 41.26).

Considerable conjunctival irritation can be caused by the lids turning in (entropion) (Fig. 41.27) or turning out (ectropion)

Figure 41.26 Kaposi's sarcoma of conjunctiva.

Figure 41.27 Entropion (courtesy of J. Beare, FRCS).

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

(Figs 41.28 and 41.29), and by ingrowing lashes. The lids should be repaired surgically to their normal position.

Vision is not commonly affected in conjunctivitis but, with some viral infections, a keratitis may be present and result in visual impairment and pain. All of the other conditions are painful and usually affect vision.

Keratitis (inflammation of the cornea)

Herpes simplex infection is the most serious cause of an acute red eye and presents as a dendritic (branching) ulcer, shown easily by staining with fluorescein or Bengal Rose. It is treated with aciclovir ointment five times per day. The use of steroid drops must be avoided as this can make the condition much worse (Fig. 41.30).

Corneal ulceration may occur as a result of ingrowing lashes or corneal foreign bodies, marginal ulceration and infected abrasions. Infected ulcers can occur in patients wearing soft contact lenses. Herpes zoster (shingles) may affect the ophthalmic division of the Vth nerve and can give rise to a keratitis and uveitis. It is important to avoid the use of steroid drops until a diagnosis has been made. Local anaesthetic drops should also not be given on a regular basis.

Uveitis

This can be anterior (iritis) or, more rarely, posterior. In anterior uveitis, the pupil will be small, sometimes irregular, there is

Figure 41.28 Ectropion, lower lid (courtesy of J. Beare, FRCS).

Figure 41.29 Ectropion, upper lid – chronic staphylococcal infection (courtesy of J. Beare, FRCS).

Bengal Rose, (or Rose Bengal) is Dichlorotetraiodofluorescein.

Figure 41.30 Dendritic staining caused by herpes keratitis.

circumcorneal injection and there may be keratic precipitates present on the posterior surface of the cornea. Pain, photophobia and some visual loss are usually present. Posterior uveitis can present with a white eye and blurred vision. It usually takes a chronic course. Granulomatous diseases, Behçet's disease, Reiter's syndrome, toxoplasmosis and cytomegalovirus infection should be excluded. Topical systemic steroids and, sometimes, immunosuppressive drugs are useful in treating these conditions.

Episcleritis and scleritis

Episcleritis or inflammation of the episcleral tissue often occurs as an idiopathic condition (Fig. 41.31).

Scleritis is a less common, more serious, condition in which the deeper sclera is involved. There is often an associated uveitis and severe pain. Thinning of the sclera may result. Systemic non-steroidal anti-inflammatory drugs (NSAIDs) or steroids may be required to treat the condition adequately.

Figure 41.31 Episcleritis.

Hulusi Behçet, 1889–1948, Professor of Dermatology, Istanbul, Turkey, described this disease in 1937.

Hans Conrad Julius Reiter, 1881–1968, President of the Health Service, and Honorary Professor of Hygiene at the University of Berlin, Germany, described this disease in 1916.

Scleritis is often associated with severe rheumatoid conditions. The presence of scleritis suggests that there is active systemic disease and it requires systemic work-up including renal function tests.

Acute glaucoma

This usually occurs in older, often hypermetropic, patients. The cornea becomes hazy, the pupil oval and dilated, the vision poor and the eye feels hard. In severe cases pain may be accompanied by vomiting and the condition can be mistaken for an acute abdominal problem. Tonometry (intraocular measurement) is diagnostic. Urgent treatment to reduce the pressure with pilocarpine, acetazolamide and, if refractory, mannitol should be started, followed by a surgical iridectomy or laser iridotomy. The condition is usually bilateral and the second eye usually needs a prophylactic iridotomy at the same time.

Except for a simple conjunctivitis and subconjunctival haemorrhage, which are self-limiting, the management of an acute red eye requires expert treatment and a specialist opinion should be sought. A painful eye with a IIIrd nerve palsy often signifies an intracranial aneurysm and should be investigated immediately.

PAINLESS LOSS OF VISION

This may occur in one or both eyes, and the visual loss may be transient or permanent. Possible causes are:

- obstruction of the central retinal artery (Fig. 41.32);
- obstruction of the central retinal vein (Fig. 41.33);
- cranial arteritis;
- ischaemic optic neuropathy;
- migraine and other vascular causes;
- retrobulbar neuritis and papillitis;
- vitreous and retinal haemorrhages;
- retinal detachment (Fig. 41.34);
- macular hole, cyst or haemorrhage;
- cystoid macular oedema, often after surgery;
- hysterical blindness;
- cataract;
- glaucoma;
- macular degeneration.

Figure 41.32 Retinal artery occlusion.

Figure 41.33 Central retinal vein occlusion.

Figure 41.34 B-scan of a retinal detachment.

Specialist help should be sought in any case of loss of vision. The erythrocyte sedimentation rate and C-reactive protein should be measured immediately if cranial arteritis is suspected, and the carotid system should be examined for bruits and other signs of arteriosclerosis in cases of ischaemic optic neuropathy and central retinal artery occlusion. Glaucoma, hypertension, hyperviscosity syndromes and diabetes should be looked for in cases of central vein thrombosis.

RECENT DEVELOPMENTS IN EYE SURGERY

In the last two decades, eye surgery has become a microsurgical specialty. Cataract surgery has been transformed by changes in local anaesthesia, implants, phakoemulsification and small-incision surgery, which allows compressible silicone or acrylic implants to be inserted through a 3-mm incision. The implant power can be more accurately measured by new formulae and the use of A-scan ultrasonography or laser wavefront biometry, and multifocal and accommodative lenses are now available.

There are new treatments for eye disorders that involve abnormal growth of blood vessels in the back of the eye, such as the wet form of age-related macular degeneration. Photodynamic

therapy involves the activation of the drug verteporfin in a localised area of the eye using a laser. Antivascular endothelial antibodies such as the drug ranibizumab may be injected directly into the vitreous cavity to reduce new vessel proliferation.

Developments in vitreous surgery have enabled membranes to be peeled off the retina and macular holes to be repaired, and have also increased the success rate in retinal detachment surgery with the additional use of gases and silicone oil or heavy liquid inserted into the vitreous cavity tamponading the retina.

Some paralytic squints can be helped by the use of adjustable sutures or injections of botulinum toxin into the overacting muscles. Refractive errors can be treated either by surgery (arcuate or radial keratotomy) or by the excimer laser. These can be combined with laser *in situ* keratomileusis (LASIK) surgery, which involves cutting a corneal flap and performing the laser surgery at a deeper level. There have been some concerns about defective contrast sensitivity and problems with night vision after laser correction of myopia. Phakic implants have also been used to correct high refractive errors. Corneal topography aids the accuracy of corneal and refractive surgery and the increased use and quality of CT and MRI scans has revolutionised the diagnosis of orbital and intracranial lesions involving the optic pathways (Figs 41.35–41.37). Fluorescein angiography, indocyanine green angiography, and the scanning laser ophthalmoscope (SLO) are invaluable in the diagnosis and treatment of macular conditions. The glaucoma detection (GDx) retinal nerve fibre analyser and Heidelberg retinal tomography (HRT) are increasingly used in the diagnosis and management of glaucoma.

LASERS IN OPHTHALMOLOGY

These were originally used for coagulation. The ruby laser was superseded by the argon blue–green laser and then the argon green-only laser, as the blue light was dangerous both to the operator and to the patient's macula. Yellow and red wavelengths are also used and the doubled-frequency doubled yttrium–aluminium–garnet (YAG) laser can be used as a coagulator with a wavelength of 533 nm. The photodisruptive YAG laser was developed together with extracapsular surgery and is used for

Figure 41.35 Magnetic resonance imaging scan, sagittal view. Craniopharyngioma. The mass in the suprasellar cistern is of high signal intensity because of the proteinaceous fluid that the cyst contains (courtesy of Dr Juliette Britton).

Figure 41.36 High-resolution computerised tomography through the orbits showing dense calcification of the optic nerve sheaths typical of optic nerve meningioma (courtesy of Dr Juliette Britton).

Figure 41.37 Axial enhanced magnetic resonance imaging scan showing a mass involving the optic chiasma and extending down the optic nerves and tracts.

capsulotomies, iridotomies and cutting anterior vitreous bands. In continuous mode it can be used to treat severe glaucomas.

Holmium and erbium lasers have been used to create subconjunctival drainage in glaucoma; the potassium–titanyl–phosphate (KTP) and holmium lasers can also be used in lacrimal obstruction during endoscopic DCR operations. CO₂ lasers are used to remove external lesions of the eyelids, and photoablative excimer lasers are used for refractive surgery. The diode laser can be used both as a retinal photocoagulator and for treating the ciliary body in advanced cases of glaucoma. Lasers combined with phakoemulsification to liquefy the human lens are being developed. Laser technology is advancing and new forms of lasers will be developed for use in the assessment, diagnosis and management of eye disorders.

SURGICAL PROCEDURES

Excision of an eyeball

Indications include a blind, painful eye, a blind, cosmetically poor eye, intraocular neoplasm and, in cadavers, for use in corneal grafting.

The operation

The speculum is introduced between the lids and opened. The conjunctiva is picked up with toothed forceps and divided completely all round as near as possible to the cornea. Tenon's capsule is entered and each of the rectus tendons is hooked up on a strabismus hook and divided close to the sclera. The speculum is now pressed backwards and the eyeball projects forwards. Blunt scissors, curved on the flat, are insinuated on the inner side of the globe, and these are used to sever the optic nerve. The eyeball can now be drawn forwards with the forceps, and the oblique muscles, together with any other strands of tissue that are still attaching the globe to the orbit, are divided. A swab, moistened with hot water and pressed into the orbit, will control the haemorrhage. If an orbital implant is inserted to give better eye movement, the muscles are sutured to the implant at the appropriate sites. The subconjunctival tissues and conjunctiva are closed in layers.

Evisceration of an eyeball

Evisceration is preferred to excision in panophthalmitis, minimising the risk of orbital and intracranial spread with meningitis. The sclera is transfixated with a pointed knife a little behind the corneosclerotic junction, and the cornea is removed entirely by completing the encircling incision in the sclera. The contents of the globe are then removed with a curette, care being exercised to remove all of the uveal tract. At the end of the operation the interior must appear perfectly white. A ball orbital implant made of acrylic or hydroxyapatite is placed within the orbit behind the sclera to improve the appearance when the artificial eye is fitted.

Incision and curettage of chalazion (meibomian cyst)

The lid margin is everted to allow the application of a meibomian clamp. The ring of the clamp is placed on the palpebral conjunctiva with the granuloma in the centre. An incision is made

with a small blade in the axis of the gland. The herniating granulomatous tissue is removed with a curette and the cavity is scraped clean. Recurrent cysts may have to have the cyst wall dissected away with scissors. A biopsy may be necessary in atypical or recurrent cysts to exclude malignant change.

ACQUIRED IMMUNODEFICIENCY SYNDROME AND THE EYE

Kaposi's sarcomas, purplish or brown non-pruritic nodules or macules, are a frequent early manifestation of acquired immunodeficiency syndrome (AIDS). Commonly affecting the face, especially the tip of the nose, the lesions may involve the eyelids and the conjunctiva. They respond to chemotherapy and so excision is not usually necessary.

Fundus lesions are 'non-infective' or 'infective'. The non-infective retinopathy is a microangiopathy consisting of cotton wool spots and blot haemorrhages. These fade over several weeks and do not affect vision. The most common infective retinitis is caused by cytomegalovirus (CMV). The retinal lesions are irregular areas of white necrosis and associated scattered haemorrhages. The appearance is likened to a 'pizza pie'. The borders of the lesions expand as a 'brushfire', leaving behind an atrophic pigmented retina. CMV retinitis is progressive and the lesions expand over a few months so that the entire retina is involved over a period of about 6 months, causing absolute blindness.

Treatment is with a course of ganciclovir or foscarnet given intravenously. Both drugs can be injected directly into the vitreous. Long-term maintenance therapy is essential to prevent further progression. A Vitrasert is a ganciclovir slow-release implant that is surgically inserted into the vitreal cavity and anchored to the sclera. It is effective in preventing progression for 9 months.

The other retinal infections are rare and include toxoplasmosis, *Pneumocystis*, *Candida*, *Cryptococcus*, herpes zoster and syphilis.

The most effective treatment of CMV retinitis and all retinal infections is the recovery of the patient's immunocompetence. This can be achieved using anti-retroviral drug combinations against human immunodeficiency virus (HIV). When the patient's immunity is restored, the retinitis becomes atrophic. Reduced vision is permanent.

Neuro-ophthalmological complications in AIDS have been reported, most frequently as nerve palsies associated with intracranial infections with cryptococci and toxoplasmosis, or as a manifestation of an intracranial lymphoma.

Cleft lip and palate: developmental abnormalities of the face, mouth and jaws

LEARNING OBJECTIVES

To understand:

- The aetiology and classification of cleft lip and palate
- The principles of reconstruction of cleft lip and palate
- The key features of the perioperative care of the child with cleft lip and palate
- The associated complications of cleft lip and palate and their management

INTRODUCTION

Clefts of the lip, alveolus and hard and soft palate are the most common congenital abnormalities of the orofacial structures. They frequently occur as isolated deformities but can be associated with other medical conditions, particularly congenital heart disease. They are also an associated feature in over 300 recognised syndromes.

All children born with a cleft lip and palate need a thorough paediatric assessment to exclude other congenital abnormalities. In certain circumstances genetic counselling must be sought if a syndrome is suspected.

INCIDENCE

The incidence of cleft lip and palate is 1:600 live births and of isolated cleft palate is 1:1000 live births. The incidence increases in Oriental groups (1:500) and decreases in the black population (1:2000). The highest incidence reported for cleft lip and palate occurs in the Indian tribes of Montana, USA (1:276).

Although cleft lip and palate is an extremely diverse and variable congenital abnormality, several distinct sub-groups exist, namely cleft lip with/without cleft palate (CL/P), cleft palate (CP) alone and submucous cleft palate (SMCP).

The typical distribution of cleft types is:

- cleft lip alone: 15%;
- cleft lip and palate: 45%;
- isolated cleft palate: 40%.

Cleft lip/palate predominates in males whereas cleft palate alone appears to be more common in females. In unilateral cleft lip the deformity affects the left side in 60% of cases.

AETIOLOGY

Contemporary opinion on the aetiology of cleft lip and palate is that cleft lip and palate and isolated cleft palate have a genetic predisposition and a contributory environmental component. A family history of cleft lip and palate in which the first-degree

relative is affected increases the risk to 1:25 live births. Genetic influence is more significant in cleft lip/palate than cleft palate alone, in which environmental factors exert a greater influence.

Environmental factors implicated in clefting include maternal epilepsy and drugs, e.g. steroids, diazepam and phenytoin. The role of antenatal folic acid supplements in preventing cleft lip and palate remains equivocal.

Although most clefts of the lip and palate occur as an isolated deformity, Pierre Robin sequence remains the most common syndrome. This syndrome comprises isolated cleft palate, retrognathia and a posteriorly displaced tongue (glossoptosis), which is associated with early respiratory and feeding difficulties.

Isolated cleft palate is more commonly associated with a syndrome than cleft lip/palate and cleft lip alone. Over 150 syndromes are associated with cleft lip and palate, although Stickler's (ophthalmic and musculoskeletal abnormalities), Shprintzen's (cardiac anomalies), Down's, Apert's and Treacher-Collins' syndromes are most frequently encountered (Summary box 42.1).

Summary box 42.1

Cleft lip and palate

- Associated with other congenital abnormalities
- Incidence varies between races from 1:300 to 1:2000 live births
- Aetiology is both genetic and environmental

Pierre Robin, 1867–1950, Professor, The French School of Dentistry, Paris, France, described this syndrome in 1929.

Gunnar B. Stickler, B. 1925, Paediatrician, The Mayo Clinic, Rochester, MN, USA.

John Langdon Haydon Down, (sometimes given as Langdon-Down), 1828–1896, Physician, The London Hospital, London, England, published his classification of aments in 1866.

Eugene Apert, 1868–1940, Physician, L'Hopital des Enfants-Malades, Paris, France, described this syndrome in 1906.

Edward Treacher Collins, 1862–1932, Ophthalmic Surgeon, The Royal London Ophthalmic Hospital, and Charing Cross Hospital, London, England, described this syndrome in 1900.

ANATOMY OF CLEFT LIP AND PALATE

Cleft lip

The abnormalities in cleft lip are the direct consequence of disruption of the muscles of the upper lip and nasolabial region. The facial muscles (Fig. 42.1) can be divided into three muscular rings of Delaire: the nasolabial muscle ring surrounds the nasal aperture; the bilabial muscle ring surrounds the oral aperture; and the labiomental muscle ring envelops the lower lip and chin regions.

Unilateral cleft lip

In the unilateral cleft lip, the nasolabial and bilabial muscle rings are disrupted on one side resulting in an asymmetrical deformity involving the external nasal cartilages, nasal septum and anterior maxilla (premaxilla) (Fig. 42.2a and b). These deformities influence the mucocutaneous tissues causing a displacement of nasal skin onto the lip and a retraction of labial skin, as well as changes to the vermilion and lip mucosa. All these changes need to be considered in planning the surgical repair of the unilateral cleft lip.

Bilateral cleft lip

In the bilateral cleft lip the deformity is more profound but symmetrical. The two superior muscular rings are disrupted on both sides producing a flaring of the nose (caused by lack of nasolabial muscle continuity), a protrusive premaxilla and an area of skin in front of the premaxilla devoid of muscle, known as the prolabium (Fig. 42.3a and b). As in the unilateral cleft lip, the muscular, cartilaginous and skeletal deformities influence the mucocutaneous tissues, which must be respected in planning the repair of the bilateral cleft lip.

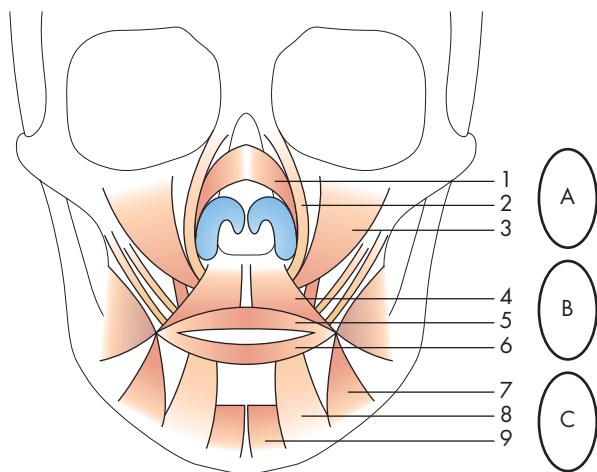

Figure 42.1 The muscle chains of the face: frontal view. The nasal cartilages are represented in blue. A, nasolabial (muscles 1–3); B, bilabial (muscles 4–6); C, labiomental (muscles 7–9); 1, transverse nasalis; 2, levator labii superioris alaeque nasi; 3, levator labii superioris; 4, orbicularis oris (oblique head) – upper lip; 5, orbicularis oris (horizontal head) – upper lip; 6, orbicularis oris – lower lip; 7, depressor anguli oris; 8, depressor labii inferioris; 9, mentalis.

Jean Delaire, Professor of Stomatology and Maxillofacial Surgery, The University of Nantes, Nantes, France from 1960 until 1991.

Cleft palate

Embryologically, the *primary* palate consists of all anatomical structures anterior to the incisive foramen, namely the alveolus and upper lip. The *secondary* palate is defined as the remainder of the palate behind the incisive foramen, divided into the hard palate and, more posteriorly, the soft palate.

Cleft palate results in failure of fusion of the two palatine shelves. This failure may be confined to the soft palate alone or involve both hard and soft palate. When the cleft of the hard palate remains attached to the nasal septum and vomer, the cleft is termed *incomplete*. When the nasal septum and vomer are completely separated from the palatine processes, the cleft palate is termed *complete* (Summary box 42.2).

Summary box 42.2

Types of cleft palate

- May involve the soft palate or the soft and hard palate
- It is complete when nasal septum and vomer are separated from the palatine process

Soft palate

In the normal soft palate, closure of the velopharynx, which is essential for normal speech, is achieved by five different muscles functioning in a complete but coordinated fashion. In general, the muscle fibres of the soft palate are orientated transversely with no significant attachment to the hard palate.

In a cleft of the soft palate (Fig. 42.4a) the muscle fibres are orientated in an anteroposterior direction, inserting into the posterior edge of the hard palate (Fig. 42.4b).

Hard palate

The normal hard palate can be divided into three anatomical and physiological zones (Fig. 42.5). The central *palatal fibromucosa* is very thin and lies directly below the floor of nose. The *maxillary fibromucosa* is thick and contains the greater palatine neurovascular bundle. The *gingival fibromucosa* lies more lateral and adjacent to the teeth.

In performing surgical closure of cleft palate the changes associated with the cleft must be understood to obtain an anatomical and functional repair. In complete cleft palate the median part of the palatal vault is absent and the palatal fibromucosa is reduced in size. The maxillary and gingival fibromucosa are not modified in thickness, width or position.

CLASSIFICATION

Any classification for such a diverse and varied condition as cleft lip and palate needs to be simple, concise, flexible and exact but graphic. It must be suitable for computerisation but descriptive and morphological. An example of such a classification is the LAHSHAL system, which is able to describe site, size and extent, as well as type of cleft (Fig. 42.6).

Complete clefts of the lip, alveolus and hard and soft palate are designated as capitals L, A, H and S respectively. Incomplete clefts are recorded in lower case letters whereas microform clefts are documented with asterisks. Hence, LAHSHAL is the anatomical paraphrase of a complete bilateral cleft lip and palate. Another example, lahSh, represents an incomplete right unilateral cleft lip and alveolus with a complete cleft of soft palate extending partly onto the hard palate.

PRIMARY MANAGEMENT

Antenatal diagnosis

An antenatal diagnosis of cleft lip, whether unilateral or bilateral, is possible by ultrasound scan after 18 weeks of gestation. Isolated cleft palate cannot be diagnosed by antenatal scan. When an antenatal diagnosis is confirmed, referral to a cleft surgeon is appropriate for counselling to allay fears. Photographs of cleft lip shown to parents 'before and after' surgery are invaluable. Introduction to a parent support group and meeting parents

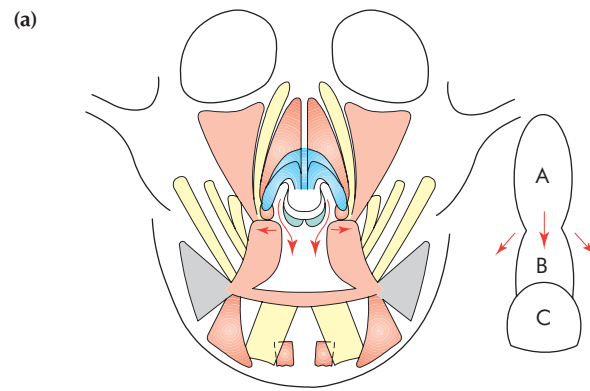

Figure 42.3 (a) Schematic representation of disruption of the nasolabial and bilabial muscle chains in bilateral cleft lip. A, nasolabial; B, bilabial; C, labiomental. (b) Bilateral cleft lip before muscular reconstruction.

of a child with a similar cleft who has undergone surgery may also be extremely helpful (Summary box 42.3).

Summary box 42.3

Antenatal diagnosis and counselling

- All but isolated cleft palate can be diagnosed by ultrasound scan after 18 weeks' gestation
- Parents will need counselling and support

Figure 42.4 (a) Cleft of soft palate and incomplete cleft of hard palate. (b) Muscles of the soft palate: left, cleft palate; right, normal anatomy. A, tensor palati; B, levator palati; C, palatopharyngeus; D, palatoglossus; E, musculus uvulae.

Figure 42.5 The three mucosal zones of the hard palate. 1, palatal fibromucosa; 2, maxillary fibromucosa; 3, gingival fibromucosa.

Feeding

Most babies born with cleft lip and palate feed well and thrive, provided that appropriate advice is given and support is available. Some mothers are successful in breast-feeding, particularly when the cleft is incomplete and confined to the lip. Good feeding patterns can be established with soft bottles (e.g. Mead Johnson)

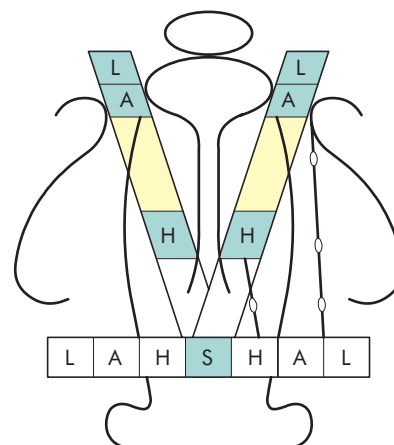

Figure 42.6 LAHSAL: an anatomical representation of cleft lip (L), alveolus (A) and hard (H) and soft palate (S).

and modified teats (orthodontic, Nuyk). Simple measures such as enlarging the hole in the teat often suffice. Feeding plates, constructed from a dental impression of the upper jaw, are rarely necessary to improve feeding. Some babies are provided with an active plate that aims not only to improve feeding but also reduce the width of the cleft lip and palate prior to surgery. The long-term benefit of such a regime remains unproven.

Airway

Major respiratory obstruction is uncommon and occurs exclusively in babies with Pierre Robin sequence. Hypoxic episodes during sleep and feeding can be life-threatening. Intermittent airway obstruction is more frequent and is managed by nursing the baby prone. More severe and persistent airway compromise can be managed by 'retained nasopharyngeal intubation' to maintain the airway. Surgical adhesion of the tongue to the lower lip (labioglossopexy) in the first few days after birth is an alternative but less commonly practised method of management (Summary box 42.4).

Summary box 42.4

Problems immediately after birth

- Some babies are able to feed normally but some will need assistance
- Breathing problems in Pierre Robin sequence may be life-threatening

PRINCIPLES OF CLEFT SURGERY

The ultimate goal in cleft lip and palate management is a patient with a normal appearance of lip, nose and face, whose speech is normal and whose dentition and facial growth fall within the range of normal development.

Surgical techniques are aimed at restoring normal anatomy. With the exception of rare conditions such as holoprosencephaly, there is no true hypoplasia of the tissues involved on either side of the cleft. There is, however, displacement, deformation and underdevelopment of the muscles and facial skeleton. Emphasis is placed on muscular reconstruction of the lip, nose and face as well as muscles of the soft palate. Normal or near-normal

anatomy promotes normal function, thereby encouraging normal growth and development of lip, nose, palate and facial skeleton. An in-depth understanding of the anatomy of the cleft is invaluable if the surgeon is to achieve normal, or near-normal, anatomical reconstruction (Summary box 42.5).

Summary box 42.5

Surgical anatomy

- Normal lip, face and nose
- There is underdevelopment and displacement of the muscles
- Restoration of normal anatomy encourages normal facial growth and function

Surgical techniques

There have been many different surgical techniques and sequences advocated in cleft lip and palate management. Cleft lip repair is commonly performed between 3 and 6 months of age whereas cleft palate repair is frequently performed between 6 and 18 months.

The Delaire technique and sequence (Table 42.1) is one of many regimes currently practised.

Cleft lip surgery

Skin incisions (Figs 42.7 and 42.8) are developed to restore displaced tissues, including skin and cartilage, to their normal position, while gaining access to the facial, nasal and lip musculature.

Table 42.1 Timing of primary cleft lip and palate procedures (after Delaire)

Cleft lip alone		
Unilateral (one side)	One operation at	5–6 months
Bilateral (both sides)	One operation at	4–5 months
Cleft palate alone		
Soft palate only	One operation at	6 months
Soft and hard palate	Two operations	Soft palate at 6 months Hard palate at 15–18 months
Cleft lip and palate		
Unilateral	Two operations	Cleft lip and soft palate at 5–6 months Hard palate and gum pad with or without lip revision at 15–18 months
Bilateral	Two operations	Cleft lip and soft palate at 4–5 months Hard palate and gum pad with or without lip revision at 15–18 months

Figure 42.7 (a and b) Skin incisions (highlighted in red) for left unilateral complete cleft lip (after Delaire).

Figure 42.8 (a–c) Skin incisions for bilateral complete cleft lip, showing the shaded area from Fig. 42.7a. Areas for removal of excess mucosa (a) or skin (b) (after Delaire).

Muscular continuity is achieved by subperiosteal undermining over the anterior maxilla. Nasolabial muscles are anchored to the premaxilla with non-resorbable sutures. Oblique muscles of orbicularis oris are sutured to the base of the anterior nasal spine and cartilaginous nasal septum. Closure of the cleft lip is completed by suturing the horizontal fibres of orbicularis oris to achieve a functioning oral sphincter (Figs 42.9 and 42.10).

When the cleft lip is incomplete (Figs 42.11a and Fig. 42.12a), meticulous assessment of the cleft deformity is of paramount importance, as complete muscle disruption may be present leading to nasal and skeletal deformity. Full muscular exposure and reconstruction is imperative in many incomplete clefts if facial symmetry is to be achieved (Figs 42.11b and 42.12b).

Cleft palate surgery

Cleft palate closure can be achieved by one- or two-stage palatoplasty. The surgical principle is mobilisation and reconstruction of the aberrant soft palate musculature (Fig. 42.13a and b) together with closure of the residual hard palate cleft by minimal dissection and subsequent scar formation (Fig. 42.14a and b). Excess scar formation in the palate adversely affects growth and development of the maxilla. The philosophy of two-stage closure encourages a physiological narrowing of the hard palate cleft to minimise surgical dissection at the time of the second procedure (Summary box 42.6).

Summary box 42.6

Principles of surgery

- Cleft lip surgery attaches and reconnects the muscles around the oral sphincter
- Cleft palate surgery aims to bring together mucosa and muscles with minimal scarring
- Two-stage procedures attempt to minimise dissection

Figure 42.9 Unilateral complete cleft lip before (a) and after (b) muscular reconstruction.

SECONDARY MANAGEMENT

Following primary surgery, regular review by a multidisciplinary team is essential. Many aspects of cleft care require long-term review:

- hearing;
- speech;
- dental development;
- facial growth.

Figure 42.10 Bilateral cleft lip before (a) and after (b) muscular reconstruction.

Hearing

Eustachian tube dysfunction plays a central role in the pathogenesis of otitis media with effusion in babies and children born with a cleft palate. Children with a cleft lip alone exhibit the same

Figure 42.11 Unilateral incomplete cleft lip before (a) and after (b) muscle reconstruction.

frequency of otitis media as their age-matched non-cleft counterparts. It has been recently recognised that a child with a craniofacial anomaly including cleft lip and palate is at increased risk of a sensorineural hearing deficit. All children born with a cleft lip and palate should undergo assessment before 12 months of age for *sensorineural and conductive hearing loss* by auditory brainstem responses (ABR) and tympanometry respectively.

Sensorineural hearing loss is managed with a hearing aid whereas the management of secretory otitis media remains more controversial. Early (6–12 months) prophylactic myringotomy and grommet insertion temporarily eliminates middle ear effusion. Regular audiological testing may be as appropriate, reserving surgery for established secretory otitis media with infection. No firm evidence is available to support the interventional approach over the conservative regime. Nevertheless, the relationship between hearing loss and potential speech problems remains important. Regular audiological assessment during childhood is of utmost importance.

Speech

Initial speech assessment should be performed early (18 months) and repeated regularly to ensure that problems are identified early and managed appropriately.

Common speech problems associated with cleft lip and palate are:

- *Velopharyngeal incompetence*. This is associated with increased nasal airflow and resonance producing a nasal or ‘hypernasal’

quality to speech. It frequently reflects poor function of the soft palate associated with inadequate muscle repair.

- *Articulation problems*. These arise either as a compensatory mechanism to overcome velopharyngeal incompetence or less commonly are caused by jaw/dental and occlusal abnormalities. Videofluoroscopy, nasal airflow studies (aerophonoscopy) and nasendoscopy are helpful in defining the exact mechanism of the problem, aiding management.
- *Speech problems*. These are managed by speech and language therapy; secondary palatal surgery, either intravelar veloplasty (muscular reconstruction of soft palate) or pharyngoplasty; and speech training devices (Summary box 42.7).

Summary box 42.7

Associated hearing and speech problems

- Higher incidence of sensorineural and conductive hearing loss
- Regular hearing tests are important if speech is to develop normally
- Speech problems may result from airflow problems

Dental

Dental anomalies are common findings in children with cleft lip and/or palate. Various phenomena including delayed tooth development, delayed eruption of teeth and morphological

Figure 42.12 Bilateral incomplete cleft lip before (a) and after (b) muscular reconstruction.

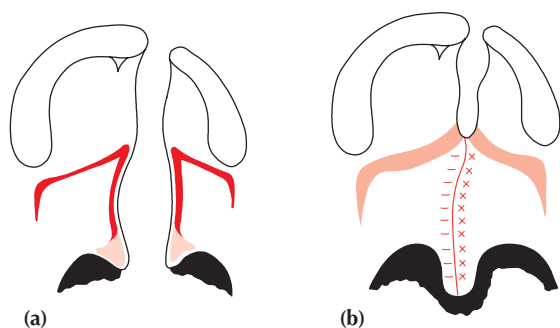

Figure 42.13 (a and b) Method of repair of cleft palate. First-stage palatoplasty to reconstruct muscles of the soft palate. Red lines represent incisions, and orange areas raw surfaces.

abnormalities are well documented. The number of teeth may be reduced (hypodontia) or increased (hyperdontia), occurring most commonly in the region of the cleft alveolus involving the maxillary lateral incisor tooth. These abnormalities can occur in both primary and secondary dentition.

All children with cleft lip and palate should undergo regular dental examination. Dental management should also include preventative measures such as dietary advice, fluoride supplements and fissure sealants.

A well-maintained and disease-free dentition in childhood is

an absolute prerequisite for orthodontic treatment (Summary box 42.8).

Summary box 42.8

Dental problems

- Too many/too few teeth or problems with eruption of teeth are common
- Good dentition is essential for successful reconstructive surgery

Orthodontic management

Many children with cleft lip and palate require orthodontic treatment. Orthodontic treatment is commonly carried out in two phases:

- 1 Mixed dentition (8–10 years) – to expand the maxillary arches as a prelude to alveolar bone graft.
- 2 Permanent dentition (14–18 years) – to align the dentition and provide a normal functioning occlusion. This phase of treatment may also include surgical correction of a malpositioned/retrusive maxilla by maxillary osteotomy (Fig. 42.15a and b).

Secondary surgery for cleft lip and palate

Good outcome in cleft lip and palate is directly attributable to the quality of the primary surgery. Secondary cleft procedures include:

- cleft lip revision (unilateral and bilateral);
- alveolar bone graft;
- simultaneous lip revision and alveolar bone graft;
- secondary palate procedures, e.g. veloplasty and pharyngoplasty, closure of a palatal fistula;
- dentoalveolar procedures, including transplantation of teeth/insertion of osseointegrated dental implants;
- orthognathic surgery;
- rhinoplasty.

Cleft lip revision

Indications for revisional surgery to the previously repaired cleft lip are dependent on the site and severity of the residual deformity.

Revisional surgery should be delayed for 2 years after primary lip closure unless the surgeon is of the opinion that the initial procedure was inadequate, particularly with respect to muscular reconstruction.

Indications for revision include:

- lip deformity:
 - malaligned vermilion;
 - asymmetrical Cupid's bow;
 - muscle discontinuity or malalignment;
- nasal deformity:
 - lateral drift of alar base;
 - poor nasal tip projection;
 - deviation of cartilaginous nasal septum into the non-cleft nostril.

Residual nasal deformity is an external manifestation of incomplete reconstruction of the nasolabial muscle ring.

Examples of lip revision are shown in Figs 42.16–42.19 (Summary box 42.9).

Summary box 42.9

Cleft lip revision surgery

- Should be delayed for at least 2 years after primary surgery
- Aims to improve incomplete primary reconstruction

Cupid's Bow. Cupid, the Roman God of Love, is often depicted holding a double-curved bow which he uses to shoot arrows into his victims.

Figure 42.15 Correction of midface retrusion by maxillary advancement osteotomy, before (a) and after (b) surgery.

Alveolar bone grafting

Alveolar bone grafting in a mixed dentition is a well-established procedure for patients with a residual alveolar cleft associated

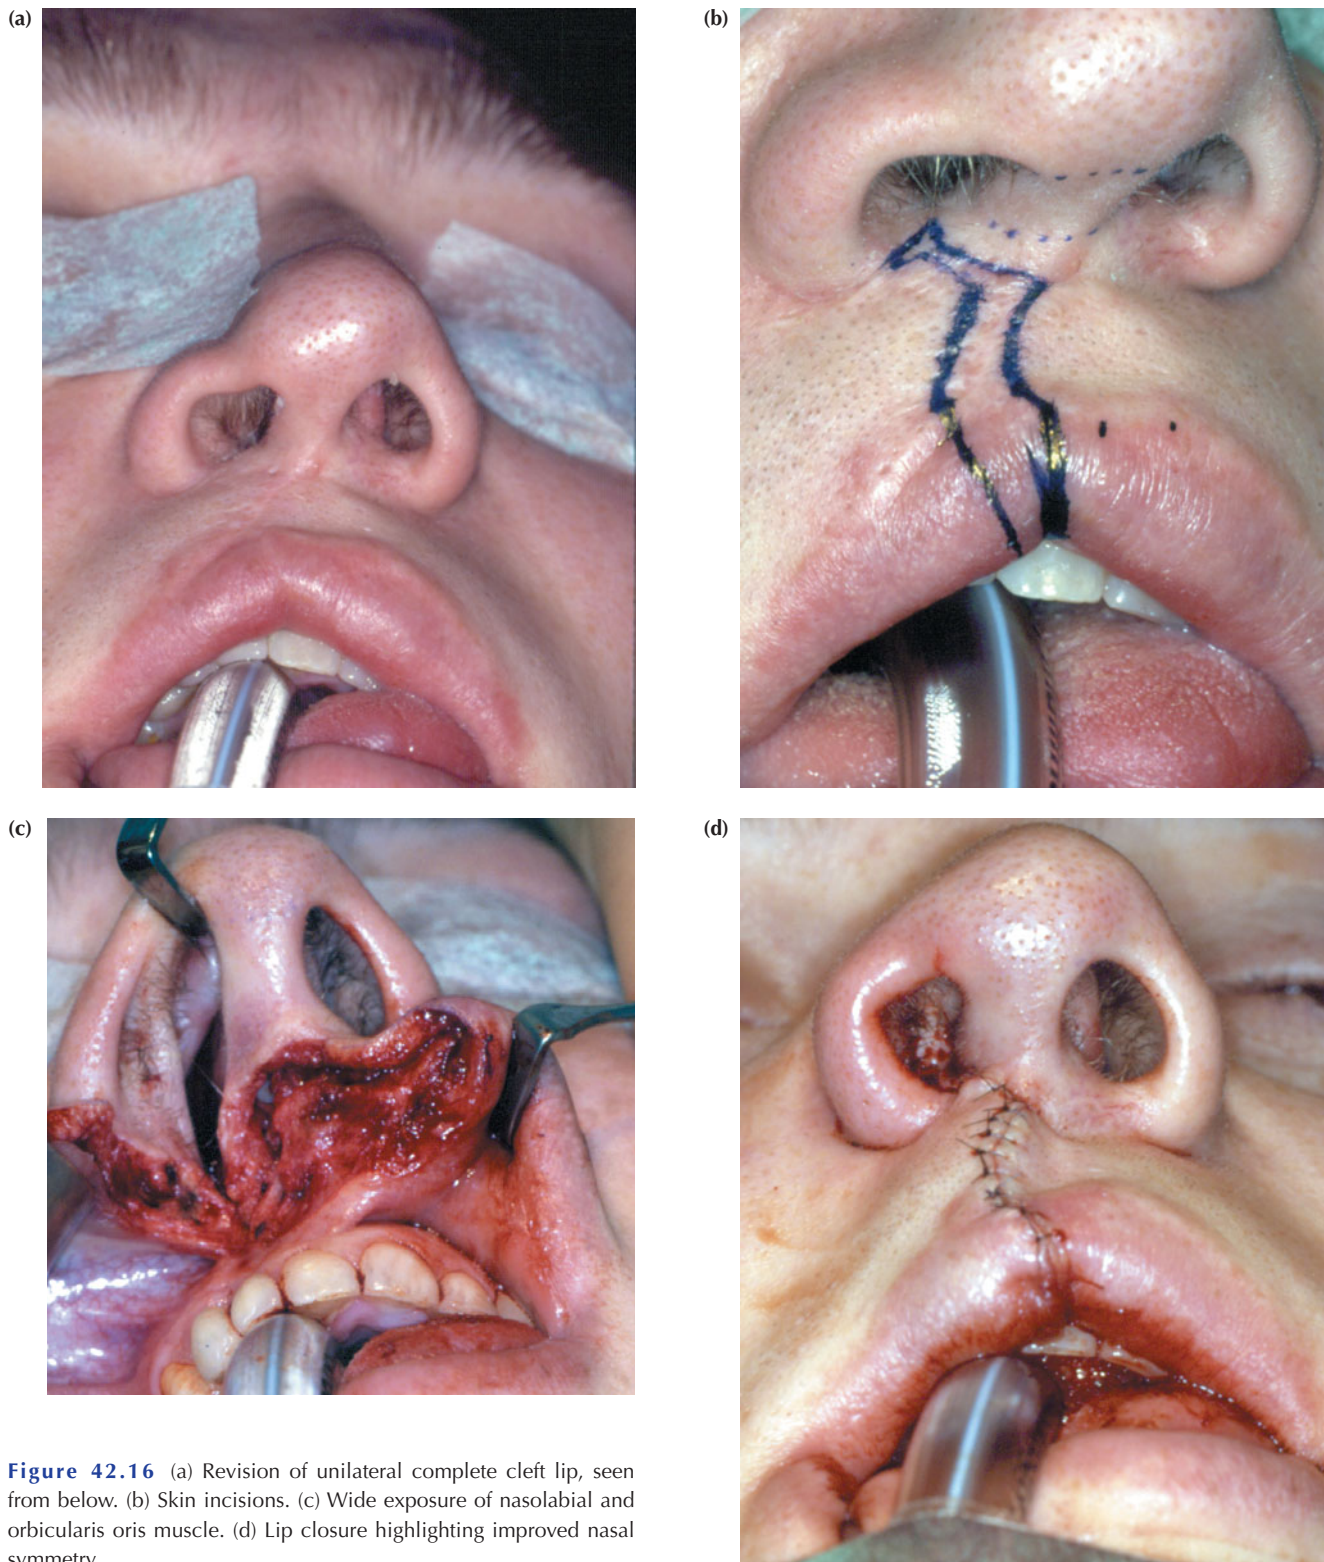

Figure 42.16 (a) Revision of unilateral complete cleft lip, seen from below. (b) Skin incisions. (c) Wide exposure of nasolabial and orbicularis oris muscle. (d) Lip closure highlighting improved nasal symmetry.

with cleft lip and palate. The rationale for performing alveolar bone grafting includes:

- stabilisation of maxillary segments;
- to promote eruption of the canine tooth into the cleft site;
- to enhance bony support of the teeth adjacent to the cleft alveolus;

- to promote closure of the oronasal fistula;
- to close residual fistula of the anterior palate;
- to provide adequate bone stock to receive an osseointegrated dental implant where a tooth is congenitally absent.

Normally, but not universally, patients undergo a period of orthodontic treatment prior to bone grafting. The collapsed maxillary

Figure 42.17 (a) Asymmetrical Cupid's bow. Revision of unilateral cleft lip – skin markings. (b) Identification and realignment of orbicularis oris muscle. (c) Postoperative appearance.

segment is expanded orthodontically to widen the cleft alveolus. The surgery is best performed before the canine tooth erupts (between 8 and 11 years of age). There is a consensus that earlier bone grafting may be beneficial not only for the unerupted canine tooth but also to promote eruption and bony support to the adjacent central and lateral incisor when present. Alveolar bone grafting can also be performed simultaneously with secondary lip revision (Fig. 42.20).

Cancellous bone is harvested from either the iliac crest or

Figure 42.18 (a) Revision of bilateral cleft lip with reconstruction of nasolabial muscles. (b) Skin incisions and development of philtrum. (c) Postoperative view – improved nasal and lip symmetry.

tibial plateau. This is achieved either through an open approach or preferably through a small incision utilising a trephine. When the defect is very small, alternative bone sites, e.g. mental symphysis, are sometimes advocated. Bone grafting is a highly successful procedure when carried out in experienced hands, with over 90% of patients achieving acceptable interdental alveolar

Figure 42.19 (a) Revision of left unilateral cleft lip to correct nasal deformity. (b) Skin incision. (c) Postoperative view.

Figure 42.20 (a) Peroperative view of alveolar bone graft demonstrating defect in alveolus (arrow) (simultaneous lip revision). (b) Cancellous bone graft (arrow) packed into defect.

bone height, but it does require the interaction of surgeon and orthodontist. When the lateral incisor is absent and the canine tooth fails to erupt, surgical exposure of the canine tooth may be required to aid its eruption. It is a fundamental principle that, following alveolar bone grafting, efforts should be made to ensure that a tooth erupts into the alveolar bone graft site. Failure to provide a tooth in the alveolar bone graft site usually results in bony resorption in the long term. This can be overcome by the insertion of an osseointegrated implant into the grafted site, thereby preserving bone stock (Fig. 42.21) (Summary box 42.10).

Summary box 42.10

Alveolar bone grafting

- Aimed at supplementing orthodontic treatment
- Promotes normal eruption of canine and other teeth

Orthognathic surgery

Impaired growth of the midface (maxilla) is now attributed to poor and traumatic primary surgery. Surgical techniques must endeavour to minimise scarring, although in many cases patients have a genetic predisposition to poor midfacial growth. Elective maxillary advancement or bimaxillary surgery is often indicated

Figure 42.21 Radiographic appearance of an implant in an alveolar bone graft site.

to restore aesthetics and dental occlusal harmony. Orthognathic surgery is usually performed when facial growth is complete (16 years in female patients, 19 years in male patients).

The principal dentofacial deformity associated with cleft lip and palate is underdevelopment in both the horizontal and vertical direction of the maxilla. This leads to a pseudopognathism in late adolescence, which is not correctable by orthodontic fixed-appliance therapy alone. Patients needing orthognathic surgery can be identified as early as 10 years old, although planning and treatment does not commence until 14–15 years of age. Treatment with fixed appliances to align teeth in each dental arch is carried out over a period of 18–24 months as a prelude to orthognathic surgery. Orthognathic surgery may require maxillary osteotomy advancement alone (Fig. 42.15a and b, see p. 665) or bimaxillary osteotomy and genioplasty (Fig. 42.22). Rigid fixation with or without bone grafting of the maxilla is essential as cleft lip and palate patients undergoing orthognathic surgery have a high risk of a skeletal relapse as a result of the scarring associated with primary cleft lip and palate surgery.

Open septorhinoplasty

Following revisional cleft lip and palate surgery, orthognathic surgery and alveolar bone grafting, many patients still require definitive surgical nasal correction. In patients with cleft lip and palate, open rhinoplasty is preferred to gain access to the external cartilaginous framework, which is frequently deformed (Fig. 42.23). The principal deformity is a collapse of the lower lateral cartilage on the cleft side together with a dislocation of the cartilaginous septum into the non-cleft nostril. The open method ensures adequate access and repositioning of the cartilaginous framework as a tertiary procedure to improve nasal tip projection, correct septal deformity and relocate alar cartilages. A post-auricular onlay graft to the middle crus of the cleft nostril lower lateral cartilage may be required to enhance good nasal tip projection and symmetry (Summary box 42.11).

Summary box 42.11

Deformities requiring nasal reconstruction

- Collapse of the lower lateral cartilage on the cleft side
- Dislocation of cartilaginous septum into the non-cleft nostril

Figure 42.22 (a) Lateral view of an adult with previously repaired cleft lip and palate demonstrating mandibular prognathism and maxillary retrusion. (b) Postoperative appearance following maxillary advancement and mandibular setback surgery.

Summary

The management of children with cleft lip and palate is complex, requiring the skill of a multidisciplinary team. Each team should include professionals who are appropriately qualified with specialist training, treating an adequate number of patients per year. Meticulous record keeping of photography, radiology, dental casts

Figure 42.23 (a) Characteristic nasal deformity of a non-functional unilateral cleft lip repair. (b) Incisions for open rhinoplasty. (c) Exposure of the cartilaginous skeleton of the external nose. (d) Repositioning of external nasal cartilages to improve nasal tip projection.

and speech recordings are indispensable to permit regular audits and improve outcomes.

DEVELOPMENTAL ABNORMALITIES OF THE TEETH AND JAWS

Teeth

Developmental abnormalities of the teeth can be divided into:

- abnormality in number;
- defects of structure and size;
- disorders of eruption of teeth.

Number

Anodontia is the term that is strictly applied to congenital absence of all teeth, which may involve both deciduous and permanent dentition. This is a rare condition that is often hereditary.

Partial anodontia is a much more common disorder in which there is a failure of development of the primary or more commonly the secondary dentition. Teeth that are most frequently absent are the third molars (wisdom teeth), second premolars and maxillary lateral incisor teeth.

Partial anodontia is associated with certain systemic disorders:

- ectodermal dysplasia;
- Down's syndrome;
- cleft lip and palate.

Management of partial anodontia involves prosthetic replacement of the teeth, usually in combination with orthodontic treatment. Congenitally missing teeth can be replaced with removable prostheses, fixed prostheses or, more recently, the use of osseointegrated dental implants.

Additional teeth (*hyperdontia*) can occur alone or in association with other syndromes. Additional teeth are termed *supernumerary* teeth and are often impacted in the jaw with abnormal morphology. The most common site for supernumerary teeth is the maxillary incisor region, particularly in the midline (mesiodens). When additional teeth are of a similar morphology to the normal dentition, the term *supplemental* is appropriate. Supplemental teeth are common in the maxillary incisor and premolar regions, and less common in the wisdom tooth region when they are termed the fourth molars. Most supernumerary teeth are removed to encourage the eruption of the permanent dentition (Summary box 42.12).

Summary box 42.12

Problems with numbers of teeth

- Absent teeth can be replaced with prosthetic teeth, which may involve osseointegrated implants
- Supernumerary teeth are often impacted and are removed to allow eruption of secondary dentition

Defects of the structure of teeth

Structural changes of the teeth can occur as a consequence of genetic disorders or environmental factors.

Genetic disorders frequently include *amelogenesis imperfecta* and *dentinogenesis imperfecta*, which affect the enamel and dentine of the teeth respectively. Both of these conditions are characterised

by defects in both dentitions, in which all teeth are affected. In *amelogenesis imperfecta* the defects are variable and may involve changes in structure (hypoplasia) or in mineralisation (hypocalcification). The loss of enamel leads to rapid attrition of the teeth to gum level in early adolescence. *Dentinogenesis imperfecta* results in soft dentine associated with short roots. *Dentinogenesis imperfecta* is strongly associated with *osteogenesis imperfecta*.

Acquired conditions producing changes in the structure of the teeth may be either local or systemic. Local causes are usually the consequence of trauma to the deciduous predecessor tooth, which interferes with enamel formation (*amelogenesis*). Common examples of systemic causes that produce tooth structure disruption are:

- measles;
- rickets;
- hypoparathyroidism;
- tetracycline;
- fluoride (Summary box 42.13).

Summary box 42.13

Causes of defects of the structure of teeth

Congenital

- Amelogenesis imperfecta
- Dentinogenesis imperfecta

Acquired local

- Trauma

Acquired systemic

- Disease – measles, rickets
- Drugs – fluoride, tetracycline

Disorders of eruption

Both primary and secondary dentition erupt in a specific sequence, although the timing of eruption does vary from child to child. Delayed eruption of teeth may involve a single tooth or may involve the entire dentition.

Local factors

There are numerous factors that impair the eruption of a single tooth. These include:

- loss of space/overcrowding;
- additional teeth;
- dentigerous cysts;
- retention of deciduous tooth.

Systemic factors

These can prevent the eruption of multiple teeth. Examples of such conditions include:

- metabolic diseases – cretinism and rickets;
- osteodystrophies – cleidocranial dysostosis and fibrous dysplasia;
- hereditary gingival fibromatosis.

Management of unerupted teeth involves the removal of the obstruction to eruption, including supernumerary teeth, as well as the relief of crowding. Patients with cleidocranial dysostosis should undergo long-term follow-up with regular radiographic assessment. Supernumerary teeth, as and when they appear,

should be removed to encourage the eruption of permanent dentition in adolescence. Many patients with cleidocranial dysostosis require multiple operations to expose teeth and encourage eruption (Summary box 42.14).

Summary box 42.14

Management of unerupted teeth

- Remove obstruction to eruption
- Surgical exposure if eruption delayed

Jaws

Disproportionate growth between the maxilla and mandible can occur, which results in derangement of the dental occlusion. The occlusion can be classified into three different subtypes:

- class I: a normal relationship of upper and lower incisors and molar dentition;
- class II: the mandibular teeth are placed posterior to the maxillary teeth;
- class III: the mandibular teeth are placed anterior to the maxillary teeth.

This classification is usually, but not invariably, the consequence of aberrant skeletal development of the maxilla and mandible, such that in a class II condition there is usually an underdevelopment of the mandible (mandibular retrognathia), whereas in a class III condition there may be simultaneous overgrowth of the mandible (mandibular prognathism) and underdevelopment of the maxilla (maxillary hypoplasia).

In the Caucasian population the commonest deformity of the facial skeleton is an underdevelopment of the mandible (retrognathia), producing a skeletal class II relationship often associated with excessive vertical growth of the maxilla. Bimaxillary protrusion is rare but is a characteristic of African races.

Condylar hyperplasia is an idiopathic condition seen in patients between 15 and 30 years of age, in which there is hyperplasia of the neck of the mandibular condyle. This gives an asymmetrical growth to the jaw in both a vertical and horizontal plane.

Facial disproportionate growth is also a characteristic of many syndromes. Such syndromes include:

- Treacher-Collins' syndrome;
- Crouzon's syndrome;
- Apert's syndrome;
- Pierre Robin sequence.

Figure 42.24 (a) Profile of class II relationship with vertical growth of maxilla and mandibular retrognathia. (b) Preoperative occlusion with anterior or open bite. (c) Postoperative view following superior repositioning of maxilla, mandibular advancement and genioplasty. (d) Postoperative occlusion.

Octave Crouzon, 1874–1938, Physician, La Salpêtrière, Paris, France, described this condition in 1912.

Orthognathic surgery

Orthognathic surgery is the term given to the surgical correction of deformities of the jaw. It is usually undertaken in close cooperation between orthodontic and maxillofacial surgeons. Surgery is directed at simultaneously changing the position of both maxilla and mandible at the end of the growth period. This is termed bimaxillary osteotomy. Treatment planning usually commences at the age of 12–13 years, in which the orthodontist aligns the dental arches in correct relation for each jaw. This frequently results in an accentuation of the facial deformity at the end of the orthodontic phase of treatment. Treatment normally takes 2 years, in which orthognathic surgery is performed towards the end of orthodontic treatment, although orthodontic treatment in the form of fixed appliances usually continues postoperatively for up to 6 months after surgery. Surgical planning should be meticulous and involves clinical examination and cephalometric assessment in the form of radiograph analysis, as well as study model analysis, working in close cooperation with maxillofacial technologists.

Orthognathic surgery is generally carried out through intraoral incisions, in which the upper and lower jaws are mobilised by achieving osteotomy cuts with saws and drills (Fig. 42.24). Following mobilisation of the mandible and maxilla, the jaws are repositioned and held with titanium plates and screws placed through an intraoral approach. This frequently avoids the use of intermaxillary fixation and allows earlier function of the jaws as well as improved early dietary intake. Examples of orthognathic surgery are shown in Figs 24.25 and 42.26.

Patients with syndromic conditions such as hemifacial microsomia and Crouzon's and Treacher-Collins' syndromes require the services of a craniofacial surgeon. As these syndromes are extremely rare, management and surgery should only be carried out in designated centres. The principal treatment is to correct

the deformity from the cranium downwards, with correction of the cranial deformity within the first 3 years of life and correction of the residual midfacial and lower facial deformity in childhood and adolescence.

A relatively new innovation is the introduction of distraction osteogenesis in the management of craniofacial deformity. This technique, in its infancy within maxillofacial surgery, may greatly change and reduce the requirements for major surgery in patients with severe facial deformity (Summary box 42.15).

Summary box 42.15

Principles of orthognathic surgery

- Orthodontist aligns the dental arches
- Surgery then corrects the jaw deformity

The nose and sinuses

CHAPTER 43

LEARNING OBJECTIVES

To be familiar with:

- The basic anatomy of the nose and paranasal sinuses
- The principles of managing post-traumatic nasal and septal deformity
- The causes and management of epistaxis
- The diagnosis and management of nasal polyposis
- The clinical features of sinus infection and its treatment and potential complications
- The common sinonasal tumours, their presentation, investigation and principles of treatment

BASIC ANATOMY OF THE NOSE AND PARANASAL SINUSES

The supporting structures of the nose are shown in Fig. 43.1. The septum consists of the anterior quadrilateral cartilage, the perpendicular plate of the ethmoid and the vomer (Fig. 43.2). The lateral wall of the nasal cavity contains the superior, middle and inferior turbinates (Fig. 43.3). Opening onto the lateral nasal wall

Figure 43.1 The nasal skeleton.

Figure 43.2 The left side of the nasal septum.

Figure 43.3 The right lateral nasal wall.

are the ostia of all of the nasal sinuses except the sphenoid sinus (Figs 43.4 and 43.5)

The nasal fossae and sinuses receive their blood supply via the external and internal carotid arteries. The external carotid artery supplies the interior of the nose via the maxillary and sphenopalatine arteries. The greater palatine artery supplies the anteroinferior septum via the incisive canal. The contribution from the internal carotid artery is via the anterior and posterior ethmoidal arteries,

Figure 43.4 The right lateral nasal wall with turbinates removed to show the sinus ostia. A, insertion of superior turbinate; B, insertion of middle turbinate; C, insertion of inferior turbinate; SM, superior meatus; MM, middle meatus; IM, inferior meatus.

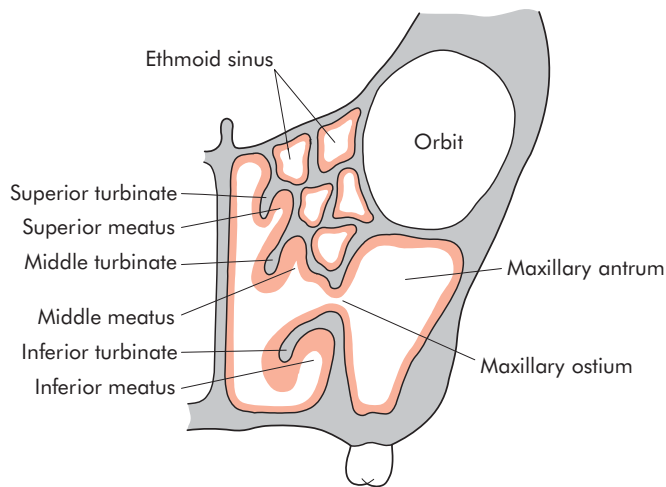

Figure 43.5 Coronal section through the left maxillary and ethmoid sinuses.

which are branches of the ophthalmic artery (Fig. 43.6). All of these arteries anastomose to form a plexus of vessels (Kiesselbach's plexus) on the anterior part of the nasal septum. Venous drainage is via the ophthalmic and facial veins and the pterygoid and pharyngeal plexuses. Intracranial drainage into the cavernous sinus via the ophthalmic vein is of particular clinical importance because of the potential for intracranial spread of nasal sepsis.

EXAMINATION OF THE NOSE AND PARANASAL SINUSES

Internal inspection of the nasal fossae can be achieved to a limited extent with the use of a Thudichum's speculum. A more thorough examination and assessment of the nose is possible with the use of either rigid or flexible endoscopes. Application of a vasoconstrictor/analgesic spray such as lidocaine hydrochloride 5% (w/v) with phenylephrine hydrochloride 0.5% (w/v) shrinks down the nasal mucosa and improves the view.

IMAGING OF PARANASAL SINUSES

Plain radiographs are of limited value in the assessment of sinus disease. A minimum of four views, namely occipitontental,

Figure 43.6 Arterial blood supply to the left side of the nasal septum.

Johann Ludwig Wilhelm Thudichum, 1829–1901, Biochemist and General Practitioner, London, England.

occipitofrontal, submentovertical and lateral, are required to demonstrate the paranasal sinuses adequately. Computerised tomography (CT) scanning is far superior in demonstrating sinus pathology. Coronal and axial scans are necessary for detailed assessment.

TRAUMA TO THE NOSE AND PARANASAL SINUSES

Fracture of the nasal bones

Blunt injury to the nose may fracture the nasal bones. This can be a simple crack of the nasal bones without displacement, but greater force may result in deviation of the bony nasal complex laterally (Fig. 43.7). A blow directly from the front may depress the bony pyramid or cause a comminuted fracture and widening of the bridge of the nose. The fracture line can extend into the lacrimal bone and tear the anterior ethmoidal artery producing catastrophic haemorrhage. This may be delayed, occurring only as the soft-tissue swelling subsides and the torn artery opens up.

Violent trauma to the frontal area of the nose can result in a fracture of the frontal and ethmoid sinuses extending into the anterior cranial fossa. Dural tears and brain injuries, which may be open or closed, are then at risk from ascending infection from the nose or sinuses. This may progress to meningitis or brain abscess.

Cerebrospinal fluid (CSF) rhinorrhoea is a certain sign of a dural tear. There may be associated surgical emphysema, proptosis with or without loss of vision, or a frontal pneumoencephalocele. Anosmia occurs in 75% of patients with these injuries and cranial nerves II–VI may be injured. A clear discharge from the nose may be identified as CSF by a simple stix test confirming the presence of glucose, which is not present in nasal mucus. Such injuries are managed by neurosurgical exploration to remove bone fragments, close the dura and repair the skull base. Late complications of this injury include CSF fistula, recurrent late

Figure 43.7 Fracture of the nasal bones with displacement of the bony nasal complex to the right side.

meningitis, brain abscess, osteomyelitis and the formation of mucopyocoeles.

Management of fractured nasal bones

Fractured nasal bones are often accompanied by extensive overlying soft tissue swelling and bruising, which may hinder the assessment of the underlying bony deformity. Reviewing the patient after 4–5 days when the soft tissue swelling has diminished will allow a better assessment of any deformity. If there is a significant degree of nasal deformity then this can be corrected by manipulation of the nasal bones under local or general anaesthesia. This should be carried out within 10–20 days of the injury while the bony fragments are still mobile. The deviated nasal bones are repositioned to restore the correct alignment of the nose or, in the case of a depressed fracture, the fragments are elevated and supported if necessary with anterior nasal packing. Often a satisfactory result can be obtained by manipulation alone but, should this fail, a rhinoplasty procedure may be necessary to obtain further improvement in the appearance of the nose.

Septal injury

A blunt injury of moderate force may lead to lateral displacement or deformity of the septal cartilage, restricting the nasal airway. A C-shaped fracture of the septal cartilage and the anterior portion of the perpendicular plate of the ethmoid bone is known as a Jarjavay fracture. Unlike the nasal bones the nasal septum cannot be manipulated back into position and requires a formal septoplasty procedure to restore the anatomy and the patency of the nasal airways.

Springing of the septal cartilage with separation of the overlying mucoperichondrium and subsequent bleeding into this potential space will cause a septal haematoma, which may be unilateral or bilateral. The haematoma will give rise to nasal obstruction and can easily be overlooked in the presence of extensive facial injuries. Untreated, a septal haematoma will progress to abscess formation and ultimately result in necrosis of the septal cartilage. Robbed of this support the tip of the nose will collapse. A septal haematoma should be treated by incision and evacuation of the blood clot. The insertion of a small silicone drain and packing of the nasal fossa will prevent reaccumulation and allow the mucoperichondrium to readhere to the septal cartilage. A broad-spectrum prophylactic antibiotic should be prescribed (Summary box 43.1).

Summary box 43.1

Nasal trauma

- Do not overlook a septal haematoma
- Displaced nasal bone fractures should be reduced within 10–20 days of injury
- Severe persistent epistaxis suggests lacrimal bone fracture and injury to the anterior ethmoid artery
- Cerebrospinal fluid rhinorrhoea indicates a fracture involving the frontal or ethmoid sinuses with a dural tear

Jean Francois Jarjavay, 1815–1868, Professor of Anatomy and Surgery, The Faculty of Paris, Paris, France.

THE NASAL SEPTUM

Septal deformity

In some individuals a naturally occurring deviated nasal septum may give rise to significant nasal obstruction. In others, minor nasal trauma is responsible for displacement of the septum and restriction of the nasal airway (Fig. 43.8). The physical obstruction of the nasal airway by a deviated septum is readily apparent on anterior rhinoscopy. Further encroachment of the anterior nasal airway can occur if the ventral edge of the septal cartilage is dislocated from the columella and projects into the nasal vestibule. Inferior turbinate hypertrophy is frequently seen on the concave side of a deviated nasal septum.

Septal deformity can be corrected by a septoplasty procedure or a submucous resection (SMR) of the septum. In the former procedure the septal cartilage is preserved but the anatomical abnormalities giving rise to its deformity, such as a twisted maxillary crest or inclination of the bony septum, are corrected. In the SMR procedure the deformed septal cartilage is excised while preserving the dorsal strut along with the anterior 5 mm of septal cartilage in order to support and maintain the normal shape of the nasal tip. Both operations are performed through a vertical incision of the septal mucosa with elevation of mucoperichondrial flaps.

Complications of septal surgery include septal perforation. If too much cartilage is excised in the SMR procedure, loss of support to the dorsum of the nose may result in a supra-tip depression or drooping of the tip of the nose.

Septal perforation

A hole in the nasal septum causes a turbulent airflow through the nose and a resulting sensation of nasal blockage. The causes of septal perforation are listed in Summary box 43.2. The most common cause is a complication of septal surgery when there is loss of cartilage and a bilateral breach in the mucoperichondrium.

Summary box 43.2

Causes of septal perforations

- Trauma
 - Surgical following septal surgery
 - Nose picking
- Infection
 - Syphilis
 - Tuberculosis
- Vasculitis
 - Wegener's granulomatosis
- Tumours
- Toxins
 - Chrome salts
 - Cocaine
- Idiopathic

Septal perforations seldom heal spontaneously. They give rise to extensive crusting at the margins of the perforation, often with mucosal bleeding. If situated to the front of the septum,

Friedrich Wegener, 1907–1990, Professor of Pathology, Lübeck, Germany, described this form of granulomatosis in 1939.

Figure 43.8 Coronal section through the anterior nasal fossae with deviated nasal septum to the right side.

embarrassing whistling can occur with nasal respiration. Crusting can be controlled to a degree with nasal douches or the use of topical antiseptic creams to minimise nasal drying. A great variety of operations have been described to close septal perforations but none has met with universal success. A more certain option is to occlude the perforation by inserting a Silastic biflanged prosthesis (Figs 43.9 and 43.10).

Wegener's granulomatosis is a systemic idiopathic autoimmune disease affecting the nose, lungs and kidneys. Mucosal granulations on the nasal septum destroy the cartilage, producing a septal perforation and a saddle deformity of the nose. Nasal symptoms include excessive crusting, blockage and serosanguinous discharge. Laboratory findings include a high erythrocyte sedimentation rate and may demonstrate impaired creatinine

Figure 43.9 Anterior and lateral views of septal perforation occluded with prosthesis.

Figure 43.10 Silastic prosthesis for septal perforation.

clearance. The presence of antineutrophil cytoplasmic antibodies (ANCA) is 80–100% sensitive in disseminated disease and 60–70% sensitive in upper airway disease.

EPISTAXIS

The causes of epistaxis are listed in Summary box 43.3. The most common site of bleeding is from Kiesselbach's plexus in Little's area of the anterior portion of the septum (see Fig. 43.6). Less often bleeding is from the lateral nasal wall. Anterior bleeding is common in children and young adults as a result of nose blowing or picking. In the elderly, arteriosclerosis and hypertension are the underlying causes of arterial bleeding from the posterior part of the nose. Epistaxis commonly occurs in elderly patients on warfarin or aspirin. Less common causes are trauma, foreign bodies within the nose, blood diseases, disorders of coagulation and malignant tumours of the nose or sinuses. Hereditary haemorrhagic telangiectasia (Osler's disease) gives rise to recurrent multifocal bleeding from thin-walled vessels deficient in muscle and elastic tissue (Fig. 43.11).

Juvenile angiofibroma is an uncommon condition that affects adolescent boys and may lead to massive life-threatening episodes of bleeding. It has a peak incidence between 14 and 18 years and can very rarely occur in adult men. It is a benign tumour that arises from the sphenopalatine fossa and expands into the nasopharynx as a smooth, lobulated red mass. The tumour extends aggressively through foramina and fissures into the ethmoid and sphenoid sinuses, orbit and skull base and eventually enters the cranial cavity. Lateral growth can occur into the infratemporal fossa (Summary box 43.3).

Summary box 43.3

Causes of epistaxis

Local

- Nose picking
- Nasal trauma
- Nasal foreign bodies
- Tumours
- Infection
- Granulomatous disorders
- Juvenile angiofibroma

Systemic

- Hypertension
- Warfarin therapy
- Aspirin therapy
- Haemophilia
- von Willebrand's disease
- Leukaemia
- Haemorrhagic telangiectasia

James Laurence Little, 1836–1885, Professor of Surgery, The University of Vermont, Montpelier, VT, USA.

Sir William Osler, 1849–1919, Professor of Medicine successively at McGill University, Montreal, Canada; The University of Philadelphia, Pennsylvania, PA, and The Johns Hopkins University, Baltimore, MD, USA, finally becoming Regius Professor of Medicine at Oxford University, Oxford, England in 1904.

Erik Adolf von Willebrand, 1870–1949, Physician, Diakonissanstaltens Hospital, Helsinki, (Helsingfors), Finland, described hereditary pseudo-haemophilia in 1926.

Figure 43.11 Osler's disease showing the multiple telangiectasia.

Diagnosis is made with contrast CT scanning or magnetic resonance imaging (MRI). Anterior bowing or indentation of the posterior antral wall (Holman–Miller or antral sign) is the classical finding but may be seen in other expansive lesions in this area. It is a very vascular tumour, which should not be biopsied because of the risk of uncontrollable haemorrhage. Excision is best carried out by a surgeon experienced in the management of the condition. Preoperative embolisation of the feeding blood vessels may help to reduce blood loss during surgery. Sometimes the tumour is managed with radiotherapy.

Management of epistaxis

Bleeding from Kiesselbach's plexus may be controlled by silver nitrate cauterisation under local anaesthesia. Posterior bleeding, as seen in the elderly, may require anterior nasal packing either with Vaseline-impregnated ribbon gauze or absorbable sponge. An alternative to anterior packing is the use of an inflatable epistaxis balloon catheter (Fig. 43.12). The catheter is passed into the nose and the distal balloon is inflated in the nasopharynx to secure it. The proximal balloon, which is sausage shaped, is then inflated within the nasal fossa to compress the bleeding point. Although usually effective they can be uncomfortable.

Sometimes anterior nasal packing alone is not sufficient to control haemorrhage and posterior nasal packing may be required. This is usually carried out under general anaesthesia by inserting a gauze pack into the nasopharynx, which is then secured by tapes passed through each side of the nose and tied

Figure 43.12 Epistaxis balloon catheter.

together across a protected columella. A third tape is brought out through the mouth and taped to the patient's cheek. The nasal fossae are then packed with anterior nasal packs. All packs are left in place for 48 hours and prophylactic antibiotics are given. The tape attached to the cheek is to facilitate removal of the pack, usually achieved without a general anaesthetic. Endoscopic-assisted cauterisation or clipping of a posterior bleeding point can be an effective alternative to nasal packing.

In uncontrolled life-threatening epistaxis in which the above methods have proved ineffective, haemostasis is secured by vascular ligation. Depending on the origin of bleeding it may be necessary to ligate the internal maxillary artery in the pterygo-palatine fossa and the anterior and posterior ethmoidal arteries. An alternative measure is external carotid artery ligation above the origin of the lingual artery.

In Osler's disease, anterior nasal packing is best avoided if at all possible because it is most likely to lead to further mucosal trauma and bleeding. High-dose oestrogen induces squamous metaplasia of the nasal mucosa and has been used effectively in treating this condition. In some cases it may be necessary to resort to excision of the diseased nasal mucosa via a lateral rhinotomy and replacement with a split-skin graft, a procedure known as a septodermoplasty. It is not unknown, however, for the grafted skin to undergo similar abnormal vascular change over time (Summary box 43.4).

Summary box 43.4

Epistaxis

- The commonest causes are nose picking, hypertension and anticoagulant therapy
- Young people bleed from the anterior septum – Kiesselbach's plexus
- Elderly people bleed from the posterior part of the nose
- Silver nitrate cauterisation is used to control anterior bleeding
- Moderate bleeding may require anterior nasal packing
- Severe bleeding may require anterior and posterior nasal packing
- Persistent bleeding may require endoscopic cauterisation/clipping or arterial ligation

NASAL POLYPS

Pathology

Nasal polyps are benign swellings of the ethmoid sinus mucosa of unknown origin. Histologically, the polyps contain a waterlogged stroma infiltrated with inflammatory cells and eosinophils. The majority of nasal polyps arise from the ethmoid sinuses, with each individual ethmoid air cell giving rise to a single polyp as its

swollen mucosal lining prolapses out of the air cell to hang down inside the nasal cavity. Polyps can arise from the other nasal sinuses and a single large polyp arising from the maxillary antrum is referred to as an antrochoanal polyp (Fig. 43.13). This usually fills the nose and eventually prolapses posteriorly down into the nasopharynx.

There is a clear association between nasal polyps and three distinct clinical conditions: asthma, aspirin sensitivity and cystic fibrosis. Samter's triad of nasal polyps, aspirin allergy and asthma is not uncommon; however, there is no conclusive evidence that polyps are caused by allergy. Several inflammatory mediators have been isolated from nasal polyps including vascular cell adhesion molecule (VCAM)-1, nitric oxide synthase and cys-leukotrienes (Cys-LT) but their role in the aetiology of polyps is unclear. Fungal colonisation of nasal mucosa has been implicated as a possible aetiological factor. Leukotriene, chemical mediators and interleukin inhibitors may have a role in the future management of nasal polyposis.

Clinical features

Patients present with nasal obstruction, watery rhinorrhoea, sinus infection and often anosmia. Polyps are easily identifiable within the nose as pale semitransparent grey masses, which are mobile and insensitive when palpated with a fine probe. This allows them to be distinguished from hypertrophied turbinates. If left untreated, extensive nasal polyposis will eventually cause expansion of the nose and the polyps may prolapse out through the nasal vestibule (Fig. 43.14).

Malignancy should be considered in adults with unilateral nasal polyps whereas in children such polyps must be distinguished from a meningocele or encephalocele by high-resolution CT scanning of the anterior cranial fossa. Nasal polyps are unusual in children and, if multiple, they occur in conjunction with cystic fibrosis in 10% of cases.

Management of nasal polyps

Medical treatment with systemic steroids will often reduce the size of nasal polyps and give short-term relief of nasal blockage. Unfortunately the polyps tend to recur when the treatment stops. Polyps occurring in association with cystic fibrosis are usually more resistant to systemic steroid treatment. Low-dose topical corticosteroid nasal sprays may reduce the growth of nasal polyps

Figure 43.13 Antrochoanal polyp.

Figure 43.14 Nasal polyp in right nasal vestibule.

but are relatively ineffective in massive nasal polyposis. They can be useful in retarding the regrowth of polyps after surgical removal. If nasal steroid sprays are used in children, monitoring is required to avoid potential growth suppression.

Surgical treatment is required in patients with severe nasal obstruction and pansinusitis that is refractory to medical treatment. Polyps may be removed either by avulsion with a nasal snare or endoscopically with a powered nasal microsector. (Fig. 43.15). Antral lavage should be performed at the same time. Preoperative CT scans allow evaluation of any anatomical variations and changes caused by polyposis or previous surgery. The objective is to remove all of the polypoid disease and provide adequate sinus ventilation. All polyps should be submitted for histological examination.

Polyps often recur after surgery in a seemingly random and unpredictable way, sometimes within a few months or even after several years. Long-term treatment with a low-dose topical steroid nasal spray postoperatively lessens the tendency for polyps to recur. After multiple recurrences, external ethmoidectomy should be considered (Summary box 43.5).

Figure 43.15 Powered nasal microsector.

Summary box 43.5

Nasal polyps

- Polyps are insensitive to touch and are mobile
- Simple polyps are bilateral
- Unilateral nasal polyps should be removed for histology
- Bleeding polyps may indicate malignancy
- Meningocele and encephalocele must be excluded in children with polyps
- Polyps can be removed with a snare or a powered microretractor
- Recurrent polyps may require external ethmoidectomy
- Transitional papilloma may mimic simple nasal polyps
- All polyps should be submitted for histology

MAXILLARY SINUSITIS

Clinical features

Local disorders such as nasal polyps, deviated nasal septum or upper dental sepsis may predispose to sinus infection. Patients with persistent maxillary sinusitis have mucopurulent postnasal discharge, headache, which is variable in severity and location, facial pain and nasal obstruction. Irritation of the superior alveolar nerve may give rise to referred upper toothache. The nasal mucosa is swollen and bathed in mucopurulent secretions. Plain sinus radiographs may show a fluid level in the antrum or complete opacity (Fig. 43.16).

The most likely causative organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. As the infection becomes chronic the likelihood of anaerobic infection increases. The consideration of *Branhamella catarrhalis* as a primary pathogen and the possible involvement of β -lactamase-producing strains of *H. influenzae* will influence the choice of antibiotic treatment. About 10% of infections of the maxillary antrum are caused by dental sepsis from anaerobic organisms. The resultant mucopurulent

Figure 43.16 Plain radiograph showing the fluid level in the left maxillary antrum and total opacity of the right antrum.

nasal secretion has a foul taste and smell. Complications of maxillary sinusitis include acute cellulitis or osteitis.

Treatment

Adequate penetration of antibiotics into chronically inflamed sinus mucosa is doubtful and, therefore, treatment may need to be prolonged. Topical nasal decongestants such as ephedrine nasal drops will often encourage the sinus to drain.

Antral lavage under general anaesthesia allows confirmation of the diagnosis and provides the opportunity to obtain samples for bacteriology. The antrum is entered through the inferior meatus below the inferior turbinate where the bone separating the antrum from the nasal fossa is extremely thin and can be easily penetrated by a trocar and cannula (Fig. 43.17).

If infection has caused a significant degree of inflammation and fibrosis of the lining of the antrum then the natural ostium may be completely obstructed. In this situation an intranasal inferior meatal antrostomy may be fashioned to facilitate drainage from the antrum. Alternatively, intranasal endoscopic techniques may be employed to create a middle meatal antrostomy or enlarge the natural ostium. Endoscopic nasal surgery allows a more functional approach to diseases of the paranasal sinuses and the indications for radical antrostomy are on the decline. Areas of chronically diseased mucosa and infected granulation tissue hinder mucociliary transport and lymphatic drainage, leading to retained secretions and the perpetuation of infection. Endoscopic surgery directed towards the middle meatus and the ethmoid system allows precise removal of diseased mucosa with minimal trauma to adjacent tissues and leads to quicker healing with return to normal function. By removing fibrotic tissue from the narrow recesses within the nose, ventilation and internal drainage of the sinuses can be restored (Summary box 43.6).

Summary box 43.6

Maxillary sinusitis

- The most common causative organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*
- Anaerobic infection may result from dental sepsis
- Acute infection should be treated with antibiotics and topical decongestants
- Antral lavage is diagnostic and therapeutic
- Intranasal antrostomy or endoscopic middle meatal antrostomy may be required
- Complications of untreated infection include cellulitis, osteitis and involvement of the orbit

FRONTOETHMOIDAL SINUSITIS

When treated promptly with antibiotics and topical nasal decongestants this type of sinus infection is unlikely to be a long-term problem. If allowed to persist, chronic frontoethmoiditis gives rise to mucopurulent catarrh, frontal headache or a feeling of pressure between the eyes, nasal obstruction and hyposmia. Nasal endoscopy will confirm pus issuing from the middle meatus. The ethmoid sinuses can only be properly assessed radiologically by CT scanning, including coronal as well as axial sections.

If frontoethmoiditis fails to settle with conservative treatment

TUMOURS OF THE NOSE AND SINUSES

There are a wide variety of tumours that can occur in the nose or paranasal sinuses. Tumours arising in the nasal fossa may present with unilateral nasal obstruction, persistent unilateral anterior rhinorrhoea, postnasal catarrh or epistaxis. These are common, non-specific symptoms and a high index of suspicion is required to avoid missing such a diagnosis. Unfortunately, the diagnosis is often delayed. Symptoms that may suggest the possibility of sinonasal malignancy include unilateral blood-stained rhinorrhoea, facial swelling and proptosis.

Benign tumours

Simple papillomas or viral warts can grow inside the nasal vestibule. They can be confused with carcinomas and are best excised for histological diagnosis.

Osteomas of the nasal skeleton are not uncommon and are usually detected on radiography as an incidental finding (Fig. 43.19). In symptomatic individuals the osteoma can be removed via the frontal sinus or an external ethmoidectomy.

Transitional cell papillomas can occur both in the nasal cavity and the nasal sinuses. They are sometimes referred to as inverted papillomas because histologically the hyperplastic epithelium inverts into the underlying stroma. The papillomas are covered with transitional epithelium. They can be quite extensive and give rise to nasal obstruction and sometimes epistaxis. They may be mistaken for simple nasal polyps. In 25% of cases the diagnosis is made by the pathologist after a routine nasal polypectomy. When large they can erode the lateral nasal wall and infiltrate the antrum or ethmoid

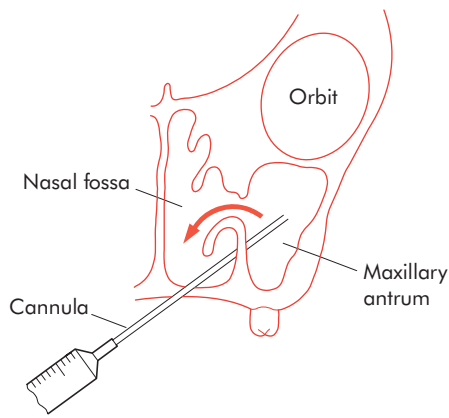

Figure 43.17 Diagram of left maxillary antral lavage.

then frontal sinus drainage may be required. Complications of frontoethmoiditis are potentially extremely serious. Orbital cellulitis (Fig. 43.18) may occur and can progress to an extra-periosteal abscess, which typically displaces the eyeball down, forwards and laterally. If unrecognised and untreated this can lead to blindness. Treatment consists of intravenous broad-spectrum antibiotics and orbital decompression by an external approach. Orbital cellulitis may also progress to cavernous sinus thrombosis and septicaemia. Spread of infection by direct bone penetration or via the diploic vein can give rise to extradural, subdural or frontal lobe abscess formation (Summary box 43.7).

Summary box 43.7

Frontoethmoiditis

- Assessment is best achieved by CT scanning
- It may require open surgical drainage
- Chronic infection may require an obliterative osteoplastic flap procedure
- Orbital infections may threaten sight
- Intracranial spread may cause meningitis, cerebral abscess or cavernous sinus thrombosis

Figure 43.18 Left periorbital cellulitis complicating acute left ethmoiditis.

Figure 43.19 Coronal computerised tomography scan showing a small osteoma in the right ethmoid sinus adjacent to the orbit.

sinus. Calcification within the tumour may be seen on CT scanning along with sclerosis of bone at the margins of the growth (Fig. 43.20). Transitional cell papillomas can undergo malignant change; synchronous lesions occur in 5–10% of cases whereas metachronous lesions develop in 1%. For this reason more radical surgery is employed than for simple polyps to ensure complete removal of all papillomata; this will usually involve a partial maxillectomy.

Malignant tumours

The most common malignant tumours to occur within the nasal cavity and paranasal sinuses are squamous cell carcinoma (Fig. 43.21), adenoid cystic carcinoma and adenocarcinoma. Adenocarcinoma has been linked to exposure to hard wood dust in the furniture industry. Adenoid cystic carcinomas arise from minor salivary glands, which can be found in the nose. Almost

50% of sinonasal cancers originate on the lateral nasal wall and 33% arise from the maxillary antrum. The incidence of ethmoid cancers is 5% and frontal/sphenoid cancers 2.5%.

Presenting symptoms include unilateral nasal obstruction, chronic nasal discharge, which is often haemorrhagic and offensive, and loss of skin sensation on the face (trigeminal nerve). There may be swelling of the cheek, buccal sulcus or medial canthus of the eye and a feeling of fullness or pressure within the nose or face. Suspicious signs of invasion of neighbouring tissues include diplopia, proptosis, loosening of the teeth (Fig. 43.22), trismus, cranial nerve palsies and regional lymphadenopathy.

A biopsy can be taken at the time of nasal endoscopy to provide a tissue diagnosis whereas assessment of bone erosion and the extent of the disease can be determined by CT scanning (Fig. 43.23).

Figure 43.20 Coronal computerised tomography scan showing extensive transitional cell papilloma involving the right maxillary antrum and ethmoid sinuses.

Figure 43.22 Maxillary antral carcinoma presenting through an oroantral fistula.

Figure 43.21 Squamous cell carcinoma of the nasal septum.

Figure 43.23 Axial computerised tomography scan of paranasal sinuses showing extensive maxillary antral carcinoma invading adjacent structures.

Patients with sinus or intranasal malignancy are best managed in a combined clinic where the expertise of ear, nose and throat (ENT) surgeons, maxillofacial surgeons and radiotherapists can be employed. Detailed surgical management is outside the scope of this book but the adequacy of any surgical resection will need to be confirmed by frozen section control of soft tissue margins. Surgery is followed by radiotherapy. At present, chemotherapy is reserved for possible palliation of inoperable tumours (Summary box 43.8).

Summary box 43.8

Tumours of the nose and sinuses

- A wide variety of tumour types can occur in the nose or sinuses
- Unilateral nasal blockage, discharge and bleeding are often presenting symptoms in nasal or sinus tumours
- Osteomas are often asymptomatic
- Transitional cell papilloma is the most common benign tumour – this tumour may undergo malignant change
- Squamous cell carcinoma is the most common malignant tumour
- Almost 50% of sinonasal cancers arise on the lateral nasal wall and 33% in the maxillary antrum
- Multidisciplinary management of malignant sinonasal tumours requires input from ENT surgeons, maxillofacial surgeons and radiotherapists

The ear

CHAPTER

44

LEARNING OBJECTIVES

To be familiar with:

- The anatomy of the ear
- The conditions of the outer, middle and inner ear
- The examination of the ear including hearing tests

To understand that:

- The outer layer of the tympanic membrane migrates outwards

- There are two types of chronic otitis media
- The facial nerve can be damaged by trauma and ear disease
- Chronic ear disease can lead to intracranial sepsis
- There are two types of hearing loss: conductive and sensorineural

INTRODUCTION

The mammalian ear is an evolutionary masterpiece. Its highly complex 'three-dimensional anatomy' is best learnt by dissecting cadaver temporal bones. In this chapter the 'surgical anatomy' is described followed by the conditions that affect the outer, middle and inner ear.

SURGICAL ANATOMY OF THE EAR

The external ear

The external ear consists of the pinna and the ear canal. The pinna is made of yellow elastic cartilage covered by tightly adherent skin. The external and middle ear develop from the first two branchial arches. The external ear canal is 3 cm in length; the outer two-thirds is cartilage and the inner third is bony. The skin on the lateral surface of the tympanic membrane is highly specialised and migrates outwards along the ear canal. As a result of this migration most people's ears are self-cleaning. The external canal is richly innervated and the skin is tightly bound down to the perichondrium so that swelling in this region results in severe pain.

The lymphatics of the external ear drain to the retroauricular, parotid, retropharyngeal and deep upper cervical lymph nodes.

The tympanic membrane and middle ear

The tympanic membrane has three layers: an inner mucosal layer, a dense fibrous middle layer and the outer stratified squamous epithelium. The upper portion that lies above the lateral process of the malleus is called the pars flaccida. The lower portion is called the pars tensa (Fig. 44.1).

The middle ear contains the ossicles. It is bounded laterally by the tympanic membrane, medially by the cochlea and anteriorly

by the Eustachian tube, and posteriorly it communicates with the mastoid air cells (Fig. 44.2). Entwined in this tiny space is the facial nerve, which pursues a tortuous course through the middle ear and exits the skull base at the stylomastoid foramen. The middle ear is separated from the middle fossa by a thin sheet of bone known as the tegmen.

The tympanic membrane and ossicles act as a transformer system converting vibrations in the air to vibrations within the fluid-filled inner ear.

The inner ear

The inner ear comprises the cochlea and vestibular labyrinth (sacculle, utricle and semicircular canals). These structures are embedded in dense bone called the otic capsule.

The cochlea is a minute spiral of two and three-quarter turns. Within this spiral, perilymph and endolymph are partitioned by the thin Reissner's membrane. The endolymph has a high concentration of potassium, similar to intracellular fluid, and the perilymph has a high sodium concentration and communicates with the cerebrospinal fluid (CSF). Maintenance of the ionic gradients is an active process and is essential for neuronal activity.

There are approximately 15 000 hair cells in the human cochlea. They are arranged in rows of inner and outer hair cells. The inner hair cells act as mechanoelectric transducers, converting the acoustic signal into an electric impulse. The outer hair cells contain contractile proteins and serve to tune the basilar membrane on which they are positioned.

Bartolomeo Eustachio, (Eustachius), ?1513–1574, was appointed Physician to the Pope in 1547, and Professor of Anatomy at Rome, Italy, in 1549.

Ernst Reissner, 1824–1878, Professor of Anatomy at Dorpat, and later at Breslau, Germany, (now Wrocław, Poland), described the vestibular membrane of the cochlea in 1851.

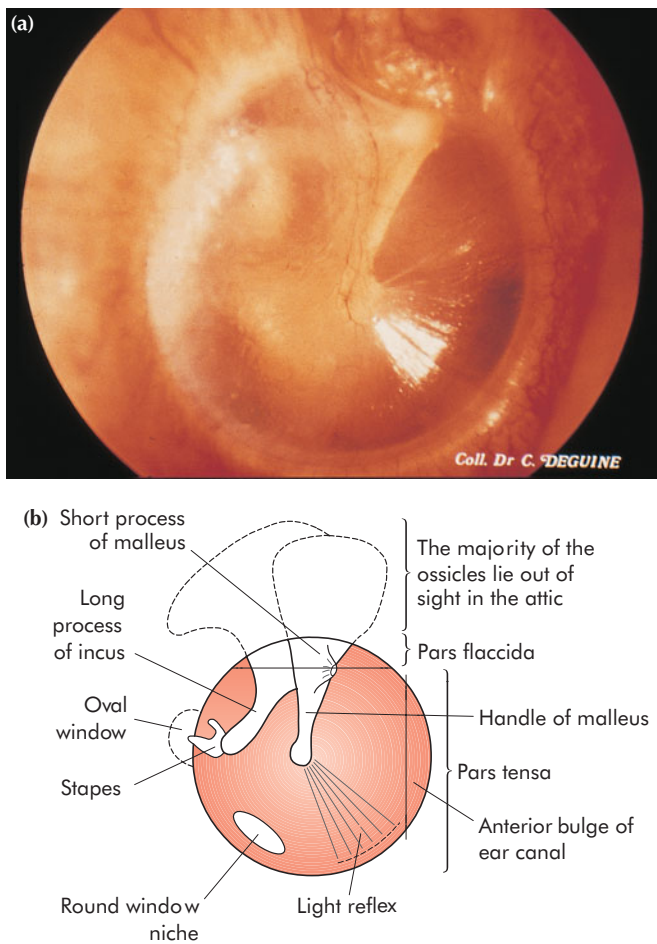

Figure 44.1 (a) Right tympanic membrane and (b) diagram to illustrate anatomy (courtesy of Dr Christian Deguine).

Each inner hair cell responds to a particular frequency of vibration. When stimulated, it depolarises and passes an impulse to the cochlear nuclei in the brainstem.

The vestibular labyrinth consists of the semicircular canals, utricle and saccule and their central connections. The three semicircular canals are arranged in the three planes of space at right angles to each other. Like the auditory system, hair cells are present. In the lateral canals, the hair cells are embedded in a gelatinous cupula. Shearing forces, caused by angular movements of the head, produce hair cell movements and generate action potentials. In the utricle and saccule the hair cells are embedded in an otocorial membrane that contains particles of calcium carbonate. These respond to changes in linear acceleration and the pull of gravity.

Impulses are carried centrally by the vestibular nerve and connections are made to the spinal cord, cerebellum and external ocular muscles.

The sensory nerve supply

The external ear is supplied by the auriculotemporal branch of the trigeminal nerve (Vth), which supplies most of the anterior half of the pinna and the external auditory meatus. The greater auricular nerve (C2/3), together with branches of the lesser occipital nerve (C2), supply the posterior part of the pinna. The VIIth, IXth and Xth cranial nerves also supply small sensory branches to the external ear; this explains why the vesicles of herpes zoster

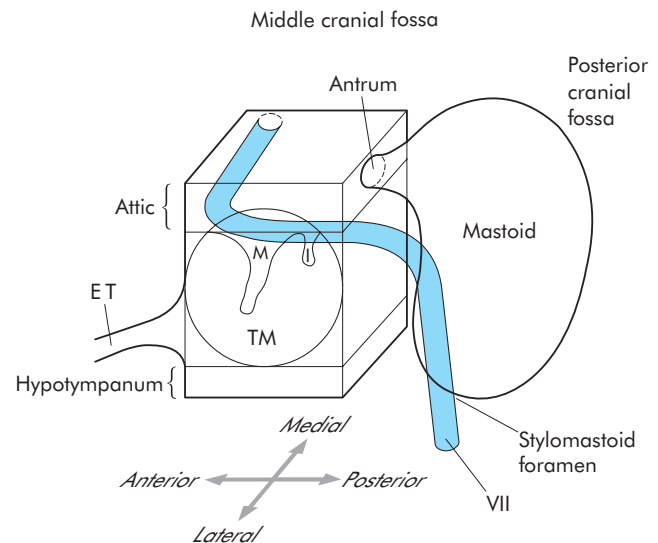

Figure 44.2 Diagram to show the relations of the middle ear (courtesy of Dr Christian Deguine). ET, Eustachian tube; M, malleus; TM, tympanic membrane; VII, facial nerve.

affecting the VIIth nerve appear in the concha (see Fig. 44.34, p. 701). The middle ear is supplied by the glossopharyngeal nerve (IXth).

This complicated and rich sensory innervation means that referred otalgia is common and may originate from the normal area of distribution of any of the above nerves. A classic example is the referred otalgia caused by cancer of the larynx (Summary box 44.1).

Summary box 44.1

Applied anatomy

- The skin on the outer surface of the eardrum migrates outwards so that the ear canal is 'self-cleaning'
- Infection of the middle ear and mastoid can easily spread to the cranial cavity
- The facial nerve pursues a tortuous course through the middle ear
- The ear has a rich sensory innervation so that 'referred otalgia' is common
- Cancer of the larynx can present with otalgia

Taking a thorough history is the most important part of the assessment; the symptoms that need to be enquired after are listed in the summary box below (Summary box 44.2).

Summary box 44.2

History taking

Ask about:

- Earache, pain and itch
- Hearing loss
- Discharge: type, quantity and smell
- Tinnitus
- Vertigo
- Facial movements
- Speech and development (in children)
- Past history: head injury, baro- or noise trauma, ototoxics, family history and previous ear surgery

EXAMINATION OF THE EAR

The tools of the trade are shown in Fig. 44.3. Examination of the ear is part of the general ear, nose and throat (ENT) examination. Make the patient comfortable and explain what you are going to do. Sit at the same height as the patient. Inspect the pinna and mastoid. The technique of otoscopy is shown in Fig. 44.4. Gently retract the pinna to straighten the ear canal. Systematically examine the canal, the pars tensa and pars flaccida. The mobility of the tympanic membrane can be tested with the pneumatic attachment. The Rinne and Weber tuning fork tests are used to

Figure 44.3 Tools of the trade: a fiberoptic otoscope, with pneumatic attachment and a selection of specula. Also a 512-Hz tuning fork.

Figure 44.4 The correct method of holding the otoscope: note the pinna is retracted to straighten the ear canal. Hold the barrel of the otoscope so that the examiner's little finger is balanced on the patient's cheek; this prevents the speculum impinging on the tympanic membrane in case of sudden movement.

Friedrich Heinrich Adolf Rinne, 1819–1868, German Otologist.
Friedrich E. Weber-Liel, 1832–1891, German Otologist.

distinguish between a conductive and a sensorineural hearing loss.

The Rinne and Weber tuning fork tests

A 512-Hz fork is used. In the Rinne test the tuning fork is placed behind the ear and then in front and the patient is asked in which position the fork sounds loudest. In a normal test, air conduction (in front) is better than bone conduction. When the bone conduction is heard better than the air conduction the most common reason is a conductive hearing loss; however, occasionally this abnormal result can occur when there is a dead ear. In this scenario, sound is transmitted across the bony skull and heard in the other ear.

In the Weber test the vibrating fork is placed in the midline (forehead) and the patient is asked to indicate in which ear the sound is loudest. Normally the sound is heard in the middle but if a conductive hearing loss is present on one side the sound localises to that side. Alternatively, if one ear has a sensorineural hearing loss the sound lateralises to the better cochlea.

The cranial nerves and especially the function of the facial nerve should be examined.

Although conversational testing can give a useful guide to the level of hearing, pure tone audiometry in a soundproof booth is the best way of establishing the air and bone hearing levels (Fig. 44.5). Other common audiological tests include speech audiometry, tympanometry, stapedial reflexes, electric response audiometry, otoacoustic emissions, caloric testing and electronystagmography (see Further reading).

Radiological investigation

Computerised tomographic (CT) scanning of the temporal bones is routinely used preoperatively to show detailed individual anatomy, as well as alerting the surgeon to anatomical variants. Pus, bone and air are shown well on high-resolution CT and so this is the imaging method of choice for investigating cholesteatoma and bony abnormalities (Fig. 44.6).

Magnetic resonance imaging (MRI) is better than CT at imaging soft tissue (e.g. facial and auditory nerve) and is the best method for imaging tumours of the acoustic nerves (Fig. 44.7).

Figure 44.5 Audiometry: the patient sits in a soundproof room and the audiologist presents sounds at different thresholds and records the responses.

Figure 44.6 The CT scan shows a normal left ear; note the air filled middle ear and the incus and stapes and the lateral and semicircular canals and IAM can be seen. In the right ear the entire middle ear and mastoid is opaque and filled with soft tissue. This is the typical appearance of cholesteatoma.

Figure 44.7 The MRI image is a high resolution T2-weighted image at the level of the IAMs showing an intra-cannicular acoustic neuroma (AN) on the left and a normal IAM on the right (Courtesy of Dr Peiter Petorius).

CONDITIONS OF THE EXTERNAL EAR

Congenital anomalies

Congenital anomalies can range from total absence of the ear through to minor cosmetic deformities. The external and middle ear originate from the first and second branchial arches, whereas the cochlea is of neuroectodermal origin. This means that an individual may have a gross deformity of the external and/or middle ear but a normal cochlea. In these circumstances, sound can be transmitted from a hearing aid connected to an osseointegrated peg that is screwed into the mastoid bone. This type of device is known as a bone-anchored hearing aid (BAHA).

Children who have a significant deformity of the pinna (microtia) can be helped with osseointegrated implants to which a prosthetic ear is connected (Fig. 44.8). The prosthetic ear can be unclipped before playing violent sport, for example rugby, and this unsettles the opposition (Summary box 44.3)!

Figure 44.8 This young man can remove his prosthetic right ear, which is attached to an osseointegrated stud, before playing rugby.

Summary box 44.3

Congenital anomalies of the external ear

- The external and middle ear originate from the first and second branchial arches but the cochlea is neuroectodermal in origin
- An individual can have a congenital abnormality of the pinna and middle ear with a normal cochlea and, therefore, the potential for normal hearing. Haematoma of the pinna needs draining and a pressure dressing
- Osseointegration allows a prosthetic ear and hearing aid to be attached to the skull

Pre-auricular sinuses are a common congenital abnormality and occasionally need excising because of recurrent infections and discharge. Prominent ears can be corrected by scoring the cartilage to create a fold.

Trauma

A haematoma of the pinna occurs when blood collects under the perichondrium. The cartilage receives its blood supply from the perichondrial layer and will die if the haematoma is not evacuated, resulting in a cauliflower ear. A generous incision under general anaesthetic, with a pressure dressing or compressive sutures and antibiotic cover, is recommended (Fig. 44.9).

Figure 44.9 Haematoma of the pinna.

Foreign bodies in the ear canal need to be treated with the greatest respect. If an object is not easily removed at the first attempt it is better to do it with the aid of a microscope and general anaesthesia. An active 2-year-old with a bead in the ear can be a formidable opponent (Fig. 44.10) (Summary box 44.4).

Summary box 44.4

Trauma of the external ear

- A haematoma of the pinna requires thorough drainage, antibiotics and a compressive dressing or sutures
- A 2-year-old with a foreign body in the ear canal is a formidable opponent; consider general anaesthesia.

Inflammation

Otitis externa is common and consists of generalised inflammation of the skin of the external auditory meatus. The cause is often multifactorial but includes general skin disorders, such as psoriasis and eczema, and trauma. Common pathogens are *Pseudomonas* and *Staphylococcus* bacteria, *Candida* and *Aspergillus*. Once the skin of the ear canal becomes oedematous, skin migration stops and debris collects in the ear canal. This acts as a substrate for the pathogens. The hallmark of acute otitis externa is severe pain (apparently on a par with childbirth). Movement of the pinna elicits pain, which distinguishes it from otitis media.

Figure 44.10 Removal of a foreign body from the ear canal can be a challenge (courtesy of Dr Christian Deguine).

The initial treatment is with topical antibiotics and steroid ear drops, together with analgesia. If this fails, meticulous removal of the debris with the aid of an operating microscope is required. Fungal infection can be recognised by the presence of hyphae within the canal (Fig. 44.11). Fungal infection causes irritation and itch. The treatment is meticulous removal of the fungus and any debris, as well as stopping any concurrent antibiotics.

Systemic antibiotics are rarely required for otitis externa but should be used if cellulitis of the pinna occurs (Fig. 44.12).

Necrotising otitis externa is a rare but important condition. It presents as a severe, persistent, unilateral otitis externa in an immunocompromised individual. It is important to think of the diagnosis in an elderly diabetic patient. Usually the infecting organism is *Pseudomonas aeruginosa*. Osteomyelitis of the skull base occurs and several cranial nerves (VII, IX, X) may be destroyed by the progressing infection. Intensive systemic antibiotics are required and the disease process should be monitored by high-resolution imaging (Summary box 44.5).

Figure 44.11 Fungal otitis externa; note the spores.

Figure 44.12 Cellulitis of the pinna.

Summary box 44.5

Types of otitis externa

- Acute bacterial otitis externa is very common and extremely painful; treat with topical steroids and topical antibiotics
- Systemic antibiotics should be reserved for cellulitis of the pinna
- Chronic otitis externa needs the underlying dermatitis to be treated; topical steroid in spirit applications is recommended
- Fungal otitis externa itches and can be diagnosed by the presence of hyphae and spores; treat with meticulous cleaning and stop antibiotics
- Necrotising otitis externa is a progressive skull base infection that occurs in immunocompromised individuals and can be life-threatening; intensive long-term antibiotic treatment is required

Neoplasms

Benign osteomas arise from the bone of the ear canal in individuals who swim in cold water (Fig. 44.13). No treatment is required unless the osteomas obstruct the canal. Other benign tumours include papillomas and adenomas.

Malignant primary tumours of the external ear are either basal cell or squamous cell carcinomas (Fig. 44.14). Both may present as ulcerating or crusting lesions that grow slowly and may be ignored by elderly patients. Squamous cell carcinomas metastasise to the parotid and/or neck nodes. The ear canal may be invaded by tumours from the parotid gland and post-nasal space

Figure 44.13 Osteomas grow from the bony part of the ear canal in response to cold and so are found in swimmers, surfers and divers. Treatment is only required if the osteomas occlude the ear canal.

Figure 44.14 Squamous cell carcinomas of the external ear usually originate from the pinna; in this case the tumour is growing from the canal (courtesy of Mr P. Beasley).

carcinomas, which ‘creep’ up the Eustachian tube. All resectable malignant tumours of the ear are treated primarily with surgery, with or without the addition of radiation therapy.

CONDITIONS OF THE MIDDLE EAR

Congenital anomalies

Congenital anomalies of the middle ear may be associated with other general congenital deformities. There are a number of branchial arch syndromes, e.g. Pierre Robin’s, craniofacial dysostosis, Down’s and Treacher Collins’ syndromes. If there is an

Pierre Robin, 1867–1950, Professor, The French School of Dentistry, Paris, France, described this syndrome in 1929.

John Langdon Haydon Down, (sometimes given as Langdon-Down), 1828–1896, Physician, The London Hospital, England, published his classification of aments in 1866.

Edward Treacher Collins, 1862–1932, Ophthalmic Surgeon, The Royal London Ophthalmic Hospital, and Charing Cross Hospital, London, England, described this syndrome in 1900.

external ear abnormality it should raise suspicion of an underlying middle ear deformity. Middle ear deformity can be assessed by high-resolution CT scanning and, if the inner ear is normal, reconstructive surgery of the middle ear can be successful.

Trauma

Trauma to the middle ear can result in a perforated tympanic membrane (Fig. 44.15a). Such perforations usually heal spontaneously (Fig. 44.15b). Trauma can also result in ossicular discontinuity and it is usually the incus that is displaced. Tympanoplasty operations are available to reconstruct the damaged ossicular chain and repair the tympanic membrane (Summary box 44.6)

Summary box 44.6

Congenital anomalies and trauma of the middle ear

- Congenital anomalies may be isolated or associated with general congenital deformities
- CT can identify middle ear abnormalities that may be corrected by surgery
- Traumatic perforations of the tympanic membrane usually heal spontaneously but explosive and welding injuries do not
- A myringoplasty is an operation that repairs the tympanic membrane
- With severe head trauma the incus can be displaced, which leads to a conductive hearing loss

Suppurative otitis media

Suppurative otitis media is extremely common in childhood and is characterised by purulent fluid in the middle ear. Mastoiditis may be associated with otitis media because the mastoid air cells connect freely with the middle ear space. The tympanic membrane bulges because of pressure from the pus in the middle ear (Fig. 44.16). The child suffers extreme pain until the tympanic membrane bursts. The most common infecting organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Appropriate systemic antibiotics should be given for 10 days.

Mastoiditis (Fig 44.17) requires hospital admission and intravenous antibiotics. If the infection does not resolve quickly, a cortical mastoidectomy is required, together with a myringotomy.

Otitis media with effusion (glue ear)

The majority of children experience at least one episode of glue ear. It is primarily thought to be caused by poor Eustachian tube function. Oxygen is continually being absorbed by the middle ear mucosa and this results in a negative middle ear pressure unless the Eustachian tube opens to replenish the air. This negative middle ear pressure initially results in transudation of fluid into the middle ear space (Fig. 44.18). If the hypoxia continues, a mucoid exudate is produced by the glands within the middle ear mucosa. This sticky exudate is referred to as 'glue ear'.

The following symptoms may be associated with glue ear:

- hearing impairment, which often fluctuates;
- delayed speech;
- behavioural problems;
- recurrent ear infections, which occur because the exudate is an ideal culture medium for micro-organisms;
- reading and learning difficulties at school.

Figure 44.15 (a) Traumatically perforated tympanic membrane. (b) The same tympanic membrane 2 days later (courtesy of Dr Christian Deguine). [Reproduced from O'Donoghue, G.M., Bates, G.J. and Narula, A. (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.]

Figure 44.16 Acute otitis media of the left ear; note the bulging tympanic membrane.

Figure 44.17 Child with acute mastoiditis whose tympanic membrane is shown in Fig. 44.16.

Figure 44.18 The initial serous transudate of glue ear, left ear (courtesy of Dr Christian Deguine). [Reproduced from O'Donoghue, G.M., Bates, G.J. and Narula, A. (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.]

The otoscopic findings with glue ear

The otoscopic findings of exudative glue ear are of a dull drum that is immobile on pneumatic otoscopy. The tympanic membrane is retracted and radial blood vessels may be present (Fig. 44.19).

In children first presenting with bilateral glue ear, 50% will be better within 6 weeks. Initially, a 'wait and watch' policy is

Figure 44.19 (a) Left exudative glue ear. The tympanic membrane is dull and retracted. The light reflex has gone and there are radial blood vessels. The drum does not move with pneumatic otoscopy. (b) Right ear. Advanced exudative glue ear with retraction pockets (courtesy of Dr Christian Deguine). [Reproduced from O'Donoghue, G.M., Bates, G.J. and Narula, A. (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.]

therefore appropriate. If a bilateral conductive hearing loss persists, the child will miss out on educational opportunities and may not fulfil his or her academic potential; in these circumstances treatment is required.

Medical treatment is of limited value. The Otovent device (Fig. 44.20) may improve Eustachian tube function and is worth trying. However, surgical intervention is the only effective way of curing glue ear. Both ventilation tubes (grommets) (Fig. 44.21) and adenoidectomy are effective. The controversy is not whether surgery works but when to intervene.

Insertion of ventilation tubes and/or an adenoidectomy requires a general anaesthetic. The ventilation tube is placed in the anterior inferior portion of the tympanic membrane. The ventilation tubes stay in position for approximately 6–18 months and are then extruded because of the migratory behaviour of the tympanic membrane. There is no reason why children with ventilation tubes should not be allowed to swim.

A middle ear effusion in adults is relatively rare and, when it occurs, it does not usually last long. The condition is often

Figure 44.20 Otovent device demonstrated by the author.

Figure 44.21 Ventilation tube in tympanic membrane, left ear (courtesy of Dr Christian Deguine).

associated with an upper respiratory tract infection. A persistent unilateral effusion in an adult should always be viewed with suspicion. A nasopharyngeal carcinoma may cause the effusion by blocking the opening of the Eustachian tube in the post-nasal space. This is the most common carcinoma in men in southern China (Summary box 44.7).

Summary box 44.7

Acute suppurative otitis media and glue ear

- Acute suppurative otitis media can progress to mastoiditis
- Glue ear is very common in children and usually resolves without treatment
- Persistent hearing loss and/or recurrent acute otitis media is best treated with grommets and/or an adenoidectomy
- A persistent middle ear effusion in an adult is rare and may be caused by a cancer of the post-nasal space, especially in Chinese and Asian races

Chronic suppurative otitis media

Chronic suppurative otitis media (CSOM) is classified into two types: (1) tubotympanic disease, in which there is a perforation of the pars tensa; and (2) atticoantral disease, in which a retraction pocket develops from the pars flaccida.

Tubotympanic CSOM results from trauma or infection. When perforated the tympanic membrane usually repairs itself but if the outer layer of the tympanic membrane fuses with inner mucosa a chronic perforation results (Fig. 44.22). The patient's main symptoms are of an intermittent mucoid discharge associated with a mild conductive hearing loss. It is rare for this type of disease to be associated with intracranial complications.

A diagnosis is made on otoscopy and the tuning forks usually suggest a conductive hearing impairment. The first-line treatment is topical antibiotics and steroid drops and, on occasion, microsuction. If medical treatment fails the patient may request

Figure 44.22 (a) Tubotympanic chronic suppurative otitis media showing central perforation, right ear. (b) Anatomy (courtesy of Dr Christian Deguine).

an operation to graft the tympanic membrane. This operation is termed a myringoplasty (type I tympanoplasty). The edges of the perforation are freshened and a small piece of temporalis fascia is inserted under the tympanic membrane to graft the drum. The raw epithelial edges then grow across the graft to repair the tympanic membrane.

Atticoantral CSOM (also known as cholesteatoma) is important because of the complications associated with it. The exact aetiology of cholesteatoma is not known although poor Eustachian tube function is implicated. Patients with cleft palates have relatively poor Eustachian tube function and have a higher incidence of cholesteatoma.

A retraction pocket develops in the pars flaccida and, if the squamous epithelium cannot migrate out of this pocket, a cholesteatoma results. A low-grade osteomyelitis results in the release of fatty acids from the bone, which gives the discharge its characteristic faecal smell. Invariably, the discharge is accompanied by hearing loss and mild discomfort. The patient may simply put up with these symptoms until a severe complication occurs.

The hearing loss that is caused by cholesteatoma may be conductive as a result of ossicular erosion or sensorineural as a result of cochlea damage. Vestibular symptoms may occur because of erosion of the semicircular canals or the migration of toxins into the vestibule. Erosion of the facial nerve is relatively unusual.

The close proximity of the middle ear and mastoid to the middle and posterior cranial fossae means that intracranial sepsis can result from chronic ear disease. The infection spreads to the dura via emissary veins, which connect the middle ear mucosa to the dura, or by direct extension of the disease through the bone. Meningitis, extradural, subdural or intracerebral abscess, or a combination of these may occur. Diagnosis should be suspected on otoscopy (Fig. 44.23). Pus, crusts, granulations or a whitish debris in the attic are hallmarks of the disease. Examination under the microscope, audiometry and, sometimes, CT scanning are indicated.

The treatment is surgical and follows the principle of exposing the disease, excising the disease and then exteriorising the affected area. Three commonly applied operations for this disease are an atticotomy, modified radical mastoidectomy or combined approach tympanoplasty (Summary box 44.8).

Summary box 44.8

Chronic suppurative middle ear disease

There are two main types of CSOM:

- Tubotympanic CSOM, in which there is a hole in the eardrum and frequently a mucoid discharge; this is seldom serious
- Atticoantral CSOM (cholesteatoma). In this condition, squamous epithelium has invaded a retraction pocket in the attic part of the eardrum and is known as a cholesteatoma. Presents with hearing loss and faecal smell from the ear. It is a common cause of intracranial sepsis

Tuberculous otitis media

This is an important cause of suppuration in many countries. The diagnosis should always be considered in any ear that fails to respond to standard therapy. A swab for appropriate culture studies, coupled with chest radiography, will usually confirm the diagnosis.

Otosclerosis

This is a condition in which new abnormal spongy bone is laid down in the temporal bone. Of particular importance is the bone that is laid down around the footplate of the stapes, which impedes the mobility of the stapes and results in a conductive hearing loss (Fig. 44.24). Toxins released from the new bone formation may also cause a gradual sensorineural hearing loss. Otosclerosis is more common in women and in 50% of patients

Figure 44.23 (a) Empty attic retraction pocket, right ear. (b) Attic crust covering cholesteatoma, right ear. (c) Attic erosion with cholesteatoma, right ear.

Figure 44.24 Section of normal stapes (a) and section of stapes affected by otosclerosis (b).

there is a family history. The typical presentation is of a conductive hearing loss in a young woman, with the condition being exacerbated by the hormonal flux of pregnancy. A similar type of stapes fixation occurs in osteogenesis imperfecta and is known as van der Hoeve's syndrome. Otosclerosis is often bilateral. A diagnosis should be suspected in any patient with a conductive hearing loss and a normal tympanic membrane.

The treatment options are simple reassurance, a hearing aid or a stapedotomy operation. The stapes crura are removed and a small hole is drilled in the fixed stapes footplate. A vein graft is then inserted over the hole and a piston linking the incus to the vein graft is delicately placed in position (Fig. 44.25). In 90% of cases the operation is highly successful but rare complications include severe sensorineural hearing loss and balance disturbance.

Neoplasms

Middle ear tumours are rare with the most common being a glomus tumour (Fig. 44.26). Glomus tumours arise from non-chromaffin paraganglionic tissue. The carotid body tumour arising in the neck is an example of this type of tumour. In the temporal bone, three types of glomus tumour are recognised and classification depends on the location: glomus tympanicum

J. van der Hoeve described this syndrome in 1918.

Figure 44.25 The stapedotomy operation showing the piston linking the incus to the vein graft, left ear.

Figure 44.26 Glomus tumour in the middle ear, left ear.

(arising in the middle ear), glomus jugularae (arising next to the jugular bulb) and glomus vagali (skull base).

Pulsatile tinnitus is a classic symptom and the hearing loss that occurs may be either conductive or sensorineural. Palsies of the VIIth, IXth, Xth, XIth and/or XIIth nerves may occur. The classic sign is a cherry-red mass lying behind the tympanic membrane. An audible bruit may be heard with a stethoscope over the temporal bone. The treatment of choice is preoperative embolisation followed by surgical excision. Radiotherapy is also effective.

Squamous cell carcinoma may also occur within the middle ear. It usually presents with deep-seated pain and a blood-stained discharge. Facial paralysis often occurs. Squamous carcinomas usually arise in a chronically discharging ear and can arise in a

chronically infected mastoid cavity. Radical surgical excision with or without radiotherapy provides the only chance of cure (Summary box 44.9).

Summary box 44.9

Neoplasms of the middle ear

- Highly vascular glomus tumours are rare and may present with pulsatile tinnitus
- Squamous cell cancer usually presents with pain and facial paralysis

CONDITIONS OF THE INNER EAR

Congenital anomalies

Congenital inner ear disorders may be associated with external or middle ear abnormalities or exist on their own. The most common anomaly is dysplasia of the membranous labyrinth, although dysplasia of the bony labyrinth and even total aplasia of the ear may occur. Intrauterine infections, including rubella, toxoplasmosis and cytomegalovirus infection, can cause inner ear damage. Perinatal hypoxia, jaundice and prematurity are also risk factors for a hearing loss. After birth, meningitis may cause profound sensorineural hearing loss.

If a child's parents suspect a hearing impairment it is important to believe them, especially when glue ear has been excluded. In children in whom there is a suspicion of sensorineural hearing loss, brainstem-evoked audiometry is used to establish hearing thresholds (Fig. 44.27). If some hearing is present, the early fitment of hearing aids can maximise the neural plasticity that is present in the developing brain. If a child has a profound hearing loss, early intervention with a cochlear implant is the ideal solution (Fig. 44.28). Most cases of profound sensorineural hearing loss are due to loss of cochlear hair cells, so that an implant inserted through the round window can selectively stimulate the cochlear neurones, which usually remain intact. The results of cochlear implantation are miraculous but it is expensive technology.

Figure 44.27 Evoked-response audiometry. A simple non-invasive objective test of hearing thresholds. [Reproduced from O'Donoghue, G.M., Bates, G.J. and Narula, A. (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.]

Figure 44.28 Multichannel cochlear implant (Cochlear Corporation).

Presbycusis

Presbycusis is characterised by a gradual loss of hearing in both ears, with or without tinnitus. The hearing loss usually affects the higher frequencies and a classical audiogram is shown in Fig. 44.29. The consonants of speech lie within the high-frequency range, which makes speech discrimination difficult. Examination of an elderly person's cochlea shows loss of hair cells, particularly at the basal turn of the cochlea. With ageing the dynamic range of hearing is also reduced so that elderly people often find loud noises uncomfortable. This phenomenon is known as 'recruitment'.

Many patients with presbycusis are concerned that they may lose their hearing completely and they need reassurance. Hearing aid technology has improved dramatically and most patients can benefit (Fig. 44.30). Care and attention to detail when fitting the hearing aid is essential, together with monitoring of the patient's progress. If this does not occur the hearing aid ends up in the bedroom drawer.

Tinnitus

Tinnitus is an abnormal noise that appears to come from the ear or within the head. It may have an extrinsic cause, for example the pulsatile tinnitus of a glomus tumour. Usually, however, the tinnitus is generated within the cochlea. Most people will experience tinnitus at some time in their lives. Tinnitus frequently accompanies presbycusis, as well as any other condition that damages the inner ear structures. Most individuals adapt to the presence of tinnitus but in some patients it proves intrusive. Reassurance and relaxation therapy are highly effective as are hearing aids for patients who also have presbycusis. An ENT surgeon who was a keen fisherman found that he could not hear his tinnitus when fishing next to a waterfall. From this observation, tinnitus maskers were developed (Fig. 44.31). A masker provides a similar noise to the tinnitus and 'blanks it out'.

Trauma

Noise exposure

Hair cells within the cochlea are damaged by sudden acoustic trauma (blast injury or gunfire) or prolonged exposure to excessive noise. The sensorineural hearing loss that results is greatest at high frequencies (particularly 4000 Hz) and is often accompanied by tinnitus (Fig. 44.32). The law in the UK requires that

Figure 44.29 Typical audiogram of presbycusis: (a) right ear; (b) left ear.

Figure 44.30 A well-known patient receives his hearing aid.

Figure 44.31 A tinnitus masker.

workers are protected from noise but in a disco an individual relies on common sense!

Head injury

The otic capsule is the hardest bone in the body but, if trauma to the head is severe, temporal bone fractures may occur. These tend to be either longitudinal (80%) or transverse (20%). Transverse fractures usually involve the labyrinth and lead to a sensorineural hearing loss that is permanent. Profound vertigo occurs initially, followed by gradual compensation. In about 50% of cases there is an associated facial nerve paralysis. When assessing a severely injured patient it is important to record the facial nerve function and, in particular, whether any facial weakness is partial or total. Important physical findings that may accompany a skull base fracture include a haematoma over the mastoid bone (Battle's sign), blood in the external ear or a laceration along the roof of the external canal. CSF otorrhoea or CSF rhinorrhoea (if the tympanic membrane is intact) may occur. A conductive hearing loss may be present because of fluid in the middle ear or disruption of the ossicular chain. A high-resolution CT scan is required to assess skull base fractures.

Barotrauma

Rapid changes in pressure across the labyrinthine membranes may occur with diving or flying and may allow air to be forced into the cochlea. Any individual with a sudden sensorineural hearing loss requires urgent hospital admission and, in those with a history of barotrauma, it may be appropriate to raise the tympanic membrane and to search for a leak of perilymph in the region of the oval or round window.

William Henry Battle, 1855–1936, Surgeon, St. Thomas's Hospital, London, England.

Figure 44.32 A typical audiogram of noise damage: (a) right ear; (b) left ear.

Drug ototoxicity

Certain drugs differentially affect the cochlea, causing hearing loss and tinnitus, whereas others affect the vestibular system, causing vertigo. Aminoglycosides are well known to be ototoxic, as is *cis*-platinum. Recognition of risk factors, such as poor renal function in patients being treated with aminoglycosides, is most important. Although many topical ear drops contain aminoglycosides there is little evidence that such topical treatment causes sensorineural hearing loss if used for short periods.

Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo (BPPV) may follow head or neck trauma. Vertigo is an illusion of movement and BPPV is characterised by intermittent attacks of vertigo that occur when the head is moved in a certain position. Typically, the vertigo only lasts for a few seconds and is not associated with other otological symptoms. Positional testing can evoke nystagmus and helps in the diagnosis of this condition. The condition is usually self-limiting, and special manoeuvres described by Epley help the majority of patients (Fig. 44.33).

Reduction in cochlear blood flow

This is the most likely cause for most cases of sudden onset of severe sensorineural hearing loss. All patients with a sudden sensorineural hearing loss should be referred immediately for specialist treatment. The treatment consists of bed rest, steroids and the administration of carbogen (an oxygen and carbon dioxide mixture). In total, 5% of patients with an acoustic neuroma present with sudden sensorineural hearing loss and, therefore, radiological investigation is required to exclude this diagnosis.

Inflammation

Viral infections are thought to account for acute vestibular failure. This condition is characterised by a sudden onset of

vertigo. The vertigo is so severe that the patient goes to bed for 5 days. Central compensation then occurs, although recurring episodes of vertigo can occur for up to 18 months.

Menière's disease

The aetiology is not known but the pathology is well documented. There is an excessive accumulation of endolymphatic fluid (hydrops) and it is thought that the distension of the endolymphatic compartment may rupture Reissner's membrane, which leads to mixing of endolymph and perilymph. The condition is characterised by a triad of symptoms: intermittent attacks of vertigo, a fluctuating sensorineural hearing loss and tinnitus. The patient often has a sensation of pressure in the affected ear before an attack. The hearing loss typically affects the lower frequencies. The vertigo characteristically lasts between 30 min and 6 hours and is often accompanied by nausea and vomiting. The investigations include pure tone audiometry, electrocochleography and an MRI scan to exclude an acoustic neuroma. Medical treatment with betahistadine and diuretics is effective, with selective destruction of the vestibular labyrinth by percolating gentamicin through a grommet being reserved for resistant cases.

Facial paralysis

Viral infections that involve the facial nerve are one of the most common causes of facial weakness (80%). Bell's palsy results from a viral infection of the facial nerve. The nerve swells and is compressed within the temporal bone. Early treatment with high-dose steroids is appropriate. Not all facial nerve palsies are due to viral infection and a thorough otoneurological examination is

John M. Epley, 20th century American Otologist.

Prosper Menière, 1799–1862, Physician, The Institute for Deaf Mutes, Paris, France, described this condition in 1861.

Sir Charles Bell, 1774–1842, Surgeon, The Middlesex Hospital, London, England (1812–1835), and later Professor of Surgery, The University of Edinburgh, Scotland (1836–1842).

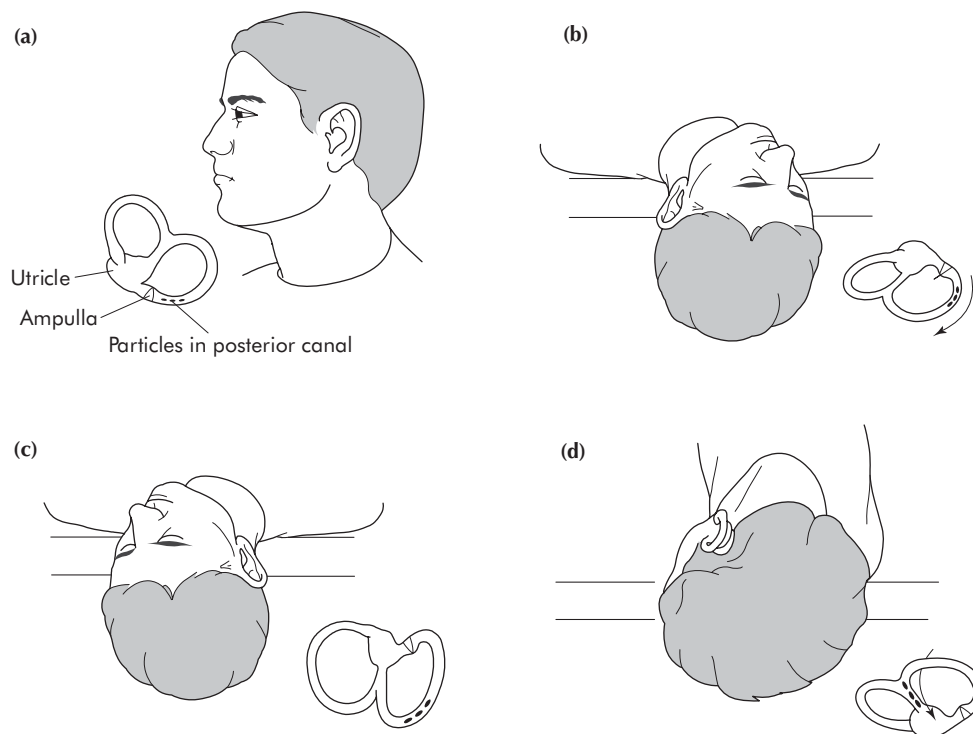

Figure 44.33 The Epley manoeuvre for benign paroxysmal positional vertigo.

required. The facial nerve can be damaged at the cerebello-pontine angle, within the internal auditory meatus, within the middle ear, at the skull base and within the parotid gland. It is essential to consider these potential sites of facial nerve damage in any patient with VIIIth nerve paralysis (Summary box 44.10).

Summary box 44.10

Facial paralysis

- The facial nerve passes through the middle ear and mastoid
- When considering a paralysis, think 'complete' or 'partial'
- Protect the eye: carry out a full otoneurological examination to find the cause
- If acute consider steroids and anti-viral agents

Ramsay-Hunt syndrome

This is caused by herpes zoster and is characterised by facial paralysis, pain and the appearance of vesicles on the tympanic membrane, ear canal and pinna (Fig. 44.34). It is accompanied by vertigo and sensorineural hearing loss (VIIIth nerve). Treatment with aciclovir is effective if given early.

The metabolic causes of inner ear damage

These include diabetes mellitus and thyroid disease, both of which may cause sensorineural hearing loss.

James Ramsay Hunt, 1874–1937, Professor of Neurology, The Columbia College of Physicians and Surgeons, New York, NY, USA.

Neoplasms

These are uncommon but can present with sensorineural hearing loss, tinnitus and vertigo. Acoustic neuromas, which are actually schwannomas of the vestibular division of the VIIIth nerve, are the most common, followed by meningiomas. Acoustic neuromas grow slowly and somewhat unpredictably and as they expand can cause cranial nerve palsies, brainstem compression and raised intracranial pressure. The early symptoms are a unilateral sensorineural hearing loss or unilateral tinnitus or both. It is important to diagnose these tumours early and remove them when they are small. The morbidity and mortality from surgery is directly related to tumour size. If the tumour is removed when it is small, there is an extremely good chance of preserving facial nerve function.

The investigation of choice for detecting acoustic neuromas is MRI (Fig. 44.35). The treatment options include a 'wait and see' policy, which may be appropriate for an elderly patient with minimal symptoms. MRI can be used to monitor the tumour.

In a small number of centres, stereotactic radiotherapy is used to treat small tumours; however, surgical resection is the most common treatment. There are three main approaches: a middle fossa approach, used for small tumours only; the translabyrinthine approach, entirely through the ear; and the suboccipital approach via a craniotomy. The physiological monitoring of the facial nerve and auditory nerve during surgery has improved acoustic nerve surgery results (Summary box 44.11).

Friedrich Theodor Schwann, 1810–1882, Professor of Anatomy and Physiology, successively at Louvain (1839–1848), and Liege (1848–1880), Belgium, described the neurilemma in 1839.

Figure 44.34 Herpes zoster infection of the VIIth (a) and VIIIth (b) nerves with vesicles on the pinna.

Figure 44.35 Magnetic resonance imaging scan of an acoustic neuroma, which presented with unilateral sensorineural hearing loss and tinnitus.

Summary box 44.11

Conditions of the inner ear

- Presbycusis is the bilateral high-frequency loss associated with ageing
- Unilateral tinnitus or sensorineural hearing loss needs to be investigated to exclude acoustic neuroma
- Sudden sensorineural hearing loss needs immediate treatment, and radiological investigation in the case of acoustic neuroma
- Menière's disease presents with the triad of sensorineural hearing loss, tinnitus and vertigo

Pharynx, larynx and neck

CHAPTER 45

LEARNING OBJECTIVES

To understand:

- The relevant anatomy, physiology, disease processes and investigations of the pharyngolarynx and neck
- The diagnosis and emergency treatment of airway obstruction
- The aetiology, prevention, natural history and management of squamous carcinoma of the upper aerodigestive tract

CLINICAL ANATOMY AND PHYSIOLOGY

The pharynx

The pharynx is a fibromuscular tube forming the upper part of the respiratory and digestive passages. It extends from the base of the skull to the level of the sixth cervical vertebra at the lower border of the cricoid cartilage where it becomes continuous with the oesophagus. It is divided into three parts: the nasopharynx, oropharynx and hypopharynx (Fig. 45.1).

Nasopharynx

The nasopharynx lies anterior to the first cervical vertebra and has the openings of the Eustachian tubes in its lateral wall,

behind which lie the pharyngeal recesses, the fossae of Rosenmüller. The adenoids are situated submucosally at the junction of the roof and posterior wall of the nasopharynx.

Oropharynx

This is bounded above by the soft palate, below by the upper surface of the epiglottis and anteriorly by the anterior faucial pillars. The oropharynx contains the palatine tonsils situated in the lateral wall between the anterior and posterior pillars of the fauces. They are part of the complete ring of lymphoid tissue (Waldeyer's ring) together with the adenoids and lingual tonsils on the posterior third of the tongue. This ring of lymphoid tissue occupying the entry to the air and food passages is constantly exposed to new antigenic stimuli and is an important part of the mucosa-associated lymphoid tissues (MALT), which process antigen and present it to T helper cells and B cells (Fig. 45.2).

Figure 45.1 The component parts of the pharynx.

Bartolomeo Eustachio (Eustachius), ?1513–1574, was appointed Physician to the Pope in 1547, and Professor of Anatomy at Rome, Italy, in 1549.

Figure 45.2 Waldeyer's ring.

Johann Christian Rosenmüller, 1771–1820, Professor of Anatomy and Surgery, Leipzig, Germany.
Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921, Professor of Pathological Anatomy, Berlin, Germany.

The tissue of Waldeyer's ring undergoes physiological hypertrophy during early childhood as the child is exposed to increasing amounts of antigenic stimuli, and there is often a similar hypertrophy of the cervical lymph nodes.

It also has an exceptionally good blood supply from the facial artery, which may be closely related to the lower pole, and laterally a plexus of paratonsillar veins, which may be the source of serious venous bleeding following tonsillectomy.

Hypopharynx

The hypopharynx is bounded above and anteriorly by the sloping laryngeal inlet. Its inferior border is the lower border of the cricoid cartilage where it continues into the oesophagus. The hypopharynx is commonly divided into three areas: the pyriform fossae, the posterior pharyngeal wall and the post-cricoid area. The mucosa of these areas is, however, continuous so disease processes, such as squamous carcinoma, can easily involve more than one area and may also spread submucosally. The motor nerve supply of the pharynx and larynx is the vagus nerve.

Understanding of the physiology of normal swallowing and the problems caused by disease has been enhanced in the last two decades by the use of videofluoroscopy in which the passage of a bolus of radio-opaque liquid or solid from the point at which it enters the oral cavity down to its passage within the stomach is examined radiologically. It is considerably more accurate than a barium swallow.

Swallowing is mediated via efferent fibres passing to the medulla oblongata through the second division of the trigeminal nerve (V), glossopharyngeal nerve (IX) and vagus nerve (X) (Fig. 45.3). The afferent pathway is from the nucleus ambiguus and is mediated via the glossopharyngeal (IX), vagus (X) and hypoglossal (XII) nerves. Damage to these major cranial nerves at any point along their pathway, by trauma or disease, may cause dysphagia with or without aspiration.

The main function of the larynx is not the production of voice but the protection of the tracheobronchial airway and lungs; it closes completely during swallowing.

RELATIONS OF THE PHARYNX (FIG. 45.4)

Parapharyngeal space

This potential space lies lateral to the pharynx and extends from the base of the skull above to the superior mediastinum below. It is occupied by the carotid vessels, internal jugular vein, deep cervical lymph nodes, the last four cranial nerves and the cervical sympathetic trunk.

Infection and suppuration of the cervical lymph node in the parapharyngeal space most commonly occurs from infections of the tonsils or teeth (particularly the third lower molar tooth). It may then spread up to the skull base or down to the para-oesophageal region and superior mediastinum.

Retropharyngeal space

This potential space lies posterior to the pharynx, bounded anteriorly by the posterior pharyngeal wall and its covering buccopharyngeal fascia and posteriorly by the cervical vertebrae and their covering muscles and fascia. It contains the retropharyngeal lymph nodes, which are usually paired lateral nodes but which are separated by a tough median partition that connects the prevertebral with the buccopharyngeal fascia.

Figure 45.3 The three phases of swallowing (a) and the muscles involved (b).

Figure 45.4 Sagittal diagram of upper aerodigestive tract.

These nodes are more developed in infancy and young children, and it is at this age that they are most likely to be involved in inflammatory processes, which, if severe, may affect swallowing and respiration as a consequence of gross swelling and suppuration of the retropharyngeal space.

Larynx

The larynx is the protective sphincter that closes off the airway during swallowing and, in humans and some other mammals, is responsible for the production of sound. The larynx has a mainly cartilaginous framework that may ossify in later life, and which consists of the hyoid bone above, the thyroid and cricoid cartilages and the intricate arytenoid cartilages posteriorly.

The cricoid cartilage is the only complete ring in the entire airway and bounds the subglottis, which is the narrowest point of the airway. This is the most common site for damage from an endotracheal tube used for intensive care unit ventilation in seriously ill patients.

An anatomical description of the larynx divides it into the supraglottis, glottis and subglottis (Fig. 45.5). The true vocal folds (often incorrectly called the vocal cords) are normally white in contrast to the pink mucosa of the rest of the larynx and airway. The true vocal folds meet anteriorly at the midlevel of the thyroid cartilage, whereas posteriorly they are separate and attached to an arytenoid cartilage. This arrangement produces the 'V' shape of the glottis (Fig. 45.6).

Figure 45.5 Anatomy of the larynx. [Reprinted from Aird's Companion in Surgical Studies, 2nd edn, Burnand, K.G. and Young, A.E. (eds), 1998, Fig. 20.37, with permission from Elsevier.]

Nerve supply

The sensory nerve supply to the larynx above the vocal folds is from the superior laryngeal nerve and below the vocal folds is from the recurrent laryngeal nerve. Both these nerves are branches of the vagus nerve (X). The motor nerve supply to the larynx is from the recurrent laryngeal nerve, which is a branch of the vagus nerve and which supplies all intrinsic muscles. Only one of these intrinsic muscles, the posterior cricoarytenoid, abducts the vocal folds during respiration. All other intrinsic muscles adduct the cords. As all of the intrinsic muscles of the larynx are supplied by the recurrent laryngeal nerve, damage to this nerve or to the vagus nerve will cause paralysis of the vocal fold on the side of the damage.

Views on indirect laryngoscopy

(a) Vocal folds abducted (open)

(b) Vocal folds adducted (closed)

Figure 45.6 A view of the larynx on indirect laryngoscopy: (a) vocal folds abducted; (b) vocal folds adducted. (c) Photograph of normal larynx in abduction. [Adapted from Aird's Companion in Surgical Studies, 2nd edn, Burnand, K.G. and Young, A.E. (eds), 1998, Fig. 20.38, with permission from Elsevier.]

Phonation/speech

The larynx functions by closing the vocal fold against the air being exhaled from the lungs, but the rise in subglottic pressure forces the vocal folds apart slightly for an instant of time with accompanying vibration of the vocal fold epithelium. The opening and closing occurs in rapid sequence to produce a vibrating column of air, which is the source of sound.

Paralysis or disease of the vocal folds or closely associated laryngeal structures will give rise to disturbance of the sound, producing hoarseness.

The functions of the larynx are given in Summary box 45.1.

Summary box 45.1

Functions of the larynx

Protection of the lower respiratory tract by

- Closure of the laryngeal inlet
- Closure of the false cords
- Closure of the glottis
- Cessation of respiration
- Cough reflex

Phonation

Respiration

- Control of pressure

Fixation of chest

- Aids lifting, straining and climbing

The neck

The neck is divided into anterior and posterior triangles by the sternocleidomastoid muscle. The anterior triangle extends from the inferior border of the mandible to the sternum below, and is bounded by the midline and the sternocleidomastoid muscle. The posterior triangle extends backwards to the anterior border of the trapezius muscle and inferiorly to the clavicle. The upper part of the anterior triangle is commonly subdivided into the submandibular triangle above the digastric muscle and the submental triangle below. The lymphatic drainage of the head and neck is of considerable clinical importance (Fig. 45.7). The most important chain of nodes are the jugular nodes (also called cervical), which run adjacent to the internal jugular vein. The other main groups are the submental, submandibular, pre- and post-auricular, occipital and posterior triangle nodes.

A system of levels is used to describe the location of these neck nodes (Fig. 45.8). The upper jugular nodes, level II, which contain the large jugulodigastric node, drain the naso- and oropharynx, including the tonsils, posterolateral aspects of the oral cavity, and the superior aspects of the larynx and pyriform fossae. They are the most common site of enlargement and may be palpated along the anterior border of the sternocleidomastoid muscle.

Metastatic spread of squamous cell carcinoma (80% of head and neck cancer) most commonly occurs with tumours of the nasopharynx, tongue base, tonsil, pyriform fossae and supra-glottic larynx. When an enlarged neck node is detected and malignant disease is suspected, these five primary sites must be carefully examined.

Figure 45.7 Distribution of cervical lymph nodes.

Figure 45.8 The level system for describing location of lymph nodes in the neck. Level I, submental and submandibular group; level II, upper jugular group; level III, middle jugular group; level IV, lower jugular group; level V, posterior triangle group; level VI, anterior compartment group.

CLINICAL EXAMINATION

Pharynx and larynx

Before examination of the pharynx, the oral cavity should be examined with the aid of a good light and tongue depressors. A reflecting mirror on the head or a headband-mounted fiberoptic light source permits use of both hands to hold instruments. Inspection should include the buccal mucosa and lips, the palate, the tongue and floor of the mouth, all surfaces of the teeth and gums, opening and closing of the mouth and dental occlusion. Patients should be asked to elevate the tongue to the roof of the mouth and protrude the tongue to both the right and the left. Palpation may be required using one or two fingers gently intraorally to feel any swellings and this may be combined with extraoral palpation of the submental and submandibular lymph nodes and salivary glands.

Following examination of the oral cavity, the oropharynx is then inspected with the tongue depressor placed firmly onto the tongue base to depress it inferiorly. The anterior and posterior faucial pillars, the tonsil, retromolar trigone and posterior pharyngeal wall

should all be inspected for colour changes, ulceration, pus, foreign bodies and swellings. Even with an experienced examiner, approximately one-third of patients cannot tolerate the depression of the posterior base of tongue without gagging. Pain and trismus as a consequence of pharyngolaryngeal or neck pathology may additionally add to the difficulty of the examination.

Fibreoptic nasendoscopes passed through the nose with or without topical anaesthesia allow high-quality examination of the entire nasopharynx, oropharynx and larynx in over 90% of patients.

The neck

The patient should be examined sitting with the whole neck exposed so that both clavicles are clearly seen. The neck is inspected from in front and the patient asked to swallow, preferably with the aid of a sip of water. Movements of the larynx and any swelling in the neck are noted. The patient should be asked to protrude the tongue if there is a midline neck swelling. A thyroglossal cyst will move upwards with the tongue protrusion. The patient is then examined from behind with the chin flexed slightly downwards to remove any undue tension in the strap muscles, platysma and sternocleidomastoids. The neck is palpated bilaterally in a sequential manner comparing the two sides of the neck.

On examining for a lump in the neck, it is often helpful to ask the patient to point to the lump first. Ask if the lump is tender. A swelling beneath the sternomastoid muscle may be considerably larger than thought on palpation. If malignancy is suspected (hard, irregular or fixed to overlying skin or to deep structures), inspection of the nasopharynx, tonsils, tongue base, pyriform fossae and supraglottic larynx is essential (Summary box 45.2).

Summary box 45.2

Key points of history and examination

Mouth

- Adequate light source and two spatulas to examine the mouth
- Examine
 - Teeth, gums, gingival sulci
 - Buccal mucosa, opening of parotid duct
 - Floor of mouth
 - Hard and soft palates
 - Retromolar trigone region ('coffin corner')
 - Anterior and posterior faucial pillars, tonsils
 - Posterior pharyngeal wall
 - Tongue (observe full movements)
- Palpate
 - Salivary glands/ducts

Larynx, oropharynx and hypopharynx

- Indirect laryngoscopy
 - Mirror and headlight
- Direct flexible fibreoptic pharyngolaryngoscopy

Nasopharynx

- Rigid Hopkins' rod endoscopy
- Flexible fibreoptic nasendoscopy

Neck

- Inspection
 - Tongue protrusion
 - Observe swallowing
- Palpation
 - If a mass is palpable, evaluate for size, site, shape, consistency, superficial and deep fixation, fluctuation, transillumination, auscultation

INVESTIGATIONS OF THE PHARYNX, LARYNX AND NECK

Plain lateral radiographs

Plain lateral radiographs of the neck and cervical spine may show soft tissue abnormalities; of particular importance is the depth and outline of the prevertebral soft tissue shadow. The outline of the laryngotracheal airway may be a useful guide to the presence of disease in the pharynx and larynx.

There should be no air within the upper oesophagus. If seen endoscopy is advised. Radio-opaque foreign bodies may be seen impacted in the pharynx, larynx or upper oesophagus on these radiographs.

Barium swallow

Barium liquid video fluoroscopic studies record the movement of a small quantity of radio-opaque liquid and allow detailed evaluation of the oral and pharyngeal phases of swallowing (Figs 45.9 and 45.10).

Computerised tomography scanning

Computerised tomography (CT) scanning provides much improved demonstration of disease in the pharynx, larynx and neck. Intravenous contrast given at the same time as the CT scan (dynamic scanning) further improves the demonstration of disease in these areas (Fig. 45.11).

Other techniques

Magnetic resonance imaging (MRI) is being increasingly used and may give better soft tissue definition of some diseases, but poorer definition of bony and cartilaginous structures (Fig. 45.12). Ultrasound scanning can be useful in differentiating solid

Figure 45.9 Plain lateral radiograph showing normal anatomy.

Figure 45.10 Videofluoroscopy image showing liquid barium in the upper pharynx in a normal swallow.

lesions, e.g. malignant lymph nodes from cystic lesions such as a branchial cyst.

Fine-needle aspiration cytology

This technique can be performed under local anaesthesia. It is useful particularly if a neck lump is thought to be malignant. Increasingly high rates of accurate histological diagnosis are reported and there is no evidence of spread of tumour through the skin track caused by the fine hypodermic needle used with this technique. Fine-needle aspiration may be further aided by ultrasound or CT guidance.

Angiography or digital subtraction vascular imaging

These may be indicated if a vascular lesion such as a carotid body tumour is suspected. Angiography may have a therapeutic role to play by facilitating embolisation of the lesion.

Direct pharyngoscopy and laryngoscopy

Examination of the pharynx, larynx and neck under general anaesthesia may be required if there are problems with the routine examination of patients such as an inadequate view as a result of trismus from pain, poor patient compliance, or large obstructive pharyngeal or laryngeal pathology. These examinations may be further aided by the use of an operating microscope or rigid endoscope (Hopkins' rods) (Fig. 45.13).

DISEASES OF THE PHARYNX

Nasopharynx

Enlarged adenoid

The most common cause of an enlarged adenoid (there is only one nasopharyngeal adenoid, despite the common use of the term

Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, The University of Reading, Reading, England. He invented the rigid rod endoscope (Hopkins' Rod, 1954), and contributed to the development of the fibres for flexible endoscopes.

Figure 45.11 Axial computerised tomography scan through the larynx at the level of the glottis.

Figure 45.12 Axial magnetic resonance imaging scan at the same level as Fig. 45.11.

Figure 45.13 A rigid Hopkins' rod or endoscope.

'adenoids') is physiological hypertrophy. The size of the adenoid alone is not an indication for removal. It is often associated with hypertrophy of the other lymphoid tissues of Waldeyer's ring. If excessive hypertrophy causes blockage of the nasopharynx in

association with tonsil hypertrophy, the upper airway may become compromised during sleep causing obstructive sleep apnoea.

Obstructive sleep apnoea

This condition is becoming increasingly diagnosed and is important because it can cause sleep deprivation and secondary cardiac complications. It has been implicated in some cases of sudden infant death syndrome. The most common symptom is snoring, which is typically irregular, with the child actually ceasing respiration (apnoea) and then restarting with a loud inspiratory snort. The child is often restless and may take up strange sleep positions as he or she tries to improve the pharyngeal airway. Surgical removal of the tonsils and adenoid is curative, but it is important to avoid sedative premedications and opiate analgesics postoperatively because they may further depress the child's respiratory drive.

Obstructive sleep apnoea may also occur in adults, where the obstruction may result from nasal deformity, a hypertrophic soft palate associated with an altered nasopharyngeal isthmus, obesity and general narrowing of the pharyngeal airway, or supraglottic laryngeal pathology. Surgery may be indicated following investigation by means of a sleep study, during which measurement of the patient's sleep pattern and arterial oxygenation are undertaken.

Hypertrophy of adenoid tissue most commonly occurs between the ages of 4 and 10, but the adenoid tissue usually undergoes spontaneous atrophy during puberty, although some remnants may persist into adult life (Fig. 45.14). The relationship of adenoid enlargement to recurrent secretory otitis media or recurrent acute otitis media is not entirely clear.

Adenoidectomy (Figs 45.15 and 45.16)

Adenoid tissue can be removed alone or in conjunction with a tonsillectomy. The indications for adenoidectomy are:

- obstructive sleep apnoea associated with post-nasal obstruction;

Figure 45.14 Plain lateral radiograph showing a large pad of adenoid tissue (arrow) in the post-nasal space.

Figure 45.15 St Clair Thomson's adenoid curette.

Figure 45.16 Curettage of the adenoid.

- post-nasal discharge;
- recurrent acute otitis media or prolonged serous otitis media, usually longer than 3 months' duration;
- recurrent rhinosinusitis.

Removal of the adenoid

Operative technique The adenoid tissue is removed with a guarded curette pressed against the roof of the nasopharynx and then carried downwards in a moderately firm sweeping movement bringing the excised adenoid into the oropharynx. The guard on the curette secures the adenoid and prevents it from dropping inferiorly into the airway. A post-nasal swab is placed into the nasopharynx until all haemorrhage has ceased.

Reactionary or secondary haemorrhage during the recovery period may require a nasopharyngeal pack under a further anaesthetic. This can occasionally cause respiratory depression in children and adults, and strict observation is required while the pack is in place.

TUMOURS OF THE NASOPHARYNX

Benign

There are two main types of benign tumour of the nasopharynx: the angiofibroma and the antrochoanal polyp. Both are rare.

Angiofibroma

This tumour is confined to young male patients most commonly between the ages of 8 and 20 years. It usually causes progressive nasal obstruction, recurrent severe epistaxis, purulent rhinorrhoea and occasionally loss of vision because of compression of the optic nerve. Although the tumour is rare, these symptoms in a young male patient should always arouse suspicion. The tumour is most common in northern India although the reasons for this are unknown. Clinical examination often shows a tumour in the nasal cavity or nasopharynx, but CT scanning best demonstrates the extent of the tumour and its accompanying bony erosion. MRI scanning defines the soft-tissue extent and, with these two modern investigations, angiography is rarely indicated. Biopsy should be avoided unless clinical and radiological examination are not diagnostic because of the risk of bleeding.

Surgical resection requires adequate exposure either through a midfacial approach or lateral rhinotomy (Figs 45.17 and 45.18). Both allow ligation of the feeding maxillary artery. Most recently, endoscopic resection has been used for smaller lesions.

Figure 45.17 Intraoperative photograph showing exposure during a midfacial degloving approach.

Figure 45.19 Intraoral view showing a fleshy polyp hanging in the oropharynx.

Figure 45.18 Intraoperative photograph showing an incision in lateral rhinotomy.

Antrochoanal polyp

This relatively uncommon lesion is a benign mucosal polyp that arises in the maxillary antrum and prolapses into the nasal cavity where it expands backwards into the nasopharynx and occasionally into the oropharynx (Figs 45.19 and 45.20). It may mimic an angiofibroma from which it is distinguished by its avascularity and pale colour, and its site of origin on endoscopic examination and imaging. It requires complete removal via an endoscopic approach through the middle meatus or, occasionally, a Caldwell–Luc procedure.

Malignant

Nasopharyngeal carcinoma

Nasopharyngeal carcinomas are usually squamous cell carcinoma and have a very variable incidence. In most parts of the world,

Figure 45.20 Axial computerised tomogram of an antrochoanal polyp (as seen in Fig. 45.19), with opaque maxillary antrum and a mass in the nasal cavity and nasopharynx.

the tumour is rare with an annual incidence of 1 case per 100 000 population; however, among southern Chinese populations the rate is 30–50 cases per 100 000 population. The aetiology of nasopharyngeal carcinoma is multifactorial. Genetic susceptibility, early infection by the Epstein–Barr virus and consumption of

George Walter Caldwell, 1834–1918, Otolaryngologist, who practised successively in New York, San Francisco, and Los Angeles, USA, devised this operation for treating suppuration in the maxillary antrum in 1893.
Henri Luc, 1855–1925, Otolaryngologist, Paris, France, described his operation in 1889.

Micheal Anthony Epstein, B. 1921, formerly Professor of Pathology, The University of Bristol, Bristol, England.
Yvonne Barr, B. 1931, a Virologist who emigrated to Australia. Epstein and Barr discovered this virus in 1964.

traditional diets, particularly salted fish, are known to contribute (Summary box 45.3).

Summary box 45.3

Aetiological factors in nasopharyngeal carcinoma

- Genetic, e.g. Cantonese
- Infective, e.g. Epstein–Barr virus
- Environmental, e.g. salted fish

The majority of tumours are undifferentiated with a characteristic morphology, comprising over 90% of nasopharyngeal malignancy in endemic areas. Rare epithelial tumours are adenocarcinoma and adenoid cystic carcinoma. B- and T-cell lymphomas also occur in this region and should not be confused with the more common undifferentiated carcinoma. Nasopharyngeal carcinoma has a bimodal distribution with an increased incidence in teenagers and young adults and then again in the 50–60 age group.

Clinical features

Symptoms are closely related to the position of the tumour in the nasopharynx and the degree of distant spread if any. Early symptoms are often minimal and may be ignored by both patient and doctor. Approximately 50% of patients will present with a mass of malignant nodes in the neck, indicating an advanced tumour. This percentage is even higher in patients under 21 years of age. Fine-needle aspiration or a biopsy of a neck node showing undifferentiated carcinoma requires immediate thorough examination of the nasopharynx. In about 5% of patients, the nasopharynx may look normal or minimally asymmetrical but contains submucosal nasopharyngeal carcinoma. A biopsy of the nasopharynx is essential if there is suspicion of nasopharyngeal malignancy. Nasal complaints occur in one-third of patients and aural symptoms of unilateral deafness as a consequence of Eustachian tube obstruction and secretory otitis media occur in approximately 20%. Neurological complications with cranial nerve palsies as a result of disease in the skull base occur relatively late in the disease, but are a poor prognostic factor (Summary box 45.4).

Summary box 45.4

Nasopharyngeal carcinoma: main presenting complaints

Systemic

- Cervical lymphadenopathy

Local

- Unilateral serous otitis media, otalgia
- Nasal obstruction, bloody discharge, epistaxis
- Cranial nerve palsies, especially III–VI then IX–XII

Investigation is by direct inspection with a flexible or rigid nasendoscope and biopsy under topical or general anaesthesia. Serological investigation for Epstein–Barr virus-associated antigenic markers in combination with the clinical and histological examination is valuable for the early detection of disease. Highly sensitive assays for anti-viral antibodies together with the newly discovered virus-

associated serological markers are useful in early detection. Immunoglobulin (Ig)A anti-viral capsid antigen antibody has recently been evaluated in mass surveys in southern China and has been found to be an excellent screening method for the early detection of nasopharyngeal carcinoma in high-risk groups.

Imaging

Imaging is essential for staging and to determine the extent of disease. CT of the head, neck and chest has a major role in planning radiotherapy and assessing the response to treatment, diagnosing recurrence and detecting complications.

Treatment

The primary treatment of nasopharyngeal carcinoma is radiotherapy as the majority of the tumours are radiosensitive undifferentiated squamous cell carcinomas. Elective bilateral external radiotherapy is given to the skull base and neck in all patients, even when no neck nodes are apparent. Brachytherapy (intracavitary and interstitial radiotherapy) and chemotherapy are increasingly used. For early disease, 3-year disease-free survival rates of more than 75% are common; however, in advanced disease the results are less good, with 3-year disease-free survival rates of 30–50%.

OROPHARYNX

Acute tonsillitis

This common condition is characterised by a sore throat, fever, general malaise, dysphagia, enlarged upper cervical nodes and sometimes referred otalgia. Approximately half the cases are bacterial, the most common cause being a pyogenic group A streptococcus. The remainder are viral and a wide variety of viruses have been implicated, in particular infectious mononucleosis, which may be mistaken for bacterial tonsillitis.

On examination, the tonsils are swollen and erythematous, and yellow or white pustules may be seen on the palatine tonsils, hence the name 'follicular tonsillitis' (Fig. 45.21). A throat swab should be taken at the time of examination as well as blood for Paul–Bunnell testing.

Figure 45.21 Acute follicular tonsillitis.

John Rodman Paul, 1893–1971, Professor of Preventative Medicine, Yale University, New Haven, CT, USA.
Walls Willard Bunnell, 1902–1966, an American Physician. Paul and Bunnell described this test in 1932.

Treatment

Paracetamol or similar analgesia may be administered to relieve pain and gargles of glycerol–thymol are soothing. The condition is frequently sensitive to benzyl- or phenoxymethylpenicillin (penicillin V) and these are given until antibiotic sensitivities are established. Ampicillin is avoided as it may precipitate a rash in patients with infectious mononucleosis. Most cases resolve in a few days.

Quinsy

This is an abscess in the peritonsillar region that causes severe pain and trismus (Fig. 45.22). The trismus caused by spasm induced in the pterygoid muscles may make examination difficult but may be overcome by instillation of local anaesthesia into the posterior nasal cavity (anaesthetising the sphenopalatine ganglion) and the oropharynx. Inspection reveals a diffuse swelling of the soft palate just superior to the involved tonsil, displacing the uvula medially. In more advanced cases, pus may be seen pointing underneath the thin mucosa.

Treatment

In the early stages intravenous broad-spectrum antibiotics may produce resolution. However, if there is frank abscess formation, incision and drainage of the pus can be carried out under local anaesthesia. A small scalpel is best modified by winding a strip of adhesive tape around the blade so that only 1 cm of the blade projects. In teenagers and young adults, the patient sits upright and an incision is made approximately midway between the base of the uvula and the third upper molar tooth (Fig. 45.23). This may produce immediate release of pus, but, if not, a dressing forceps is pushed firmly through the incision and, on opening, pus may then be encountered. In small children, general anaesthesia is required.

Chronic tonsillitis

Chronic tonsillitis usually results from repeated attacks of acute tonsillitis in which the tonsils become progressively damaged and provide a reservoir for infective organisms.

Tonsillectomy

Recurrent acute tonsillitis is the most common relative indication for tonsillectomy in children and adolescents, although it is important that these attacks are well documented and do not

Figure 45.22 Quinsy (peritonsillar abscess).

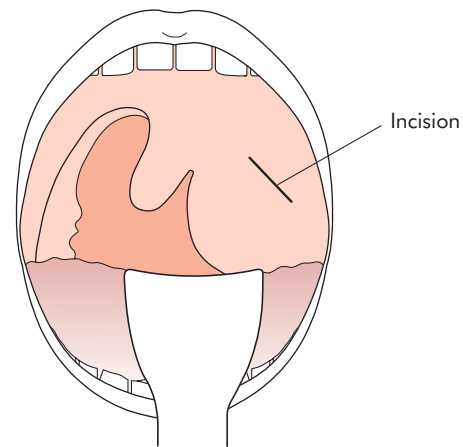

Figure 45.23 Site of incision in peritonsillar abscess.

simply constitute a minor viral sore throat. Chronic tonsillitis more frequently affects young adults in whom it is important to establish that chronic mouth breathing secondary to nasal obstruction is not the main problem rather than the tonsils themselves. Absolute indications for tonsillectomy are when the size of the tonsils is contributing to airway obstruction or a malignancy of the tonsils is suspected (Table 45.1).

Ideally, the procedure should be undertaken when the tonsils are not acutely infected, and it is important to discuss factors that may increase the tendency to bleed. Blood transfusion is rarely required, but it is normal practice to type and screen blood for cross-match in children under 15 kg in weight.

Dissection tonsillectomy is carried out under general anaesthesia. The mucosa of the anterior faucial pillar is incised and the tonsil capsule identified. Using blunt dissection, the tonsil is separated from its bed until only a small inferior pedicle is left (Fig. 45.24). Usually a snare is used to separate it from the lingual tonsil. A tonsil swab is placed in the tonsillar bed and pressure applied for some minutes, following which bleeding points may be controlled by ligature or by bipolar diathermy.

Following surgery, the patient is kept under close observation for any systemic or local evidence of bleeding, with regular pulse and blood pressure measurements and observation to see if the patient is swallowing excessively (Fig. 45.25). Postoperatively patients are encouraged to eat normally. Paracetamol is preferred to aspirin-containing analgesics. Patients are allowed home on the following day and are warned that they may experience otalgia as a result of referred pain from the glossopharyngeal

Table 45.1 Indications for tonsillectomy

Absolute	Sleep apnoea, chronic respiratory tract obstruction, cor pulmonale Suspected tonsillar malignancy
Relative	Documented recurrent acute tonsillitis Chronic tonsillitis Peritonsillar abscess (quinsy) Tonsillitis resulting in febrile convulsions Diphtheria carriers Systemic disease caused by β -haemolytic <i>Streptococcus</i> (nephritis, rheumatic fever)

Figure 45.24 Removal of the tonsils.

nerve and that secondary haemorrhage may occur up to 10 days following the surgery.

Haemorrhage is the most common complication in the immediate postoperative period. Local pressure may help in mild cases, but it is generally wisest to return to theatre for definitive treatment, particularly in younger patients. Under general anaesthesia, it may be possible to identify a bleeding spot, but often a more generalised ooze is observed and suturing of the tonsil bed combined with the application of Surgicel and bipolar diathermy is often more successful than attempted placement of ligatures.

Late haemorrhage is generally secondary to infection and patients should be commenced on intravenous antibiotics with aerobic and anaerobic cover. Significant or persistent bleeding may require a further general anaesthetic and undersewing of the surgical bed, which by this time will often be covered with slough and granulation tissue. Postoperative tonsillar haemorrhage is still a serious and life-threatening complication and should not be underestimated, particularly in the younger patient (Summary box 45.5).

Summary box 45.5

Complications of tonsillectomy

Anaesthetic

- Traumatic intubation
- Cardiopulmonary arrest
- Malignant hyperthermia

Surgical

- Haemorrhage (immediate or late)
- Infection
- Pain/otalgia
- Postoperative airway obstruction
- Velopharyngeal insufficiency

Parapharyngeal abscess

Parapharyngeal abscess may be confused with a peritonsillar abscess, but the maximal swelling is *behind* the posterior faucial pillar and there may be little oedema of the soft palate. The

Figure 45.25 Positioning of the patient after tonsillectomy.

patient is usually a young child and there may be a severe general malaise. In early cases, admission to hospital and the institution of fluid replacements coupled with intravenous antibiotics may produce resolution. In advanced cases, drainage and intravenous antibiotics are required. With an obvious abscess pointing into the oropharynx, drainage may be carried out with a blunt instrument or the glove finger, but general anaesthesia is frequently required and the expertise of a senior anaesthetist, good illumination and good suction are absolutely essential. A large parapharyngeal abscess may compromise both the airway and swallowing.

Acute retropharyngeal abscess

This is the result of suppuration of the retropharyngeal lymph nodes and, again, is most commonly seen in children, with most cases occurring under 1 year of age. It is associated with infection of the tonsils, nasopharynx or oropharynx, and is frequently accompanied by severe general malaise, neck rigidity, dysphagia, drooling, a croupy cough, an altered cry and marked dyspnoea.

Dyspnoea may be the prominent symptom and may also be accompanied by febrile convulsions and vomiting. These children should always be carefully examined. Inspection of the posterior wall of the pharynx may show gross swelling and an abscess pointing beneath the thinned mucosa.

In countries where diphtheria still occurs, an acute retropharyngeal abscess may be confused with this, but the presence of the greyish green membrane aids differentiation. Occasionally, a foreign body, most commonly a fish bone which has perforated the posterior pharyngeal mucosa, will give rise to a retropharyngeal abscess in older children and young adults. Intravenous antibiotics are commenced immediately but surgical drainage of the abscess is often necessary. It requires experienced anaesthesia because, on induction, care must be taken to avoid rupturing the abscess. The airway is protected by placing the child in a head-down position while a pair of dressing forceps guided by the finger may be thrust into an obvious abscess in the posterior wall and the contents evacuated. On other occasions, an approach anterior and medial to the carotid sheath via a cervical incision may be required.

Chronic retropharyngeal abscess

This condition is now rare and is most commonly the result of an extension of tuberculosis of the cervical spine, which has spread through the anterior longitudinal ligament to reach the retropharyngeal space. In addition to the retropharyngeal swelling seen intraorally there may be fullness behind the sternocleidomastoid muscle on one side. In contrast to an acute retropharyngeal abscess, this condition occurs almost solely in adults.

Radiology usually shows evidence of bone destruction and loss of the normal curvature of the cervical spine. The spine may be quite unstable and undue manipulation may precipitate a neurological event.

A chronic retropharyngeal abscess must not be opened into the mouth, as such a procedure may lead to secondary infection. Drainage of the abscess may not be necessary if suitable treatment of the underlying tuberculosis disease is instituted. If it is necessary, drainage should be carried out through a cervical incision anterior to the sternocleidomastoid muscle with an approach anterior and medial to the carotid sheath to enter the retropharyngeal space. The cavity is opened and suctioned dry after taking biopsy material. Occasionally, surgery is required to decompress the spinal cord if there is a progressive neurological deficit.

Glandular fever (infectious mononucleosis)

This systemic condition is usually caused by the Epstein–Barr virus, but similar features can be caused by cytomegalovirus or toxoplasmosis. The tonsils are typically erythematous with a creamy grey exudate and appear almost confluent, usually symmetrical in contrast to a quinsy. In addition to the discomfort and dysphagia, patients may drool saliva and have respiratory difficulty, particularly on inspiration. They commonly have a high temperature and gross general malaise with other notable cervical or generalised lymphadenopathy. Occasionally, an enlarged spleen or liver may be detected. The condition is most frequent in teenagers and young adults. The diagnosis can be confirmed by serological testing showing a positive Paul–Bunnell test, an absolute and relative lymphocytosis, and the presence of atypical monocytes in the peripheral blood.

Treatment

Analgesia and maintenance of fluid intake are important. A small number of patients require admission to hospital if the airway is compromised and a short course of steroids may be helpful. Antibiotics are of little value and ampicillin is contraindicated because of the frequent appearance of a widespread skin rash. Rarely if the airway is severely compromised, an unhurried elective tracheostomy under local anaesthesia is safer and less traumatic than an emergency intubation. Emergency tonsillectomy is contraindicated because of the generalised pharyngeal oedema and compromised airway.

Human immunodeficiency virus

Acquired immune deficiency syndrome (AIDS) can affect the ear, nose and throat (ENT) system at any point during the disease. The initial seroconversion may present with the symptoms of glandular fever, which is followed by an asymptomatic period of variable length. In the pre-AIDS period, before the full-blown symptoms of the AIDS-related complex, many patients have minor upper respiratory tract symptoms that are often overlooked, such as otitis externa, rhinosinusitis and a non-specific pharyngitis. As the patient moves into the full-blown AIDS-related complex, a persistent, generalised lymphadenopathy is frequently found affecting the cervical nodes, which is usually due to follicular hyperplasia. However, patients may also develop tumours such as Kaposi's sarcoma, sometimes seen in the oral

cavity, and high-grade malignant B-cell lymphoma affecting the cervical lymph nodes and nasopharynx. In addition, multiple ulcers may be found in the oral cavity or pharynx associated with herpes infection. Severe candida may affect the oral cavity, pharynx, oesophagus or even larynx, and a hairy leucoplakia may affect the tongue (Fig. 45.26).

The globus syndrome

A wide variety of patients experience the feeling of a lump in the throat (from the Latin *globus* = lump). The symptom most commonly affects adults between 30 and 60 years of age. This feeling is not true dysphagia as there is no difficulty in swallowing. Most patients notice the symptom more if they swallow their own saliva, i.e. a forced, dry swallow, rather than when they eat or drink.

The aetiology of this common symptom is unknown, but some patients may have gastro-oesophageal reflux or spasm of their cricopharyngeus muscle.

The original name of 'globus hystericus' is unhelpful and although these patients may be anxious and at times introverted, they nonetheless require full examination to exclude local disease. Radiological and endoscopic investigation may be necessary to exclude an underlying cause.

Pharyngeal pouch

A pharyngeal pouch is a protrusion of mucosa though Killian's dehiscence, a weak area of the posterior pharyngeal wall between the oblique fibres of the thyropharyngeus and the transverse fibres of cricopharyngeus at the lower end of the inferior constrictor muscle (Fig. 45.27). These fibres, along with the circular fibres of the upper oesophagus, form the physiological upper oesophageal sphincter mechanism. Why the pouch forms is not yet clear, even with modern videofluoroscopic and manometric studies. Many patients with pharyngeal pouches have been demonstrated to have normal relaxation of the upper oesophageal sphincter mechanism in relation to swallowing, but others have been shown to have incomplete pharyngeal relaxation, early cricopharyngeal contraction and abnormalities of the pharyngeal contraction wave.

Figure 45.26 Intraoral view showing hairy tongue in a human immunodeficiency virus-positive patient.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

Gustav Killian, 1860–1921, Professor of Laryngology at Freiburg, and later at Berlin, Germany.

Figure 45.27 A pharyngeal pouch.

Clinical features

Patients suffering from this condition are commonly more than 60 years of age and it is twice as common in women as men. As the diverticulum enlarges, patients may experience regurgitation of undigested food, sometimes hours after a meal, particularly if they are bending down or turning over in bed at night. They sometimes wake at night with a feeling of tightness in the throat and a fit of coughing. Occasionally, they may present with recurrent, unexplained chest infections as a result of aspiration of the contents of the pouch. As the pouch increases in size, the patients may notice gurgling noises from the neck on swallowing and the pouch may become large enough to form a visible swelling in the neck.

Radiological examination

A thin emulsion of barium is given to the patient as a barium swallow (Fig. 45.28) or ideally as part of a videofluoroscopic swallowing study. Care should be exercised in patients who cough on swallowing, indicating they may have aspiration. A small volume of barium is sufficient to outline the pharynx, pouch and upper oesophagus. The videofluoroscopic study gives

Figure 45.28 Barium swallow showing a pharyngeal pouch.

additional information about the pharyngeal contraction waves and the performance of the upper oesophageal sphincter.

Treatment

Surgery is indicated when the pouch is associated with progressive symptoms and particularly when a prominent cricopharyngeal bar of muscle associated with abnormality of the upper oesophageal sphincter mechanism causes considerable dysphagia. In elderly patients, a decision to operate may be influenced by their general condition. Preoperative chest physiotherapy and attention to the respiratory, cardiovascular and nutritional aspects of the patient are important. Perioperative antibiotics are recommended.

In the classic external operation, the opening to the pouch is first identified using a pharyngoscope and a nasogastric tube placed into the oesophageal lumen for postoperative nutrition. This initial endoscopy is often difficult because the normal oesophageal opening is small compared with the lumen of the pouch, but it may be better visualised using a Dohlmann's rigid endoscope. The pouch may be packed with ribbon gauze soaked in proflavin solution to further aid identification of its neck.

A lower neck incision along the anterior border of the left sternocleidomastoid muscle, or a transverse crease incision, is used and the muscle and carotid sheath are retracted laterally and the trachea and larynx medially. The pouch is found medially behind the lower pharynx and is carefully isolated and dissected back to its origin at Killian's dehiscence. It is then excised and the pharynx closed in two layers or, if it is small, the pouch may be invaginated into the pharyngeal lumen before closing the muscle layers. In all cases, a myotomy dividing the fibres of the cricopharyngeus muscle and the upper oesophageal circular muscle fibres must be performed. The wound is usually closed with drainage and the patient fed through a nasogastric tube for 3–7 days.

Complications

The classic operation has been associated with wound infection, mediastinitis, pharyngeal fistula formation and stenosis of the upper oesophagus. Variations have been tried which include simply hitching up the pouch into a superior position without excising it, thus allowing the fundus and body to empty continuously into the oesophagus. This is unsatisfactory with larger pouches, and upper oesophageal myotomy is still required.

Endoscopic operations

Endoscopic division of the bar of muscle forming the anterior wall of the pouch and the posterior aspect of the lumen of the oesophagus has been advocated for many years using Dohlmann's instruments or a carbon dioxide laser applied via a special pharyngoscope. An endoscopic stapling technique using a modified pharyngoscope to safely divide the anterior wall of the pouch and the posterior wall of the oesophagus is increasingly used. This completes a full myotomy and allows any food and fluid to drain from the pouch directly down the oesophagus. The endoscopic technique is associated with a high symptomatic success rate and a low morbidity which is particularly important in the elderly.

Sideropenic dysphagia

Prolonged iron deficiency anaemia may lead to dysphagia, particularly in middle-aged women. In addition, they may have koilonychia, cheilosis, angular stomatitis together with lassitude

and poor exercise tolerance. The dysphagia is caused by a post-cricoid or upper oesophageal web and these patients have a higher incidence of post-cricoid malignancy. The syndrome is associated with the names of Plummer and Vinson, Paterson and Brown Kelly.

TUMOURS OF THE OROPHARYNX

Benign

Benign tumours of the oropharynx are rare, papillomas being the most common. These are usually incidental findings and are rarely of any importance.

Malignant

The most important epithelial tumour is squamous cell carcinoma, which constitutes approximately 90% of all epithelial tumours in the upper aerodigestive tract (Figs 45.29 and 45.30). In the oropharynx, the proportion is less (70%) because of the higher incidence of lymphoma (25%) and salivary gland tumours (5%).

Aetiology

Squamous carcinomas of the oropharynx are strongly associated with cigarette smoking and consumption of alcohol. In countries where the consumption of tobacco and alcohol are associated with poor oral hygiene, these malignancies assume major importance. Because of the rich lymphatic drainage of the oropharynx, cervical node metastases are common. They may be the only presenting feature with an apparent occult primary tumour often being unsuspected and missed in the tonsil or tongue base.

Treatment

Treatment varies with facilities around the world, but early tumours may be cured by radiotherapy, laser excision or more

Figure 45.29 Squamous cell carcinoma of the right tonsil.

Henry Stanley Plummer, 1874–1937, Physician, The Mayo Clinic, Rochester, MN, USA, described this syndrome in 1912.
 Porter Paisley Vinson, 1890–1959, Physician, The Mayo Clinic, Rochester, MN, who later practised in Richmond, VA, USA.
 Donald Rose Paterson, 1863–1939, Surgeon, The Ear, Nose and Throat Department, The Royal Infirmary, Cardiff, Wales.
 Adam Brown Kelly, 1865–1941, Surgeon, The Ear, Nose and Throat Department, The Royal Victoria Infirmary, Glasgow, Scotland.
 Vinson, Paterson and Kelly all described this syndrome independently in 1919.

Figure 45.30 Squamous cell carcinoma of the soft palate.

conventional excision. Recurrent disease following radiotherapy is managed surgically and repair of the oropharynx may require regionally based myocutaneous flaps or free flaps with microvascular anastomosis. Neck dissection is required in a large proportion of cases of advanced disease. Postoperative dysphagia with aspiration as a result of interference in the complex neuromuscular control of the second phase of swallowing is a particular problem in these patients. This type of surgery is best carried out in a major centre undertaking this work on a regular basis.

Lymphoma of the head and neck

Lymphomas of the head and neck may arise in nodal or extranodal sites and both Hodgkin's disease and non-Hodgkin's lymphoma commonly present as lymph node enlargement in the neck. Hodgkin's disease is rare in the oropharynx, but non-Hodgkin's lymphoma accounts for 15–20% of tumours at this site in some countries. Most are of the B-cell type and have features in common with other tumours of MALT. Further evaluation with CT scanning of the thorax and abdomen, and bone marrow evaluation are essential.

Radiotherapy is the treatment of choice for localised non-Hodgkin's lymphoma and may give control rates as high as 75% at 5 years. For disseminated non-Hodgkin's lymphoma, systemic chemotherapy is preferred.

TUMOURS OF THE HYPOPHARYNX

Benign

Benign tumours of the hypopharynx are very rare, the most common being the fibroma and the leiomyoma. They show a smooth, constant mass lying in the lumen of the hypopharynx or oesophagus.

Malignant

Malignant tumours of the hypopharynx are almost exclusively squamous cell carcinomas with a predominance of moderate and poor differentiation. The tumours are usually classified according to their probable anatomical site of origin from the pyriform fossa,

Thomas Hodgkin, 1798–1866, Curator of the Museum, and Demonstrator of Morbid Anatomy, Guy's Hospital, London, England, described lymphadenoma in 1832.

post-cricoid region or posterior pharyngeal wall. Marked differences in the incidence of these tumours occur globally because of factors such as iron-deficiency anaemia (see Sideropenic dysphagia, p. 714). They may be associated with marked submucosal spread of 10 mm or more, which further complicates evaluation. Tumours arising from the pyriform fossa and posterior pharyngeal wall may spread to upper or lower cervical nodes. Tumours arising in the post-cricoid area typically metastasise to paratracheal and paraoesophageal nodes, which may not be palpable. As with oropharyngeal tumours, alcohol and tobacco are two principal carcinogens. Post-cricoid carcinoma, though rare, is more common in women than men.

The diagnosis of hypopharyngeal carcinoma should be considered in all patients presenting with dysphagia, hoarseness or referred otalgia, particularly if they have a history of iron-deficiency anaemia, smoking or significant alcohol consumption.

Laryngoscopy may show only subtle signs of disease such as oedema or pooling of saliva unilaterally in a pyriform fossa, or diminution of vocal fold mobility. All regions of the neck must be assessed in a systematic manner. Fine-needle aspirate is advocated for suspicious nodes. A suspected primary may require videofluoroscopy or barium swallow study, endoscopy and biopsy, and CT or MRI scanning if available. A chest radiograph should be taken to detect a second primary or metastasis.

Treatment

Squamous carcinoma of the hypopharynx commonly presents late and carries a poor prognosis. Early lesions may be treated with radiotherapy alone or transoral endoscopic carbon dioxide laser resection. Major open excisional surgery is generally used for recurrence after radiotherapy or as primary excision in advanced disease. Total pharyngolaryngectomy is commonly required (Fig. 45.31) and for lesions extending into the upper oesophagus,

oesophagectomy and total thyroidectomy may additionally be needed. Myocutaneous flaps, transposed jejunum or stomach are used to reconstruct the pharynx. Swallowing and voice rehabilitation are necessary to support patients after this major surgery if they are to adjust and maintain some quality of life (Summary box 45.6).

Summary box 45.6

Tumours of the hypopharynx

- Variable symptoms – discomfort, pain, dysphagia, hoarseness
- Awareness increased by history of smoking and alcohol
- Expert examination with nasendoscopy
- Referral to expert for detailed assessment and treatment – radiotherapy, laser or extensive surgery

DISEASES OF THE LARYNX

Emergencies

Stridor

Stridor means noisy breathing. It may be inspiratory or expiratory, or occurring in both phases of respiration. Inspiratory stridor is usually due to an obstruction at or above the vocal folds and is most commonly the result of an inhaled foreign body or acute infections such as epiglottitis. Expiratory stridor is usually from the lower respiratory tract and gives rise to a prolonged expiratory wheeze. It is most commonly associated with acute asthma or acute infective tracheobronchitis. Biphasic stridor is usually due to obstruction or disease of the tracheobronchial airway and distal lungs (Summary box 45.7).

Summary box 45.7

Stridor

Inspiratory

- Foreign body or epiglottitis

Expiratory

- Acute asthma or infective tracheobronchitis

Biphasic

- Obstruction, disease of tracheobronchial airway or distal lungs

Stridor in children

Infants and children presenting with stridor need careful assessment with a full history and examination as appropriate. If, on presentation, a child is cyanosed and severely unwell, the airway must be secured as soon as possible, but a brief history with important pointers can often be obtained from the parents.

History In infants in the first year of life, it is important to establish if the stridor is associated with particular activities such as swallowing, crying or movement. These may suggest congenital laryngomalacia or subglottic stenosis. If the stridor is exacerbated by feeding, particularly in the first 4 weeks of life, this suggests a vascular ring or tracheo-oesophageal fistula. If the cry is weak or abnormal, this suggests a vocal fold palsy. If the problem only

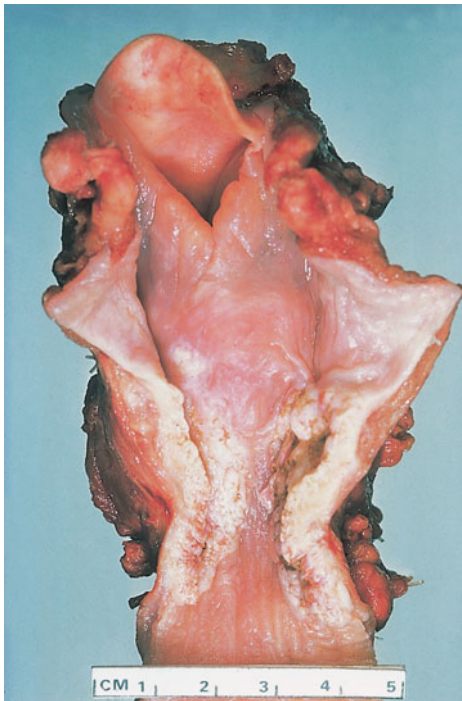

Figure 45.31 Total pharyngolaryngectomy specimen showing hypopharyngeal carcinoma (hypopharynx opened from posterior).

occurs in association with an upper respiratory tract infection and, in particular, is biphasic, this would suggest congenital subglottic stenosis. In a young child, inspiratory stridor and drooling suggest acute epiglottitis, whereas biphasic stridor without drooling suggests laryngotracheobronchitis or croup (Summary box 45.8).

Summary box 45.8

Acute paediatric stridor

Congenital

- Laryngomalacia
- Laryngeal web
- Subglottic stenosis

Acquired

- Inflammatory
 - Angioneurotic oedema
- Traumatic
 - Impacted foreign body, laryngeal fracture
- Infective
 - Epiglottitis, laryngotracheobronchitis
- Neurological
 - Vocal fold palsy
- Neoplasia
 - Benign laryngeal papillomatosis

Examination It is important when possible to observe the child carefully at rest. Once a baby starts to cry, it may be impossible to study its resting respiratory pattern for some time. Ask the mother, not a nurse or a colleague, to move a baby or young child into different positions, such as face down and supine, and watch for changes in respiratory pattern and level of distress. Observe any drooling and, with neonates and infants, always try to watch the child being fed, listening to the trachea and chest with a stethoscope if possible. Always examine the whole child, looking for any evidence of congenital abnormalities before attempting any examination of the throat.

If a child is stridulous and drooling and sitting upright in its mother's arms or a chair, do not attempt to lay it down and do not attempt to look inside the mouth. These manoeuvres are potentially life-threatening as the child may aspirate a large quantity of thick saliva contained within the oral cavity. The child does not wish to attempt swallowing in the case of a retropharyngeal abscess, parapharyngeal abscess or acute epiglottitis as these conditions are so painful. It is particularly important in acute epiglottitis as the aspiration of thick saliva may be associated with further laryngeal spasm and a respiratory arrest. Restlessness, increasing tachycardia and cyanosis are important signs of hypoxia. If the child is not distressed and drooling, and not markedly stridulous, he/she may be cooperative enough that it is possible to look inside the mouth and check the palate, tongue and oropharynx. In stridulous children, particularly neonates and infants, a transcutaneous oximeter is invaluable. A resuscitation trolley with the necessary equipment for emergency intubation or tracheostomy should be close at hand if at all possible before commencing examination.

Investigation Plain lateral radiographs of the neck and a chest radiograph can be obtained but only if the child's condition permits. If a child is severely stridulous, they should *not* be sent to a

radiography department without access to medical staff or resuscitation equipment.

Examination under anaesthesia is essential in all children whose diagnosis remains in doubt. This requires a high level of skill and appropriate rigid laryngoscopes, bronchoscopes, endoscopic Hopkins' rods and an operating microscope should be made available if possible. Equipment should be available at all times to undertake an urgent tracheostomy to establish or maintain an airway.

Acute epiglottitis

In children acute epiglottitis is of rapid onset. It tends to occur in children of 2 years of age and over. Stridor is usually associated with drooling of saliva. The condition is caused by *Haemophilus influenzae* infection, which initially causes a severe pharyngitis at the junction of the oro- and hypopharynx before producing inflammation and oedema of the laryngeal inlet. As it progresses, it involves the whole of the supraglottic larynx, with severe oedema of the aryepiglottic folds and epiglottitis being the most notable component, hence the commonly used term 'acute epiglottitis'.

These children frequently require intensive management with emergency intubation or tracheostomy followed by oxygenation, humidification, continuous oximetry and antibiotics such as ampicillin or chloramphenicol. There may be associated septicaemia so blood cultures should be obtained. Attempted examination with a spatula into the mouth may precipitate a respiratory arrest and should be avoided.

Laryngotracheobronchitis (croup)

Croup is usually of slower onset than acute epiglottitis and occurs most commonly in children under 2 years of age. It is usually viral in origin and the cases often occur in clusters. The children have biphasic stridor, and are often hoarse with a typical barking cough. Airway intervention is required less often, but admission to hospital with oxygenation and humidification, coupled with antibiotics, may be necessary if there are signs of secondary infection.

Foreign bodies

Both children and adults may inhale foreign bodies. Young children will attempt to swallow a wide variety of objects, but coins, beads and parts of toys are particularly common. In adults, the aspiration is usually food, particularly inadequately chewed bones and meat. This is more common in elderly edentulous adults. Occasionally, portions of dentures may be inhaled, particularly in association with road traffic accidents.

Clinical features

The history is paramount and a history of foreign body ingestion or inhalation in a child, even though the pain, dysphagia, coughing, etc. may have settled, should always be taken seriously.

Adults usually have a clear recall, which facilitates diagnosis. Fish bones may lodge in the tonsils or base of tongue with minimal symptoms, but small fish bones may give rise to para- and retropharyngeal abscess formation.

Examination

Examination may be prevented by trismus, pain and anxiety, but the presence of a foreign body may be suspected by a salivary pool within the pyriform fossa or adjacent oedema and erythema of the pharyngolaryngeal mucosa.

Radiology

Radiology may be helpful but is not critical. Fish bones are often invisible on plain radiographs and a normal plain radiograph does not exclude a foreign body within the pharynx, larynx, oesophagus or lungs.

Specialised studies may help in cases of doubt, using a CT scan or a gastrografin swallow in the case of a suspected oesophageal foreign body.

Treatment

In the case of an inhaled foreign body causing severe stridor in a neonate or infant, it may be removed either by hooking it from the pharynx with a finger or by inverting the child carefully by the ankles and slapping his/her back. In a larger child, it may be more appropriate to bend them over your knee with their head hanging down and again strike them firmly between the shoulders. In the case of adults, an impacted laryngeal foreign body may be coughed out using a Heimlich manoeuvre. This involves standing behind the patient, clasp the arms around the lower thorax, such that the knuckles of the clasped hands come into contact with the patient's xiphisternum, and then a brief, firm compression of the lower thorax may aid instant expiration of the foreign body. If none of these immediate emergency measures removes the foreign body and the patient is cyanosed and severely stridulous, an immediate cricothyroidotomy or tracheostomy may be necessary. In less urgent cases, and when a foreign body is strongly suspected, endoscopy under general anaesthesia may be indicated.

Other causes of acute pharyngolaryngeal oedema

Angioneurotic oedema, radiotherapy, laryngeal trauma associated with road traffic accidents, corrosives, scalds and smoke ingestion may all cause significant pharyngolaryngeal oedema, in addition to the acute infective conditions mentioned elsewhere. Hoarseness is the predominant symptom along with dysphagia prior to the increase in dyspnoea. If laryngoscopic examination is possible, marked oedema of the supraglottis and pharynx can be seen. Humidified oxygen, adrenaline nebulisers, systemic antihistamines and steroids may be valuable. Morphine should not be given as it may cause respiratory depression and respiratory arrest. If the dyspnoea progresses, intubation or tracheostomy will be necessary.

TRACHEOSTOMY AND OTHER EMERGENCY AIRWAY MEASURES

This procedure relieves airway obstruction or protects the airway by fashioning a direct entrance into the trachea through the skin of the neck. Tracheostomy may be carried out as an emergency when the patient is *in extremis* and the larynx cannot be intubated, but it is not always an easy procedure, particularly in an obese patient. An easier alternative for the inexperienced is insertion of a large intravenous cannula or a small tube into the cricothyroid membrane, which lies in the midline immediately below the thyroid cartilage. Emergency intubation is a further option when the laryngotracheal airway is not obstructed and

tracheostomy may be performed thereafter. *The time to do a tracheostomy is when you first think it may be necessary.*

If time allows, the following should be undertaken:

- inspection and palpation of the neck to assess the laryngotracheal anatomy in the individual patient;
- indirect or direct laryngoscopy;
- assessment of pulmonary function.

Whenever possible, the procedure should be adequately explained to the patient beforehand, with particular emphasis on the inability to speak immediately following the operation. Ample reassurance is required that they will not have 'lost' their voice permanently. The indications for tracheostomy are shown in Summary box 45.9

Summary box 45.9

Indications for tracheostomy

Acute upper airway obstruction

- For example, an inhaled foreign body, a large pharyngolaryngeal tumour, or acute pharyngolaryngeal infections in children

Potential upper airway obstruction

- For example, after major surgery involving the oral cavity, pharynx, larynx or neck

Protection of the lower airway

- For example, protection against aspiration of saliva in unconscious patients as a consequence of head injuries, faciomaxillary injuries, comas, bulbar poliomyelitis or tetanus

Patients requiring prolonged artificial respiration

Emergency tracheostomy

If a skilled anaesthetist is unavailable, local anaesthesia is employed, but in desperate cases when the patient is unconscious, none is required. In patients who have suffered severe head and neck trauma and who may have an unstable cervical spine fracture, cricothyroidotomy may be more suitable. If it is possible, the patient should be laid supine with padding placed under the shoulders and the extended neck kept as steady as possible in the midline. This aids palpation of the thyroid and cricoid cartilage between the thumb and index finger of the free hand. The movements of the fingers of the free hand are important in this technique. The operation is more difficult in small children and thick-necked adults as the landmarks are difficult to palpate (Figs 45.32 and 45.33).

A vertical midline incision is made from the inferior aspect of the thyroid cartilage to the suprasternal notch and continued down between the infrahyoid muscles. There may be heavy bleeding from the wound at this point, particularly if the neck is congested as a result of the patient's efforts to breathe around an acute upper airway obstruction. No steps should be taken to control this haemorrhage, although an assistant and suction are valuable. The operator should feel carefully for the cricoid cartilage using the index finger of the free hand while retracting the skin edges by pressure applied by the thumb and middle finger. If the situation is one of extreme urgency, a further vertical incision straight into the trachea at the level of the second, third and

Henry Jay Heimlich, B. 1920, Thoracic Surgeon, Xavier University, Cincinnati, OH, USA.

in extremis is Latin for 'in the last things'.

Figure 45.32 The position of skin incision in an emergency tracheostomy.

fourth ring should be made immediately without regard to the presence of the thyroid isthmus. The knife blade is rotated through 90°, thus opening the trachea. At this point the patient may cough violently as blood enters the airway. The operator should be aware of this possibility and avoid losing the position of the scalpel in the open trachea. Any form of available tube should be inserted into the trachea as soon as possible and blood and secretion sucked out. Once an airway has been established, haemostasis is then secured. With the emergency under control, the tracheostomy should be refashioned as soon as possible.

Should additional equipment and more time be available once the cricoid cartilage has been identified, blunt finger dissection inferiorly can be used to mobilise the thyroid isthmus, which should be divided between haemostats, clearing the trachea before making a vertical incision through the second to the fourth rings. A tracheal dilator is inserted through the tracheal incision and the edges of the tracheal wound are separated gently. In cases of suspected human immunodeficiency virus (HIV) infection or diphtheria, the surgeon places a swab over the wound so that the violent expiratory efforts which may follow do not contaminate the operator(s) with infected mucus and blood. When respiratory efforts have become less violent, a tracheostomy tube is inserted into the trachea and the dilator removed. It is important that the surgeon keeps a finger on the tube while the assistant ties the attached tapes around the patient's neck. Return the neck to a neutral position before tying the tapes firmly.

Elective tracheostomy

The advantage of an elective procedure is that there is complete airway control at all times, unhurried dissection and careful

Figure 45.33 An incision in the trachea in an emergency tracheostomy.

placement of an appropriate tube. Close cooperation between the surgeon, anaesthetist and scrub nurse is essential, and attention to detail will markedly reduce possible complications and morbidity from the procedure.

Following induction of general anaesthesia and endotracheal intubation, the patient is positioned with a combination of head extension and placement of an appropriate sandbag under the shoulders (Fig. 45.34). There should be no rotation of the head. Children's heads should not be overextended as it is possible to enter the trachea in the fifth and sixth rings in these circumstances. Insertion of a bronchoscope in the trachea may help when performing tracheostomy in young children. A transverse incision may be used in the elective situation (Fig. 45.35). The tracheal isthmus is divided carefully and oversewn and tension sutures placed either side of the tracheal fenestration in children (Fig. 45.36). A Bjork flap may be used in adults (Figs 45.37 and 45.38).

The advantages of the Bjork method far outweigh the potential disadvantages and the method is particularly useful for those

Viking Olaf Bjork, B. 1918, formerly Cardiac Surgeon, Karolinska Sjukset, Stockholm, Sweden.

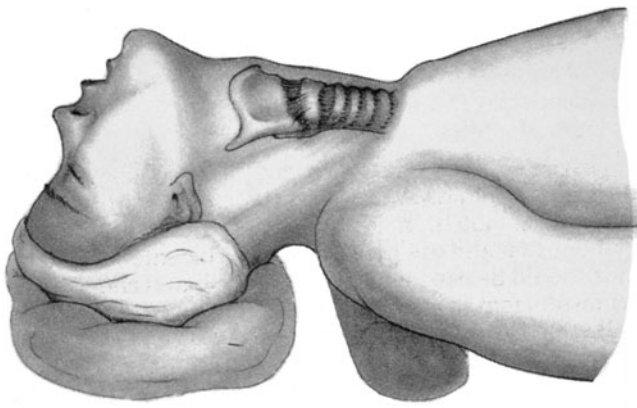

Figure 45.34 Position of the patient for elective tracheostomy.

Figure 45.36 Tracheal fenestration in an elective tracheostomy.

Figure 45.35 Position of a skin incision in an elective tracheostomy.

Figure 45.37 Bjork flap.

surgeons who undertake occasional tracheostomy or when the level of skill and experience of the nursing staff is limited. Performed correctly, it is safe and allows reintroduction of a displaced tube with the minimum of difficulty.

The inferiorly based flap is begun at its apex with an incision on the superior aspects of the second ring and extends down either side through the second and third rings. The tip of the flap should be stitched to the inferior edge of the transverse skin incision using horizontal mattress sutures through the structure of the second ring. These sutures should be generous enough so that they will not cut out. The first tracheal ring should not be violated in any circumstances.

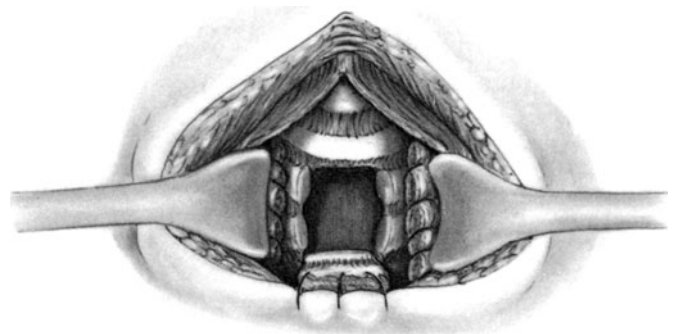

Figure 45.38 Fenestration in a Bjork flap.

Tracheostomy tubes (Figs 45.39 and 45.40)

These are basically made of two materials: silver or plastic. Both materials have been used to make tubes of various sizes with varying curves, angles, cuffs, inner tubes and speaking valves. A cuffed tube is used initially, which may be changed after 3–4 days to a non-cuffed plastic or silver tube. The pressure within the tube cuff should be carefully monitored and should be low enough so as not to occlude circulation in the mucosal capillaries. When in position, the tube should be retained by double tapes passed around the patient's neck with a reef knot on either side. It is important that the patient's head is flexed when the tapes are tied, otherwise they may become slack when the patient is moved from the position of extension, thereby resulting in a possible displacement of the tube if the patient coughs.

Figure 45.39 Silver tracheostomy tube. From above: introducer, outer tube and inner tube.

Figure 45.40 Modern plastic tracheostomy tube with introducer, low-pressure cuff and inner canula.

Alternatively, the flanges of the plastic tube may be stitched directly to the underlying neck skin.

All forms of tracheostomy and cricothyroidotomy bypass the upper airway and have the following advantages:

- the anatomical dead space is reduced by approximately 50%;
- the work of breathing is reduced;
- alveolar ventilation is increased;
- the level of sedation needed for patient comfort is decreased and, unlike endotracheal intubation, the patient may be able to talk and eat with a tube in place.

However, there are several disadvantages:

- loss of heat and moisture exchange performed in the upper respiratory tract;
- desiccation of tracheal epithelium, loss of ciliated cells and metaplasia;
- the presence of a foreign body in the trachea stimulates mucous production; where no cilia are present, this mucociliary stream is arrested;
- the increased mucus is more viscid and thick crusts may form and block the tube;
- although many patients with a tracheostomy can feed satisfactorily, there is some splinting of the larynx, which may prevent normal swallowing and lead to aspiration; this aspiration may not be apparent.

Postoperative treatment is designed to counteract these effects and frequent suction and humidification are most important. A trolley must be placed by the bed containing a tracheal dilator, duplicate tubes and introducers, retractors and dressings. Oxygen is at hand and, in the initial period, a nurse must be in constant attendance. Humidification will render the secretions less viscid and a sucker with a catheter attached should be on hand to keep the tracheobronchial tree free from secretions (Summary box 45.10).

Summary box 45.10

Tracheostomy: postoperative management

- Suction – efficient, sterile and as often as required
- Humidification (with or without oxygen)
- A warm, well-ventilated room
- Position of the tube and patient
- Spare tube, introducer, tapes, tracheal dilator
- Change of tube, inner tube, possible speaking valve
- Physiotherapy

Complications of tracheostomy

The intraoperative, early and late postoperative complications of tracheostomy are listed in Table 45.2.

OTHER EMERGENCY AIRWAY PROCEDURES

Fibreoptic endotracheal intubation

In most emergency situations, endotracheal intubation is the most direct and satisfactory method of securing the airway. Nasotracheal intubation in expert hands is also a well-established technique and is particularly useful if the patient has trismus, severe mandibular injuries, cervical spine rigidity or an obstructing mass within the oral cavity. Both forms of intubation can be

Table 45.2 Tracheostomy: complications

Intraoperative complications	Haemorrhage Injury to paratracheal structures, particularly the carotid artery, recurrent laryngeal nerve and oesophagus Damage to the trachea
Early postoperative complications	Apnoea caused by a fall in the P_{CO_2} Haemorrhage Subcutaneous emphysema, pneumomediastinum and pneumothorax Accidental extubation, anterior displacement of the tube, obstruction of the tube lumen and tip occlusion against the tracheal wall Infection Swallowing dysfunction
Late postoperative complications	Difficult decannulation Tracheocutaneous fistula Tracheo-oesophageal fistula, tracheoinnominate artery fistula with severe haemorrhage Tracheal stenosis

facilitated in case of difficulty by passing a fiberoptic endoscope through the centre of an endotracheal tube, hence guiding it into the larynx and trachea under direct vision.

Laryngeal mask airway

The laryngeal mask airway (LMA) is a wide-bore airway with an inflatable cuff at the distal end, which forms a seal in the pharynx around the laryngeal inlet. Provided the laryngotracheal airway is clear, the LMA provides a clear and secure airway. The technique can easily be learnt by non-anaesthetists and secures an airway in most cases. It comes in a range of sizes covering infants to large adults. It is particularly useful in cases of difficult intubation (Fig. 45.41).

Transtracheal ventilation

This technique is simple and effective and allows ventilation for periods in excess of 1 hour providing time to allow for more elective intubation. The cricothyroid membrane is located by palpation of the neck with the index finger, and a 14- or 16-gauge plastic sheathed intravascular needle and a 10-ml syringe containing a few millilitres of lignocaine are introduced in the midline and directed downwards and backwards into the tracheal lumen. The needle is advanced steadily and negative pressure is

placed on the syringe until bubbles of air are clearly seen (Fig. 45.42). The tissues of the neck may be infiltrated with the anaesthetic if desired and the tracheal mucosa likewise partly anaesthetised by the introduction of 1–2 ml after gaining the lumen. The needle is removed and the plastic sheath cannula remains in the tracheal lumen and must be carefully held and fixed in place by the operator so that it does not come out of the lumen into the soft tissues of the neck. It is attached by means of a Luer connection to the high-pressure oxygen supply. Ventilation may be undertaken in a controlled manner with a jetting device with the chest being observed for appropriate movements.

If there is severe obstruction of the laryngopharynx by the foreign body or tumour, the exhaled outflow of gases can be aided

Figure 45.41 Laryngeal mask airway being inserted.

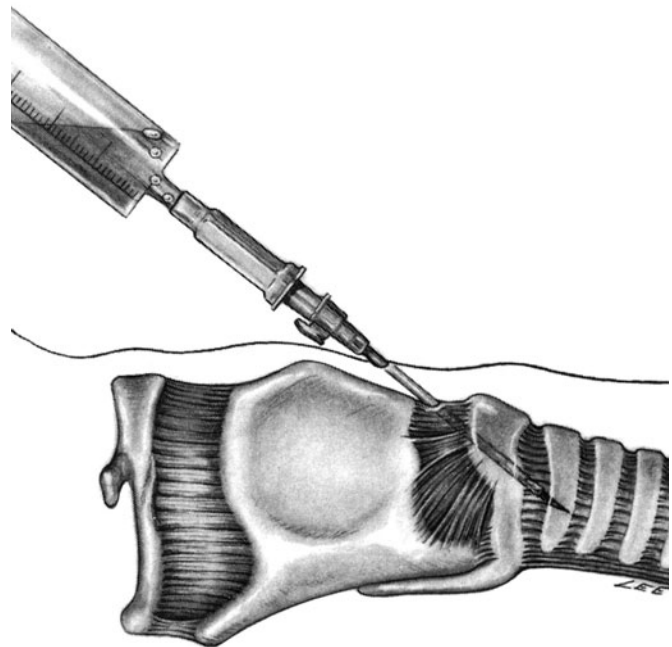

Figure 45.42 Transtracheal needle introduction.

Luer was a German instrument maker who was working in Paris, France, at the end of the 19th century.

by the placement of one or two further cannulae as exhalation ports. This procedure gains extremely rapid control of ventilation and requires a minimum of technical expertise. Its only notable complication is surgical emphysema of the neck tissues if the cannula dislodges from the tracheal lumen.

Cricothyroidotomy

Cricothyroidotomy has the advantages of speed and ease requiring little equipment and surgical expertise. However, its use for all but the briefest access to the airway remains controversial and there are conflicting reports with regard to the subsequent incidence of complications, particularly those of subglottic stenosis and long-term voice changes.

The patient's neck is extended and the area between the prominence of the thyroid cartilage and the cricoid cartilage below is palpated with the index finger of the free hand. In the emergency situation, a vertical skin incision is recommended with dissection rapidly carried down to the cricothyroid membrane. A 1-cm transverse incision is made through the membrane immediately above the cricoid cartilage and the scalpel twisted through a right angle to gain access to the airway. If available, artery forceps, dilator or tracheal hook will improve the aperture and insertion of an available tube (Figs 45.43 and 45.44).

Depending on the degree of emergency, it may be necessary for the surgeon to assess the results of the procedure by direct laryngoscopy and the authors recommend that careful consideration should be given to conversion of the cricothyroidotomy to a tracheostomy. Although there is debate about the frequency of subglottic stenosis following this procedure, there is general agreement that it is much increased if any long-term ventilation

Figure 45.43 Incision in a cricothyroidotomy.

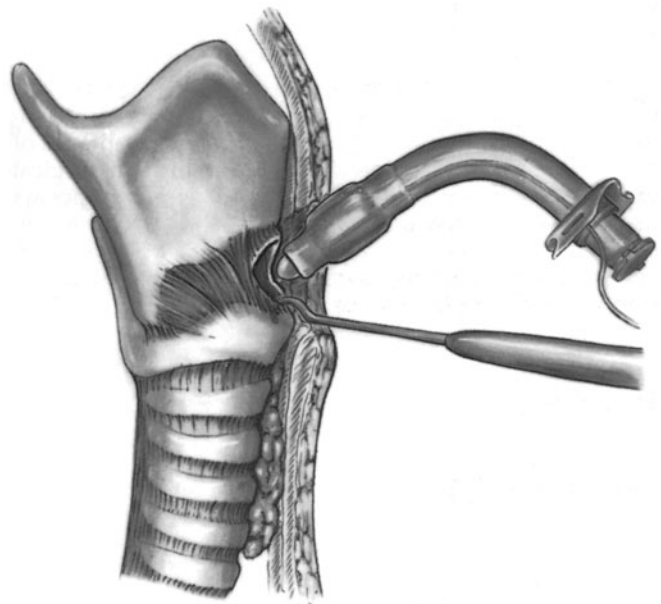

Figure 45.44 Insertion of a tube after cricothyroidotomy.

is undertaken via even a modestly size tracheostomy tube through the cricothyroid membrane.

LARYNGEAL DISEASE CAUSING VOICE DISORDERS

Vocal nodules

These are fibrous thickenings of the vocal folds at the junction of the middle and anterior third (Fig. 45.45), and are the result of vocal abuse; they are known as singers' nodules in adults and screamers' nodules in children. Speech therapy is therefore the preferred treatment and the lesions will resolve spontaneously in most cases. Occasionally, the nodules will need to be surgically removed using modern microlaryngoscopic dissection or laser techniques (Summary box 45.11).

Figure 45.45 Vocal fold nodules.

Summary box 45.11

Causes of hoarseness

- Localised vocal fold pathology, e.g. vocal nodule, polyps or laryngeal papillomatosis, acute or chronic laryngitis
- Vocal fold palsy
- Laryngeal tumours
- Non-specific voice disorders, functional dysphonia

Vocal fold polyps

These are usually unilateral and may be associated with an acute infective episode, cigarette smoking and vocal abuse (Fig. 45.46). Speech therapy is again indicated, but they do usually require removal by microdissection or laser surgery.

Laryngeal papillomata

These occur mainly in children, but can also present in adults. They are most commonly found on the vocal folds, but may spread throughout the larynx and tracheobronchial airway (Fig. 45.47). They are caused by papillomaviruses and need removal by carbon dioxide laser or microsurgery to maintain a reasonable voice and airway. Anti-viral treatment is of doubtful value at present and new therapeutic vaccines are awaited.

Acute laryngitis

This often occurs in association with upper respiratory tract infections in association with a cough and pharyngitis. Usually viral, it may be localised to the larynx and it settles quickly if the voice is rested during the acute inflammation. Steam inhalations are soothing along with mild analgesia, but antibiotics are unnecessary (Summary box 45.12).

Summary box 45.12

Warning

- Hoarseness lasting for 3–4 weeks should always be referred for an ENT opinion, particularly in smokers

Figure 45.46 A vocal fold polyp.

Figure 45.47 Laryngeal papillomata.

Chronic laryngitis

Chronic laryngitis may be specific and can be caused by mycobacteria, syphilis and fungi. Treatment is directed towards the causative organism. Non-specific laryngitis is common, the main predisposing factors being smoking, chronic upper and lower respiratory sepsis and voice abuse. Gastro-oesophageal reflux has been implicated as a factor in laryngitis, vocal fold nodules and polyps, but the evidence is controversial. There is, however, a vogue for treatment with anti-reflux medication and proton pump inhibitors. Diagnosis of chronic laryngitis should not be made unless the larynx has been fully evaluated by a laryngologist.

Vocal fold palsy

This may be unilateral or bilateral (Fig. 45.48), but a unilateral left vocal fold palsy is the most common because of the long intrathoracic course of the left recurrent laryngeal nerve, which arches around the aorta and may be commonly involved in inflammatory and neoplastic conditions involving the left hilum. Lung cancer is the most common cancer in many parts of the world, and should be considered the cause of a left vocal palsy until proved otherwise.

Other malignant lesions can cause a similar effect and may arise in the nasopharynx, thyroid gland or oesophagus. Bilateral vocal fold paralysis is uncommon and tends to occur after thyroid surgery or head injuries (Summary box 45.13).

Figure 45.48 Vocal fold positions. (a) Normal; (b) unilateral vocal fold palsy.

Summary box 45.13

Causes of vocal fold palsy

Congenital (infants)

Acquired

- Traumatic
 - Direct to neck
 - Post-surgical, e.g. thyroidectomy
- Infective
 - Viral (rare)
- Neoplastic
 - Carcinoma of the lung involving the left hilum
 - Carcinoma of the larynx
 - Carcinoma of the thyroid
 - Carcinoma of the oesophagus
- Vascular
 - Aortic aneurysm
- Neurological
 - Lower motor neurone disease

Clinical features

Unilateral recurrent laryngeal nerve palsy of sudden onset produces hoarseness, difficulty in swallowing liquids and a weakened cough. These symptoms may be short-lived and the voice may return to normal within a few weeks as the muscles in the opposite vocal fold compensate and move it across the midline to meet the paralysed vocal fold, which usually lies in the paramedian position. Bilateral recurrent laryngeal nerve palsy is an occasional and serious complication of thyroidectomy. Acute dyspnoea occurs as a result of the paramedian position of both vocal folds, which reduce the airway to 2–3 mm and which tend to get sucked together on inspiration. In severe cases, tracheostomy or intubation is necessary immediately, otherwise death occurs from asphyxia.

Investigation of vocal fold paralysis is by a CT scan from skull base to diaphragm. Approximately 20–25% of vocal fold paralysis occurs without known pathology and spontaneous recovery may occur. When compensation does not occur, a unilateral paralysed fold may be medialised by a small external operation on the thyroid cartilage (thyroplasty).

In bilateral vocal fold palsy, surgery may be carried out to remove a small portion of the posterior aspect of one vocal fold or a portion of one arytenoid cartilage. These procedures are most easily performed endoscopically with a carbon dioxide laser. They increase the size of the posterior glottic airway, allowing the patient to be decannulated or even the avoidance of an initial tracheostomy.

TUMOURS OF THE LARYNX

Benign tumours of the larynx are extremely rare. Squamous carcinoma is the most common malignant tumour, being responsible for more than 90% of tumours within the larynx. It is the most common head and neck cancer and previously almost always occurred in elderly male smokers. However, over the past two decades, the incidence among women is rising as a consequence of increased smoking habits. The incidence of laryngeal cancer in the three compartments, supraglottis, glottis and subglottis, varies around the world. The glottis is generally the most common site for cancer in patients in the UK, followed by the supraglottis (Fig. 45.49).

Figure 45.49 A total laryngectomy specimen with transglottic tumour.

Clinical features

Patients almost always present with hoarseness. If an early diagnosis can be made, i.e. confined to one vocal fold, treatment with radiotherapy or carbon dioxide laser excision is associated with a 5-year disease-free survival of approximately 90%. This rate drops dramatically once the lymphatically rich supraglottis or subglottis is involved because of spread to neck nodes. Tumour spread to just one neck gland halves the overall prognosis for the patient.

Investigations

Direct laryngoscopy, preferably a microlaryngoscopy, together with Hopkins' rod examination, allows precise determination of the extent of the tumour and biopsy confirms the histology. CT and MRI give further details of the extent of larger tumours, demonstrating spread outside the larynx and suspicious nodal involvement within the neck, which may not be obvious clinically. The tumour–node–metastasis (TNM) classification of laryngeal cancer is given in Table 45.3.

Treatment

Early supraglottic and glottic tumours, stages 1 and 2, are optimally treated with megavoltage radiotherapy. Five-year cure rates for stages 1 and 2 are approximately 90 and 70%, respectively, with excellent voice preservation. If radiotherapy is not feasible, tumours may be excised by means of endoscopic laser

Table 45.3 Tumour–node–metastasis (TNM) classification of laryngeal carcinoma

T – primary tumour			
■ TX	Primary tumour cannot be assessed		
■ T0	No evidence of primary tumour		
■ Tis	Carcinoma <i>in situ</i>		
■ Supraglottis			
– T1	Tumour limited to one subsite of supraglottis, with normal vocal fold mobility		
– T2	Tumour invades more than one subsite of supraglottis, with normal vocal fold mobility		
– T3	Tumour limited to larynx with vocal fold fixation and/or invades post-cricoid area, medial wall of piriform sinus or pre-epiglottic tissues		
– T4	Tumour invades through cartilage and/or extends to other tissues beyond the larynx, e.g. to oropharynx, soft tissues of neck		
■ Glottis			
– T1	Tumour limited to vocal fold(s) (may involve anterior or posterior commissures) with normal mobility		
– T1a	Tumour limited to one vocal fold		
– T1b	Tumour involves both vocal folds		
– T2	Tumour extends to supraglottis and/or subglottis, and/or with impaired vocal fold mobility		
– T3	Tumour limited to the larynx with vocal fold fixation		
– T4	Tumour invades through thyroid cartilage and/or extends to other tissues beyond the larynx, e.g. to oropharynx, soft tissues of the neck		
■ Subglottis			
– T1	Tumour limited to the subglottis		
– T2	Tumour extends to vocal fold(s) with normal or impaired mobility		
– T3	Tumour limited to the larynx with vocal fixation		
– T4	Tumour invades through thyroid cartilage and/or extends to other tissues beyond the larynx, e.g. to oropharynx, soft tissues of the neck		
N – regional lymph nodes			
■ N0	No regional lymph node metastases		
■ N1	Metastasis in a single ipsilateral lymph node 3 cm or less in greatest diameter		
■ N2	Metastasis in a single ipsilateral lymph node more than 3 cm or in multiple ipsilateral nodes or in bilateral or contralateral nodes		
M – distant metastasis			
Stage grouping			
Stage 0	Tis	N0	M0

surgery or open partial laryngeal surgery. The latter may be in the form of a laryngofissure when the thyroid cartilage is opened anteriorly in the midline or, in the case of more extensive unilateral glottic and supraglottic growths, a vertical hemilaryngectomy (Fig. 45.50). This leaves a defect on one side of the larynx, which is usually reconstructed with adjacent strap muscles. With early bilateral supraglottic tumours, a horizontal laryngectomy may be undertaken, excising the supraglottic growth. The remaining glottis and supraglottis are then stitched to the tongue base.

Advanced laryngeal disease

Once the squamous carcinoma has caused fixation of the vocal fold or has infiltrated outside the larynx into adjacent structures such as the thyroid gland and strap muscles, some form of subtotal or total laryngectomy is required (Figs 45.51–45.53).

After the larynx has been removed, the remaining trachea is brought out onto the lower neck as a permanent tracheal stoma and the hypopharynx, which is opened at the time of the operation, is closed to restore continuity for swallowing. Thus the upper aero- and digestive tracts are permanently disconnected. Part or all of the thyroid gland and associated parathyroid glands may also be removed, depending on the extent of the disease.

Vocal rehabilitation

The loss of the larynx as a generator of sound does not prevent patients speaking as long as an alternative source of vibration can be created in the pharynx. This can be achieved in one of three ways:

- 1 An external device when applied to the soft tissues of the neck produces sound, which is turned into speech by the vocal tract comprising the tongue, pharynx, oral cavity, lips, teeth and nasal sinuses. These devices are usually battery powered.
- 2 Some patients may learn to swallow air into the pharynx and upper oesophagus. On regurgitating the air, a segment of the pharyngo-oesophageal mucosa vibrates to produce sound, which is modified by the vocal tract into speech (Fig. 45.54).
- 3 A small one-way valve may be inserted through the back wall of the tracheal stoma into the pharynx (Fig. 45.55). This allows air from the trachea to pass into the pharynx, but does not allow food and liquid to pass into the airway. These valves must not be confused with tracheostomy tubes. Like all foreign bodies, the speaking valves are associated with minor complications, such as the formation of granulations, bleeding or leakage of pharyngeal contents.

THE NECK

Lump in the neck

The correct diagnosis of a lump in the neck can often be made with a careful history and examination. The clinical signs of size, site, shape, consistency, fixation to skin or deep structures, pulsation, compressibility, transillumination or the presence of a bruit still remain as important as ever (Summary box 45.14).

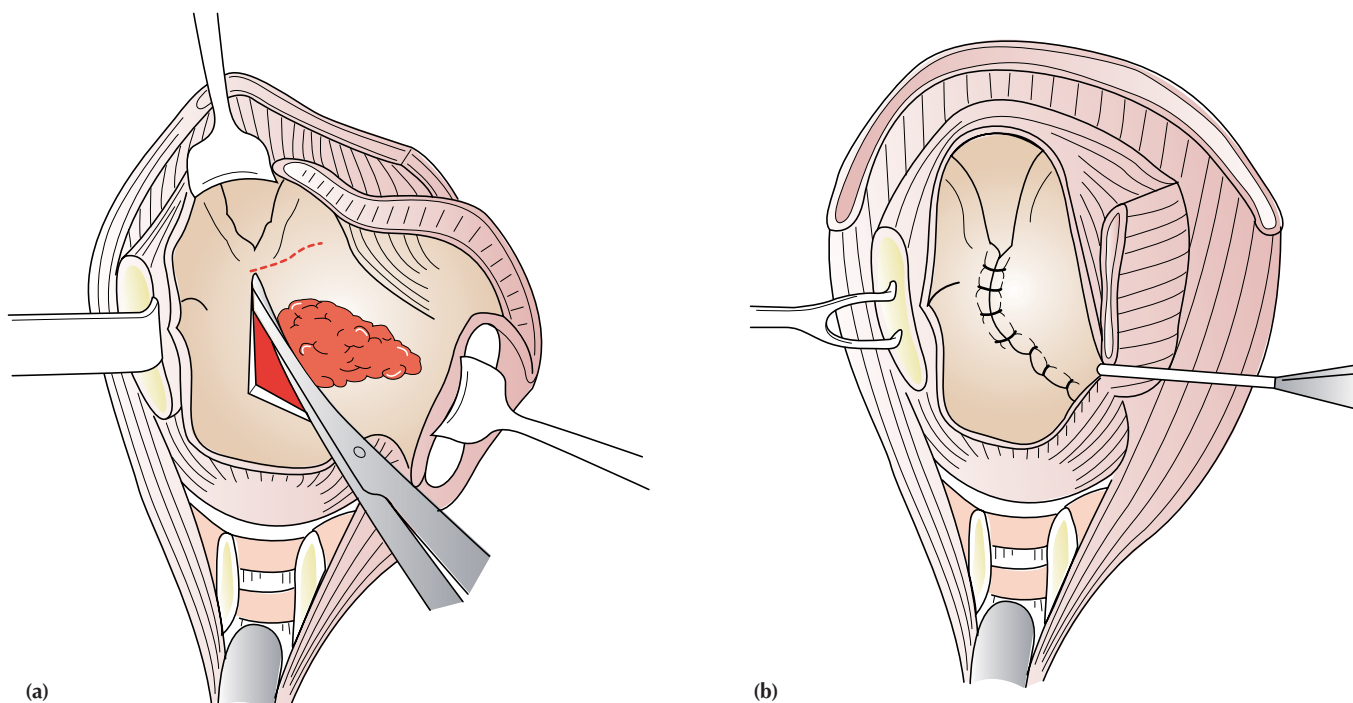

Figure 45.50 (a and b) Resection of tumour with left vertical partial hemilaryngectomy.

- Bruit

Branchial cyst

A branchial cyst probably develops from the vestigial remnants of the second branchial cleft, is usually lined by squamous epithelium, and contains thick, turbid fluid full of cholesterol crystals. The cyst usually presents in the upper neck in early or middle adulthood and is found at the junction of the upper third and middle third of the sternomastoid muscle at its anterior border. It is a fluctuant swelling that may transilluminate and is often soft in its early stages so that it may be difficult to palpate.

If the cyst becomes infected it becomes erythematous and tender and, on occasions, it may be difficult to differentiate from a tuberculous abscess. Ultrasound and fine-needle aspiration both aid diagnosis and treatment is by complete excision, which is best undertaken when the lesion is quiescent. Although the anterior aspect of the cyst is easy to dissect, it may pass backwards and upwards through the bifurcation of the common carotid

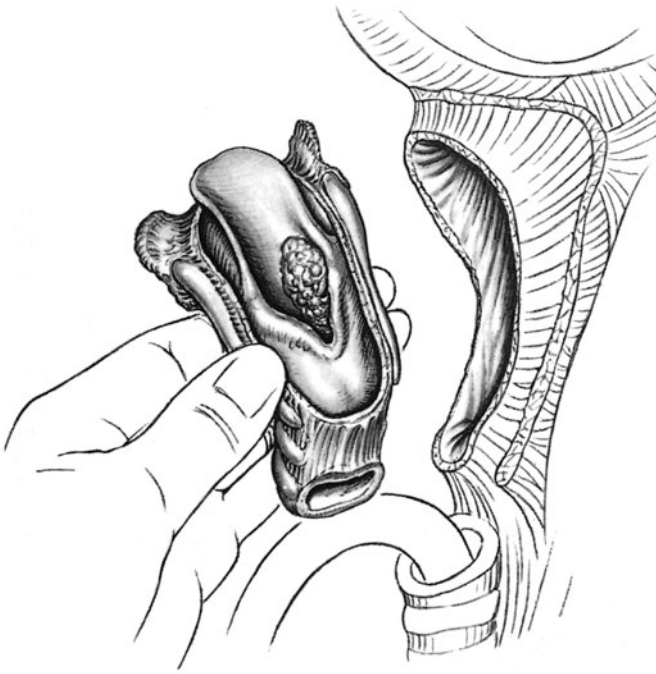

Figure 45.52 Removal of a laryngeal specimen.

artery as far as the pharyngeal constrictors. It passes superficial to the hypoglossal and glossopharyngeal nerves, but deep to the posterior belly of the digastric. These structures and the spinal accessory nerve must be positively identified to avoid damage.

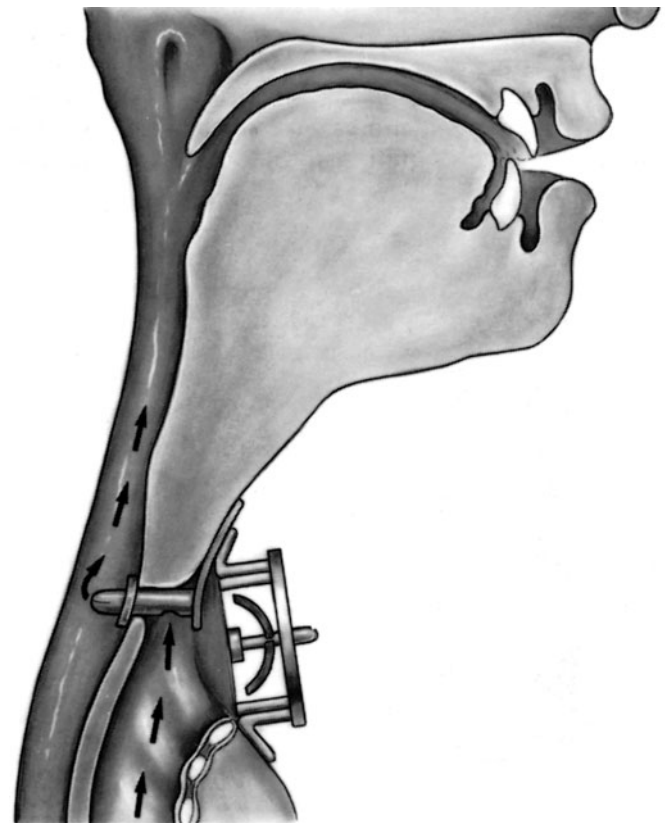

Figure 45.55 A Blom-Singer valve with a tracheo-oesophageal fistula and an outer stoma valve.

Branchial fistula (Fig. 45.56)

A branchial fistula may be unilateral or bilateral and is thought to represent a persistent second branchial cleft. The external orifice is nearly always situated in the lower third of the neck near the anterior border of the sternocleidomastoid, whilst the internal

Figure 45.56 (a) Plain radiograph with radio-opaque dye in the fistula tract. (b) Probing of the fistula tract. (c) Excision of the fistula tract.

orifice is located on the anterior aspect of the posterior faucial pillar just behind the tonsil. However, the internal aspect of the tract may end blindly at or close to the lateral pharyngeal wall, constituting a sinus rather than a fistula. The tract is lined by ciliated columnar epithelium and, as such, there may be a small amount of recurrent mucous or mucopurulent discharge onto the neck. The tract follows the same path as a branchial cyst and requires complete excision, often by more than one transverse incision in the neck.

Cystic hygroma (Fig. 45.57)

Cystic hygroma usually present in the neonate or in early infancy, and occasionally may present at birth and be so large as to obstruct labour. The cysts are filled with clear lymph and lined by a single layer of epithelium with a mosaic appearance. Swelling usually occurs in the neck and may involve the parotid, submandibular, tongue and floor of mouth areas. The swelling may be bilateral and is soft and partially compressible, visibly increasing in size when the child coughs or cries. The characteristic that distinguishes it from all other neck swellings is that it is brilliantly translucent. The cheek, axilla, groin and mediastinum are other less frequent sites for a cystic hygroma.

The behaviour of cystic hygromas during infancy is unpredictable. Sometimes the cyst expands rapidly and occasionally respiratory difficulty ensues, requiring immediate aspiration and even occasionally a tracheostomy. The cyst may become infected.

Definitive treatment is complete excision of the cyst at an early stage. Injection of a sclerosing agent, for example picibanil (OK-432), may reduce the size of the cyst; however, they are commonly multicystic and if the injection is extracystic subsequent surgery may be more difficult.

Thyroglossal duct cysts**Embryology**

The thyroid gland descends early in fetal life from the base of the tongue towards its position in the lower neck with the isthmus

Figure 45.57 Cystic hygroma.

lying over the second and third tracheal rings. At the time of its descent, the hyoid bone has not been formed and the track of the descent of the thyroid gland is variable, passing in front, through or behind the eventual position of the hyoid body. Thyroglossal duct cysts represent a persistence of this track and may therefore be found anywhere in or adjacent to the midline from the tongue base to the thyroid isthmus. Rarely, a thyroglossal cyst may contain the only functioning thyroid tissue in the body.

Clinical features

The cysts almost always arise in the midline but, when they are adjacent to the thyroid cartilage, they may lie slightly to one side of the midline. Classically, the cyst moves upwards on swallowing and with tongue protrusion, but this can also occur with other midline cysts such as dermoid cysts, as it merely indicates attachment to the hyoid bone.

Thyroglossal cysts may become infected and rupture onto the skin of the neck presenting as a discharging sinus. Although they often occur in children, they may also present in adults, even as late as the sixth or seventh decade of life (Fig. 45.58).

Treatment

Treatment must include excision of the whole thyroglossal tract, which involves removal of the body of the hyoid bone and the suprahyoid tract through the tongue base to the vallecula at the site of the primitive foramen caecum, together with a core of

Figure 45.58 A patient with thyroglossal fistula from a cyst in the midline of the neck.

tissue on either side. This operation is known as Sistrunk's operation and prevents recurrence, most notably from small side branches of the thyroglossal tract.

TRAUMA TO THE NECK

Wounds above the hyoid bone

The cavity of the mouth or pharynx may have been entered and the epiglottis may be divided via the pre-epiglottic space. These wounds require repair with absorbable sutures on a formal basis under a general anaesthetic. If there is any degree of associated oedema or bleeding, particularly in relation to the tongue base or laryngeal inlet, it is advisable to perform a tracheostomy to avoid any subsequent respiratory distress.

Wounds of the thyroid and cricoid cartilage

Blunt crushing injuries or severe laceration injuries to the laryngeal skeleton can cause marked haematoma formation and rapid loss of the airway. There may be significant disruption of the laryngeal skeleton. These patients should not have an endotracheal intubation for any length of time, even if this is the initial emergency way of protecting the airway. The larynx is a delicate three-tiered sphincter and the presence of a foreign body in its lumen after severe disruption gives rise to major fibrosis and loss of laryngeal function. These injuries are frequently an absolute indication for a low tracheostomy, following which the larynx can be carefully explored, damaged cartilages repositioned and sutured, and the paraglottic space drained.

An indwelling stent of soft sponge shaped to fit the laryngeal lumen and held by a nylon retaining suture through the neck may be left in place for approximately 5 days. This stent can be removed endoscopically after cutting the retaining suture and, as the laryngeal damage heals, the patient may then be decannulated.

Division of the trachea

Wounds of the trachea are rare. They should all be formally explored and, in order to obtain adequate exposure, it is usually necessary to divide and ligate the thyroid isthmus. A small tracheostomy below the wound followed by repair of the trachea with a limited number of submucosal sutures is appropriate. In self-inflicted wounds, the recurrent laryngeal nerves, which lie protected in the tracheo-oesophageal grooves, are rarely injured. Primary repair is rarely possible but may be undertaken at the time of formal exploration of a major neck wound.

Neurovascular injury

Penetrating wounds of the neck may involve the common carotid or the external or internal carotid arteries. Major haemorrhagic shock may occur. Venous air embolism may occur as a result of damage to one of the major veins, most commonly the internal jugular. Compression, resuscitation and exploration under general anaesthetic, with control of vessels above and below the injury, and primary repair should be undertaken. All cervical nerves are vulnerable to injury, particularly the vagus and recurrent laryngeal nerves and cervical sympathetic chain.

Walter Ellis Sistrunk, Jr., 1880–1933, Professor of Clinical Surgery, Baylor University College of Medicine, Dallas, TX, USA.

Thoracic duct injury

Wounds to the thoracic duct are rare and most often occur in association with dissection of lymph nodes in the left supraclavicular fossa. When damage to the duct is not recognised at the time of operation, chyle may subsequently leak from the wound in amounts up to 2 l day⁻¹ with profound effects on nutrition.

Treatment

Should the damage be recognised during an operation, the proximal end of the duct must be ligated. Ligation of the duct is not harmful because there are a number of anastomotic channels between the lymphatic and venous system in the lower neck. If undetected, chyle usually starts to discharge from the neck wound within 24 hours of the operation. On occasion, firm pressure by a pad to the lower neck may stop the leakage, but frequently this is unsuccessful and the wound should be re-explored and the damaged duct ligated.

Inflammatory conditions of the neck

Ludwig's angina

Ludwig described a clinical entity characterised by a brawny swelling of the submandibular region combined with inflammatory oedema of the mouth. It is these combined cervical and intraoral signs that constitute the characteristic feature of the lesion, as well as the accompanying putrid halitosis.

The infection is often caused by a virulent streptococcal infection associated with anaerobic organisms and sometimes with other lesions of the floor of the mouth such as carcinoma. The infection encompasses both sides of the mylohyoid muscle causing oedema and inflammation such that the tongue may be displaced upwards and backwards, giving rise to dysphagia and subsequently to painful obstruction of the airway. Unless treated, cellulitis may extend beneath the deep fascial layers of the neck to involve the larynx, causing glottic oedema and airway compromise.

Antibiotic therapy should be instituted as soon as possible using intravenous broad-spectrum antibiotics, such as amoxicillin or cefuroxime, combined with metronidazole to combat the anaerobes.

In advanced cases when the swelling does not subside rapidly with such treatment, a curved submental incision may be used to drain both submandibular triangles. The mylohyoid muscle may be incised to decompress the floor of the mouth and corrugated drains placed in the wound, which is then lightly sutured. This operation may be conducted under local anaesthetic. Rarely, a tracheostomy may be necessary.

Cervical lymphadenitis

Cervical lymphadenitis is common due to infection or inflammation in the oral and nasal cavities, pharynx, larynx, ear, scalp and face.

Acute lymphadenitis

The affected lymph nodes are enlarged and tender, and there may be varying degrees of general constitutional disturbance such as pyrexia, anorexia and general malaise. The treatment in the first

instance is directed to the primary focus of infection, for example tonsillitis or a dental abscess.

Chronic lymphadenitis

Chronic, painless lymphadenopathy may be caused by tuberculosis in young children or adults, or be secondary to malignant disease, most commonly from a squamous carcinoma in older individuals. Lymphoma and/or HIV infection may also present in the cervical nodes (Summary box 45.15).

Summary box 45.15

Causes of cervical lymphadenopathy

Inflammatory

- Reactive hyperplasia

Infective

- Viral
 - For example, infectious mononucleosis, HIV
- Bacterial
 - Streptococcus, Staphylococcus*
 - Actinomycosis
 - Tuberculosis
 - Brucellosis
- Protozoan
 - Toxoplasmosis

Neoplastic

- Malignant
 - Primary, e.g. lymphoma
 - Secondary, e.g. squamous cell carcinoma
 - Known primary
 - Occult primary

Tuberculous adenitis

The condition most commonly affects children or young adults, but can occur at any age. The deep upper cervical nodes are most commonly affected, but there may be a widespread cervical lymphadenitis with many matting together. In most cases, the tubercular bacilli gain entrance through the tonsil of the corresponding side as the lymphadenopathy. Both bovine and human tuberculosis may be responsible. In approximately 80% of patients, the tuberculous process is limited to the clinically affected group of lymph nodes, but a primary focus in the lungs must always be suspected.

As renal and pulmonary tuberculosis occasionally coexist, the urine should be examined carefully. Rarely, the patient may develop a natural resistance to the infection and the nodes may be detected at a later date as evidenced by calcification on radiography. This can also be seen after appropriate general treatment of tuberculosis adenitis. If treatment is not instituted, the caseated node may liquefy and break down with the formation of a cold abscess in the neck. The pus is initially confined by the deep cervical fascia, but after weeks or months, this may become eroded at one point and the pus flows through the small opening into the space beneath the superficial fascia. The process has now reached the well-known stage of a 'collar-stud' abscess. The superficial abscess enlarges steadily and, unless suitably treated, a discharging sinus results.

Treatment

The patient should be treated by appropriate chemotherapy, dependent on the sensitivities derived from the abscess contents.

Wilhelm Friedrich von Ludwig, 1790–1865, Professor of Surgery and Midwifery, Tübingen, Germany.

If an abscess fails to resolve despite appropriate chemotherapy and general measures, occasionally excision of the abscess and its surrounding fibrous capsule is necessary, together with the relevant lymph nodes. If there is active tuberculosis of another system, for example pulmonary tuberculosis, then removal of tuberculous lymph nodes in the neck is inappropriate. The nodes are commonly related to the internal jugular vein, common carotid and vagus nerve, and are usually associated with significant fibrosis making surgery difficult. A portion of the internal jugular vein may require excision, taking considerable care to avoid damage to the vagus or the cervical sympathetic trunk. To facilitate access, the sternocleidomastoid muscle should be divided, particularly if the disease is adjacent to the spinal accessory nerve or the hypoglossal nerve. The resected nodes should be sent for both histology and microbiology.

PRIMARY TUMOURS OF THE NECK

Neurogenic tumours

Chemodectoma (carotid body tumour)

This is a rare tumour that has a higher incidence in areas where people live at high altitudes because of chronic hypoxia leading to carotid body hyperplasia. The tumours most commonly present in the fifth decade and approximately 10% of patients have a family history. There is an association with pheochromocytoma. The tumours arise from the chemoreceptor cells on the medial side of the carotid bulb and, at this point, the tumour is adherent to the carotid wall. The cells of the chemodectoma are not hormonally active and the tumours are usually benign with only a small number of cases producing proven metastases (Fig. 45.59).

Figure 45.59 Sites for chemodectomas.

Clinical features

There is often a long history of a slowly enlarging, painless lump at the carotid bifurcation. About one-third of patients present with a pharyngeal mass that pushes the tonsil medially and anteriorly. The mass is firm, rubbery, pulsatile, mobile from side to side but not up and down, and can sometimes be emptied by firm pressure, after which it slowly refills in a pulsatile manner. A bruit may also be present. Swellings in the parapharyngeal space, which often displace the tonsil medially, should not be biopsied from within the mouth.

Investigations

When a chemodectoma is suspected, a carotid angiogram can be carried out to demonstrate the carotid bifurcation, which is usually splayed, and a blush, which outlines the tumour vessels. MRI scanning also provides excellent detail in most cases. This tumour must not be biopsied and fine-needle aspiration is also contraindicated.

Treatment

Because these tumours rarely metastasise and their overall rate of growth is slow, the need for surgical removal must be considered carefully as complications of surgery are potentially serious. The operation is best avoided in elderly patients. Radiotherapy has no effect. In some cases it may be possible to dissect the tumour away from the carotid bifurcation but, at times, when the tumour is large, it may not be separable from the vessels and resection will be necessary, such that all appropriate facilities should be available to establish a bypass while a vein autograph is inserted to restore arterial continuity in the carotid system.

Vagal body tumours

Vagal paragangliomas arise from nests of paraganglionic tissue of the vagus nerve just below the base of the skull near the jugular foramen. They may also be found at various sites along the nerve down to the level of the carotid artery bifurcation.

They also present as slowly growing and painless masses in the anterolateral aspect of the neck, and may also have a long history, commonly of 2–3 years, before diagnosis. They may spread into the cranial cavity. Diagnosis is confirmed by CT and MRI scanning and additional arteriography if necessary. Treatment is surgical excision.

Peripheral nerve tumours

Schwannomas are solitary and encapsulated tumours attached to or surrounded by nerve, although paralysis of the associated nerve is unusual. The vagus nerve is the most common site. Neurofibromas also arise from the Schwann cell and may be part of von Recklinghausen's syndrome of multiple neurofibromatosis. Multiple neurofibromatosis is an autosomal dominant, hereditary disease and the neurofibromata may be present at birth and often multiply.

Diagnosis requires CT or MRI scanning to differentiate them from other parapharyngeal tumours but, on occasions, the diagnosis must wait until excision.

Friedrich Theodor Schwann, 1810–1882, Professor of Anatomy and Physiology, successively at Louvain (1839–1848), and Liege (1848–1880), Belgium, described the neurilemma in 1839.

Friedrich Daniel von Recklinghausen, 1833–1910, Professor of Pathology, Strasbourg, France, described generalised neurofibromatosis in 1882.

Secondary carcinoma

Metastatic spread of squamous carcinoma to the cervical lymph nodes is a common occurrence from head and neck primary cancers. The nasopharynx, tonsil, tongue, pyriform fossa and supraglottic larynx must be carefully examined by panendoscopy for the primary growth before considering biopsy or any surgery on the neck. Investigation is further assisted by ultrasound and fine needle aspirate of the neck node.

Management

The management of malignant cervical lymph nodes depends on the overall treatment regime.

- If surgery is being used to treat the primary disease and the cervical nodes are palpable and > 3 cm, they may be excised with the primary lesion.
- If radiotherapy is used initially, as is always the case in carcinoma of the nasopharynx, then radiotherapy may also be given to the neck nodes, whatever their stage. In the case of the tongue, pharynx or larynx, however, if the node exceeds 3 cm in diameter, then surgery may be necessary for the neck nodes, even if the primary tumour is treated by chemoradiation.
- If radiotherapy is used initially with resolution of the primary tumour, but there is subsequent residual or recurrent nodal disease, then this situation will require cervical lymph node dissection.

Type of neck dissection

Classical radical neck dissection (Crile)

The classic operation involves resection of the cervical lymphatics and lymph nodes and those structures closely associated: the internal jugular vein, the accessory nerve, the submandibular gland and the sternocleidomastoid muscle. These structures are all removed *en bloc* and in continuity with the primary disease if possible. The main disability that follows the operation is weakness and drooping of the shoulder due to paralysis of the trapezius muscle as a consequence of excision of the accessory nerve.

Modified radical neck dissection

In selected cases, one or more of the three following structures are preserved: the accessory nerve, the sternocleidomastoid

George Washington Crile, 1864–1943, Professor of Surgery, The Western Reserve University, and one of the Founders of the Cleveland Clinic, Cleveland, OH, USA.

muscle or the internal jugular vein. Otherwise, all major lymph node groups and lymphatics are excised. Whichever structures are preserved should be clearly noted.

Selective neck dissection

In this type of dissection, one or more of the major lymph node groups is preserved along with the sternocleidomastoid muscle, accessory nerve and internal jugular vein. In these circumstances, the exact groups of nodes excised must be documented.

SUMMARY

The anatomical and physiological performance of the pharyngo-larynx is involved in the important mechanisms of breathing, coughing, voice production and swallowing. A variety of congenital, traumatic, infectious and neoplastic conditions disturb these functions, giving rise to the common symptoms of pain, swelling, hoarseness, dyspnoea and dysphagia.

Squamous carcinomas are the most common malignancies, accounting for approximately 80% of all head and neck tumours. Their incidence and anatomical site vary around the world, but they are mainly caused by the preventable aetiological agents of smoking and alcohol, although nasopharyngeal squamous carcinomas have additional genetic and environmental factors. These head and neck cancers have a high morbidity and mortality, and require expert treatment.

Oropharyngeal cancer

CHAPTER 46

LEARNING OBJECTIVES

To understand:

- The relationship between oral cancers and the use of alcohol and tobacco
- The cardinal features of oropharyngeal cancer
- The investigation and treatment of patients with oropharyngeal cancer

INTRODUCTION AND EPIDEMIOLOGY

In the western world oral/oropharyngeal cancer is rare, accounting for 2–4% of all malignant tumours, although there is evidence that the incidence is on the increase, particularly among young people. In the Indian subcontinent, however, oropharyngeal cancer is the most common malignant tumour, accounting for 40% of all cancers.

Epidemiology

The principal aetiological agents are tobacco and alcohol. In Europe and North America this is mainly through cigarette smoking combined with alcohol abuse. Synergism between alcohol abuse and tobacco use in the development of squamous cell carcinoma (SCC) of the head and neck is well established. Risk factors associated with cancer of the head and neck are outlined in Summary box 46.1.

Summary box 46.1

Risk factors associated with cancer of the head and neck

- Tobacco
- Alcohol
- Areca nut/pan masala
- Human papillomavirus
- Epstein–Barr virus
- Plummer–Vinson syndrome
- Poor nutrition

Michael Anthony Epstein, B. 1921, formerly Professor of Pathology, The University of Bristol, Bristol, England.

Yvonne Barr, B. 1931, a Virologist who emigrated to Australia. Epstein and Barr discovered this virus in 1964.

Henry Stanley Plummer, 1874–1937, Physician, The Mayo Clinic, Rochester, MN, USA, described this syndrome in 1912.

Porter Paisley Vinson, 1890–1959, Physician, The Mayo Clinic, Rochester, MN, who later practised in Richmond, VA, USA.

In the Indian subcontinent, the use of 'pan' (a combination of betel nut, areca nut, lime and tobacco) as well as reverse smoking (smoking a cheroot with the burning end inside the mouth) are responsible for the high incidence of oropharyngeal cancer. Betel quid appears to be the major carcinogen, although there is also a relationship between slaked lime and the areca nut and cancer.

INCIDENCE

The incidence is greater in men than in women and it is predominantly a disease of the elderly (those over 60 years of age). The incidence in women is increasing, particularly in young patients, with oral tongue cancer being the cancer that is usually, but not exclusively, present. In Europe and North America the current trend of binge drinking and acute tobacco abuse has been observed to correlate with the rising incidence of tongue cancer in younger people.

ANATOMY

Lip and oral cavity

The oral cavity extends from the skin–vermillion border of the lips anteriorly to the junction of the soft palate superiorly and the line of the circumvallate papillae on the junction of the posterior one-third and anterior two-thirds of the tongue posteriorly. The anatomical sites that are frequently involved in mouth cancer include the floor of the mouth, the lateral border of the anterior tongue and the retromolar trigone (Fig. 46.1). The retromolar trigone is defined as the attached mucosa overlying the ascending ramus of the mandible posterior to the last molar tooth and extending superiorly to the maxillary tuberosity.

Oropharynx

The oropharynx extends vertically from the oral surface of the soft palate to the superior surface of the hyoid bone (floor of vallecula). This includes the base of the tongue, the soft palate and the anterior and posterior tonsillar pillars, as well as the pharyngeal tonsils and the lateral and posterior pharyngeal walls.

Figure 46.1 Common anatomical sites (blue) for oral squamous cell carcinoma.

The lateral boundaries include the pharyngeal constrictor muscles and the medial aspect of the mandible.

PATHOLOGY

The anatomy of the oral cavity and the oropharynx is complex and the course of the nerves, blood vessels, lymphatic pathways and fascial planes influences the spread of disease. Fascial planes, including the periosteum, serve as barriers to the direct spread of tumours but contribute to the spread of tumours into the cervical lymph nodes. Perineural invasion acts as a conduit for the direct spread of tumours and profoundly impacts on prognosis and survival. Angio-invasion also carries a negative prognosis and correlates directly with distant metastases, particularly of oral tongue cancer.

Histology

SCC is the predominant histology for tumours arising in the oral cavity and oropharynx. Tumours mainly arise from the mucosal epithelium, although malignant salivary gland tumours from the minor salivary glands are a rare but important group of lesions. Lymphomas, particularly around the Waldeyer's ring (tonsils, tongue base, lingual tonsil regions, posterior one-third of the tongue), make up the last of the three principal pathological groups of oropharyngeal cancer.

Chronic exposure of the mucosal surface to carcinogenic substances, i.e. tobacco and alcohol, can produce multiple sub-clinical sites of carcinoma that can at any stage develop into malignant tumour. This pathological process supports the preventative measures of smoking cessation and alcohol rehabilitation in patients with head and neck cancer, thereby minimising the occurrence of synchronous and metachronous tumours (see below).

Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921, Professor of Pathological Anatomy, Berlin, Germany.

Pre-malignant lesions

The majority of oral carcinomas are not preceded by or associated with clinically obvious pre-malignant lesions. There are, however, a group of oral pathological conditions in which an association with malignant transformation exists (Summary box 46.2).

Summary box 46.2

Conditions associated with malignant transformation

High-risk lesions

- Erythroplakia
- Speckled erythroplakia
- Chronic hyperplastic candidiasis

Medium-risk lesions

- Oral submucous fibrosis
- Syphilitic glossitis
- Sideropenic dysphagia (Paterson–Kelly syndrome)

Low-risk/equivocal-risk lesions

- Oral lichen planus
- Discoid lupus erythematosus
- Discoid keratosis congenita

Clinical features

Pre-malignant lesions of the oral mucosa and oropharyngeal mucosa present as either:

- leucoplakia;
- speckled leucoplakia;
- erythroplakia/plasia.

Leucoplakia

Leucoplakia is defined as any white patch or plaque that cannot be characterised clinically or pathologically. It is purely a descriptive term with no histological correlation. Leucoplakia varies from a small, well-circumscribed, homogenous white plaque to an extensive lesion involving large surface areas of the oral mucosa. It may be smooth or wrinkled, fissured and vary in colour depending on the thickness of the lesion.

Speckled leucoplakia

This is a variation of leucoplakia arising on an erythematous base (Fig. 46.2). It has the highest rate of malignant transformation.

Erythroplakia

Erythroplakia is defined as any lesion of the oral mucosa that presents as a bright red plaque which cannot be characterised clinically or pathologically as any other recognisable condition. The lesions are irregular in outline and separated from adjacent normal mucosa (Fig. 46.3). The surfaces may be nodular. These lesions occasionally coexist with leucoplakia.

Donald Rose Paterson, 1863–1939, Surgeon, The Ear, Nose and Throat Department, The Royal Infirmary, Cardiff, Wales.
Adam Brown Kelly, 1865–1941, Surgeon, The Ear, Nose and Throat Department, The Royal Victoria Infirmary, Glasgow, Scotland.

Figure 46.2 Speckled leucoplakia on the lateral border of the tongue. Histology confirms carcinoma *in situ*.

Figure 46.3 Erythroplakia of the left soft palate and lateral pharyngeal wall.

FIELD CHANGE AND SECOND PRIMARY TUMOURS

The diffuse and chronic exposure of the mucosa of the upper aerodigestive tract to carcinogenic substances, e.g. tobacco and alcohol, causes widespread adverse changes in the mucosal epithelium. The consequence of the diffuse exposure is the development of separate tumours at different anatomical sites. These may present simultaneously, within 6 months (synchronous) or may be delayed (metachronous). Slaughter, in 1950, first proposed the concept of field change or 'cancerisation'. Separate primary tumours may not represent distinct genetic mutational events but rather the same clonal origin of cells, which migrate to separate sites in the upper aerodigestive tract. Nevertheless, minimising exposure of the oropharyngeal tissues to potential insults is the cornerstone of long-term management for patients with head and neck cancer.

Patients who develop a first tumour in the oral cavity and the oropharynx are more likely to develop a second primary tumour in the upper oesophagus. The overall rate of second primary tumour development is 15%. In total, 80% of these are metachronous tumours, of which 50% develop within the first 2 years of

initial presentation (Fig. 46.4). The prevalence of synchronous second primary tumours is 4%.

Potential for malignant change

The potential risk for malignant transformation:

- increases with increasing age of the patient;
- increases with increasing age of the lesion;
- is higher in smokers;
- increases with alcohol consumption;
- depends on the anatomical site of the pre-malignant lesion;
- is particularly high for leucoplakia on the floor of the mouth and ventral surface of the tongue, particularly in younger women, even in the absence of associated risk factors.

PRE-MALIGNANT CONDITIONS

Chronic hyperplastic candidiasis

Chronic hyperplastic candidiasis produces dense plaques of leucoplakia, particularly around the commissures of the mouth. The lesions occasionally extend on to the vermillion and even the facial skin (Fig. 46.5). These lesions have a high incidence of malignant transformation, thought to be the result of invasion of

Figure 46.4 Metachronous tumour in the right mandibular alveolus after previous partial glossectomy and forearm flap reconstruction.

Figure 46.5 Chronic hyperplastic candidiasis of the left buccal mucosa.

the lesion by *Candida albicans*. A small percentage of patients have an associated immunological defect, which encourages the invasion of *C. albicans*, rendering the patient susceptible to malignant transformation. Specific management of chronic hyperplastic candidiasis includes prolonged (6 weeks) topical anti-fungal treatment or systemic anti-fungal treatment (2 weeks). If the lesions persist after medical therapy, surgical excision or laser vaporisation is strongly recommended.

Oral submucous fibrosis

Oral submucous fibrosis is a progressive disease in which fibrous bands form beneath the oral mucosa. Scarring produces contraction, resulting in limited mouth opening and restricted tongue movement. The condition is almost entirely confined to the Asian population and is characterised pathologically by epithelial fibrosis with associated atrophy and hyperplasia of the overlying epithelium (Fig. 46.6). The epithelium also shows changes of epithelial dysplasia. Restricted mouth opening can be treated with either intralesional steroids or surgical excision and skin grafts.

Research strongly indicates that oral submucous fibrosis is significantly associated with the use of pan masala areca nut, with or without concurrent alcohol use. Tobacco smoking alone is not associated with oral submucous fibrosis.

Sideropenic dysphagia (Plummer–Vincent and Paterson–Kelly syndromes)

There is a well-known relationship between sideropenia (iron deficiency in the absence of anaemia) and the development of oral cancer. Sideropenia is common in Scandinavian women and leads to epithelial atrophy, which renders the oral mucosa vulnerable to irritation from topical carcinogens. Correction of the sideropenia with iron supplements reduces the epithelial atrophy and risk of malignant transformation.

CLASSIFICATION AND STAGING

TNM staging

Staging of head and neck cancer is defined by the American Joint Committee on Cancer (AJCC) and follows the TNM system. The system also takes into account the pretreatment computerised tomography (CT) or magnetic resonance imaging (MRI) of the

Figure 46.6 Oral submucous fibrosis of the right buccal mucosa and soft palate.

tumour. The T classification indicates the extent of the primary tumour and the N classification relates to the extent of regional neck metastases to the cervical lymph nodes; this is identical for all mucosal sites of the head and neck except for the nasopharynx. The M classification relates to distant metastasis. The risk of distant metastasis is dependent on nodal disease rather than the size of the primary tumour. Tumours close to the midline are at a greater risk of developing bilateral or contralateral cervical node metastasis.

The TNM staging system is outlined in Table 46.1.

Patterns of lymph node metastasis

The cervical lymph nodes are divided into five principal levels as outlined in Fig. 46.7.

The spread of tumour from the primary site has been well addressed. SCC in the oral cavity and lips tends to metastasise to lymph nodes at levels I, II and III. However, with SCC of the oral tongue there is a risk of skip metastasis directly to lymph node levels III or IV, without the involvement of higher-level lymph node groups. Tumours arising in the oropharynx commonly metastasise to lymph node levels II, III and IV, as well as retropharyngeal and contralateral nodal groups.

Table 46.1 The TNM staging system

Primary tumour (T)

TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Carcinoma <i>in situ</i>
T1	Tumour < 2 cm in greatest dimension
T2	Tumour > 2 but < 4 cm
T3	Tumour > 4 cm but < 6 cm
T4	Tumour invades adjacent structures, e.g. mandible, skin

Regional lymph nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node < 3 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node > 3 cm but not more than 6 cm
N2b	Metastasis in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none greater than 6 cm in greatest dimension
N3	Metastasis in any lymph node > 6 cm

Distant metastasis

M0	No evidence of distant metastasis
M1	Evidence of distant metastasis

Stage

0	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
III	T3	N0	M0
	T1, T2, T3	N1	M0
IV	T4	N0	M0
	Any T	N2	M0

Figure 46.7 Cervical lymph nodes: (I) submandibular; (II) upper deep cervical; (III) mid-cervical; (IV) lower cervical; (V) posterior triangle.

Distant metastases are relatively uncommon but sites involved include lung, brain, liver, bone and skin.

CLINICAL FEATURES

Between 25% and 50% of patients with cancer of the oral cavity or oropharynx present late. Many of these patients are elderly and frail and delay visiting the doctor or the dentist partly because they wear dentures and are accustomed to the discomfort and associated ulceration. Occasionally, dental and medical practitioners fail to recognise that a lesion may be malignant and further delay referral. Moreover, early oral cancer is usually not painful until either the ulcer becomes infected or the tumour invades local sensory nerve fibres. Clinical presentation is markedly dependent on the anatomical site.

Lip cancer

Lip cancer presents early as it is readily visible to the patient. It usually arises as an ulcer on the vermillion border (Fig. 46.8). In total, 95% of carcinomas of the lip arise on the lower lip and 15%

Figure 46.8 Squamous cell carcinoma of the lower lip.

arise in the central one-third and commissures. Tumours tend to spread laterally over the mucosal surface. Lymph node metastases, usually to the submental or submandibular nodes, occur late.

Oral cavity

Cancers of the oral cavity present in a variable way (Fig. 46.9) but are often associated with persisting swelling or ulceration within the oral cavity (Summary box 46.3).

Summary box 46.3

Clinical features of oral cancer

- Persistent oral swelling for > 4 weeks
- Mouth ulceration for > 4 weeks
- Sore tongue
- Difficulty swallowing
- Jaw or facial swelling
- Painless neck lump
- Unexplained tooth mobility
- Trismus

The duration of symptoms is highly variable, from several weeks to many months.

Figure 46.9 (a) Ulcerative squamous cell carcinoma of the anterior floor of the mouth. (b) Exophytic squamous cell carcinoma of the right lateral border of the tongue.

Oropharynx

Cancer of the oropharynx frequently presents much later than cancer of the lip and oral cavity. An ipsilateral or contralateral lump in the neck may be the single presenting complaint from a patient with a carcinoma arising from the tongue base, tonsil or soft palate. Palpable asymmetry, particularly in the tonsil, often represents submucosal infiltration of tumour. Deeper infiltration of the tongue base, pterygoid muscles or adherence of the tumour to the jaw results in poor mobility of the tongue or palate. Common clinical features of oropharyngeal cancer are outlined in Summary box 46.4.

Summary box 46.4

Clinical features of oropharyngeal cancer

- Localised and persistent sore throat
- Difficulty and/or painful swallowing for > 4 weeks
- Painless neck lump
- Unilateral tonsillar enlargement or ulceration
- Otalgia

INVESTIGATIONS

When a clinical diagnosis of oropharyngeal cancer is suspected, a comprehensive protocol of investigations should be instituted. An incisional biopsy should be carried out in all cases. Formal examination under anaesthetic is preferred in the vast majority of cases, not only to carry out the biopsy, but also to palpate and examine the extent of the tumour, which can be exquisitely tender in the conscious patient. Under the same anaesthetic, extraction of teeth with a dubious prognosis can be performed. Where available, and when the diagnosis is clear-cut, insertion of a percutaneous endoscopic gastrostomy (PEG) should be performed to facilitate feeding in the treatment phase. The biopsy should be generous and include the most suspicious area of the lesion, as well as normal adjacent tissue. Areas of necrosis or gross infection should be avoided.

Radiography

Plain radiography of the jaw is of limited value but does provide an opportunity for dental assessment. Before examination under anaesthesia, an orthopantomogram of the jaws is helpful to assess bony invasion, particularly from tumours arising on the alveolus and maxillary antrum.

Magnetic resonance imaging

MRI is the investigation of choice for cancer of the oral cavity and oropharynx, as it is not distorted by metallic dental restorations and provides excellent visualisation of soft-tissue infiltration of the tumour (Fig. 46.10). Its specificity and sensitivity in diagnosing cervical node metastasis is similar to that of CT. Patients who suffer with claustrophobia may have difficulty in tolerating the investigation.

Computerised tomography

CT is much more widely available than MRI but has limited value in oral cavity and oropharyngeal cancer. It is useful when bony invasion is suspected. CT of the thorax and abdomen is also indicated for patients who have proven cervical lymph node

Figure 46.10 Magnetic resonance imaging of a primary tumour of the left tongue base (blue arrow) and neck node metastasis (red arrow).

metastasis or who have large-volume disease, in which the risk of distant metastasis is high.

Radionuclide studies

A radioisotope bone scan of the facial skeleton adds little to the diagnosis and assessment of oropharyngeal cancer. The scan is not specific and tends to show increased uptake wherever there is increased metabolic activity in bone. A false-positive diagnosis is common and 'over-staging' of the disease frequent.

Fine-needle aspiration cytology

Fine-needle aspiration cytology (FNAC) is useful for the assessment and pathological diagnosis of enlarged cervical lymph nodes. It involves the use of a fine-needle puncture into the mass and immediate aspiration for cytological examination. It has few complications and does not spread tumour. It requires no specialist equipment other than a 21G or 23G needle and a 10 ml syringe. Aspiration should be carried out only when the needle enters the swelling. If the specimen can be assessed immediately by an expert cytologist, then it can be sent without fixation. If there is delay in microscopic examination, then the specimen, smeared on a microscope slide, should be fixed before transfer to the laboratory. The positive yield from FNAC is dependent not only on the quality of the aspirate, but also on the skill of the cytologist.

Ultrasound

Ultrasound has limited use in the management of oropharyngeal cancer. It is useful as an adjunct in FNAC to ensure accurate aspiration of a deeply seated neck node swelling. It also has a place in abdominal assessment, particularly when metastases of the liver are suspected.

TREATMENT

General principles

The two principal treatment modalities of oropharyngeal cancer are surgery and radiotherapy. Small tumours can be managed either by primary radiotherapy or surgery. Large-volume disease, i.e. advanced tumour, usually requires a combination of surgery and radiotherapy. There is an increasing move to manage extensive disease of the oropharynx with chemoradiotherapy, provided that patients are medically fit to tolerate the toxicity. Factors that need to be taken into consideration include:

- the site of disease;
- the stage;
- histology;
- concomitant medical disease;
- social factors.

The management of head and neck cancer involves a team approach, whereby patients are assessed objectively by several specialists who agree on an optimum treatment strategy.

Cancer of the oral cavity is frequently managed with primary surgery whereas cancer of the oropharynx can be treated with either primary radiotherapy or primary surgery, or a combination, i.e. surgery for neck nodes and radiotherapy for the primary site.

When the tumour invades bone, e.g. the mandible, primary surgery is deemed appropriate as radiotherapy is less effective in controlling disease. Surgery is also more appropriate for bulky advanced disease, usually followed by postoperative radiotherapy. Tumours of intermediate size, e.g. T2 and T3 tumours, are more problematic and treatment regimes more controversial, hence the need for planning by a multidisciplinary team.

Cervical node involvement

When cervical lymph node involvement occurs, treatment should be geared towards a single modality to deal simultaneously with the lymph node disease and the primary tumour.

Histology

The degree of differentiation of SCC does not normally influence the management of the tumour alone. Management of verrucous carcinoma, a variant of SCC, is identical to that of any other SCC.

Malignant tumours of the minor salivary glands require primary surgery whereas lymphoma is managed by radiotherapy or chemotherapy and radiotherapy, depending on the stage. Postoperative radiotherapy for minor salivary gland tumours is often indicated to reduce the risk of locoregional recurrence.

Age

Modern anaesthesia and postoperative critical care facilities have allowed major head and neck surgery to be carried out on patients with significant medical comorbidity. Advancing age is now not considered to be a contraindication to major head and neck cancer surgery. Conversely, young patients should not be denied radiotherapy for fear of inducing a second malignancy, e.g. sarcoma, in later life.

Previous radiotherapy

A second course of radiotherapy to a previously irradiated site is contraindicated as the tumour is likely to be radioresistant

and re-irradiation will invariably result in extensive tissue necrosis.

Field change

Surgery is preferred when multiple tumours are present or there is extensive pre-malignant change of the oropharyngeal mucosa. Radiotherapy is unsatisfactory as the entire oral cavity requires treatment, causing severe morbidity. In addition, subsequent post-radiotherapy changes make the diagnosis of future pre-malignancy and malignancy more difficult.

Management of pre-malignant conditions

Elimination of associated aetiological factors is the basis of the management of pre-malignant oral mucosal lesions. Cessation of smoking, elimination of the areca nut/pan habit and reduction in alcohol consumption should be encouraged in all patients with pre-malignant lesions. A photographic record of the lesion is useful, particularly for long-term follow-up. All erythroplakia and speckled leucoplakia should undergo urgent incisional biopsy. Biopsy from more than one site provides a better representation of histological changes within a lesion.

Severe epithelial dysplasia and carcinoma *in situ* should be ablated by surgical excision or laser vaporisation. Small lesions, particularly on the lateral border of the tongue or buccal mucosa, may be managed with surgical excision and primary closure by undermining the adjacent mucosa. Larger defects can be managed with laser vaporisation and allowed to epithelialise spontaneously (Fig. 46.11). With mild to moderate epithelial dysplasia, treatment is facilitated by elimination of causative agents. Patients who continue to smoke should be managed as for severe dysplasia and carcinoma *in situ*. Patients who cease smoking and areca nut/pan habits may be followed up closely at 3-monthly intervals.

LIP CANCER

Surgery and external beam radiotherapy are highly effective methods of treatment for lip cancer. The cure rate approaches 90% for either modality.

Pre-malignant changes on the lower lip mucosa are frequently extensive and are best managed by a lower lip shave, in which the vermilion defect is closed by advancement of the lower labial mucosa.

Small tumours

Small tumours (< 2 cm) of the lip can be managed with either a V- or W-shaped excision under local or general anaesthesia. The defect, which should be no larger than one-third of the total lip size, is closed in three layers – mucosa, muscle and skin – with particular attention paid to the correct alignment of the vermilion border (Fig. 46.12).

Intermediate tumours

Larger tumours, which produce defects of between one-third and two-thirds the size of the lower lip, require local flaps for reconstruction. V or W excision will result in microstomia. Large central defects are best managed using the Johansen step technique (Fig. 46.13). This allows closure of the defect by symmetrical advancement of soft-tissue flaps, utilising the excess skin in the labio-mental grooves. Alternative techniques include the Bernard rotational flap.

Figure 46.11 (a) Leucoplakia with severe dysplasia of the lateral border of the tongue. (b) Laser vaporisation.

Total lip reconstruction

Extensive tumours of the lower lip, which invade adjacent tissues (T4), have a high incidence of neck node metastasis. Patients with such advanced disease require surgery that may include unilateral or bilateral selective neck dissection and total excision of the lower lip and chin. The lower lip defect is best reconstructed with a forearm flap (Fig. 46.14).

TONGUE CANCER

Up to 30% of patients with a T1 (< 2 cm diameter) tumour (Fig. 46.15) have occult metastasis at presentation and should undergo simultaneous treatment of the neck by either selective neck dissection or radiotherapy. When performing surgical excision of the primary tumour, a 2-cm margin in all planes should be achieved to ensure a wide, complete excision. Resection resulting in partial or hemiglossectomy can be performed with either a cutting diathermy or laser if available. Advanced tumours (T3 and T4) often encroach upon the floor of the mouth and, occasionally, the mandible. In these circumstances a major resection of the tongue and floor of the mouth and mandible is required. T4 tumours of the oral tongue often cross the midline, for which total glossectomy is the only option to achieve adequate tumour clearance.

When a patient undergoes simultaneous neck dissection, the resection of the primary tumour should preferably be in continuity with the neck node specimen. This eliminates 'lingual' lymph nodes [lying between the primary tumour and submandibular (level I) nodes]; these nodes may contain micro-deposits of tumour, which may lead to local recurrence.

Access

Access for oropharyngeal cancer is important to allow accurate

Figure 46.12 (a) Skin markings for wedge excision of the lower lip. (b) Primary closure.

Figure 46.13 (a) Skin markings for Johansen step reconstruction. (b) Closure of lip and labio-mental steps.

Figure 46.14 (a) Skin markings for total excision of the lower lip, chin and left selective neck dissection. (b) Postoperative view of the reconstructed lower lip using a radial artery forearm flap.

assessment and clear visualisation to enable tumour clearance to be achieved. Access techniques include:

- transoral – small anterior oral tumours only;
- lip-split technique and paramedian or median mandibulotomy (Fig. 46.16);
- visor incision (Fig. 46.17).

Reconstruction

Small defects of the lateral tongue can be managed by primary closure or allowed to heal by secondary intention. Larger defects, e.g. T2, T3 and T4 resections, require formal reconstruction to encourage good speech and swallowing. A radial forearm flap either with skin (Fig. 46.18) and/or fascia, utilising microvascular anastomosis, gives a good functional result. Large-volume defects including total glossectomy require more bulky flaps such as the rectus abdominus free flap. If feasible, the preservation of one or both hypoglossal nerves is useful to encourage floor of mouth function to help relearn swallowing.

Figure 46.15 Ulcerative squamous cell carcinoma of the right lateral border of the tongue.

Figure 46.17 Visor approach to the anterior mandible/floor of the mouth and tongue.

FLOOR OF MOUTH

Carcinoma of the floor of the mouth can spread to the ventral surface of the anterior tongue or encroach upon the lower anterior alveolus (Fig. 46.19). Surgical excision may include a partial anterior glossectomy and anterior mandibular resection. Only very small tumours of the floor of mouth can be managed by simple excision. The visor procedure provides excellent access (see Fig. 46.17).

Reconstruction

Small tumours of the floor of the mouth frequently require formal reconstruction. It is unacceptable to advance the cut surface of the ventral tongue to the labial mucosa as severe difficulties with speech, swallowing and mastication ensue. Simple soft-tissue defects of the anterior floor of mouth are best reconstructed with a radial artery forearm flap. If a patient is unfit for microvascular free-flap surgery or the facilities are limited, bilateral nasolabial flaps tunnelled into the mouth and interdigitated provide an acceptable alternative (Fig. 46.20). Large defects that involve rim

Figure 46.18 Radial artery forearm flap raised before division of vascular pedicle and cephalic vein (arrow).

Figure 46.19 Spread of tumour from the anterior floor of the mouth showing the different patterns in a dentate (left) and edentulous (right) mandible.

resection of the anterior mandible may also be managed with soft-tissue reconstruction only. Full-thickness resection of the anterior mandible, however, requires immediate reconstruction to prevent severe functional defects or a cosmetic deformity. Vascularised bone with a soft-tissue component provides the most up-to-date method of reconstruction. A fibula flap or a vascularised iliac crest graft [deep circumflex iliac artery (DCIA)] are two options in the management of anterior mandible defects with simultaneous floor of mouth defects.

BUCCAL MUCOSA

SCC of the buccal mucosa (Fig. 46.21) should be excised widely, including the underlying buccinator muscle. Larger tumours occasionally extend onto the maxillary tuberosity, tonsillar fossa or mandibular alveolus. Facial skin involvement is rare but carries a poor prognosis. Although cervical node metastasis from buccal mucosa usually occurs less readily than in tongue and floor of mouth cancer, a simultaneous ipsilateral selective supraomohyoid neck dissection (levels I, II, III) is considered good practice.

Access for buccal carcinoma can be achieved either transorally for smaller lesions (T1, T2) or using the lip-splitting technique for larger lesions (T3, T4).

Reconstruction of the buccal mucosa prevents scarring and trismus. Options include the radial artery forearm flap or a temporalis muscle flap. Raw temporalis muscle inset into the

Figure 46.20 (a) Skin markings for bilateral nasolabial flaps. (b) Transposition of bilateral nasolabial flaps into the anterior floor of the mouth.

buccal mucosal defect will epithelialise spontaneously over several weeks.

LOWER ALVEOLUS

Surgery is the treatment of choice for tumours that involve the mandibular alveolus (Fig. 46.22a). Ipsilateral selective neck dissections should be performed for lateral tumours although the incidence of occult subclinical neck node metastasis is low. Bilateral selective neck dissection should be considered for anterior tumours. Bone invasion (Fig. 46.22b) demands segmental resection of the mandible in continuity with neck dissection. Primary or immediate reconstruction is preferred as the functional and cosmetic outcomes are usually superior to those of delayed reconstruction. Options for bony reconstruction are shown in Table 46.2. They include the fibula flap for the edentulous mandible (Fig. 46.22c, d) and the iliac crest (DCIA) for

Figure 46.21 Exophytic squamous cell carcinoma of the right buccal mucosa.

Table 46.2 Mandibular reconstruction

Method	Technique
No reconstruction	Primary closure
Soft tissue only	Pectoralis major myocutaneous flap
Alloplastic material	2.4 mm reconstruction plate alone
Combination alloplastic/soft tissue	2.4 mm reconstruction plate and pectoralis major flap
Non-vascularised bone grafts	Titanium tray and cancellous chips (iliac crest)
Vascularised bone grafts	Fibula (edentulous and dentate); iliac crest (dentate); scapula (concomitant large soft-tissue defect)

Figure 46.22 (a) Extensive squamous cell carcinoma of the anterior mandible involving the floor of the mouth. (b) Plain radiography (orthopantomogram) revealing bony destruction of the anterior mandible. (c) Osseocutaneous fibula flap. (d) Postoperative radiograph of the reconstructed mandible with fibula flap and reconstruction plate.

patients with a dentate mandible (Fig. 46.23). The vascularised iliac crest can be wrapped with internal oblique abdominal wall muscle, which epithelialises spontaneously. This intraoral epithelialisation provides an excellent surface for prosthetic replacement.

Although non-vascularised bone grafts have a place in mandibular reconstruction, the long-term success is frequently low as many patients receive postoperative radiotherapy, which results in the loss of the bone and dehiscence of the titanium tray or reconstruction plate.

RETROMOLAR PAD

Tumours at this site frequently, but not always, invade the ascending ramus of the mandible. They also spread medially into the soft palate or even the tonsillar fossa. Access for excision is

carried out via a lip split and mandibulotomy (see Fig. 46.16 p. 743). Small defects are managed either with a temporalis muscle flap or a radial artery forearm flap. Segmental mandibular resections require vascularised bone to achieve adequate reconstruction.

HARD PALATE AND MAXILLARY ALVEOLUS

The maxillary alveolus and hard palate are relatively uncommon sites for SCC. A tumour arising in these areas may arise either from the oral mucosa per se or from the maxillary antrum penetrating the oral cavity. In the Indian subcontinent, carcinoma of the hard palate is particularly associated with reverse smoking. Occasionally, malignant tumours of minor salivary glands present as swellings of the hard palate. Small tumours of the maxillary alveolus can be managed by transoral partial maxillectomy. More

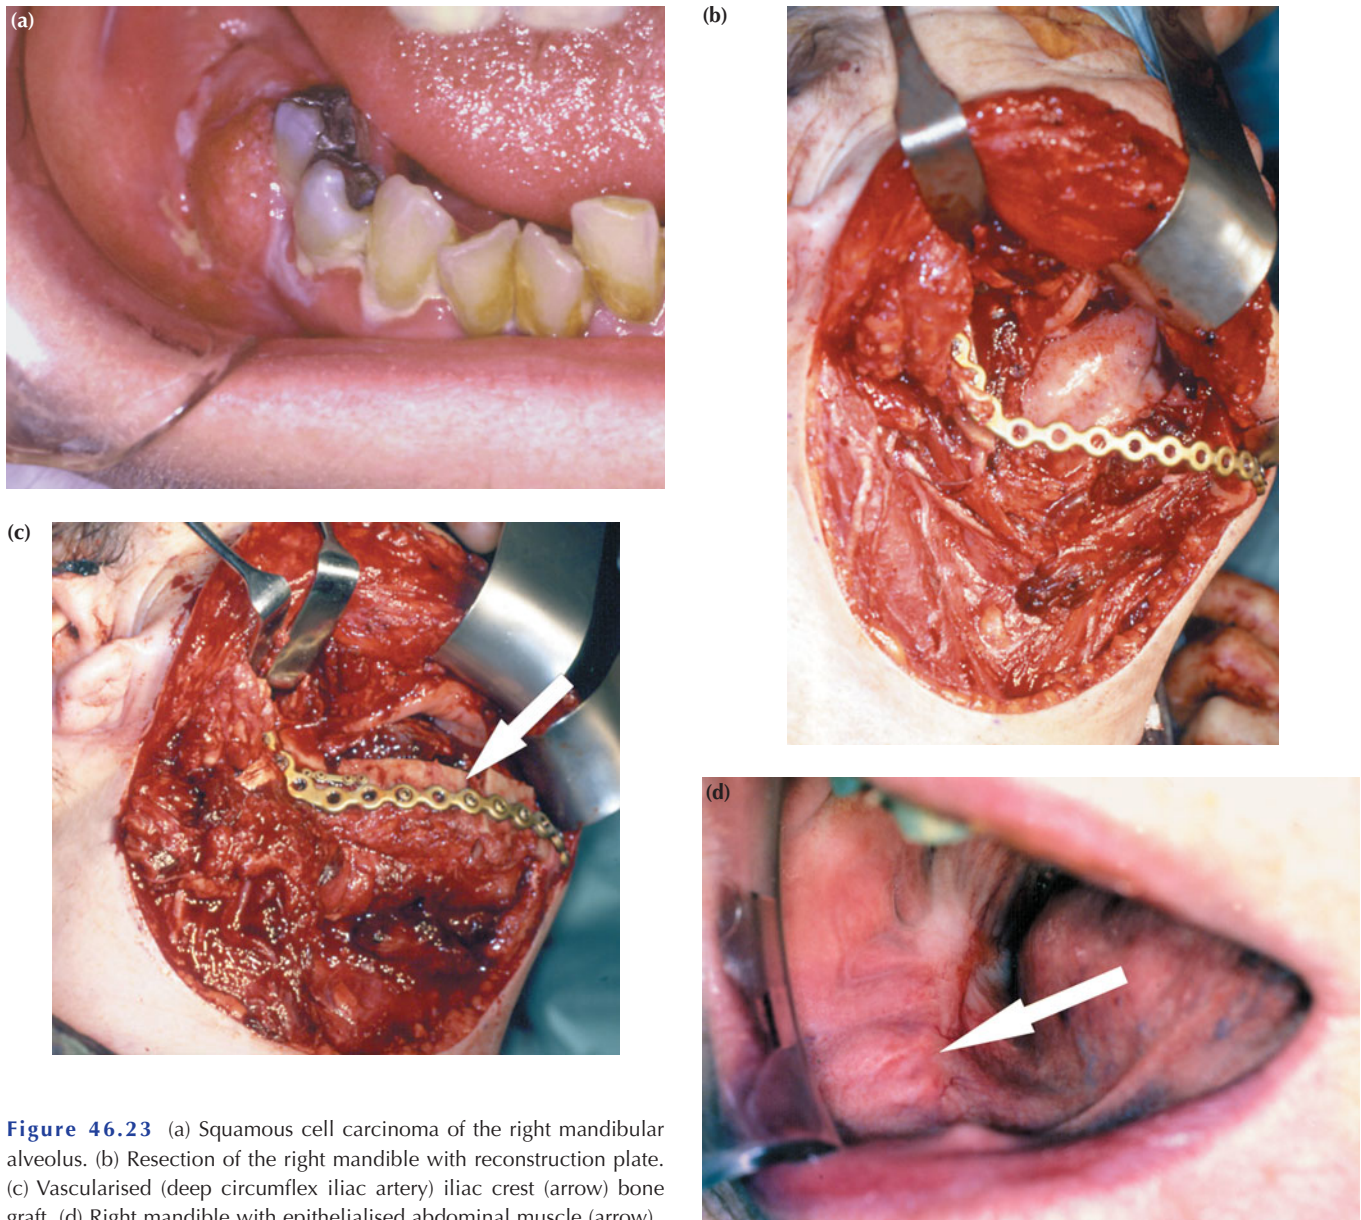

Figure 46.23 (a) Squamous cell carcinoma of the right mandibular alveolus. (b) Resection of the right mandible with reconstruction plate. (c) Vascularised (deep circumflex iliac artery) iliac crest (arrow) bone graft. (d) Right mandible with epithelialised abdominal muscle (arrow).

extensive tumours involving the floor of the maxillary sinus require wider access by a Weber–Ferguson incision (Fig. 46.24). If the preoperative investigations demonstrate extension of the disease into the pterygoid space or the infratemporal fossa, the prognosis is poor as surgical clearance is difficult if not impossible. Tumour extending into the orbit requires simultaneous orbital exenteration or even a combined neurosurgical resection. The vascularised iliac crest graft is the method of choice for immediate maxillary reconstruction although the fibula provides adequate bony replacement to maintain facial contour.

Microvascular free tissue transfer remains the method of choice for the management of defects in the oropharynx (Table 46.3). Free flaps are superior reconstructive options to pedicled or local flaps, which may be used for salvage procedures or recurrent disease. Each ‘free’ flap has a principal blood supply and a concomitant venous drainage. The flaps can be tailored to the defect to include skin, fascia, bone and muscle. The techniques of free tissue transfer demand specialist training and a microscope to connect blood vessels in the neck after neck dissection, e.g. facial artery to the prepared artery attached to the flap. The vascular anatomy of microvascular free flaps is highlighted in Table 46.4.

OROPHARYNX

Tumours of the oropharynx are frequently not amenable to surgery because of the morbid nature of the resection – small and intermediate (T1, T2) tongue base tumours may necessitate total glossectomy to achieve adequate clearance at the root of the tongue. Tumours of the soft palate and tonsil, however, can be managed with either primary surgery in continuity with neck dissection or primary radiotherapy. Subsequent defects of the

Figure 46.24 Weber–Ferguson incision for maxillectomy (lower eyelid extension is rarely required).

tonsillar area can be managed with a forearm flap. Defects of the soft palate, including total soft palate reconstruction, are best managed with a combined reconstruction consisting of a superiorly based pharyngeal flap to line the nasal surface and a forearm flap for the oral surface of the new soft palate. Chemoradiotherapy is now increasingly used to manage tumours of the oropharynx in which organ preservation, but not necessarily function, is the goal. In patients with large-volume neck

Table 46.3 Primary reconstructive options in oropharyngeal cancer

Anatomical site	Microvascular free flap	Alternative flaps
Floor of mouth	Forearm	Nasolabial flaps (bilateral)
Lateral tongue	Forearm	Platysma skin flap
Total tongue/glossectomy	Rectus abdominus	Pectoralis major
Buccal mucosa	Forearm	Temporalis muscle
Mandible		
Dentate	Iliac crest	Fibula
Edentulous	Fibula	Reconstruction plate and pectoralis major
Maxilla		
Low-level/hard palate	Temporalis muscle	Forearm
High	Iliac crest	Fibula
Soft palate/tonsil	Forearm	Temporalis muscle, galeal flap, pectoralis major
Tongue base	Forearm	Pectoralis major

Table 46.4 Microvascular ‘free’ flaps in oropharyngeal reconstruction

Flap	Blood supply	Common variants
Forearm	Radial artery	Skin only; fascia only
Composite forearm	Radial artery	Skin and bone (radius)
Anterolateral thigh	Perforator vessels of the profunda femoris artery	Skin only; skin and muscle
Rectus abdominus	Deep inferior epigastric artery	Skin and muscle; muscle only
Fibula	Peroneal artery	Bone and skin; bone only; bone and fascia/fat
Ilium	Deep circumflex iliac artery	Bone only; bone and muscle; bone, muscle and skin
Scapula	Subscapular artery	Bone and skin; bone and muscle

disease, e.g. N2 and N3, a combined modality of neck dissection followed by chemoradiotherapy to manage the tumour at the primary site and residual neck disease is the optimum strategy.

Chemotherapy

The role of chemotherapy has evolved over the last 20–30 years. It was initially reserved for treatment of recurrent and incurable disease, often using single-agent therapy. Combination chemotherapy, particularly platinum agents and 5-fluorouracil, is now more effective in controlling recurrent and incurable disease. However, combination chemotherapy is associated with more severe side-effects and a balance needs to be reached between efficacy, palliation and quality of life.

Chemotherapy also now has an important role in the treatment of locally advanced and previously untreated oropharyngeal carcinoma. There is compelling evidence that tumours of the tongue base may best be managed with primary chemoradiotherapy rather than radical surgery. The addition of chemotherapy with radiotherapy does, however, increase the morbidity and mortality rates. Patients who are frail or who have significant medical comorbidity may not tolerate the regime.

Chemoradiotherapy has been shown to improve survival in patients whose tumours are deemed unresectable, although organ preservation, i.e. swallowing and speech, is not always sustained.

There is good evidence for the superiority of chemoradiotherapy over radiotherapy alone; however, chemoradiotherapy is rarely effective in large-volume disease.

Management of the neck

The management of the cervical lymph nodes is highly dependent on the planned treatment of the primary tumour. When surgery is deemed appropriate for the primary tumour, simultaneous neck dissection should be considered. If radiotherapy is preferred, treatment to the neck should be contemplated, particularly when there is a high risk of occult metastases, e.g. tongue.

The clinically node-negative neck

The cervical lymph nodes contain occult metastases in up to 30% of patients. This is particularly significant with patients presenting with primary carcinomas of the tongue and, to a lesser extent, floor of mouth. Tumours arising in the buccal mucosa and mandibular alveolus are less likely to have occult metastasis. Nevertheless, increasing evidence exists that active treatment of cervical lymph nodes in the absence of obvious disease is considered good practice. Patients with carcinoma of the lateral tongue, floor of mouth and mandibular alveolus are best managed by supraomohyoid neck dissection (surgical removal of lymph node levels I, II and III in continuity with the primary tumour) (Fig. 46.25).

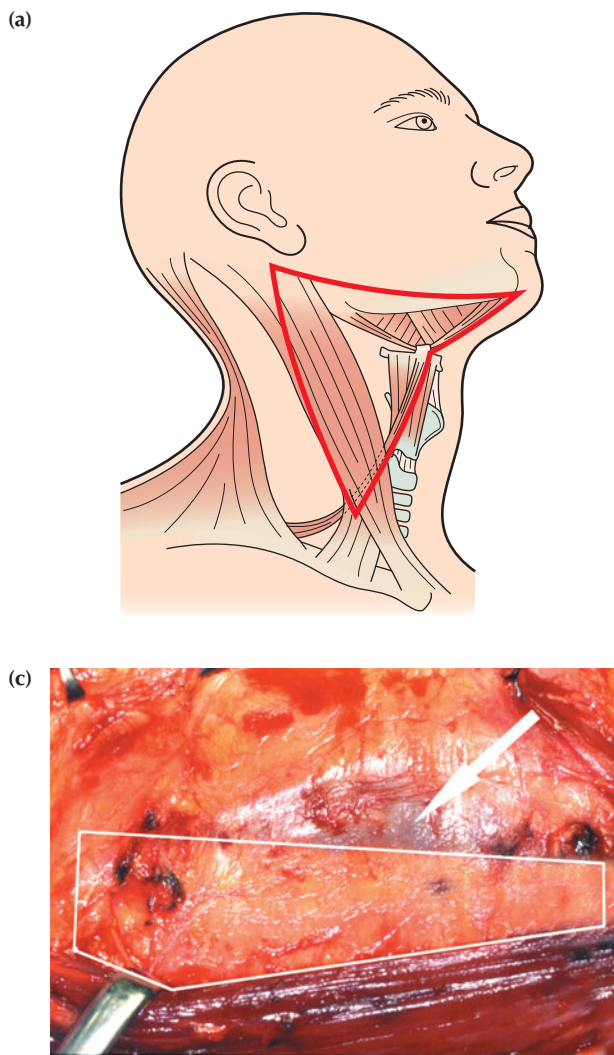

Figure 46.25 (a) Anatomical boundaries for supraomohyoid neck dissection (levels I, II, III). (b) Standard skin incision for neck dissection (solid line). (c) Deep cervical lymph nodes (box) posterolateral to the internal jugular vein (arrow). (d) Completed supraomohyoid neck dissection revealing great vessels of the neck (arrow).

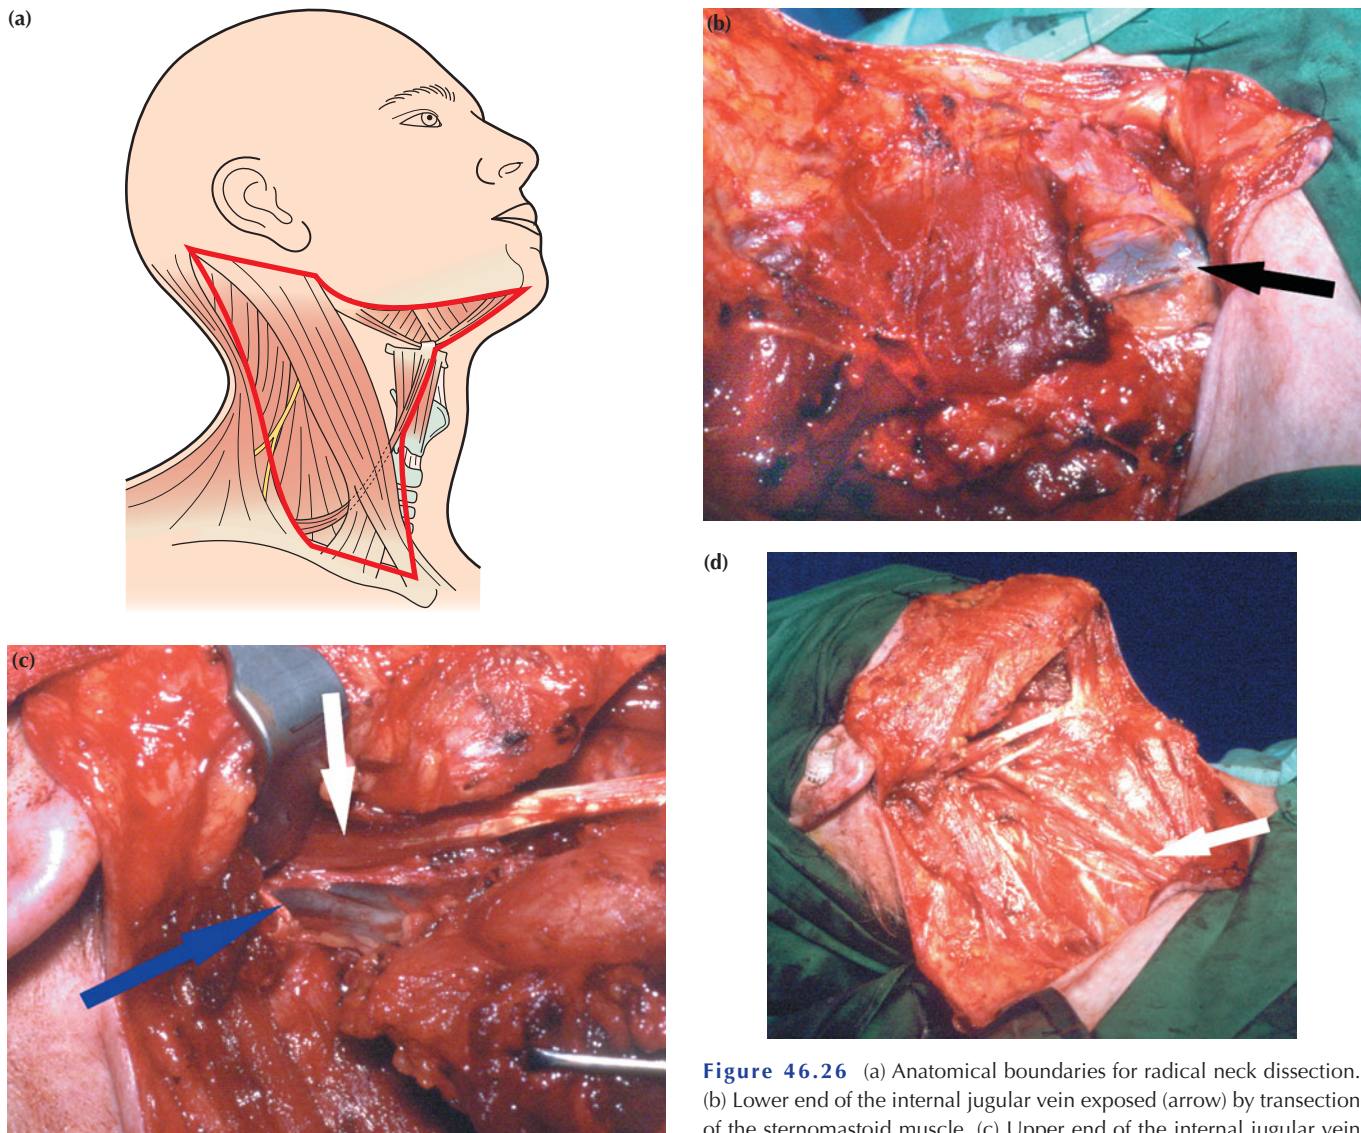

Figure 46.26 (a) Anatomical boundaries for radical neck dissection. (b) Lower end of the internal jugular vein exposed (arrow) by transection of the sternomastoid muscle. (c) Upper end of the internal jugular vein (blue arrow) isolated beneath digastric muscle (white arrow). (d) Appearance after radical neck dissection, revealing the common carotid artery system (arrow).

Good evidence exists that carcinoma of the tongue can produce occult cervical metastasis directly to lymph node level IV. Consequently, the extended supraomohyoid neck dissection removing lymph node levels I, II, III and IV is indicated for patients with carcinoma of the tongue with N0 neck disease. Selective neck dissection is regarded as a staging as much as a therapeutic procedure. Patients who have two or more positive nodes or evidence of extracapsular spread should be managed with postoperative radiotherapy to the neck and the primary site.

Elective external beam radiotherapy is an alternative when radiotherapy is planned for the primary site.

The clinically node-positive neck

The presence of an isolated ipsilateral cytologically positive lymph node of < 3 cm is now considered best managed by selective supraomohyoid neck dissection. There is good evidence that radical or modified radical neck dissection is not required for patients with N1 neck disease associated with oropharyngeal cancer.

N2a and N2b disease

Radical or modified radical neck dissection (Fig. 46.26), often followed by postoperative radiotherapy, is appropriate to control neck disease. Patients unfit for surgery can be offered external beam radiotherapy palliation.

N2c disease

Patients with mouth cancer presenting with bilateral nodes often have a large, inoperable, primary tumour. Bilateral neck dissection can be undertaken although morbidity is high. One internal jugular vein needs to be spared, usually on the side that is less involved with disease. Postoperative radiotherapy is indicated if there is multiple node involvement or extracapsular spread. Postoperative neck oedema and facial congestion occurs and may take months to resolve.

N3 disease

In N3 disease there is extensive involvement of the neck, often with fixation to the overlying skin. This is associated with

advanced primary disease. Radical neck dissection may be feasible in such circumstances but strong consideration should be given to radiotherapy if there is evidence of tumour involving the internal carotid artery or the skull base.

The different types of neck dissection and their indications are summarised in Table 46.5.

COMPLICATIONS

Notwithstanding the general complications of major surgery, complications specifically associated with the treatment of oropharyngeal cancer are speech deficiencies, especially with resection of the anterior floor of the mouth and tongue; swallowing dysfunction and aspiration, especially after oropharyngeal resection; neurological injury, e.g. lingual nerve, hypoglossal nerve palsy; wound breakdown and cervical fistula formation; failure of internal fixation/reconstruction plates; failure of microvascular anastomosis; and flap failure. Other complications that may occur are listed in Summary box 46.5.

Summary box 46.5

Complications of treatment for oropharyngeal cancer

Surgical

- Accessory nerve palsy – shoulder dysfunction and pain
- Soft-tissue oedema, especially bilateral neck dissection
- Phrenic nerve injury
- Thoracic duct injury
- Cranial nerve injury
- Rupture of the carotid artery

Radiotherapy

- Osteoradionecrosis of the mandible
- Hypothyroidism
- Atherosclerosis of the carotid artery
- Neck and shoulder dysfunction
- Trismus
- Xerostomia
- Visual impairment
- Radiation neuritis

Chemotherapy

- Nausea and vomiting
- Diarrhoea
- Stomatitis
- Gastrointestinal upset
- Renal toxicity
- Leucopenia and thrombocytopenia

Patients undergoing treatment for oropharyngeal cancer frequently develop severe functional problems. The size and location of the tumour will dictate the extent of resection and the sacrifice of important structures.

Loss of tongue and floor of mouth musculature and the removal of bone and associated muscle attachments together with the sacrifice of sensory and motor cranial nerves all greatly affect not only appearance but also speech, swallowing and nutritional status. Psychological disturbance is universal in patients undergoing major head and neck cancer surgery and radiotherapy.

The techniques of immediate reconstruction, particularly with microvascular flaps, minimise the complications and side-effects but many patients are nevertheless radically changed for the remainder of their lives. Patients undergoing 'salvage' surgery following primary radiotherapy frequently undergo delayed wound healing, cervical fistula formation and, occasionally, carotid artery blowout/rupture. Skin anaesthesia associated with scar contraction creates additional problems, particular with neck mobility and trismus.

POST-TREATMENT MANAGEMENT

Patients with oropharyngeal cancer need to be followed up regularly not only to detect possible recurrence, but also to manage the morbidity associated with treatment. In total, 70% of recurrences occur in the first 12 months following treatment and 90% in the first 2 years. Patients who survive for 5 years are cured and discharged. Recurrence after extensive surgery and radiotherapy is frequently beyond any further treatment and palliative care is a logical pathway.

OUTCOME AND PROGNOSIS

Survival after oropharyngeal cancer is directly related to:

- the size of the primary tumour (T stage);
- the evidence of neck node metastasis (N stage);
- concomitant medical problems, e.g. cardiorespiratory disease.

Patients with large primary tumours are more likely to develop cervical node metastasis. Cervical node metastasis, particularly with extracapsular spread, is the most significant factor in determining prognosis for oropharyngeal cancer. The overall 5-year survival rates are shown in Table 46.6.

Supportive treatment is important for patients with oropharyngeal cancer, particularly in the form of speech and language support and dietetic and psychological input. Smoking

Table 46.5 Neck dissection in oropharyngeal cancer

Type of neck dissection	Lymph node levels removed	Indication
Selective		
Supraomohyoid	I–III	N0; N1; neck access for microsurgery
Extended supraomohyoid neck dissection	I–IV	Oral tongue cancer with N0 neck nodes; N1
Radical		
Full	I–V	N2; N3; neck recurrence after radiotherapy
Modified radical neck dissection	I–V, with preservation of internal jugular vein, accessory nerve and/or sternomastoid muscle	Involvement of neck skin; recurrence after selective neck dissection

cessation and a drastic reduction in alcohol intake reduces the risk of developing further metachronous carcinomas in the aerodigestive tract.

Table 46.6 Five-year survival rates for oropharyngeal cancer

Stage at presentation	Survival rate (%)
I	80–90
II	65–75
III	40–50
IV	30

Disorders of the salivary glands

CHAPTER 47

LEARNING OBJECTIVES

To understand:

- The surgical anatomy of the salivary glands
- The presentation, pathology and investigation of salivary gland disease
- The medical and surgical treatment of stones, infections and tumours that affect salivary glands

There are four main salivary glands, two submandibular glands and two parotid glands. In addition, there are multiple minor salivary glands.

MINOR SALIVARY GLANDS

Anatomy

The mucosa of the oral cavity contains approximately 450 minor salivary glands. They are distributed in the mucosa of the lips, cheeks, palate, floor of the mouth and retromolar area. These minor salivary glands also appear in other areas of the upper aerodigestive tract including the oropharynx, larynx and trachea as well as the sinuses. They have a histological structure similar to that of mucous-secreting major salivary glands. Overall, they contribute to 10% of the total salivary volume (Summary box 47.1).

Summary box 47.1

Anatomy of salivary glands

- Two submandibular glands
- Two parotid glands
- Two sublingual glands
- Approximately 450 minor salivary glands

Common disorders of minor salivary glands

Cysts

Extravasation cysts are common and result from trauma to the overlying mucosa. They usually affect minor salivary glands within the lower lip, producing a variable swelling that is painless and usually, but not always, translucent (Fig. 47.1). Some resolve spontaneously, but most require formal surgical excision that includes the overlying mucosa and the underlying minor salivary gland. Recurrence is rare.

Tumours

Few tumours show more diversity in histological appearance and anatomical site than those that arise from mucous glands of the

Figure 47.1 Mucous retention cyst. A translucent swelling on the lower lip is typical.

upper aerodigestive tract. Tumours of minor salivary glands are histologically similar to those of major glands; however, up to 90% of minor salivary gland tumours are malignant. Although tumours of minor salivary gland origin occur anywhere in the upper aerodigestive tract, common sites for tumour formation include the upper lip, palate and retromolar regions. Less common sites for minor salivary gland tumours include the nasal and pharyngeal cavities. Minor salivary gland tumours have also been reported in the paranasal sinuses and throughout the pharynx. These tumours arise in submucosal seromucous glands that are found throughout the upper aerodigestive tract. Very rarely, a muco-epidermoid carcinoma can present as an intraosseous tumour of the mandible.

Benign minor salivary gland tumours present as painless, firm, slow-growing swellings. Overlying ulceration is extremely rare. Minor salivary gland tumours of the upper lip are managed by excision to include the overlying mucosa, with primary closure (Fig. 47.2a–c).

Benign tumours of the palate, less than 1 cm in diameter, can be managed by excisional biopsy, and the defect is allowed to heal by secondary intention (Fig. 47.3a–d). Where tumours of the palate are greater than 1 cm in diameter, incisional biopsy is recommended to establish a diagnosis prior to formal excision.

Malignant minor salivary gland tumours are rare. They have a firm consistency, and the overlying mucosa may have a varied

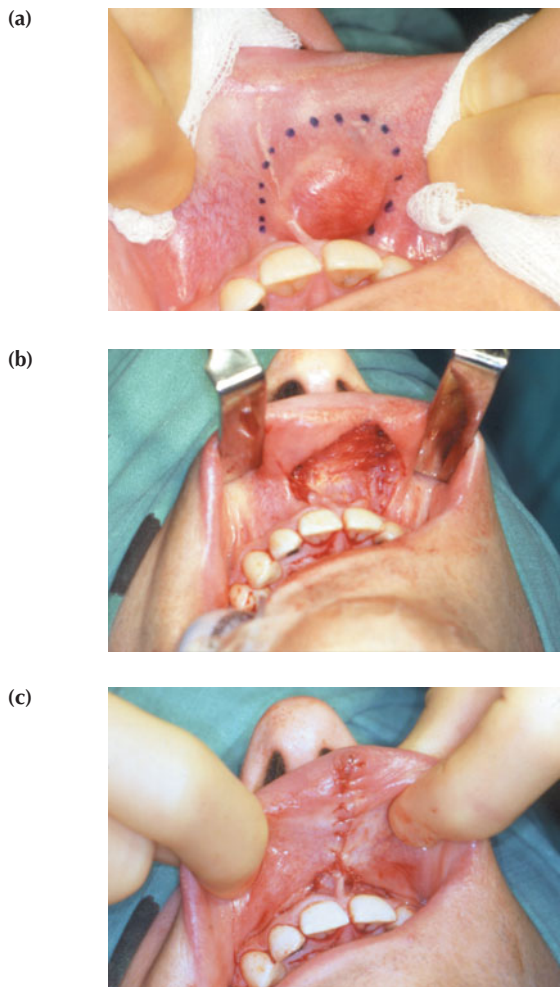

Figure 47.2 (a) Pleomorphic adenoma of the upper lip. (b) Tumour excised with overlying mucosa. (c) Primary closure of the defect.

discolouration from pink to blue or black (Fig. 47.4). The tumour may become necrotic with ulceration as a late presentation.

Malignant minor salivary gland tumours of the palate are managed by wide excision which may involve partial or total maxillectomy. The subsequent defect can be managed by either prosthetic obturation or immediate reconstruction. Various microvascular flaps have been designed to reconstruct maxillectomy defects including radial forearm flap, fibular flap, rectus abdominus, latissimus dorsi and the vascularised iliac crest graft (Fig. 47.5a and b).

THE SUBLINGUAL GLANDS

Anatomy

The sublingual glands are a paired set of minor salivary glands lying in the anterior part of the floor of mouth between the mucous membrane, the mylohyoid muscle and the body of the mandible close to the mental symphysis. Each gland has numerous excretory ducts that open either directly into the oral cavity or indirectly via ducts that drain into the submandibular duct (Summary box 47.2).

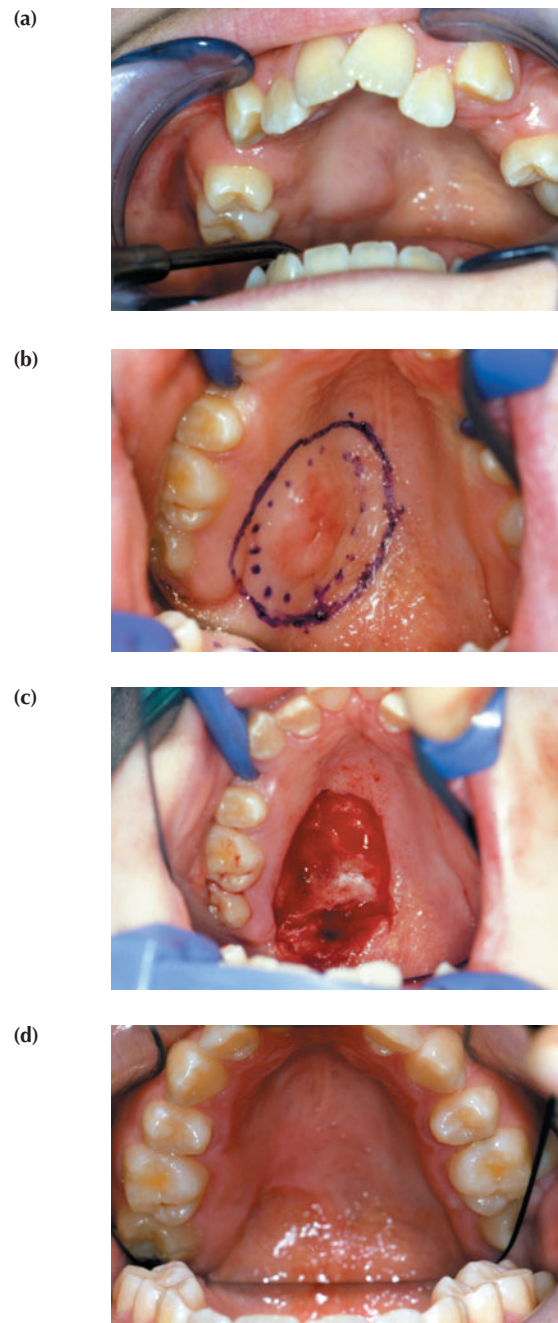

Figure 47.3 (a) Pleomorphic adenoma in the right palate in a 12-year-old girl. (b) Tumour marked out with adequate margins including the overlying mucosa. (c) The subsequent defect. (d) Healing by secondary intention 3 years after surgery.

Summary box 47.2

Sublingual glands

- Problems are rare
- Minor mucous retention cysts may need surgery
- Plunging ranula is a retention cyst that tunnels deep
- Nearly all tumours are malignant

Common disorders of the sublingual glands

Cysts

Minor mucous retention cysts develop in the floor of the mouth either from an obstructed minor salivary gland or from the sublingual salivary gland. The term 'ranula' should be applied only to a mucous extravasation cyst that arises from a sublingual gland. It produces a characteristic translucent swelling that takes on the appearance of a 'frog's belly' (ranula) (Fig. 47.6). A ranula can resolve spontaneously, but many also require formal surgical excision of the cyst and the affected sublingual gland. Incision and drainage, however tempting, usually results in recurrence.

Ranula is derived from 'rana', the Latin for frog.

Figure 47.6 Large ranula affecting the floor of the mouth.

Plunging ranula

Plunging ranula is a rare form of mucous retention cyst that can arise from both sublingual and submandibular salivary glands. Mucus collects within the cyst, which perforates through the mylohyoid muscle diaphragm to enter the neck. Patients present with a dumbbell-shaped swelling that is soft, fluctuant and painless in the submandibular or submental region of the neck (Fig. 47.7a and b). Diagnosis is made on ultrasound or magnetic resonance imaging (MRI) examination. Excision is usually performed via a cervical approach removing the cyst and both the submandibular and sublingual glands. Smaller plunging ranulas can be treated successfully by transoral sublingual gland excision with or without marsupialisation.

Tumours

Tumours involving the sublingual gland are extremely rare and are usually (85%) malignant. They present as a hard or firm painless swelling in the floor of the mouth. Treatment requires wide excision involving the overlying mucosa and simultaneous neck dissection. Immediate reconstruction of the intraoral defect is recommended using, for example, a radial artery forearm flap.

(b)

Figure 47.7 Plunging ranula in the left submandibular region.

THE SUBMANDIBULAR GLANDS

Anatomy

The submandibular glands are paired salivary glands that lie below the mandible on either side. They consist of a larger superficial and a smaller deep lobe that are continuous around the posterior border of the mylohyoid muscle. Important anatomical relations include the anterior facial vein running over the surface of the gland and the facial artery. The deep part of the gland lies on the hyoglossus muscle closely related to the lingual nerve and inferior to the hypoglossal nerve. The gland is surrounded by a well-defined capsule that is derived from the deep cervical fascia which splits to enclose it. The gland is drained by a single submandibular duct (Wharton's duct) that emerges from its deep surface and runs in the space between the hyoglossus and mylohyoid muscles. It drains into the anterior floor of the mouth at the sublingual papilla. There are several lymph nodes immediately adjacent and sometimes within the superficial part of the gland (Summary box 47.3).

Summary box 47.3

Important anatomical relationships of the submandibular glands

- Lingual nerve
- Hypoglossal nerve
- Anterior facial vein
- Facial artery
- Marginal mandibular branch of the facial nerve

Ectopic/aberrant salivary gland tissue

The most common ectopic salivary tissue is the Stafne bone cyst. This presents as an asymptomatic, clearly demarcated radiolucency of the angle of the mandible, characteristically below the inferior dental neurovascular bundle (Fig. 47.8). It is formed by invagination into the bone on the lingual aspect of the mandible of an ectopic lobe of the juxtaposed submandibular gland. No treatment is required.

Inflammatory disorders of the submandibular gland

Inflammation of the submandibular gland is termed sialadenitis. Submandibular sialadenitis may be acute, chronic or acute on chronic.

Figure 47.8 Plain radiographic appearance of a Stafne bone cyst.

Thomas Wharton, ?1616–1673, Physician, St. Thomas's Hospital, London, England, described the submandibular duct in 1656.
Edward C. Stafne, 1894–1981, Dental Surgeon, The Mayo Clinic, Rochester, MN, USA, described these cysts in 1942.

Common causes are:

- 1 Acute submandibular sialadenitis
 - (a) *Viral*. The paramyxovirus (mumps) is a viral illness of the salivary glands that usually produces parotitis. The submandibular glands are occasionally involved, causing painful tender swollen glands. Other viral infections of the submandibular gland are extremely rare.
 - (b) *Bacterial*. Bacterial sialadenitis is more common than viral sialadenitis and occurs secondary to obstruction. Following infection and despite control of acute symptoms with antibiotics, the gland frequently becomes chronically inflamed and requires formal excision.
- 2 Chronic submandibular sialadenitis.

Obstruction and trauma

The most common cause of obstruction within the submandibular gland is stone formation (sialolithiasis) within the gland and its associated duct system. Eighty per cent of all salivary stones occur in the submandibular glands because their secretions are highly viscous. Eighty per cent of submandibular stones are radio-opaque and can be identified on plain radiography (Fig. 47.9).

Clinical symptoms

Patients usually present with acute painful swelling in the region of the submandibular gland, precipitated by eating (Fig. 47.10). The swelling occurs rapidly and often resolves spontaneously over 1–2 hours after the meal is completed. This classical picture occurs when the stone causes complete obstruction, usually at the opening of the submandibular duct. More frequently, the stone causes only partial obstruction when it lies within the hilum of the gland or within the duct in the floor of the mouth. In such circumstances, symptoms are more infrequent, producing minimal discomfort and swelling, not confined to mealtimes. Clinical examination reveals an enlarged firm submandibular gland, tender on bimanual examination. Pus may be visible, draining from

Figure 47.9 Lower occlusal X-ray highlighting a radio-opaque submandibular duct stone (arrowhead). Note the larger stone posteriorly located in the hilum of the gland (arrow).

Figure 47.10 Acute left submandibular sialadenitis.

the sublingual papilla (Fig. 47.11), the consequence of chronic and non-specific bacterial infection.

Management

If the stone is lying within the submandibular duct in the floor of the mouth anterior to the point at which the duct crosses the lingual nerve (second molar region), the stone can be removed by incising longitudinally over the duct. Once the stone has been delivered, the wall of the duct should be left open to promote free drainage of saliva. Suturing the duct will lead to stricture formation and the recurrence of obstructive symptoms. Where the stone is proximal to the lingual nerve, i.e. at the hilum of the gland, stone retrieval via an intraoral approach should be avoided as there is a high risk of damage to the lingual nerve during exploration in the posterior lingual gutter. Treatment is by simultaneous submandibular gland excision and removal of the stone and ligation of the submandibular duct under direct vision.

Other causes of submandibular duct obstruction include external pressure, particularly trauma to the floor of the mouth. This may result from an overextended flange on a lower denture that impinges on the sublingual papilla and causes inflammation and subsequent stricture.

Submandibular gland excision

Submandibular gland excision is indicated for:

- sialadenitis;
- salivary tumours.

Excision of the submandibular gland involves four distinct phases:

Incision and exposure of gland

Surgery is usually performed under endotracheal general anaesthesia with moderate neck extension and the chin rotated to the

Figure 47.11 Acute suppurative submandibular sialadenitis. There is pus extruding from the left sublingual papilla.

opposite side. The incision should be marked at least 3–4 cm below the lower border of the mandible to avoid damage to the marginal mandibular branch of the facial nerve (Fig. 47.12a). The incision should be sited within the nearest skin crease and should be no more than 6 cm long. Infiltration with lidocaine with adrenaline is optional. Sharp dissection is performed down to the platysma muscle, which should be clearly identified to facilitate later closure (Fig. 47.12b). The muscle is incised and then retracted. The underlying investing layer of deep cervical fascia is then divided, and the marginal mandibular branch of the facial nerve that normally runs on the deep surface of the platysma muscle is preserved. Posteriorly, the incision approaches the angular tract where the deep cervical fascia splits to form the investing layer around the sternomastoid muscle. Superficial veins, including the anterior facial vein, require ligation.

Gland mobilisation

Deepening the incision divides the submandibular gland capsule. In inflammatory conditions, the submandibular gland is excised by intracapsular dissection, mobilising the gland by sharp dissection. For tumours of the submandibular gland, extracapsular dissection by suprahyoid neck dissection is performed.

The superficial lobe of the submandibular gland is first mobilised by retracting superiorly with Allis's forceps. As dissection proceeds, the posterior belly and anterior belly of the digastric muscle are identified. Dissection posteriorly identifies the facial artery (Fig. 47.13), which is divided to facilitate further mobilisation. The course of the facial artery is variable, sometimes penetrating the gland emerging on the upper border, and sometimes lying in a groove on the deeper aspect of the gland. The gland is further mobilised by blunt and sharp dissection. A

Figure 47.13 Submandibular gland mobilisation and exposure of the facial artery.

number of small arteries and veins are encountered, which require control with bipolar diathermy.

Dissection of the deep lobe and identification of the lingual nerve

An important landmark in submandibular gland dissection is the posterior border of the mylohyoid muscle. Once identified, it can be retracted forwards to reveal the deep lobe of the gland. Several veins are usually encountered, which need to be controlled with diathermy. The gland is then retracted inferiorly, invariably attached to the lingual nerve through parasympathetic secretor motor fibres. In the presence of chronic infection and subsequent fibrosis, identification of the lingual nerve on the deep aspect of the gland is sometimes difficult. It is imperative that the lingual nerve is formally identified prior to division of the parasympathetic fibres. The gland is then pedicled entirely on the submandibular duct, which, once identified, is ligated. The gland is delivered and sent for histological examination. The hypoglossal nerves lie deep to the submandibular capsule and should not be damaged during intracapsular dissection (Fig. 47.14).

Three cranial nerves are at risk during removal of the submandibular gland:

- 1 the marginal mandibular branch of the facial nerve;
- 2 the lingual nerve;
- 3 the hypoglossal nerve.

An adequate incision coupled with meticulous haemostasis allows the surgeon to identify these important structures during surgery.

Wound closure

Haemostasis is confirmed and a vacuum suction drain inserted. The wound is closed using a continuous resorbable suture to the

Figure 47.14 Bed of the submandibular triangle following submandibular gland removal, revealing the posterior edge of the mylohyoid muscle and the tendon of the digastric muscle.

platysma muscle, as the platysma muscle has a direct contribution to the depressor activity of the corner of the mouth. The skin may be closed with a subcuticular non-resorbable suture, removed 7 days after surgery. The drain remains for 24 hours.

Complications of submandibular gland excision

- 1 Haematoma;
- 2 wound infection;
- 3 marginal mandibular nerve injury;
- 4 lingual nerve injury;
- 5 hypoglossal nerve injury;
- 6 transection of the nerve to the mylohyoid muscle producing submental skin anaesthesia.

Tumours of the submandibular gland

Tumours of the submandibular gland are uncommon and usually present as a slow-growing, painless swelling within the submandibular triangle (Fig. 47.15). Only 50% of submandibular gland tumours are benign, in contrast to 80–90% of parotid gland tumours (Table 47.1). In many circumstances, the swelling cannot, on clinical examination, be differentiated from submandibular lymphadenopathy. Most salivary neoplasms, even malignant tumours, are often slow-growing, painless swellings. Unfortunately, pain is not a reliable indication of malignancy as benign tumours often present with pain in the affected gland, presumably due to capsular distension or outflow obstruction.

Clinical features of malignant salivary tumours

- 1 Facial nerve weakness;
- 2 rapid enlargement of the swelling;
- 3 induration and/or ulceration of the overlying skin;
- 4 cervical node enlargement.

Investigation

Computerised tomography (CT) and MRI scanning are the most helpful techniques for imaging tumours arising in the major salivary glands. The tumour is intrinsic to the gland, and its border can be imaged to highlight whether it is circumscribed and

Table 47.1 Salivary gland tumours – frequency and distribution

Type	Location	Frequency	Malignant
Major	Parotid	Common	10–20%
	Submandibular	Uncommon	50%
	Sublingual	Very rare	85%
Minor	Upper aerodigestive tract	Rare	90%

Figure 47.15 Benign tumour of the right submandibular gland.

probably benign or diffuse, invasive and probably malignant. The scan will highlight the relationship of the tumour to other anatomical structures, which is helpful in planning surgery.

Open surgical biopsy is contraindicated as this may seed the tumour into surrounding tissues, making it impossible to eradicate microscopic deposits of tumour cells.

Fine-needle aspiration biopsy is a safe alternative to open biopsy. There is evidence to suggest that, provided the needle gauge does not exceed 18G, there is no risk of seeding viable tumour cells. The role of fine-needle aspiration biopsy is, however, controversial as it rarely alters surgical management.

Management of submandibular gland tumours

As with all salivary gland tumours, surgical excision with a cuff of normal tissue is the goal. When the tumour is small and entirely encased within the submandibular gland parenchyma, straightforward intracapsular submandibular gland excision is appropriate. However, benign tumours that are large and project beyond the submandibular gland are best served by suprahyoid neck dissection, preserving the marginal mandibular branch of the facial nerve, lingual nerve and hypoglossal nerves. This entails a full clearance of the submandibular triangle, involving the development of a subplatysmal skin flap (Fig. 47.16a–e), dissection of periosteum along the lower border and inner aspect of the mandible, and delivery of the gland and tumour with a cuff of

normal tissue. In cases of overt malignancy, modified neck dissection or radical neck dissection is appropriate. This may necessitate sacrifice of the lingual and hypoglossal nerves if the tumour is adherent to the deep bed of the gland (Fig. 47.17a–d).

THE PAROTID GLAND

Anatomy

The parotid gland lies in a recess bounded by the ramus of the mandible, the base of the skull and the mastoid process. It lies on the carotid sheath and the XIth and XIIth cranial nerves and extends forward over the masseter muscle. The gland is enclosed in a sheath of dense deep cervical fascia. Its upper pole extends just below the zygoma and its lower pole into the neck.

Several important structures run through the parotid gland. These include:

- 1 branches of the facial nerve;
- 2 the terminal branch of the external carotid artery that divides into the maxillary artery and the superficial temporal artery;
- 3 the retromandibular vein;
- 4 intraparotid lymph nodes.

The gland is arbitrarily divided into deep and superficial lobes, separated by the facial nerve. Eighty per cent of the parotid gland

(d) Completion of radical neck dissection revealing the great vessels of the neck (arrow).

lies superficial and 20% deep to the nerve entering. An accessory lobe is occasionally present.

Developmental disorders

Developmental disorders such as agenesis, duct atresia and congenital fistula are extremely rare.

Inflammatory disorders

Viral infections

Mumps is the most common cause of acute painful parotid swelling and predominantly affects children. It is spread via airborne droplets of infected saliva. The disease starts with a prodromal period of 1–2 days, during which the patient experiences fever, nausea and headache. This is followed by pain and swelling in one or both parotid glands. Parotid pain can be very severe and exacerbated by eating and drinking. Symptoms resolve within 5–10 days. The diagnosis is based on history and clinical examination: a recent contact with an infected patient with a painful parotid swelling is often sufficient to lead to a diagnosis. Atypical viral parotitis does occur and may present with predominantly unilateral swelling or even submandibular involvement. A single episode of infection confers lifelong immunity. Treatment of mumps is symptomatic with regular paracetamol and adequate oral fluid intake. Complications of orchitis, oophoritis, pancreatitis, sensorineural deafness and meningoencephalitis are rare, but are more likely to occur in adults.

Other viral agents that produce parotitis include Coxsackie A and B, parainfluenza 1 and 3, Echo and lymphocytic choriomeningitis.

Bacterial infections

Acute ascending bacterial sialadenitis is historically described in dehydrated elderly patients following major surgery. Reduced salivary flow secondary to dehydration results in ascending infection via the parotid duct into the parotid parenchyma. Acute bacterial parotitis is now more common with no obvious precipitating factors. The patient presents with a tender, painful parotid swelling that arises over several hours (Fig. 47.18). There is generalised malaise, pyrexia and occasional cervical lymphadenopathy.

Figure 47.18 Acute left bacterial parotitis.

The pain is exacerbated by eating or drinking. The parotid swelling may be diffuse, but often localises to the lower pole of the gland. Intraoral examination may reveal pus exuding from the parotid gland papilla. The infecting organism is usually *Staphylococcus aureus* or *Streptococcus viridans*, and treatment is with appropriate intravenous antibiotics. If the gland becomes fluctuant, ultrasound may identify abscess formation within the gland that may require aspiration with a large-bore needle or formal drainage under general anaesthesia. In the latter procedure, the skin incision should be made low to avoid damage to the lower branch of the facial nerve. Blunt dissection using sinus forceps is preferred, and the cavity is opened to facilitate drainage. A drain is inserted and left *in situ* for 24–72 hours. Sialography is contraindicated during acute infection. Chronic bacterial sialadenitis is rare in the parotid gland.

Recurrent parotitis of childhood

Recurrent parotitis of childhood is a distinct clinical entity of unknown aetiology and variable prognosis. It is characterised by rapid swelling of one or both parotid glands, in which the symptoms are made worse by chewing and eating. Systemic upset with fever and malaise is variable. The symptoms usually last from 3 to 7 days, and are then followed by a quiescent period of weeks to several months. Children usually present between the ages of 3 and 6 years, although symptoms have been reported in infants as young as 4 months. The diagnosis is based on the characteristic history and can be confirmed by sialography. This shows a characteristic punctate sialectasis likened to a ‘snowstorm’ (Fig. 47.19). The condition usually responds to short courses of antibiotics although, if recurrence is frequent, prophylactic low-dose antibiotics may be required for several months or even years. Few children require formal parotidectomy. However, if the onset of symptoms is late, e.g. adolescence/early adulthood, fewer patients respond to conservative measures and may require total conservative parotidectomy.

Human immunodeficiency virus (HIV)-associated sialadenitis

Chronic parotitis in children is pathognomonic of HIV infection. The presentation of HIV-associated sialadenitis is very similar to

Figure 47.19 Characteristic ‘snowstorm’ appearance of recurrent parotitis of childhood (circled).

Figure 47.20 Magnetic resonance imaging (MRI) scan. Giant bilateral parotid cysts in human immunodeficiency virus (HIV) infection.

classical Sjögren’s syndrome in adulthood. Although HIV-associated sialadenitis and Sjögren’s syndrome are histologically similar, the former condition is usually associated with a negative autoantibody screen. Other presentations of salivary gland disease in HIV-positive patients include multiple parotid cysts, which cause gross parotid swelling and facial disfigurement. CT and MRI demonstrate the characteristic ‘Swiss cheese’ appearance of multiple large cystic lesions (Fig. 47.20). The glands are usually painless, although surgery may be indicated to improve the appearance.

Obstructive parotitis

There are several causes of obstructive parotitis, which produces intermittent painful swelling of the parotid gland, particularly at mealtimes.

Papillary obstruction

Obstructive parotitis is less common than obstructive submandibular sialadenitis but, nevertheless, can be caused by trauma to the parotid papilla through either an overextended upper denture flange or a fractured upper molar tooth. The subsequent inflammation and oedema obstructs salivary flow, particularly at mealtimes. The patient usually experiences rapid onset pain and swelling at mealtimes. If left untreated, progressive scarring and fibrosis in and around the parotid duct papilla will produce a permanent stenosis. Symptoms are unlikely to resolve unless a papillotomy is performed. This is a simple procedure performed under either local or general anaesthesia. The parotid duct is cannulated, and the distal parotid duct is laid open by

Henrik Samuel Conrad Sjögren, 1899–1986, Professor of Ophthalmology, Göthenburg, Sweden, described this condition in 1933.
A Swiss cheese is one with many holes in it.

incising longitudinally down onto the probe allowing free drainage of saliva.

Stone formation

Sialolithiasis is less common in the parotid gland (20%) than in the submandibular gland (80%). Parotid duct stones are usually radiolucent and rarely visible on plain radiography. They are frequently located at the confluence of the collecting ducts or located in the distal aspect of the parotid duct adjacent to the parotid papilla. Parotid gland sialography is usually required to identify the stone. A stone located in the collecting duct or within the gland requires surgical removal via a parotidectomy approach. The stone is identified by palpation and, once exposed, the surrounding parotid duct is incised longitudinally to release the stone.

Tumours of the parotid gland

The parotid gland is the most common site for salivary tumours. Most tumours arise in the superficial lobe and present as slow-growing, painless swellings below the ear (Fig. 47.21a), in front of the ear (Fig. 47.21b) or in the upper aspect of the neck. Less commonly, tumours may arise from the accessory lobe and present as persistent swellings within the cheek. Rarely, tumours may arise from the deep lobe of the gland and present as parapharyngeal masses (Fig. 47.21c and d). Symptoms include difficulty in

swallowing and snoring. Clinical examination reveals a diffuse firm swelling in the soft palate and tonsil.

Some 80–90% of tumours of the parotid gland are benign, the most common being pleomorphic adenoma (Table 47.2).

Malignant salivary gland tumours are divided into two distinct sub-groups:

- 1 *Low-grade malignant tumours*, e.g. acinic cell carcinoma, are indistinguishable on clinical examination from benign neoplasms.
- 2 *High-grade malignant tumours* usually present as rapidly growing, often painless swellings in and around the parotid gland. The tumour presents as either a discrete mass with infiltration into the overlying skin (Fig. 47.22) or a diffuse but hard swelling of the gland with no discrete mass. Presentation with advanced disease is common, and cervical lymph node metastases may be present.

Investigations

CT and MRI scanning are the most useful imaging techniques (Fig. 47.23a and b). Fine-needle aspiration biopsy may aid in obtaining a preoperative diagnosis, but open surgical biopsy is contraindicated unless malignancy is suspected, and preoperative histological diagnosis is required as a prelude to radical parotidectomy.

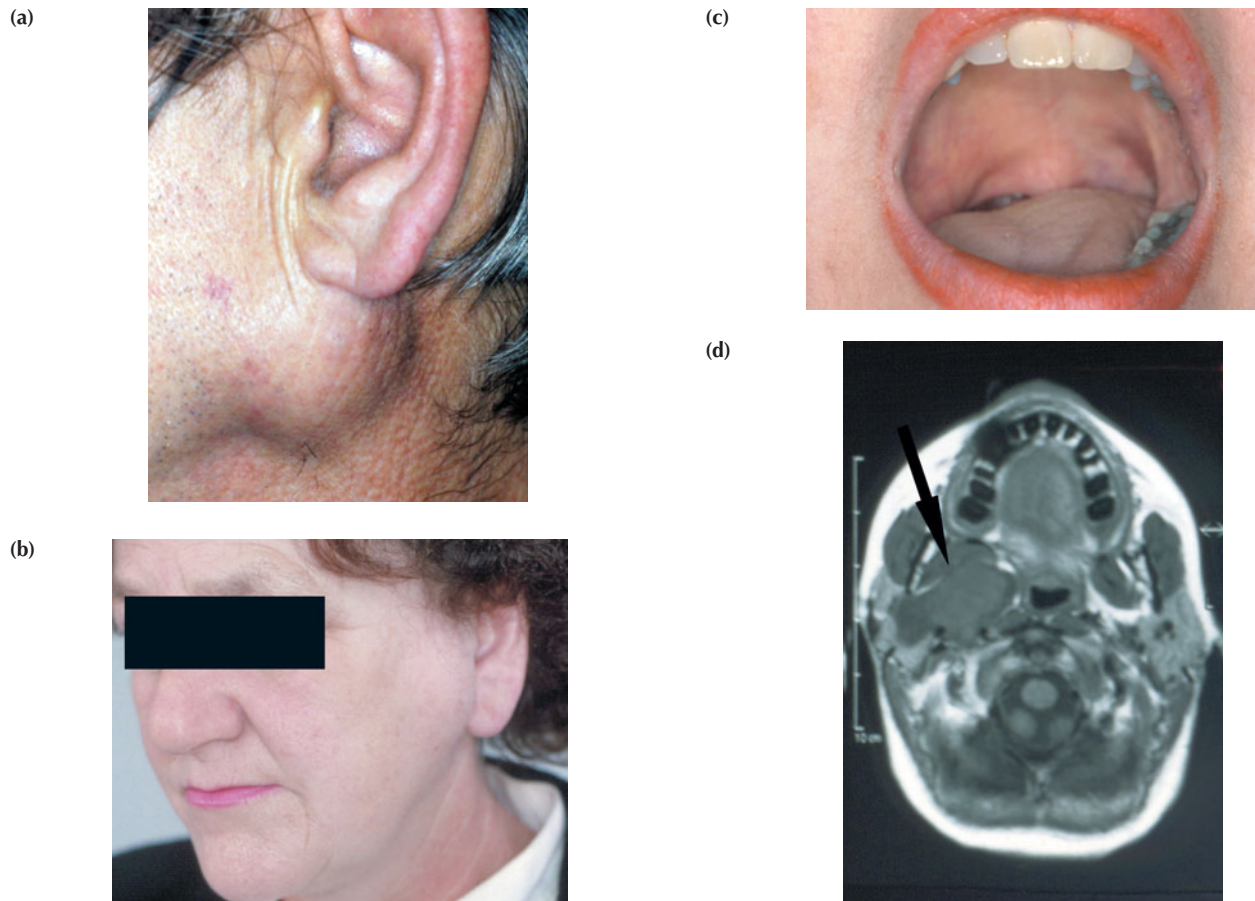

Figure 47.21 (a) Benign tumour of the left parotid gland producing characteristic deflection of the ear lobe. (b) Pleomorphic adenoma arising from the upper pole of the left parotid gland producing a pre-auricular swelling. (c) Deep lobe tumour of the right parotid presenting with a swelling of the right soft palate. (d) Magnetic resonance imaging (MRI) scan revealing a large deep lobe tumour (arrow) of the right parotid gland, occupying the parapharyngeal space.

Table 47.2 Classification of salivary gland tumours (simplified)

Type	Sub-group	Common examples
I Adenoma	Pleomorphic Monomorphic	Pleomorphic adenoma Adenolymphoma (Warthin's tumour)
II Carcinoma	Low grade	Acinic cell carcinoma Adenoid cystic carcinoma Low-grade muco-epidermoid carcinoma
	High grade	Adenocarcinoma Squamous cell carcinoma High-grade muco-epidermoid carcinoma
III Non-epithelial tumours		Haemangioma, lymphangioma
IV Lymphomas	Primary lymphomas	Non-Hodgkin's lymphomas
	Secondary lymphomas	Lymphomas in Sjögren's syndrome
V Secondary tumours	Local	Tumours of the head and neck especially Skin and bronchus
	Distant	
VI Unclassified tumours		
VII Tumour-like lesions	Solid lesions	Benign lymphoepithelial lesion Adenomatoid hyperplasia
	Cystic lesions	Salivary gland cysts

All tumours of the superficial lobe of the parotid gland should be managed by superficial parotidectomy. There is no role for enucleation even if a benign lesion is suspected. The aim of superficial parotidectomy is to remove the tumour with a cuff of normal surrounding tissue. The term 'suprafacial parotidectomy' has been used as not all branches of the facial nerve need be formally dissected, particularly if a tumour lies in the lower pole of the parotid gland.

Parotidectomy

Superficial parotidectomy

Superficial parotidectomy is the commonest procedure for parotid gland pathology. Surgery is performed under endotracheal general anaesthesia, which may or may not be accompanied by hypotensive anaesthesia to facilitate dissection, improve the visual surgical field and reduce blood loss. The operation has several distinct phases.

Incision and development of a skin flap

The most commonly used incision is the 'lazy S' pre-auricular-mastoid-cervical (Fig. 47.24a). The incision is marked out and

Figure 47.22 Malignant tumour of the left parotid gland with invasion of the overlying skin.

marked at three points along its length to facilitate closure. Infiltration with local anaesthetic and adrenaline is optional, but does aid in the development of the skin flap, improves visibility and reduces blood loss in the initial phase. The skin flap is developed in an anterior direction by either scalpel or scissors dissection. The plane of dissection is well below the hair follicles, just above the parotid fascia. The skin flap is developed forwards to the anterior border of the gland. Posterior undermining of the incision in the cervical region facilitates access to the anterior border of the sternomastoid muscle.

Mobilisation of the gland

This phase of the dissection aims to free the posterior margin of the gland, allowing identification of the facial nerve. Clips are applied along the fascia overlying the sternomastoid muscle, with the assistant applying traction anteriorly. By sharp dissection along the anterior border of the sternomastoid, an avascular plane is developed (Fig. 47.24b), which requires elective transection of the great auricular nerve. At the lower end of the dissection, the external jugular vein is often encountered and ligated. The gland is gradually mobilised by sharp dissection up to and on to the anterior aspect of the mastoid process, identifying the posterior belly of the digastric muscle.

A second avascular plane is developed along the anterior border of the cartilaginous and bony external auditory meatus immediately anterior to the tragus. The two avascular planes are then connected by blunt and sharp dissection. By developing two broad avascular planes, identification of the facial nerve trunk is facilitated (Fig. 47.24c). It is best achieved by scissors dissection

Aldred Scott Warthin, 1866–1931, Professor of Pathology, University of Michigan, Ann Arbor, MI, USA.

Thomas Hodgkin, 1798–1866, Curator of the Museum, and Demonstrator of Morbid Anatomy, Guy's Hospital, London, England, described lymphadenoma in 1832.

Figure 47.23 (a) Magnetic resonance imaging (MRI) scan revealing a space-occupying lesion (arrow) in the right parotid gland; histology revealed pleomorphic adenoma. (b) Computerised tomographic (CT) scan of the left parotid gland revealing a cystic lesion (arrow). Histology revealed acinic cell carcinoma.

in the line of the facial nerve trunk. A facial nerve stimulator is optional but helpful. Landmarks commonly used to aid identification of the trunk of the facial nerve are:

- 1 The inferior portion of the cartilaginous canal. This is termed Conley's pointer and indicates the position of the facial nerve, which lies 1 cm deep and inferior to its tip.
- 2 The upper border of the posterior belly of the digastric muscle. Identification of this muscle not only mobilises the parotid gland, but also exposes an area immediately superior, in which the facial nerve is usually located.

Location of the facial nerve trunk

Once the facial nerve trunk is identified, gentle traction anteriorly facilitates further mobilisation. Control of haemorrhage at this stage is vital as bleeding, no matter how minor, significantly impedes visibility for the surgeon. Haemostasis can be achieved with bipolar diathermy, although caution is necessary particularly when the facial nerve is approached. Damage to the stylomastoid artery, which lies immediately lateral to the nerve, can result in troublesome bleeding immediately prior to identification. Pledget swabs soaked in adrenaline are sometimes helpful in reducing the ooze associated with this phase of the dissection.

Dissection of the gland off the facial nerve

Once the facial nerve trunk is identified, further exposure of the branch of the facial nerve can be achieved by scissors dissection

in the perineural plane immediately above the nerve. The tunnel thus created is then laid open, and divisions and branches of the facial nerve are followed to the periphery in a sequential manner, usually beginning with the upper division. The upper division divides into a temporal and a zygomatic branch, and the lower division into mandibular and cervical branches. In this way, the superficial lobe and its associated tumour are mobilised in a superior to inferior direction (Fig. 47.24d). The upper division of the nerve is frequently tortuous in its course and can be damaged unless great care is taken during perineural dissection. It is often not necessary to dissect all branches of the facial nerve completely, as adequate tumour clearance can be achieved with a more conservative resection of the superficial lobe. When a branch of the facial nerve is adherent to the tumour or running through the tumour, it may require elective division. With the exception of the buccal branch, the transected nerve should be repaired immediately with a cable graft, harvested from the great auricular nerve.

Closure

The patient is placed into a Trendelenburg position to identify any residual bleeding vessels. A suction drain is applied for a period of 24–48 hours, and the wound closed in layers (Fig. 47.24f).

Radical parotidectomy

Radical parotidectomy is performed for patients in whom there is clear histological evidence of a high-grade malignant tumour, e.g. squamous cell carcinoma. Low-grade malignant tumours can usually be managed by standard superficial parotidectomy. Radical parotidectomy involves removal of all parotid gland tissue and elective sectioning of the facial nerve, usually through the main trunk (Fig. 47.25a–f). The surgery inevitably removes the ipsilateral masseter muscle and may also require simultaneous neck dissection, particularly where there is clinical, radiological and cytological evidence of lymph node metastases in the ipsilateral neck.

Complications of parotid gland surgery

Complications of parotid gland surgery include:

- 1 haematoma formation;
- 2 infection;
- 3 temporary facial nerve weakness;
- 4 transection of the facial nerve and permanent facial weakness;
- 5 sialocele;
- 6 facial numbness;
- 7 permanent numbness of the ear lobe associated with great auricular nerve transection;
- 8 Frey's syndrome.

Frey's syndrome

Frey's syndrome (gustatory sweating) is now considered an inevitable consequence of parotidectomy, unless preventative measures are taken (see below). It results from damage to the autonomic innervation of the salivary gland with inappropriate regeneration

Friedrich Trendelenburg, 1844–1924, successively Professor of Surgery at Rostock (1875–1882), Bonn (1882–1895), and Leipzig, (1895–1911), Germany. The Trendelenburg Position was first described in 1885.
Lucie Frey, 1896–1944, Physician, The Neurological Clinic, Warsaw, Poland.

(f) Wound closure with a vacuum drain.

of parasympathetic nerve fibres that stimulate the sweat glands of the overlying skin. The clinical features include sweating and erythema over the region of surgical excision of the parotid gland as a consequence of autonomic stimulation of salivation by the smell or taste of food. The symptoms are entirely variable and are clinically demonstrated by a starch iodine test. This involves painting the affected area with iodine, which is allowed to dry before applying dry starch, which turns blue on exposure to iodine in the presence of sweat. Sweating is stimulated by salivary stimulation. The management of Frey's syndrome involves the prevention as well as the management of established symptoms.

Prevention

There are a number of techniques described to prevent Frey's syndrome following parotidectomy. These include:

- sternomastoid muscle flap;
- temporalis fascial flap;

- insertion of artificial membranes between the skin and the parotid bed.

All these methods place a barrier between the skin and the parotid bed to minimise inappropriate regeneration of autonomic nerve fibres.

Management of established Frey's syndrome

Methods of managing Frey's syndrome include:

- anti-perspirants, usually containing aluminium chloride;
- denervation by tympanic neurectomy;
- the injection of botulinum toxin into the affected skin.

The last is the most effective and can be performed as an out-patient.

Granulomatous sialadenitis

This is a group of rare conditions that affect the salivary glands producing a variety of signs and symptoms, particularly painless

Figure 47.25 (a) High-grade malignant tumour in the left parotid gland. (b) Magnetic resonance imaging (MRI) scan demonstrating a diffuse infiltrative malignant tumour of the left parotid gland (arrow). (c) Skin incision outlined for radical neck dissection and left radical parotidectomy including the removal of overlying skin. (d) Skin flap developed. (e) Appearance after left radical neck dissection and left radical parotidectomy. Posterior mandible (upper arrow) and great vessels of the neck (lower arrow) are visible. (f) Wound closure after left radical neck dissection.

swellings of the parotid and/or submandibular glands. Systemic upset is variable. These include the following.

Mycobacterial infection

Tuberculosis and non-tuberculous sialadenitis typically present as a tumour-like swelling of the salivary gland. There is little pain and no fever. Preoperative investigations may be of some help, and the diagnosis is only confirmed when the swelling has been excised by either submandibular gland excision or formal parotidectomy.

Sarcoidosis

Sarcoidosis can affect the salivary tissue and presents with persistent salivary gland swelling that may be associated with xerostomia. Occasionally, the patient will present with a localised tumour-like swelling in one salivary gland, more commonly the parotid – the so called sarcoid pseudotumour. In such circumstances, the diagnosis is only likely to be made following surgical excision for a presumed neoplasm.

Heerfordt's syndrome is sarcoidosis that involves parotid swelling, anterior uveitis, facial palsy and fever.

Other

These include cat scratch disease, toxoplasmosis, syphilis, deep mycoses and Wegener's granulomatosis, allergic sialadenitis and sialadenitis associated with radiotherapy of the head and neck.

Tumour-like lesions

There is a group of pathological conditions that affect the salivary glands which do not fall into any particular classification or category and are often difficult to diagnose. These include such conditions as sialadenitis, adenomatoid hyperplasia and multifocal monomorphic adenomatosis.

Christian Frederick Heerfordt, 1871–1953, a Danish Ophthalmologist, described this syndrome in 1909.

Friedrich Wegener, 1907–1990, Professor of Pathology, Lübeck, Germany, described this form of granulomatosis in 1939.

Sialadenosis

Sialadenosis (sialosis) is used to describe non-inflammatory swelling particularly affecting the parotid gland. It is usually occurs in association with a variety of conditions including diabetes mellitus, alcoholism, other endocrine diseases, pregnancy, drugs, bulimia and other eating disorders, and idiopathic diseases.

Most patients present between 40 and 70 years of age, and the salivary swellings are soft and often symmetrical (Fig. 47.26). When the parotid glands are affected, patients may complain of a hamster-like appearance. Drug-induced sialosis is particularly common with sympathomimetic drugs. In many patients, no underlying disorder can be identified. Severe and prolonged malnutrition, as seen in eating disorders, produces sialadenosis by a process of glandular atrophy and fatty replacement. The pathological mechanism of sialadenosis can be associated with a process of neuropathy, which interferes with salivary gland function and subsequent acinar cell atrophy. This may be the case in diabetes mellitus, where autonomic neuropathy is a recognised complication as well as drug-induced sialosis.

The treatment of sialosis is unsatisfactory, but treatment is aimed at the correction of the underlying disorder. Drug-associated sialadenosis may regress when the drug responsible is withdrawn.

Degenerative conditions

Sjögren's syndrome

Sjögren's syndrome is an autoimmune condition causing progressive destruction of salivary and lacrimal glands. Primary Sjögren's syndrome differs from secondary Sjögren's syndrome in that xerostomia and keratoconjunctivitis sicca occur without the associated connective tissue disorder. However, the symptoms are often more severe, and the incidence of lymphomatous transformation (see below) in the primary group is higher than that in the secondary group (Table 47.3).

Figure 47.26 Sialosis of the parotid glands secondary to excess alcohol intake.

A hamster is a small nocturnal Eurasian rodent.

Table 47.3 Degenerative disorders

Primary Sjögren's syndrome	More severe xerostomia Widespread exocrine gland dysfunction No connective tissue disorder
Secondary Sjögren's syndrome	M:F: 1:10 Middle age Underlying connective tissue disorder
Benign lymphoepithelial lesion	20% develop lymphoma Diffuse parotid swelling 20% bilateral

Females are affected more than males in the ratio 10:1. Occasionally, there is enlargement of the salivary glands, more commonly the parotid rather than the submandibular glands. The glands are occasionally painful, and the patient sometimes develops a bacterial sialadenitis due to ascending infection from the associated xerostomia.

The characteristic pathological feature of Sjögren's syndrome is the progressive lymphocytic infiltration, acinar cell destruction and proliferation of duct epithelium in all salivary and lacrimal gland tissue. The diagnosis is based on the history as no single laboratory investigation is pathognomonic of either primary or secondary Sjögren's syndrome (Fig. 47.27).

Management

Management of Sjögren's syndrome remains symptomatic. No known treatment modifies or improves the xerostomia or keratoconjunctivitis sicca. An ophthalmological assessment is important, and artificial tears are essential to preserve corneal function. For dry mouth, various artificial salivary substitutes are available, but patients often consume large volumes of water, carrying a bottle of water with them at all times. In the dentate patient, the use of salivary substitutes with fluoride is important to counter the risk of accelerating dental caries. Other oral complications include oral candidosis and accelerated periodontal disease.

Figure 47.27 Clinical appearance of primary biliary cirrhosis associated with Sjögren's syndrome.

Complications of Sjögren's syndrome

There is an increased incidence of developing lymphoma (most commonly monocytoid B-cell lymphoma) in patients with Sjögren's syndrome. The risk is highest within the primary group, and the onset of lymphoma is heralded by immunological change within the blood.

Benign lymphoepithelial lesion

The use of the word 'benign' to describe this lesion is misleading because 20% of patients with benign lymphoepithelial lesion ultimately develop lymphoma. It is not possible to distinguish on histological grounds benign lymphoepithelial lesion from Sjögren's syndrome. Both are characterised by lymphocytic infiltration, acinar atrophy and ductal epithelial proliferation. Clinically, benign lymphoepithelial lesion presents as a diffuse swelling of the parotid gland. The swelling is firm, often painful and, in 20% of patients, the presentation is bilateral. Most patients are female and over 50 years of age. Parotidectomy is often undertaken to establish a diagnosis. Prolonged follow-up is essential.

Xerostomia

Xerostomia is a common symptom in many aspects of medical practice. Normal salivary flows decrease with age in both men and women, although many patients with xerostomia are postmenopausal women who also complain of a burning tongue or mouth. Common causes of xerostomia are:

- 1 chronic anxiety states and depression;
- 2 dehydration;
- 3 anti-cholinergic drugs, especially antidepressants;

- 4 salivary gland disorders – Sjögren's syndrome. Ascending parotitis is an occasional complication of xerostomia and is managed with antibiotics and increased fluid intake;
- 5 radiotherapy to the head and neck.

Sialorrhoea

Certain drugs and oral infection produce a transient increase in salivary flow rates. In healthy individuals, excess salivation is rarely a symptom as excess saliva is swallowed spontaneously. Uncontrolled drooling is usually seen in the presence of normal salivary production. It is seen in children with mental and physical handicap, notably cerebral palsy.

Management

Uncontrollable drooling is managed surgically, and many operations are available. Surgical options include:

- bilateral submandibular duct repositioning and simultaneous sublingual gland excision;
- bilateral submandibular gland excision;
- transposition of the parotid ducts and simultaneous submandibular gland excision.

Most resting salivary gland flow arises from the submandibular glands, and surgery should be focused on this gland to control uncontrolled sialorrhoea.

The thyroid and parathyroid glands

LEARNING OBJECTIVES

To understand:

- The development and anatomy of the thyroid and parathyroid glands
- The physiology and investigation of thyroid and parathyroid function
- The investigation of thyroid swelling
- The treatment of thyrotoxicosis and thyroid failure
- The indications for and technique of thyroid surgery
- The management of thyroid cancer
- The investigation and management of hyperparathyroidism
- The risks and complications of thyroid and parathyroid surgery

EMBRYOLOGY

The thyroglossal duct develops from the median bud of the pharynx. The foramen caecum at the base of the tongue is the vestigial remnant of the duct. This initially hollow structure migrates caudally and passes in close continuity with, and sometimes through, the developing hyoid cartilage. The parathyroid glands develop from the third and fourth pharyngeal pouches (Fig. 48.1). The thymus also develops from the third pouch. As it descends it takes the associated parathyroid gland with it, which explains why the inferior parathyroid arising from the third pouch normally lies inferior to the superior gland. However, the inferior parathyroid may be found anywhere along this line of descent. The developing thyroid lobes amalgamate with the structures arising in the fourth pharyngeal pouch, i.e. the superior parathyroid gland and the ultimobranchial body. Parafollicular cells (C cells) from the neural crest reach the thyroid via the ultimobranchial body.

SURGICAL ANATOMY (FIGS 48.2–48.4)

The normal thyroid gland weighs 20–25 g. The functioning unit is the lobule supplied by a single arteriole and consisting of 24–40 follicles lined with cuboidal epithelium. The follicle contains colloid in which thyroglobulin is stored (Fig. 48.2). The arterial supply is rich, and extensive anastomoses occur between the main thyroid arteries and branches of the tracheal and oesophageal arteries (Fig. 48.3). There is an extensive lymphatic network within the gland. Although some lymph channels pass directly to the deep cervical nodes, the subcapsular plexus drains principally to the central compartment juxtathyroid nodes – ‘Delphian’ (level 6) –

Delphi, a sacred site near the Gulf of Corinth in Greece, is the place where Pythia, the snake-woman oracle, resided. She sat on a tripod clutching the ribbons of the monolithic ‘omphalos’ of the world, and after inhaling sulphurous fumes, would utter meaningless jargon which was interpreted equivocally by the attendant priests for those who came to consult her. Formerly the purpose of these lymph nodes was uncertain, and they were therefore called ‘Delphic’.

paratracheal nodes (level 7) and nodes on the superior and inferior thyroid veins, and from there to the deep cervical (levels 2, 3, 4 and 5) and mediastinal groups of nodes.

The normal parathyroid gland weighs up to 50 mg with a characteristic orange/brown colour and mobility within the surrounding fat and thymic tissue. Most adults have four parathyroid

Figure 48.1 Embryology of the thyroid and parathyroid. Diagram of an anterior view of the pharynx in a four week embryo showing the relationship of the third and fourth pharyngeal pouches to final position of the thyroid and parathyroid glands.

Figure 48.2 Histology of the normal thyroid.

Figure 48.3 The thyroid gland from the front.

glands but supernumerary glands occur and nests of parathyroid tissue are commonly found in the thymus. The superior parathyroid is more consistent in position than the inferior. The superior gland is commonly found in fat above the inferior thyroid artery and close to the cricothyroid articulation (Fig. 48.4). It should be noted that the anatomical and radiological site, usually described as above the artery and posterior to the recurrent laryngeal nerve (RLN), is different from the surgical anatomy when the thyroid lobe is mobilised and rotated anteriorly. When the superior gland enlarges it tends to pass behind the inferior thyroid artery and descend inferiorly behind the oesophagus. The inferior parathyroid gland is usually found under the capsule of the upper horn of the thymus or on the inferior pole of the thyroid lobe. A mal-descended gland, however, can be found anywhere along the line of descent, virtually from the base of the skull to the aortopulmonary window (Summary box 48.1).

Figure 48.4 Surgical anatomy of the thyroid. The situation after mobilisation of the right lobe and the relationships of the recurrent laryngeal nerve, inferior thyroid artery and the parathyroid glands as they are usually found are shown. 1 and 2, common sites for the superior parathyroid gland – the arrow shows the tendency for an enlarged gland to migrate from position 1 to position 2, i.e. in an inferior direction, to lie posterior to the inferior thyroid artery (5) and oesophagus (8); 3 and 4, common sites for the inferior parathyroid gland (the upper horn of the thymus points like an index finger to the inferior parathyroid, which may lie under the ‘fingernail’); 5, inferior thyroid artery; 6, recurrent laryngeal nerve; 7, thymus; 8, oesophagus (see Fig. 48.49a).

- Know the surgical and radiological anatomy of the thyroid

PHYSIOLOGY

Thyroxine

The hormones tri-iodothyronine (T_3) and L-thyroxine (T_4) (extracted by E.C. Kendall in 1915) are bound to thyroglobulin within the colloid. Synthesis within the thyroglobulin complex is controlled by several enzymes, in distinct steps:

- trapping of inorganic iodide from the blood;
- oxidation of iodide to iodine;
- binding of iodine with tyrosine to form iodotyrosines;
- coupling of monoiodotyrosines and di-iodotyrosines to form T_3 and T_4 .

When hormones are required, the complex is resorbed into the cell and thyroglobulin is broken down. T_3 and T_4 are liberated and enter the blood, where they are bound to serum proteins: albumin, thyroxine-binding globulin (TBG) and thyroxine-binding prealbumin (TBPA). The small amount of hormone that remains free in the serum is biologically active.

The metabolic effects of the thyroid hormones are due to unbound free T_4 and T_3 (0.03% and 0.3% of the total circulating hormones respectively). T_3 is the more important physiological hormone and is also produced in the periphery by conversion from T_4 . T_3 is quick acting (within a few hours), whereas T_4 acts more slowly (4–14 days).

Edward Calvin Kendall, 1886–1972, Professor of Physiological Chemistry, The Graduate Medical School, The Mayo Foundation, Rochester, MN, USA. He shared the 1950 Nobel Prize for Physiology or Medicine with Hench and Reichstein ‘for their discoveries concerning the suprarenal cortex hormones, their structure and biological effects’.

Parathyroid hormone

The parathyroid glands secrete the 84-amino-acid peptide parathyroid hormone (PTH), which controls the level of serum calcium and extracellular fluid. PTH is released in response to a low serum calcium or high serum magnesium level. PTH activates osteoclasts to resorb bone and increases calcium reabsorption from urine and renal activation of vitamin D, with subsequent increased gut absorption of calcium. Renal excretion of phosphate is also increased.

Calcitonin

The parafollicular C-cells of the thyroid are of neuroendocrine origin and arrive in the thyroid via the ultimobranchial body (see Fig. 48.1). They produce calcitonin, which is a serum marker for recurrence of medullary thyroid cancer.

The pituitary–thyroid axis

The synthesis and liberation of thyroid hormones from the thyroid is controlled by thyroid-stimulating hormone (TSH) from the anterior pituitary. Secretion of TSH depends upon the level of circulating thyroid hormones and is modified in a classic negative feedback manner. In hyperthyroidism, when hormone levels in the blood are high, TSH production is suppressed whereas in hypothyroidism it is stimulated. Regulation of TSH secretion also results from the action of thyrotrophin-releasing hormone (TRH) produced in the hypothalamus.

Thyroid-stimulating antibodies

A family of IgG immunoglobulins bind with TSH receptor sites (TSH-RABs) and activate TSH receptors on the follicular cell membrane. They have a more protracted action than TSH (16–24 vs. 1.5–3 hours) and are responsible for virtually all cases of thyrotoxicosis not due to autonomous toxic nodules. Serum concentrations are very low but their measurement is not essential to make the diagnosis.

Therapeutic notes

T₄ is given once daily; an average replacement dose is 150 µg and a suppressive dose is 200 µg. T₃ is given in divided doses, usually as a suppressive dose of 4–60 µg. Recombinant human TSH is now available and is used to maximise (radioactive) iodine uptake as an alternative to thyroid hormone withdrawal.

TESTS OF THYROID FUNCTION

There is a large variety of available tests of thyroid function. In a surgical setting the investigations requested should be the minimum necessary to reach a diagnosis and formulate a management plan. Only a small number of parameters need to be measured as a routine, although this may require supplementation or the measurements may need to be repeated when inconclusive.

Table 48.1 Results of thyroid function tests in normal and pathological states

Thyroid functional state	TSH (0.3–3.3 mU l ⁻¹)	Free T ₄ (10–30 nmol l ⁻¹)	Free T ₃ (3.5–7.5 µmol l ⁻¹)
Euthyroid	Normal	Normal	Normal
Thyrotoxic	Undetectable	High	High
Myxoedema	High	Low	Low
Suppressive T ₄ therapy	Undetectable	High	High (may be normal)
T ₃ toxicity	Low/undetectable	Normal	High

Serum thyroid hormones

Serum TSH

TSH levels can be measured accurately down to very low serum concentrations with an immunochemiluminometric assay. When the serum TSH level is in the normal range, measuring the T₃ and T₄ levels is redundant. Interpretation of deranged TSH levels, however, depends on knowledge of the T₃ and T₄ values (Table 48.1). In the euthyroid state, T₃, T₄ and TSH levels will all be within the normal range. Florid thyroid failure results in depressed T₃ and T₄ levels, with gross elevation of the TSH. Incipient or developing thyroid failure is characterised by low-normal values of T₃ and T₄ and elevation of TSH. In toxic states the TSH level is suppressed and undetectable.

Thyroxine (T₄) and tri-iodothyronine (T₃)

These are transported in plasma bound to specific proteins (TBG). Only a small fraction of the total (0.03% of T₄ and 0.3% of T₃) is free and physiologically active. Assays of total hormone for both are now obsolete because of the confounding effect of circulating protein concentrations, influenced by the level of circulating oestrogen and the nutritional state. Highly accurate radioimmunoassays of free T₃ and free T₄ are now routine. T₃ toxicity (with a normal T₄) is a distinct entity and may only be diagnosed by measuring the serum T₃, although a suppressed TSH level with a normal T₄ may suggest the diagnosis.

An appropriate combination to establish the functional thyroid status at initial assessment is measurement of serum TSH and assay of anti-thyroid antibodies, supplemented by free T₄ and T₃ evaluation when TSH is abnormal.

Thyroid autoantibodies

Serum levels of antibodies against thyroid peroxidase (TPO; previously referred to as thyroid microsomal antigen) and thyroglobulin are useful in determining the cause of thyroid dysfunction and swellings. Autoimmune thyroiditis may be associated with thyroid toxicity, failure or euthyroid goitre. Levels above 25 units ml⁻¹ for TPO antibody and titres of greater than 1:100 for anti-thyroglobulin are considered significant, although a proportion of patients with histological evidence of lymphocytic (autoimmune) thyroiditis are seronegative. The presence of anti-thyroglobulin antibody interferes with assays of serum thyroglobulin with implications for the follow-up of thyroid cancers.

Thyroid imaging

Chest and thoracic inlet radiography (Fig. 48.5)

Simple radiographs of the chest and thoracic inlet will rapidly and economically confirm the presence of significant retrosternal goitre and clinically important degrees of tracheal deviation and compression. Chest radiographs tend to underestimate the extent of retrosternal extensions. Pulmonary metastases may also be detected.

Figure 48.5 Chest radiograph showing a retrosternal goitre with tracheal displacement.

Ultrasound scanning (Fig. 48.6)

High-frequency ultrasound scanning gives good anatomical images of the thyroid and surrounding structures but, unfortunately, reveals more thyroid swellings than are clinically relevant. After a period of years in the relative doldrums ultrasound is enjoying a revival as a means of reducing the number of unsatisfactory aspiration cytology samples; it permits more targeted sampling, allowing the identification of parathyroid adenomas and nodes involved in thyroid cancer.

Figure 48.6 Ultrasound scanning. (a) Transverse scan of a normal thyroid. R, right lobe; L, left lobe; T, trachea. (b) Longitudinal scan of normal jugular lymph nodes (white arrows).

Computerised tomography, magnetic resonance imaging and positron emission tomography scanning (Fig. 48.7)

Like ultrasound scanning, routine computerised tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography (PET) of unexceptional thyroid swellings are not indicated and are reserved for the assessment of known malignancy and to assess the extent of retrosternal and, occasionally, recurrent goitres. The appearance of a retrosternal goitre on CT can give a misleading impression of the operative difficulty in delivery through a neck incision.

Isotope scanning (Fig. 48.8)

The uptake by the thyroid of a low dose of either radiolabelled iodine (^{123}I) or the cheaper technetium ($^{99\text{m}}\text{Tc}$) will demonstrate the distribution of activity in the whole gland. Routine isotope scanning is unnecessary and inappropriate for distinguishing benign from malignant lesions because the majority (80%) of 'cold' swellings are benign and some (5%) functioning or 'warm' swellings will be malignant. Its principal value is in the toxic patient with a nodule or nodularity of the thyroid. Localisation of overactivity in the gland will differentiate between a toxic nodule with suppression of the remainder of the gland and toxic multinodular goitre

Figure 48.7 Computerised tomography scan of the chest showing a retrosternal goitre with tracheal displacement (arrowed).

Figure 48.8 Technetium thyroid scan showing a 'cold' nodule that does not take up isotope expanding the left thyroid lobe.

with several areas of increased uptake, with important implications for therapy.

Whole-body scanning is used to demonstrate metastases but the patient must have all normally functioning thyroid tissue ablated, either by surgery or radioiodine, before the scan is performed, because thyroid cancer cannot compete with normal thyroid tissue in the uptake of iodine.

Fine-needle aspiration cytology

Fine-needle aspiration cytology (FNAC) is the investigation of choice for discrete thyroid swellings. FNAC has excellent patient compliance, is simple and quick to perform in the out-patient department and is readily repeated. This technique, developed in Scandinavia some 35 years ago, has become routine throughout the world in the last 25 years. FNAC results should be reported using standard terminology (Table 48.2). There is a trend to use ultrasound to guide the needle to achieve more accurate sampling and reduce the rate of unsatisfactory aspirates (Summary box 48.2).

Summary box 48.2

Thyroid investigations

Essential

- Serum: TSH (T_3 and T_4 if abnormal); thyroid autoantibodies
- FNAC of palpable discrete swellings; ultrasound guidance may reduce the 'Thy1' rate

Optional

- Corrected serum calcium
- Serum calcitonin (carcinoembryonic antigen may be used as an alternative screening test for medullary cancer)
- Imaging: chest radiograph and thoracic inlet if tracheal deviation/retrosternal goitre; ultrasound, CT and MRI scan for known cancer, some reoperations and some retrosternal goitres; isotope scan if discrete swelling and toxicity coexist

HYPOTHYROIDISM

A scheme for classifying hypothyroidism is given in Table 48.3.

Cretinism (fetal or infantile hypothyroidism)

Cretinism is the consequence of inadequate thyroid hormone production during fetal and neonatal development. 'Endemic cretinism' is due to dietary iodine deficiency, whereas sporadic cases are due to either an inborn error of thyroid metabolism or complete or partial agenesis of the gland. A hoarse cry, macroglossia and umbilical hernia in a neonate with features of thyroid failure suggests the diagnosis. Immediate diagnosis and treatment with thyroxine within a few days of birth are essential

Table 48.2 Classification of fine-needle aspiration cytology reports

Thy1	Non-diagnostic
Thy2	Non-neoplastic
Thy3	Follicular
Thy4	Suspicious of malignancy
Thy5	Malignant

Table 48.3 Classification of hypothyroidism

Autoimmune thyroiditis (chronic lymphocytic thyroiditis)

Non-goitrous: primary myxoedema
Goitrous: Hashimoto's disease

Iatrogenic

After thyroidectomy
After radioiodine therapy
Drug induced (anti-thyroid drugs, para-aminosalicylic acid and iodides in excess)

Dyshormonogenesis

Goitrogens

Secondary to pituitary or hypothalamic disease

Thyroid agenesis

Endemic cretinism

Often goitrous and due to iodine deficiency

to prevent damage *in utero* progressing and if physical and mental development are to be normal. In non-endemic areas and societies with iodised salt, sporadic hypothyroidism still occurs at a rate of 1:4000 live births, and biochemical screening of neonates for hypothyroidism using TSH and T_4 assays on a heel-prick blood sample is widespread. Women taking anti-thyroid drugs may give birth to a hypothyroid infant and radioactive iodine must never be given to pregnant women.

Adult hypothyroidism

The term myxoedema should be reserved for severe thyroid failure and not applied to the much commoner mild thyroid deficiency. The signs of thyroid deficiency are:

- bradycardia;
- cold extremities;
- dry skin and hair;
- periorbital puffiness;
- hoarse voice;
- bradykinesia, slow movements;
- delayed relaxation phase of ankle jerks.

The symptoms are:

- tiredness;
- mental lethargy;
- cold intolerance;
- weight gain;
- constipation;
- menstrual disturbance;
- carpal tunnel syndrome.

Hakaru Hashimoto, 1881–1934, Director of The Hashimoto Hospital, Mie, Japan described chronic lymphocytic thyroiditis in 1912. The link to an autoimmune basis was first defined by Roitt and his co-workers.

Ivan Maurice Roitt, (dates unknown), Professor of Immunology, The Middlesex Hospital, London, England.

in utero is Latin for 'in the uterus'.

Myxoedema was first described in 1873 by Sir William Withey Gull, 1816–1890, Physician, Guy's Hospital, London, England.

Comparison of the facial appearance with a previous photograph may be helpful. Delayed relaxation of the ankle jerk reflex is the most useful clinical sign in making the diagnosis.

Thyroid function tests

These show low T_4 and T_3 levels with a high TSH (except in the rare event of pituitary failure) (see Table 48.1). High serum levels of TPO antibodies are characteristic of autoimmune disease.

Treatment

Oral thyroxine (0.10–0.20 mg) as a single daily dose is curative. Caution is required in the elderly or those with cardiac disease; in such cases the replacement dose is commenced at 0.05 mg daily and increased cautiously. If a rapid response is required, triiodothyronine (20 μ g t.d.s.) may be used.

Myxoedema (Fig. 48.9)

The signs and symptoms of hypothyroidism are accentuated. The facial appearance is typical; there is often supraclavicular puffiness, a malar flush and a yellow tinge to the skin. Myxoedema coma, characterised by altered mental state, hypothermia and a precipitating medical condition, for example cardiac failure or infection, carries a high mortality rate. Treatment comprises thyroid replacement, either a bolus of 500 mg of T_4 or 10 μ g of T_3 either intravenously or orally every 4–6 hours. If the body temperature is less than 30°C the patient must be warmed slowly. Intravenous broad-spectrum antibiotics and hydrocortisone (in divided doses) are recommended.

Primary or atrophic myxoedema is considered to be an autoimmune disease similar to chronic lymphocytic (Hashimoto's) thyroiditis (see below) but without goitre formation. Delay in diagnosis is common and the degree of hypothyroidism is usually more severe than in goitrous autoimmune thyroiditis.

Dyshormonogenesis

Genetic deficiencies in the enzymes controlling the synthesis of thyroid hormones account for a minority of cases of neonatal hypothyroidism and goitre. These are usually inherited in an autosomal recessive pattern and a family history is common. If

Figure 48.9 Myxoedema. Note the bloated look, the pouting lips and the dull expression (courtesy of Dr V.K. Summers, Liverpool, UK).

the biochemical effect is of moderate degree, thyroid enlargement may be the only manifestation; dyshormonogenesis should be considered in young patients presenting with euthyroid goitre. The most common abnormalities affect TPO activity and thyroglobulin synthesis. A classic example of dyshormonogenesis due to TPO deficiency is Pendred's syndrome, in which goitre is associated with severe sensorineural hearing impairment and abnormality of the bony labyrinth observed on CT examination of the temporal bones.

THYROID ENLARGEMENT

The normal thyroid gland is impalpable. The term goitre (from the Latin *guttur* = the throat) is used to describe *generalised* enlargement of the thyroid gland. A discrete swelling (nodule) in one lobe with no palpable abnormality elsewhere is termed an *isolated* (or *solitary*) swelling. Discrete swellings with evidence of abnormality elsewhere in the gland are termed *dominant* (Summary box 48.3).

Summary box 48.3

Thyroid swellings

- Know how to describe thyroid swellings
- Use appropriate investigations
- Know the indications for surgery
- Select the appropriate procedure
- Describe and manage postoperative complications

A scheme for classifying thyroid enlargement is given in Table 48.4.

Simple goitre

Aetiology

Simple goitre may develop as a result of stimulation of the thyroid gland by TSH, either as a result of inappropriate secretion from a microadenoma in the anterior pituitary (which is rare) or in response to a chronically low level of circulating thyroid hormones. The most important factor in endemic goitre is dietary deficiency of iodine (see below), but defective hormone synthesis probably accounts for many sporadic goitres (see below).

TSH is not the only stimulus to thyroid follicular cell proliferation; other growth factors, including immunoglobulins, exert an influence. The heterogeneous structural and functional response in the thyroid resulting in characteristic nodularity may be due to the presence of clones of cells that are particularly sensitive to growth stimulation.

Iodine deficiency

The daily requirement for iodine is about 0.1–0.15 mg. In nearly all districts where simple goitre is endemic there is a very low iodide content in the water and food. Endemic areas are found in the mountainous ranges, such as the Rocky Mountains, the Alps, the Andes and the Himalayas. In the UK endemic areas include Derbyshire and Yorkshire. Endemic goitre is also found in lowland

Vaughan Pendred, 1869–1946, a General Practitioner of Durham, England, described this syndrome in 1896. Exactly 100 years later the defect was mapped to chromosome 7q.

areas where the soil lacks iodide or the water supply comes from far-away mountain ranges, e.g. the Great Lakes of North America, the plains of Lombardy, the Struma valley, the Nile valley and the Congo. Calcium is also goitrogenic and goitre is common in low-iodine areas on chalk or limestone, for example Derbyshire and southern Ireland. Although iodides in food and water may be adequate, failure of intestinal absorption may produce iodine deficiency.

Dyshormonogenesis

Enzyme deficiencies of varying severity may be responsible for many sporadic goitres, i.e. in non-endemic areas (Fig. 48.10). There is often a family history, suggesting a genetic defect. Environmental factors may compensate in areas of high iodine intake; for example, goitre is almost unknown in Iceland where the fish diet is rich in iodine. Similarly, a low intake of iodine encourages goitre formation in those with a metabolic predisposition.

Goitrogens

Well-known goitrogens are the vegetables of the brassica family (cabbage, kale and rape), which contain thiocyanate, drugs such

Bernhard Moritz Carl Ludwig Riedel, 1846–1916, Professor of Surgery, Jena, Germany, described this form of thyroiditis in 1896.

Struma. The River Struma arises in the mountains of Bulgaria and flows into the Aegean Sea. Along its banks, and those of its tributaries, dwell peoples of several nationalities amongst whom endemic goitre has long been prevalent. Struma is a European continental term for goitre.

Figure 48.10 Total thyroidectomy for dysmorphogenetic goitre in a 14-year-old girl.

as para-aminosalicylic acid (PAS) and, of course, the anti-thyroid drugs. Thiocyanates and perchlorates interfere with iodide trapping whereas carbimazole and thiouracil compounds interfere with the oxidation of iodide and the binding of iodine to tyrosine.

Surprisingly enough, iodides in large quantities are goitrogenic because they inhibit the organic binding of iodine and produce an iodide goitre. Excessive iodine intake may be associated with an increased incidence of autoimmune thyroid disease.

The natural history of simple goitre

The stages in goitre formation are as follows:

- Persistent growth stimulation causes diffuse hyperplasia; all lobules are composed of active follicles and iodine uptake is uniform. This is a diffuse hyperplastic goitre, which may persist for a long time but is reversible if stimulation ceases.
- Later, as a result of fluctuating stimulation, a mixed pattern develops with areas of active lobules and areas of inactive lobules.
- Active lobules become more vascular and hyperplastic until haemorrhage occurs, causing central necrosis and leaving only a surrounding rind of active follicles.
- Necrotic lobules coalesce to form nodules filled with either iodine-free colloid or a mass of new but inactive follicles.
- Continual repetition of this process results in a nodular goitre. Most nodules are inactive, and active follicles are present only in the internodular tissue.

Diffuse hyperplastic goitre

Diffuse hyperplasia corresponds to the first stages of the natural history. The goitre appears in childhood in endemic areas but, in sporadic cases, it usually occurs at puberty when metabolic demands are high. If TSH stimulation ceases the goitre may regress; however, it tends to recur later at times of stress such as pregnancy. The goitre is soft, diffuse and may become large enough to cause discomfort. A colloid goitre is a late stage of diffuse hyperplasia when TSH stimulation has fallen off and when many follicles are inactive and full of colloid (Fig. 48.11).

Nodular goitre

Nodules are usually multiple, forming a multinodular goitre (Fig. 48.12). Occasionally, only one macroscopic nodule is found, but

Figure 48.11 Colloid goitre.

Figure 48.12 Large multinodular goitre.

microscopic changes will be present throughout the gland; this is one form of a clinically solitary nodule. Nodules may be colloid or cellular, and cystic degeneration and haemorrhage are common, as is subsequent calcification. Nodules appear early in endemic goitre and later (between 20 and 30 years) in sporadic goitre, although the patient may be unaware of the goitre until his or her late 40s or 50s. All types of simple goitre are more common in

females than males because of the presence of oestrogen receptors in thyroid tissue.

Diagnosis

Diagnosis is usually straightforward. The patient is euthyroid, the nodules are palpable and often visible (smooth, usually firm and not hard) and the goitre is painless and moves freely on swallowing. Hardness and irregularity, due to calcification, may simulate carcinoma. A painful nodule or the sudden appearance or rapid enlargement of a nodule raises suspicion of carcinoma; however, such cases are usually due to haemorrhage into a simple nodule. Differential diagnosis from autoimmune thyroiditis may be difficult and the two conditions frequently coexist.

Investigations

Thyroid function should be assessed to exclude mild hyperthyroidism, and the presence of circulating thyroid antibodies tested to differentiate from autoimmune thyroiditis. Plain radiographs of the chest and thoracic inlet will rapidly demonstrate clinically significant tracheal deviation or compression. Ultrasound and CT give more detailed images but rarely influence clinical management. FNAC is only required for a dominant swelling in a generalised goitre.

Complications

Tracheal obstruction may occur because of gross lateral displacement or compression in a lateral or anteroposterior plane by retrosternal extension of the goitre (see Figs 48.5 and 48.7, p. 774). Acute respiratory obstruction may follow haemorrhage into a nodule impacted in the thoracic inlet.

Secondary thyrotoxicosis

Transient episodes of mild hyperthyroidism are common, occurring in up to 30% of patients.

Carcinoma

An increased incidence of cancer (usually follicular) has been reported from endemic areas. Dominant or rapidly growing nodules in longstanding goitres should always be subjected to aspiration cytology.

Prevention and treatment of simple goitre

In endemic areas, for example Switzerland, parts of the USA and Argentina, the incidence of goitre has been strikingly reduced by the introduction of iodised salt. In the early stages a hyperplastic goitre may regress if thyroxine is given at a dose of 0.15–0.2 mg daily for a few months.

Although the nodular stage of simple goitre is irreversible, more than half of benign nodules will regress in size over 10 years (Kuma). Most patients with multinodular goitre are asymptomatic and do not require operation. Operation may be indicated on cosmetic grounds, for pressure symptoms or in response to patient anxiety. Retrosternal extension with actual or incipient tracheal compression is also an indication for operation, as is the presence of a dominant area of enlargement that may be neoplastic.

There is a choice of surgical treatment in multinodular goitre. This includes *total thyroidectomy*, with immediate and lifelong replacement of thyroxine, or some form of partial resection, to conserve sufficient functioning thyroid tissue to subserve normal function while reducing the risk of hypoparathyroidism that

accompanies total thyroidectomy. *Subtotal thyroidectomy* involves partial resection of each lobe, removing the bulk of the gland and leaving up to 8 g of relatively normal tissue in each remnant. The technique is essentially the same as described for toxic goitre, as are the postoperative complications. More often, however, the multinodular change is asymmetrically distributed, with one lobe more significantly involved than the other. In these circumstances, particularly in older patients, *total lobectomy* on the more affected side is the appropriate management, with either subtotal resection (Dunhill procedure) or no intervention on the less affected side.

In many cases the causative factors persist and recurrence is likely. Reoperation for recurrent nodular goitre is more difficult and hazardous and, for this reason, an increasing number of thyroid surgeons favour total thyroidectomy in younger patients. However, when the first operation comprised unilateral lobectomy alone for asymmetrical goitre, reoperation and completion of total thyroidectomy is straightforward if required for progression of nodularity in the remaining lobe.

After subtotal resection it has been customary to give thyroxine to suppress TSH secretion, with the aim of preventing recurrence. Whether this is either necessary or effective is uncertain, although the evidence of benefit in endemic areas is better than elsewhere. There is some evidence that radioactive iodine may reduce the size of recurrent nodular goitre after previous subtotal resection and, in some circumstances, this may be a safer alternative than reoperation, particularly if there has been more than one previous thyroid procedure.

Clinically discrete swellings

Discrete thyroid swellings (thyroid nodules) are common and are present in 3–4% of the adult population in the UK and USA. They are three to four times more frequent in women than men.

Diagnosis

A discrete swelling in an otherwise impalpable gland is termed *isolated* or *solitary*, whereas the preferred term is *dominant* for a similar swelling in a gland with clinical evidence of generalised abnormality in the form of a palpable contralateral lobe or generalised mild nodularity. About 70% of discrete thyroid swellings are clinically isolated and about 30% are dominant. The true incidence of isolated swellings is somewhat less than the clinical estimate. Clinical classification is inevitably subjective and overestimates the frequency of truly isolated swellings. When such a gland is exposed at operation or examined by ultrasonography, CT or MRI, clinically impalpable nodules are often detected. The true frequency of thyroid nodularity compared with the clinical detection rate by palpation is shown in Fig. 48.13. Establishing the presence of such minor abnormality is unnecessary because the management of discrete swellings, be they isolated or dominant, is similar.

The importance of discrete swellings lies in the increased risk of neoplasia compared with other thyroid swellings. Some 15% of isolated swellings prove to be malignant, and an additional 30–40% are follicular adenomas. The remainder are non-neoplastic, largely consisting of areas of colloid degeneration,

Figure 48.13 The prevalence of thyroid nodules detected on palpation (broken line) or by ultrasonography or post-mortem examination (solid line) (after Mazzaferri).

thyroiditis or cysts. Although the incidence of malignancy or follicular adenoma in clinically dominant swellings is approximately half of that of truly isolated swellings, it is substantial and cannot be ignored (Fig. 48.14).

Investigation

Thyroid function

Serum TSH and thyroid hormone levels should be measured. If hyperthyroidism associated with a discrete swelling is confirmed biochemically, it indicates either a 'toxic adenoma' or a manifestation of toxic multinodular goitre. The combination of toxicity and nodularity is important and is an indication for isotope scanning to localise the area(s) of hyperfunction.

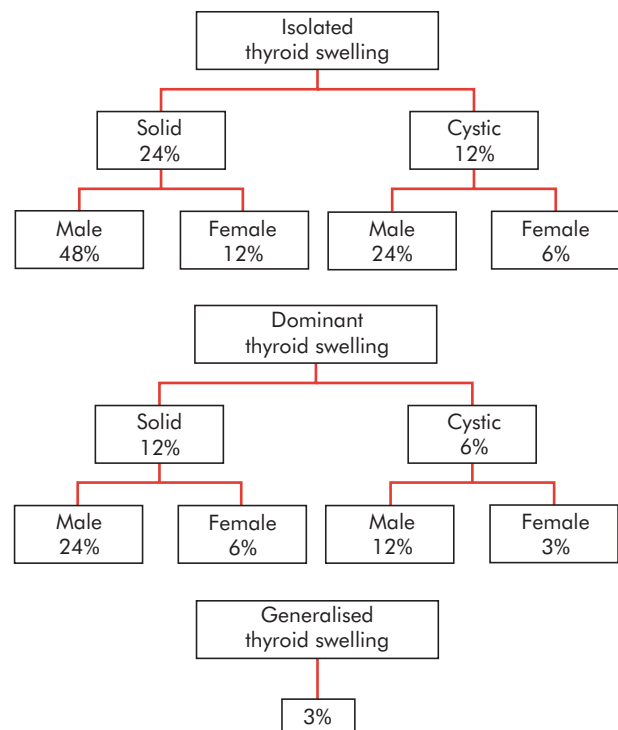

Figure 48.14 The risk of malignancy in thyroid swellings ('rule of 12'). The risk of cancer in a thyroid swelling can be expressed as a factor of 12. The risk is greater in isolated vs. dominant swellings, solid vs. cystic swellings and men vs. women.

Sir Thomas Peel Dunhill, 1876–1957, Surgeon, St. Bartholomew's Hospital, London, England.

Autoantibody titres

The autoantibody status may determine whether a swelling is a manifestation of chronic lymphocytic thyroiditis. The presence of circulating antibodies may increase the risk of thyroid failure after lobectomy.

Isotope scan

Isotope scanning used to be the mainstay of investigation of discrete thyroid swellings to determine the functional activity relative to the surrounding gland according to isotope uptake.

On scanning, swellings are categorised as 'hot' (overactive), 'warm' (active) or 'cold' (underactive). A hot nodule is one that takes up isotope while the surrounding thyroid tissue does not. Here, the surrounding thyroid tissue is inactive because the nodule is producing such high levels of thyroid hormones that TSH secretion is suppressed. A warm nodule takes up isotope, as does the normal thyroid tissue around it. A cold nodule does not take up isotope (see Fig. 48.8, p. 774).

About 80% of discrete swellings are cold, but only 15% prove to be malignant and the use of this criterion as an indication for operation lacks discrimination. Routine isotope scanning has been abandoned except when toxicity is associated with nodularity.

Ultrasonography

This was formerly widely used as a non-invasive supplement to clinical examination in determining the physical characteristics of thyroid swellings. Although ultrasonography can demonstrate subclinical nodularity and cyst formation, the former is clinically irrelevant and the latter apparent at aspiration, which should be routine in all discrete swellings. There was a decline in the use of ultrasound because it had a minimal impact on management; however, it is becoming more popular again as an adjunct to FNAC and in the assessment of malignant lymphadenopathy.

Fine-needle aspiration cytology

FNAC is the investigation of choice in discrete thyroid swellings. FNAC has excellent patient compliance, is simple and quick to perform in the out-patient department and is readily repeated.

Thyroid conditions that may be diagnosed by FNAC include colloid nodules (Fig. 48.15), thyroiditis, papillary carcinoma

(Fig. 48.16), medullary carcinoma, anaplastic carcinoma and lymphoma. FNAC cannot distinguish between a benign follicular adenoma (Fig. 48.17) and follicular carcinoma, as this distinction is dependent not on cytology but on histological criteria, which include capsular and vascular invasion.

Although FNAC was reported as being highly accurate by Lowhagen and his colleagues (who were its pioneers) at the Karolinska Hospital, high accuracy has not always been reproducible, especially when results are analysed critically. There are very few false positives with respect to malignancy but there is a definite false-negative rate with respect to both benign and malignant neoplasia. In addition, there can be a high rate of unsatisfactory aspirates, particularly in cystic or partly cystic swellings. These often yield only cyst fluid with macrophages and degenerate cells with few thyroid follicular cells upon which to report. After aspiration, a further sample for cytology should be taken from the cyst wall. There has been a recent trend to use ultrasound to guide the needle to achieve more accurate sampling and reduce the rate of unsatisfactory aspirates.

Figure 48.16 Thy5 aspiration cytology. Papillary carcinoma with typical cellular variability and nuclear inclusions.

Figure 48.15 Thy2 aspiration cytology. Non-neoplastic appearances with scanty normal follicular cells together with colloid (= colloid nodule).

Figure 48.17 Thy3 aspiration cytology. Follicular neoplasm showing increased cellularity with a follicular pattern.

Torsten Lowhagen, Cytologist, The Department of Tumour Pathology, The Karolinska Hospital, Stockholm, Sweden.

Relatively few cysts are permanently abolished by one or more aspirations and, because of the risk of malignancy, recurrent cysts should be removed.

Radiology

Chest and thoracic inlet radiographs may confirm tracheal deviation, compression or retrosternal extension and are required when either clinical suspicion or FNAC indicates malignancy.

Ultrasound scan

Although ultrasound gives additional information to supplement clinical examination it will also often reveal previously unsuspected nodularity, which raises the problem of managing such incidentally found lesions.

Other scans

CT and MRI scans give excellent anatomical detail of thyroid swellings but have no role in the first line of investigation. They are most useful in assessing retrosternal (see Fig. 48.7 p. 774) and recurrent swellings, particularly if initial surgery has been performed elsewhere. A PET scan (Fig. 48.18) may be useful, particularly in localising disease that does not take up radioiodine.

Laryngoscopy

Flexible laryngoscopy has rendered indirect laryngoscopy obsolete and is widely used preoperatively to determine the mobility of the vocal cords, although usually for medico-legal rather than clinical reasons. Nevertheless, the presence of a unilateral cord palsy coexisting with a swelling suggestive of malignancy is usually diagnostic.

Core biopsy

Core biopsy gives a strip of tissue for histological rather than cytological assessment. It has a high diagnostic accuracy but requires local anaesthesia and may be associated with complications such as pain, bleeding and tracheal and recurrent laryngeal nerve damage. It has little application in routine assessment except in locally advanced, surgically unresectable malignancy (either anaplastic carcinoma or lymphoma), when core biopsy may avoid operation. In some centres core biopsy is recommended in cases of Thy1 FNAC (inadequate cytology) specimens to avoid operating

Figure 48.18 Fused computerised tomography and positron emission tomography scans showing a left-sided thyroid neoplasm (courtesy of Dr M. Brooks, Aberdeen, UK).

on patients in whom the risk of malignancy is very low. It is unlikely to be useful in differentiating Thy3 specimens (i.e. follicular lesions) because of sampling issues.

Treatment

The main indication for operation is the risk of neoplasia. The reason for advocating the removal of all follicular neoplasms is that it is seldom possible to distinguish between a follicular adenoma and a carcinoma except on the basis of histological evidence of capsular or vascular invasion. FNAC cannot make this distinction although, on occasion, cellular nuclear features may be so abnormal as to suggest malignant change. On this basis, some 50% of isolated swellings and 25% of dominant swellings should be removed on the grounds of neoplasia. Even when the cytology is negative, the age and sex of the patient and the size of the swelling may be relative indications for surgery, especially when a large swelling is symptomatic.

There are useful clinical criteria to assist in selection for operation according to the risk of neoplasia and malignancy. Hard texture alone is not reliable as tense cystic swellings may be suspiciously hard; however, a hard, irregular swelling with any apparent fixity, which is unusual, is highly suspicious. Evidence of recurrent laryngeal nerve paralysis, suggested by hoarseness and a non-occlusive cough and confirmed by laryngoscopy, is almost pathognomonic. Deep cervical lymphadenopathy along the internal jugular vein in association with a clinically suspicious swelling is almost diagnostic of papillary carcinoma. In most patients, however, such features are absent, but there are risk factors associated with sex and age. The incidence of thyroid carcinoma in women is about three times that in men; however, a discrete swelling in a man is much more likely to be malignant than a swelling in a woman and should be removed. The risk of carcinoma is increased at either end of the age range and a discrete swelling in a teenager of either sex must be provisionally diagnosed as carcinoma. The risk increases over the age of 50 years, more so in men.

Thyroid cysts

Routine FNAC (or ultrasonography) shows that over 30% of clinically isolated swellings contain fluid and are cystic or partly cystic. Tense cysts may be hard and mimic carcinoma. Bleeding into a cyst often presents with a history of sudden painful swelling, which resolves to a variable extent over a period of weeks if untreated. Aspiration yields altered blood but reaccumulation is frequent. About 50% of cystic swellings are the result of colloid degeneration or are of uncertain aetiology, because of an absence of epithelial cells in the lining. Although most of the remainder are the result of involution in follicular adenomas (Fig. 48.19), some 10–15% of cystic follicular swellings are histologically malignant

Figure 48.19 An apparently simple cystic thyroid swelling, the wall of which comprised follicular neoplastic tissue.

(30% in men and 10% in women). Papillary carcinoma is often associated with cyst formation (Fig. 48.20).

Most patients with discrete swellings, however, are women aged 20–40 years, in whom the risk of malignancy is low and the indications for operation are not clear. FNAC is the most appropriate investigation to aid selection.

The indications for operation in isolated or dominant thyroid swellings are listed in Table 48.5.

Selection of thyroid procedure

The choice of thyroid operation depends on:

- diagnosis (if known preoperatively);
- risk of thyroid failure;
- risk of RLN injury;
- risk of recurrence;
- Graves' disease;
- multinodular goitre;
- differentiated thyroid cancer (DTC);
- risk of hypoparathyroidism.

Total and near-total thyroidectomy do not conserve sufficient thyroid tissue for normal thyroid function and thyroid replacement therapy is necessary. In most patients with negative anti-thyroid antibodies, one thyroid lobe will maintain normal

Robert James Graves, Physician, The Meath Hospital, Dublin, Ireland, published an account of exophthalmic goitre in 1835.

function. In subtotal thyroidectomy the volume of thyroid tissue preserved influences the risk of thyroid failure; larger remnants have a better chance of normal function but a higher risk of recurrence in Graves' disease.

Subtotal resections for colloid goitre run the risk of later growth of the remnant and, if a second operation is required years later, this greatly increases the risk to the RLN and parathyroid glands. In young patients, total thyroidectomy should be considered. It may be preferable to leave the least affected lobe untouched to permit a straightforward lobectomy in the future if required, rather than carry out subtotal resections.

In Graves' disease, preserving large remnants increases the risk of recurrence of the toxicity and, in these cases, it is better to err on the side of removing too much thyroid tissue than too little (Table 48.6). Thyroid failure need not be regarded as a failure of treatment but recurrent toxicity is.

The relative merits of routine total vs. selective total thyroidectomy in DTC are discussed below (Summary box 48.4).

Summary box 48.4

Thyroid operations

All thyroid operations can be assembled from three basic elements:

- Total lobectomy
- Isthmusectomy
- Subtotal lobectomy

$$\text{Total thyroidectomy} = 2 \times \text{total lobectomy} + \text{isthmusectomy}$$

$$\text{Subtotal thyroidectomy} = 2 \times \text{subtotal lobectomy} + \text{isthmusectomy}$$

$$\text{Near-total thyroidectomy} = \text{total lobectomy} + \text{isthmusectomy} + \text{subtotal lobectomy}$$

$$\text{Lobectomy} = \text{total lobectomy} + \text{isthmusectomy}$$

Retrosternal goitre

Very few retrosternal goitres arise from ectopic thyroid tissue; most arise from the lower pole of a nodular goitre. If the neck is short and the pretracheal muscles are strong, particularly in men, the negative intrathoracic pressure tends to draw these nodules into the superior mediastinum.

Clinical features

A retrosternal goitre is often symptomless and discovered on a routine chest radiograph (see Fig. 48.5, p. 774). There may, however, be severe symptoms:

- *Dyspnoea*, particularly at night, cough and stridor (harsh sound on inspiration). Many patients attend a chest clinic with a diagnosis of asthma before the true nature of the problem is discovered.
- *Dysphagia*.
- *Engorgement of facial, neck and superficial chest wall veins*; in severe cases there may be obstruction of the superior vena cava (Fig. 48.21).
- *Recurrent nerve paralysis* is rare; the goitre may also be malignant or toxic.

Table 48.6 Comparison of surgical options for Graves' disease

	Total thyroidectomy	Subtotal thyroidectomy
Control of toxicity	Immediate	Immediate
Return to euthyroid state	Immediate	Variable – up to 12 months
Risk of recurrence	None	Lifelong – up to 5% ^a
Risk of thyroid failure	100%	Lifelong – up to 25% ^a
Risk of permanent hypoparathyroidism	5%	1%
Need for follow-up	Minimal	Lifelong

^a The risk of recurrence and late failure are a function of the size of the remnant as a proportion of the total gland weight. Large remnants in small glands have a higher risk of recurrence and a low risk of failure, and small remnants in large glands have a higher risk of thyroid failure but a low risk of recurrence.

Chest and thoracic inlet radiographs show a soft-tissue shadow in the superior mediastinum, sometimes with calcification and often causing deviation and compression of the trachea. A CT scan gives the most accurate and often dramatic anatomical visualisation (see Fig. 48.7 p. 774).

Significant tracheal compression and obstruction may be demonstrated objectively by a flow–volume loop pulmonary function test in which the rate of flow is plotted against the volume of air inspired and then expired. Deterioration in flow because of an increase in tracheal compression, either acutely or in the long term, may be used to monitor progression of the disease and indicate the need for surgery. The changes are reversed by operation (Fig. 48.22).

Treatment

If obstructive symptoms are present in association with thyrotoxicosis it is unwise to treat a retrosternal goitre with anti-thyroid drugs or radioiodine as these may enlarge the goitre. Resection can almost always be carried out from the neck, but median sternotomy is sometimes necessary (see Fig. 48.21b). The cervical part of the goitre should first be mobilised by ligation and division of the superior thyroid vessels and the middle thyroid vein. The retrosternal goitre can then be delivered by traction, which may be facilitated by inserting a series of sutures, a finger or, traditionally, a spoon. Haemorrhage is rarely a problem because the goitre takes its blood supply with it from the neck. The RLN should be identified before delivering the retrosternal goitre, as it may be considerably displaced and is particularly vulnerable to injury from traction or tearing. If a large retrosternal goitre cannot be delivered intact, piecemeal delivery is possible; however, this risks leaving a fragment of nodular goitre deep in the mediastinum, which may result in a very difficult reoperation many years later. Fragmentation must be avoided when malignancy is likely. These problems are avoided with a timely median sternotomy.

Thyroid incidentaloma

The increased use of imaging modalities for non-thyroid head and neck pathology has created the clinical conundrum of the 'thyroid incidentaloma'. These are clinically unsuspected and impalpable thyroid swellings and, in some parts of the world, this has reached 'epidemic' proportions. Injudicious reporting generates needless anxiety if the possibility of malignancy is raised inappropriately. The vast majority of impalpable thyroid swellings can be safely managed expectantly by a single annual review, with no intervention unless certain criteria are met or the swelling becomes palpable (Fig. 48.23).

HYPERTHYROIDISM

Thyrotoxicosis

The term thyrotoxicosis is retained because hyperthyroidism, i.e. symptoms due to a raised level of circulating thyroid hormones, is not responsible for all manifestations of the disease. Clinical types are:

- diffuse toxic goitre (Graves' disease);
- toxic nodular goitre;
- toxic nodule;
- hyperthyroidism due to rarer causes.

Diffuse toxic goitre

Graves' disease, a diffuse vascular goitre appearing at the same time as the hyperthyroidism, usually occurs in younger women and is frequently associated with eye signs. The syndrome is that of primary thyrotoxicosis (Fig. 48.24); 50% of patients have a family history of autoimmune endocrine diseases. The whole of the functioning thyroid tissue is involved, and the hypertrophy and hyperplasia are due to abnormal thyroid-stimulating antibodies (TSH-RABs) that bind to TSH receptor sites and produce a disproportionate and prolonged effect.

Toxic nodular goitre

A simple nodular goitre is present for a long time before the hyperthyroidism, usually in the middle-aged or elderly, and is very infrequently associated with eye signs. The syndrome is that of secondary thyrotoxicosis.

In many cases of toxic nodular goitre the nodules are inactive and it is the internodular thyroid tissue that is overactive. However, in some toxic nodular goitres, one or more nodules are overactive and here the hyperthyroidism is due to autonomous thyroid tissue as in a toxic adenoma.

Toxic nodule

A toxic nodule is a solitary overactive nodule, which may be part of a generalised nodularity or a true toxic adenoma. It is autonomous and its hypertrophy and hyperplasia are not due to TSH-RAB. TSH secretion is suppressed by the high level of circulating thyroid hormones and the normal thyroid tissue surrounding the nodule is itself suppressed and inactive.

Histology

The normal thyroid gland consists of acini lined with flattened cuboidal epithelium and filled with homogeneous colloid (see Fig. 48.2, p. 772). In hyperthyroidism (Fig. 48.25) there is hyperplasia

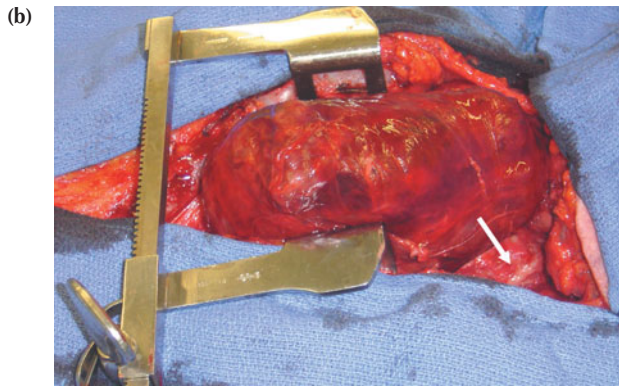

Figure 48.21 (a) Retrosternal goitre with superior vena cava obstruction. Preoperative appearance showing venous congestion. (b) Sternal split to deliver impacted left thyroid lobe. The recurrent laryngeal nerve is visible (arrow). (c) Postoperative appearance.

of acini, which are lined by high columnar epithelium. Many of them are empty and others contain vacuolated colloid with a characteristic ‘scallop’ pattern adjacent to the thyrocytes.

Clinical features

The symptoms are:

- tiredness;
- emotional lability;
- heat intolerance;
- weight loss;
- excessive appetite;
- palpitations.

The signs of thyrotoxicosis are:

- tachycardia;
- hot, moist palms;
- exophthalmos;
- lid lag/retraction;
- agitation;
- thyroid goitre and bruit.

Figure 48.24 Graves' disease.

Figure 48.25 Histology of thyrotoxicosis.

Symptomatology

Thyrotoxicosis is eight times more common in women than in men. It may occur at any age. The most significant symptoms are loss of weight despite a good appetite, a recent preference for cold, and palpitations. The most significant signs are the excitability of the patient, the presence of a goitre, exophthalmos and tachycardia or cardiac arrhythmia.

The goitre in primary thyrotoxicosis is diffuse and vascular; it may be large or small, firm or soft, and a thrill and a bruit may be present. The onset is abrupt but remissions and exacerbations are not infrequent. Hyperthyroidism is usually more severe than in secondary thyrotoxicosis but cardiac failure is rare. Manifestations of thyrotoxicosis not due to hyperthyroidism *per se*, for example orbital proptosis, ophthalmoplegia and pretibial myxoedema, may occur in primary thyrotoxicosis.

In secondary thyrotoxicosis the goitre is nodular. The onset is insidious and may present with cardiac failure or atrial fibrillation. It is characteristic that the hyperthyroidism is not severe. Eye

signs other than lid lag and lid spasm (due to hyperthyroidism) are very rare.

Cardiac rhythm

A fast heart rate, which persists during sleep, is characteristic. Cardiac arrhythmias are superimposed on the sinus tachycardia as the disease progresses, and they are more common in older patients with thyrotoxicosis because of the prevalence of coincidental heart disease. Stages of development of thyrotoxic arrhythmias are:

- 1 multiple extrasystoles;
- 2 paroxysmal atrial tachycardia;
- 3 paroxysmal atrial fibrillation;
- 4 persistent atrial fibrillation, not responsive to digoxin.

Myopathy

Weakness of the proximal limb muscles is commonly found if looked for. Severe muscular weakness (thyrotoxic myopathy), resembling myasthenia gravis, occasionally occurs. Recovery proceeds as hyperthyroidism is controlled.

Eye signs

Some degree of exophthalmos is common (see Fig. 48.24). It may be unilateral. True exophthalmos is a proptosis of the eye, caused by infiltration of the retrobulbar tissues with fluid and round cells, with a varying degree of retraction or spasm of the upper eyelid. (Lid spasm occurs because the levator palpebrae superioris muscle is partly innervated by sympathetic fibres.) This results in widening of the palpebral fissure so that the sclera may be seen clearly above the upper margin of the iris and cornea (above the 'limbus').

Spasm and retraction usually disappear when the hyperthyroidism is controlled. They may be improved by beta-adrenergic blocking drugs, for example guanethidine eye drops. Oedema of the eyelids, conjunctival injection and chemosis are aggravated by compression of the ophthalmic veins (Fig. 48.26). Weakness of the extraocular muscles, particularly the elevators (inferior oblique), results in diplopia. In severe cases papilloedema and corneal ulceration occur. When severe and progressive it is known as malignant exophthalmos (Fig. 48.27) and the eye may be destroyed. Graves' ophthalmopathy is an autoimmune disease in which there are antibody-mediated effects on the ocular muscles.

Figure 48.26 Severe Graves' ophthalmopathy (courtesy of Dr J.S. Bevan, Aberdeen, UK).

per se is Latin for 'through itself'.

Figure 48.27 (a) Progressive (malignant) exophthalmos. (b) Following treatment with steroids, orbital radiotherapy and bilateral tarsorrhaphy (courtesy of Dr J.S. Bevan, Aberdeen, UK).

Exophthalmos tends to improve with time. Sleeping propped up and lateral tarsorrhaphy will help to protect the eye but will not prevent progression. Hypothyroidism increases proptosis by a few millimetres and should be avoided.

Improvement has been reported with massive doses of prednisone. Intraorbital injection of steroids is dangerous because of the venous congestion, and total thyroid ablation has not proved effective. When the eye is in danger, orbital decompression may be required.

Thyroid dermopathy ('pretibial myxoedema') (Fig. 48.28) is a rare condition characterised by thickening of the skin, usually in areas of trauma, by deposition of hyaluronic acid in the dermis and subcutis. It usually occurs a few years after the onset of thyrotoxicosis and usually responds to treatment of the underlying thyroid disorder and topical steroids.

Diagnosis of thyrotoxicosis

Most cases are readily diagnosed clinically. Difficulty is most likely to arise in the differentiation of mild hyperthyroidism from an anxiety state when a goitre is present. In these cases the thyroid status is determined by the diagnostic tests described earlier. A TRH test is rarely indicated.

T_3 thyrotoxicosis is diagnosed by estimating the free T_3 . It should be suspected if the clinical picture is suggestive but routine tests of thyroid function reveal a normal T_4 but suppressed TSH.

Figure 48.28 Thyroid dermopathy (pretibial myxoedema). It is usually symmetrical and minor degrees are not uncommon but are easily missed. The earliest stage is a shiny red plaque of thickened skin with coarse hair, which may be cyanotic when cold. In severe cases the skin of the whole leg below the knee is involved, together with that of the foot and the ankle, and there may be clubbing of the fingers and toes (thyroid acropachy).

A thyroid scan is required to diagnose an autonomous toxic nodule and differentiate it from a dominant swelling in a toxic multinodular goitre.

Thyrotoxicosis should always be considered in:

- children with a growth spurt, behaviour problems or myopathy;
- tachycardia or arrhythmia in the elderly;
- unexplained diarrhoea;
- loss of weight.

Principles of treatment of thyrotoxicosis

Non-specific measures are rest and sedation; in established thyrotoxicosis these should be used only in conjunction with specific measures, i.e. the use of anti-thyroid drugs, surgery and radioiodine.

Anti-thyroid drugs

Those in common use are carbimazole and propylthiouracil. β -Adrenergic blockers such as propranolol and nadolol are used to block the cardiovascular effects of the elevated T_4 . Iodides, which may reduce the vascularity of the thyroid, should be used only as immediate preoperative preparation in the 10 days before surgery. Anti-thyroid drugs are used to restore the patient to a euthyroid state and to maintain this for a prolonged period in the hope that a permanent remission will occur, i.e. that the production of TSH-RABs will diminish or cease. Anti-thyroid drugs cannot cure a toxic nodule. The overactive thyroid tissue is autonomous and recurrence of the hyperthyroidism is certain when the drug is discontinued.

- *Advantages.* No surgery and no use of radioactive materials.
- *Disadvantages.* Treatment is prolonged and the failure rate is at

least 50%. The duration of treatment may be tailored to the severity of the toxicity, with milder cases being treated for only 6 months and severe cases for 2 years before stopping therapy.

It is impossible to predict which patient is likely to go into permanent remission although large gland size, severity of disease and TSH-RAb levels are indicators of poor prognosis.

Some goitres enlarge and become very vascular during treatment, even if thyroxine is given at the same time. This is probably due to TSH-RAb stimulation during the prolonged course of treatment and not a direct effect of the drug.

Very rarely there is a dangerous drug reaction, particularly agranulocytosis or aplastic anaemia. If a sore throat develops the patient should be instructed to discontinue treatment until the white cell count has been checked because of the risk of agranulocytosis.

Initially, 10 mg of carbimazole is given three or four times a day, with a latent interval of 7–14 days before clinical improvement is apparent. It is important to maintain a high concentration of the drug throughout a 24-hour period by spacing the doses at 8- or 6-hourly intervals. When the patient becomes biochemically euthyroid, a maintenance dose of 5 mg two or three times a day is given for 6–24 months. An alternative technique is to continue with the high dose of carbimazole and inhibit all T_3 and T_4 production by giving a maintenance dose of 0.1–0.15 mg of thyroxine daily. There is no risk of producing iatrogenic thyroid insufficiency and follow-up is less demanding ('block and replacement').

The levels of TSH-RAbs usually fall during treatment and this accounts for the permanent cure that occurs in 50% of patients.

Surgery

In diffuse toxic goitre and toxic nodular goitre with overactive internodular tissue, surgery cures by reducing the mass of overactive tissue. Cure is probable if the thyroid tissue can be reduced below a critical mass but there is a risk of both permanent thyroid failure and recurrence of toxicity following subtotal resection. Operations may result in a reduction of TSH-RAbs or it may be that circulating TSH-RAbs, however high their levels, can only produce limited hypertrophy and hyperplasia when the mass of thyroid tissue is small. In the autonomous toxic nodule, and in toxic nodular goitre with overactive autonomous toxic nodules, surgery cures by removing all of the overactive thyroid tissue; this allows the suppressed normal tissue to function again.

- *Advantages.* The goitre is removed, the cure is rapid and the cure rate is high if surgery has been adequate.
- *Disadvantages.* Recurrence of thyrotoxicosis occurs in approximately 5% of cases if less than total thyroidectomy is carried out. There is a risk of permanent hypoparathyroidism and nerve injury. Young women tend to have a worse cosmetic result from the scar.

Every operation carries a risk, but with suitable preparation and an experienced surgeon the mortality is negligible and the morbidity low.

Postoperative thyroid insufficiency occurs in 20–45% of cases. Long-term follow-up is necessary as the few patients who develop recurrence may do so at any time in the future. In addition, although it is usually apparent within 1 or 2 years, thyroid failure may also be a late development.

Parathyroid insufficiency should be permanent in less than 5%.

Radioiodine

Radioiodine destroys thyroid cells and, as in thyroidectomy, reduces the mass of functioning thyroid tissue to below a critical level.

- *Advantages.* No surgery and no prolonged drug therapy.
- *Disadvantages.* Isotope facilities must be available.

The rate and timing of late thyroid failure are influenced by the dose selected (200–600 MBq). The higher dose is likely to result in thyroid failure in 6 months, whereas the lower dose may result in late thyroid insufficiency. This is due to sublethal damage to those cells not actually destroyed by the initial treatment and this eventually causes failure of cellular reproduction. Indefinite follow-up is essential.

There is no evidence that therapeutic radioiodine is carcinogenic or teratogenic. In some clinics, radioiodine is given to almost all patients over the age of 25 years, i.e. when development is complete. Follow-up requirements are reduced if a total ablative dose of radioiodine is administered followed by routine replacement treatment with thyroxine. In the UK, reluctance to prescribe radioiodine to those under the age of 45 years has faded. The response is slow but a substantial improvement is to be expected in 8–12 weeks. Accurate dosage is difficult and, should there be no clinical improvement after 12 weeks, a further dose is given. Two or more doses are necessary in 20–30% of patients.

Choice of therapy

Patients must be considered individually. Below are listed guiding principles on the most satisfactory treatment for a particular toxic goitre at a particular age; these must, however, be modified according to the facilities available and the personality, intelligence and wishes of the individual patient, business or family commitments and any other coexisting medical or surgical condition. Access to post-treatment care and availability of replacement thyroxine can be important considerations in the Third World.

In advising treatment, compliance, influenced by social and intellectual factors, is important; many patients cannot be trusted to take drugs regularly if they feel well, and indefinite follow-up, which is essential after radioiodine or subtotal thyroidectomy, is a burden for all.

Diffuse toxic goitre

In patients over 45 years, radioiodine is appropriate. In those under 45 years, surgery for the large goitre and anti-thyroid drugs or radioiodine for the small goitre is recommended. As mentioned above, radioiodine is being increasingly used in younger patients, particularly when their families are complete.

Toxic nodular goitre

Toxic nodular goitre is often large and uncomfortable and enlarges still further with anti-thyroid drugs. Large goitres should be treated surgically because they do not respond as well or as rapidly to radioiodine or anti-thyroid drugs as a diffuse toxic goitre.

Toxic nodule

Surgery or radioiodine treatment is appropriate. Resection is easy, certain and without morbidity. Radioiodine is a good alternative for those over the age of 45 years because the suppressed thyroid tissue does not take up iodine and there is thus no risk of delayed thyroid insufficiency.

Recurrent thyrotoxicosis after surgery

In general, radioiodine is the treatment of choice, but anti-thyroid drugs may be used in young women intending to have children. Further surgery has little place.

Failure of previous treatment with anti-thyroid drugs or radioiodine

In this case, surgery or thyroid ablation with ^{123}I is appropriate.

Special problems in treatment

Pregnancy

Radioiodine is absolutely contraindicated in pregnancy because of the risk to the fetus. The danger of surgery is miscarriage and the danger of anti-thyroid drugs is of inducing thyroid insufficiency in the mother and, because both TSH and anti-thyroid drugs cross the placenta, of the baby being born goitrous (Fig. 48.29) and hypothyroid. The risk of either surgery in the second trimester, in competent hands, or careful administration of anti-thyroid drugs is very small and the choice is exactly as in a non-pregnant woman.

Post-partum hyperthyroidism

Pregnancy may lead to an exacerbation of a variety of autoimmune diseases in the post-partum period. Post-partum hyperthyroidism may be a problem in a patient previously diagnosed with hyperthyroidism or may occur in a patient without any previous history of thyroid disease.

Children

Radioiodine is contraindicated because of the theoretical risk of inducing thyroid carcinoma. There is an increased risk of recurrence after thyroidectomy because thyroid cells are highly active in the young. Children and adolescents should be treated with anti-thyroid drugs until the late teens, failing which total or near-total thyroidectomy by an expert surgeon should be undertaken.

The thyrocardiac

This is a patient with severe cardiac damage due wholly or partly to hyperthyroidism. The patient is usually middle aged or elderly

Figure 48.29 Transmitted thiouracil goitre. This does not occur if T_3 is given with anti-thyroid drugs as it too crosses the placenta.

with secondary thyrotoxicosis and the hyperthyroidism is not very severe; untreated Graves' disease sufficient to produce the level of emaciation and cardiomyopathy that was common before 1900 is rare in contemporary Western practice. The cardiac condition is far more significant than the hyperthyroidism, but this must be rapidly controlled to prevent further cardiac damage. β -Blockade (propranolol) can assist rapid control of cardiac effects.

Radioiodine is the treatment of choice together with anti-thyroid drugs started either before or after and continued until the radioiodine has had an effect (usually 6 weeks).

High titres of thyroid antibodies

The presence of high titres of thyroid antibodies indicates lymphatic infiltration of the goitre, i.e. a diffuse or focal thyroiditis, and a liability to spontaneous remission. These patients are best treated with anti-thyroid drugs but, if medical treatment fails, definitive treatment by operation or radioiodine is not contraindicated. Steroids may help to reduce pain and swelling.

Proptosis of recent onset

There is a view that treating thyrotoxicosis abruptly with radioiodine or surgery when proptosis is recent may induce malignant exophthalmos. It is reasonable to treat these patients with anti-thyroid drugs until the proptosis has been stable for 6 months.

Hyperthyroidism due to other causes

Thyrotoxicosis factitia

Hyperthyroidism may be induced by taking thyroxine, but only if the dosage exceeds the normal requirements of 0.15–0.25 mg day⁻¹. Doses below the normal requirements simply suppress normal hormone production by the thyroid.

Jod–Basedow thyrotoxicosis

In European countries diffuse toxic goitre is often called Basedow's disease or Jod–Basedow thyrotoxicosis (*Jod* = German for iodine + Basedow). Large doses of iodide given to a hyperplastic endemic goitre that is iodine avid may produce temporary hyperthyroidism and, very occasionally, persistent hyperthyroidism.

Subacute/acute forms of autoimmune thyroiditis or of de Quervain's thyroiditis

In subacute or acute forms of autoimmune thyroiditis or of de Quervain's thyroiditis (see later), mild hyperthyroidism may occur in the early stages because of the liberation of thyroid hormones from damaged tissue.

Secondary carcinoma

A large mass of secondary carcinoma will rarely produce sufficient hormone to induce mild hyperthyroidism.

Neonatal thyrotoxicosis

Neonatal thyrotoxicosis occurs in babies born to hyperthyroid mothers or to euthyroid mothers who have had thyrotoxicosis. High TSH-RAB titres are present in both mother and child because TSH-RABs can cross the placental barrier. The

Karl Adolf Basedow, 1799–1854, a General Practitioner of Merseberg, Germany, published his account of exophthalmic goitre in 1840.
Friedrich Joseph de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of thyroiditis in 1902.

hyperthyroidism gradually subsides after 3–4 weeks as the TSH-RAb titres in the baby's serum fall.

Surgery for thyrotoxicosis

Preoperative preparation

Traditional preparation aims to make the patient biochemically euthyroid at operation. The thyroid state is determined by clinical assessment, i.e. by improvement in previous symptoms and by objective signs such as weight gain and lowering of the pulse rate, and by serial estimations of the thyroid profile.

Preparation is as an out-patient and only rarely is admission to hospital necessary, because of severe symptoms at presentation, failure to control the hyperthyroidism or non-compliance with medication. Failure to control with anti-thyroid drugs is unusual but may be the result of uneven dosage, i.e. not taking the drug at 6- or 8-hourly intervals.

Carbimazole 30–40 mg day⁻¹ is the drug of choice for preparation. When euthyroid (after 8–12 weeks), the dose may be reduced to 5 mg 8-hourly or a 'block and replace' regime used (see above). The last dose of carbimazole may be given on the evening before surgery. Iodides are not used alone because if the patient needs preoperative treatment a more effective drug should be given.

An alternative method of preparation is to abolish the clinical manifestations of the toxic state using β -blocking drugs. β -blockers act on the target organs and not on the gland itself. Propranolol inhibits the peripheral conversion of T₄ to T₃. This results in very rapid control and operation may be arranged within 1 week. The appropriate drugs are propranolol 40 mg t.d.s. or, preferably, a slow-release preparation once daily. Clinical response to β -blockade is rapid and the patient may be rendered clinically euthyroid and operation arranged in a few days rather than weeks. The dose of β -blocker is increased to achieve the required clinical response and quite often larger doses (propranolol 80 mg t.d.s. or nadolol 320 mg once daily) are necessary.

β -Blockers do not interfere with synthesis of thyroid hormones, and hormone levels remain high during treatment and for some days after thyroidectomy. It is therefore important to continue to give the drug for 7 days postoperatively.

Iodine may be given with carbimazole or β -blocker for the 10 days before operation. Iodide alone produces a transient remission and may reduce vascularity, thereby marginally improving safety. The use of iodine preparations is not universal because of more effective alternatives. Iodine gives an additional measure of safety in case the early morning dose of β -blocker is mistakenly omitted on the day of operation.

Propranolol or nadolol controls symptoms very rapidly and has additional value in combination with carbimazole in the immediate treatment of patients with very severe hyperthyroidism.

Surgery

Preoperative investigations to be carried out and recorded are:

- *Thyroid function tests.*
- *Laryngoscopy.* Whether this is routine is a matter for local protocols because every RLN must be routinely and obsessively preserved.
- *Thyroid antibodies.*

Carbimazole also has an immunosuppressive action on TSH-RAB production.

- *Serum calcium estimation.*
- An *isotope scan* before preoperative preparation in toxic nodular goitre if total thyroidectomy is not planned. The surgeon should know which nodules, if any, are autonomous and active in order to ensure their resection. A scan is of no value in diffuse toxic goitre when uptake, for practical purposes, is uniform. The diagnosis of a single toxic nodule can only be made by demonstrating that the nodule is active and the remaining thyroid tissue is suppressed.

The extent of the resection depends on the size of the gland, the age of the patient, the experience of the surgeon, the need to minimise the risk of recurrent toxicity and the wish to avoid postoperative thyroid replacement (see Table 48.6 p. 783). Thus, young patients with small glands are at greatest risk of recurrence even with very small remnant sizes. There is an increasing trend towards total thyroidectomy, which simplifies subsequent management and rapidly achieves a permanent euthyroid state on thyroxine replacement. In contrast, a patient with a large goitre who wishes to avoid postoperative medication is suitable for subtotal thyroidectomy.

Technique

General anaesthesia is administered through an endotracheal tube and good muscle relaxation obtained. The patient is supine on the operating table with the table tilted up 15° at the head end to reduce venous engorgement (reverse Trendelenburg). A gel pad or sandbag is placed transversely under the shoulders and the neck is extended (with care, particularly in the elderly) to make the thyroid gland more prominent and to apply tension to skin, platysma and strap muscles, which makes dissection easier.

A gently curved skin crease incision is made midway between the notch of the thyroid cartilage and the suprasternal notch; a lower incision is easier to hide but is more likely to result in a hypertrophic scar. Flaps of skin, subcutaneous tissue and platysma are raised upwards to the superior thyroid notch and downwards to the suprasternal notch. The deep cervical fascia is divided in the midline between the sternothyroid muscles down to the plane of the thyroid capsule. The strap muscles are not divided as a routine but may be if greater exposure is required. The sternothyroid muscle is mobilised off the thyroid lobes, taking care to stay close to the muscle and outside the capsule.

In 30% of patients, middle thyroid veins passing directly into the internal jugular vein require ligation and division. The plane between the medial aspect of the upper pole and the cricothyroid muscle is developed by keeping close to the thyroid to minimise the risk of trauma to the external branch of the superior laryngeal nerve. The branches of the superior thyroid artery splay out over the upper pole and our preference is to ligate these individually. This permits progressive downward delivery of even the highest upper pole. The lobe is then free to rotate medially out of its bed. The inferior thyroid arteries are not routinely ligated to preserve the parathyroid blood supply.

The RLN should be identified in its course in the operative field. It should first be sought below the level of the inferior thyroid artery as it passes obliquely upwards and forwards. This course (Fig. 48.30), oblique to the trachea and oesophagus, is accentuated by mobilisation of the thyroid lobe. If not immediately seen the nerve can usually be palpated as a taut strand crossing the tracheo-oesophageal groove. At a higher level, the nerve lies between the branches of the inferior thyroid artery. The

Figure 48.30 Identification of the recurrent laryngeal nerve (see text). Note how rotating the gland anteriorly (open arrow) kinks the nerve (closed arrow) that is normally intimately related to the terminal branches of the inferior thyroid artery.

nerve passes into the larynx under the inferior border of the inferior constrictor immediately behind the inferior cornu of the thyroid cartilage. If the right nerve cannot be found in its usual course, an anomalous (non-recurrent) nerve, present in 1% of cases, should be suspected; this arises from the vagus trunk, usually passes from behind the carotid sheath, curving medially, forwards and upwards, and may be mistaken for the inferior thyroid artery (Fig. 48.31).

The parathyroid glands are identified by careful inspection in the common sites (see Fig. 48.2, p. 772). The thymus is detached by serially dividing the inferior thyroid veins.

In subtotal thyroidectomy the isthmus is transected and the lobe resected obliquely from the medial and lateral aspects to produce a V-shaped surface. This facilitates subsequent suturing of the divided surface for haemostasis. Care is required to avoid devascularisation of the parathyroids and damage to the RLNs, particularly from the medial aspect. If a parathyroid gland is inadvertently or unavoidably excised or devascularised, it should be fragmented and autotransplanted immediately within the sternomastoid muscle.

Subtotal resection of each lobe is carried out, leaving a remnant of 4–5 g on each side. Absolute haemostasis is secured by ligation of individual vessels and by suture of the thyroid remnants to the tracheal fascia.

Figure 48.31 Operative photograph of non-recurrent laryngeal nerve (arrow). As is often the case, the inferior thyroid artery is absent.

Total thyroidectomy (see Fig. 48.10, p. 777) avoids transection of thyroid tissue by complete excision of the gland, including the pyramidal lobe, with preservation *in situ* or autotransplantation of as many parathyroids as can be identified.

The pretracheal muscles and cervical fascia are sutured and the wound closed. Randomised clinical trials have confirmed that routine drainage to the deep cervical space is not required.

New technology in thyroidectomy

The major immediate risk following thyroidectomy is haemorrhage. Conventionally, artery forceps, ligature and suture have been used to secure the meticulous haemostasis necessary to minimise the frequency of haemorrhage. Ultrasonic shears and enhanced bipolar diathermy are increasingly used in thyroid surgery and may be advantageous in complex procedures.

Postoperative complications

Haemorrhage A tension haematoma deep to the cervical fascia is usually due to reactionary haemorrhage from one of the thyroid arteries; occasionally, haemorrhage from a thyroid remnant or a thyroid vein may be responsible. This is a rare but desperate emergency requiring urgent decompression by opening the layers of the wound, not simply the skin closure, to relieve tension before urgent transfer to theatre to secure the bleeding vessel (Fig. 48.32).

A subcutaneous haematoma or collection of serum may form under the skin flaps and require evacuation in the following 48 hours. This should not be confused with the potentially life-threatening deep tension haematoma.

Respiratory obstruction This is very rarely due to collapse or kinking of the trachea (tracheomalacia). Most cases are caused by laryngeal oedema. The most important cause of laryngeal oedema is a tension haematoma. However, trauma to the larynx by anaesthetic intubation and surgical manipulation are important contributory factors, particularly if the goitre is very vascular, and may cause laryngeal oedema without a tension haematoma. Unilateral or bilateral recurrent nerve paralysis will not cause immediate postoperative respiratory obstruction unless laryngeal oedema is also present but it will aggravate the obstruction.

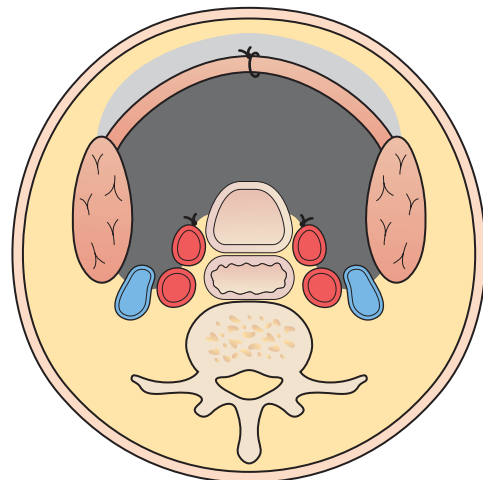

Figure 48.32 Postoperative haematoma. Subplatysmal haematoma (light grey) may need to be evacuated but tension haematoma (dark grey) deep to strap muscles requires urgent decompression and haemostasis.

If releasing the tension haematoma does not immediately relieve airway obstruction, the trachea should be intubated at once. An endotracheal tube can be left in place for several days; steroids are given to reduce oedema and a tracheostomy is rarely necessary. Intubation in the presence of laryngeal oedema may be very difficult and should be carried out by an experienced anaesthetist. Repeated unsuccessful attempts may aggravate the problem and, in a crisis, it is safer to perform a needle tracheostomy as a temporary measure; a large bore 12G intravenous cannula (diameter 2.3 mm) is satisfactory.

Recurrent laryngeal nerve paralysis and voice change RLN injury may be unilateral or bilateral, transient or permanent. Early routine postoperative laryngoscopy reveals a much higher incidence of transient cord paralysis than is detectable by simple assessment of the integrity of the voice and cough. Such temporary dysfunction is not clinically important, however, but voice and cord function should be assessed at the first follow-up 4 weeks postoperatively. An audit of the British Association of Endocrine Surgeons revealed an RLN palsy rate of 1.8% at 1 month declining to 0.5% at 3 months for first-time operations. Permanent paralysis is rare if the nerve has been identified at operation. Injury to the external branch of the superior laryngeal nerve is more common because of its proximity to the superior thyroid artery. This leads to loss of tension in the vocal cord with diminished power and range in the voice. Patients, particularly those who use their voices professionally, must be advised that any thyroid operation will result in change to the voice even in the absence of nerve trauma. Fortunately, for most patients the changes are subtle and only demonstrable on formal voice assessment.

Thyroid insufficiency Following subtotal thyroidectomy this usually occurs within 2 years; however, there is a small but progressive annual incidence over many years, which is often insidious and difficult to recognise. The incidence is considerably higher than was previously thought and rates of 20–45% at 10 years have been reported. This results from a change in the autoimmune response, from stimulation to destruction of the thyroid cells. There is a definite relationship between the estimated weight of the thyroid remnant and the development of thyroid failure after subtotal thyroidectomy for Graves' disease. Thyroid insufficiency is rare after surgery for a toxic adenoma because there is no autoimmune disease present.

Parathyroid insufficiency This is due to removal of the parathyroid glands or to infarction through damage to the parathyroid end artery; often, both factors occur together. Vascular injury is probably far more important than inadvertent removal. The incidence of permanent hypoparathyroidism should be less than 1% and most cases present dramatically 2–5 days after operation; however, very rarely the onset is delayed for 2–3 weeks or a patient with marked hypocalcaemia is asymptomatic.

Thyrotoxic crisis (storm) This is an acute exacerbation of hyperthyroidism. It occurs if a thyrotoxic patient has been inadequately prepared for thyroidectomy and is now extremely rare. Very rarely, a thyrotoxic patient presents in a crisis and this may follow an unrelated operation. Symptomatic and supportive treatment is for dehydration, hyperpyrexia and restlessness. This requires the administration of intravenous fluids, cooling the

patient with ice packs, the administration of oxygen, diuretics for cardiac failure, digoxin for uncontrolled atrial fibrillation, sedation and intravenous hydrocortisone. Specific treatment is with carbimazole 10–20 mg 6-hourly, Lugol's iodine 10 drops 8-hourly by mouth or sodium iodide 1 g intravenously. Propranolol intravenously (1–2 mg) or orally (40 mg 6-hourly) will block β -adrenergic effects.

Wound infection Cellulitis requiring prescription of antibiotics, often by the general practitioner, is more common than most surgeons appreciate. A significant subcutaneous or deep cervical abscess is exceptionally rare and should be drained.

Hypertrophic or keloid scar This is more likely to form if the incision overlies the sternum and in dark-skinned individuals. Intra-dermal injections of corticosteroid should be given at once and repeated monthly if necessary. Scar revision rarely results in significant long-term improvement.

Stitch granuloma This may occur with or without sinus formation and is seen after the use of non-absorbable, particularly silk, suture material. Absorbable ligatures and sutures must be used throughout thyroid surgery. Some surgeons use a subcuticular absorbable skin suture rather than the traditional skin clips or staples. Skin staples, if used, can be removed safely in less than 48 hours because the skin closure is supported by the platysma stitch.

Postoperative care

If the voice is normal and the cough occlusive it is not essential to carry out laryngoscopy before leaving hospital. Transient cord palsies are probably more common than generally appreciated. Even if routine cord visualisation is not part of the normal postoperative review, persisting voice change requires visualisation of the cords.

Hypocalcaemia depends not only on the identification but also on the preservation of the parathyroid glands with an intact blood supply. In addition, metabolic bone disease, 'hungry bones syndrome', results in the rapid influx of serum calcium into bones, particularly if preoperative preparation has been with β -blockade rather than normalisation of the serum T_4 . Hypocalcaemia is more common after total than subtotal thyroidectomy and reflects the increased trauma to the parathyroids. About 25% of patients develop transient hypocalcaemia and oral calcium may be necessary (1 g three or four times daily). If associated symptoms are severe and the serum calcium less, 10 ml of 10% calcium gluconate (equivalent to 8.4 mg or 2.3 mmol calcium) should be given. To screen for parathyroid insufficiency the serum calcium should be measured at the first review attendance 4–6 weeks after operation.

After subtotal resection, stability in terms of thyroid function takes time. It is important that biochemical (subclinical) thyroid failure should not be an indication for treatment during the first year, as the majority of patients with early subclinical failure, which is common, ultimately regain normality. Even when there are clinical features of failure, thyroxine should be withheld if possible during the first 6 months. Most patients who develop thyroid failure do so within the first 2 years but there is a continuing incidence thereafter. Recurrent thyrotoxicosis may occur at

Jean Guillaume Lugol, 1786–1851, Physician, Hôpital St. Louis, Paris, France.

any time after operation and follow-up should therefore be for life.

Once a stable situation has been achieved, follow-up after thyroid surgery should be carried out by an automated computerised system, which dramatically reduces the number of patient attendances at the thyroid clinic.

The incidences quoted for thyroid failure (20–45%) and recurrent thyrotoxicosis (5%) after subtotal thyroidectomy for Graves' disease refer to UK experience and may be different elsewhere in the world. In Iceland, for example, an area of high dietary iodine intake, the incidence of thyroid failure is much lower and that of recurrent toxicity much higher than in the UK (Summary box 48.5).

Relative incidence	(%)	Relative incidence	(%)
Papillary carcinoma	60	Medullary carcinoma	5
Follicular carcinoma	20	Malignant lymphoma	5
Anaplastic carcinoma	10		

Benign tumours

Follicular adenomas present as clinically solitary nodules (Fig. 48.33) and the distinction between a follicular carcinoma and an adenoma can only be made by histological examination; in the adenoma there is no invasion of the capsule or of pericapsular blood vessels. Treatment is therefore by wide excision, i.e. lobectomy. The remaining thyroid tissue is normal so that prolonged follow-up is unnecessary. It is doubtful if there is such an entity as a papillary adenoma and all papillary tumours should be considered as malignant, even if encapsulated.

Malignant tumours

The vast majority of primary malignancies are carcinomas derived from follicular cells (Table 48.7). Dunhill classified them histologically as differentiated and undifferentiated; the differentiated carcinomas are further subdivided into follicular and papillary. Lymphoma makes up the remainder of primary malignancies. Metastases to the thyroid account for < 5% of malignancies. Secondary disease should be considered when there is a history of malignancy, particularly kidney and breast cancer, and when the cytology of a thyroid swelling is atypical. Direct invasion by upper aerodigestive squamous cancer is a rare but lethal event. Lymph node and blood-borne metastases to bone and lung occur and may be the mode of presentation (Figs 48.34 and 48.35).

Aetiology of malignant thyroid tumours

The single most important aetiological factor in differentiated thyroid carcinoma, particularly papillary carcinoma, is irradiation of the thyroid under 5 years of age. The incidence of childhood thyroid cancer in the Ukraine rose from 57 cases in the 5 years before the Chernobyl nuclear incident in 1986 to 577 cases in the subsequent 10 years. In the town of Gomel, the incidence rose from < 1 case per million population to 96 cases per million population.

Short-latency aggressive papillary cancer is associated with the *ret/PTC3* oncogene and later-developing, possibly less aggressive, cancers are associated with *ret/PTC1*. The incidence of follicular carcinoma is high in endemic goitrous areas, possibly as a result of TSH stimulation. Malignant lymphomas sometimes develop in autoimmune thyroiditis, and the lymphocytic infiltration in the autoimmune process may be an aetiological factor.

Figure 48.35 Metastasis in the left parietal bone from a carcinoma of the thyroid (courtesy of Professor A.K. Toufееq, Lahore, Pakistan).

Clinical features of thyroid cancers

The annual incidence of thyroid cancers is about 3.7 cases per 100 000 population and the female–male sex ratio is 3:1. The overall mortality rate should be low because most patients are in a low-risk category; however, older patients have more aggressive disease with a worse prognosis. The most common presenting symptom is a thyroid swelling (Figs 48.33 and 48.36) and a 5-year history is not uncommon in differentiated growths. Enlarged cervical lymph nodes may be the presentation of papillary carcinoma. Recurrent laryngeal nerve paralysis is very suggestive of locally advanced disease.

Anaplastic growths are usually hard, irregular and infiltrating. A differentiated carcinoma may be suspiciously firm and irregular but is often indistinguishable from a benign swelling. Small papillary tumours may be impalpable, even when lymphatic metastases are present. Pain, often referred to the ear, is frequent in infiltrating growths.

Diagnosis of thyroid neoplasms

Diagnosis is obvious on clinical examination in most cases of anaplastic carcinoma, although Riedel's thyroiditis (see later) is

Figure 48.36 Follicular neoplasm of the thyroid presenting as an isolated swelling.

indistinguishable. The localised forms of granulomatous thyroiditis and lymphadenoid goitre may simulate carcinoma. It is not always easy to exclude a carcinoma in a multinodular goitre, and solitary nodules, particularly in a young male patient, are always suspect. Failure to take up radioiodine is characteristic of almost all thyroid carcinomas [only very rarely will differentiated carcinoma (primary or secondary) take up ^{123}I in the presence of normal thyroid tissue], but this also occurs in degenerating nodules and all forms of thyroiditis. TSH levels are often raised in carcinoma but this may be clouded by simultaneous elevation of anti-thyroid antibodies. The key role of FNAC in preoperative diagnosis has already been discussed. There is a false-negative rate with all investigations, and lobectomy is appropriate when there is a strong clinical suspicion. Incisional biopsy may cause seeding of cells and local recurrence and is not advised in a resectable carcinoma. In an anaplastic and obviously irremovable carcinoma, however, incisional or core needle biopsy is justified.

When a preoperative diagnosis is made, imaging with ultrasound, MRI or CT is required. As well as additional information on the extent of the primary tumour, imaging provides valuable information on nodal involvement (Figs 48.37 and 48.38), which permits preoperative planning for nodal dissection.

Frozen section histology has a limited role in thyroid surgery. It cannot reliably differentiate between encapsulated benign and malignant follicular neoplasms and is of more value in confirming whether nodes are involved with papillary cancer, thereby influencing the extent of nodal surgery.

Papillary carcinoma

Most papillary tumours contain a mixture of papillary and colloid-filled follicles and, in some, the follicular structure predominates. Nevertheless, if any papillary structure or characteristic cytology is present, the tumour will behave in a predictable fashion as a papillary carcinoma. Histologically the tumour shows papillary projections and characteristic pale empty nuclei (Orphan Annie-eyed nuclei) (Fig. 48.39). Papillary carcinomas are very seldom encapsulated.

Multiple foci may occur in the same lobe as the primary tumour or, less commonly, in both lobes. They may be due to lymphatic

Orphan Annie is a character from a strip cartoon, who, along with others, such as Daddy Warbucks, are drawn with empty circles for eyes.

Figure 48.37 Magnetic resonance imaging scan of papillary cancer with multiple node metastases.

spread in the rich intrathyroidal lymph plexus or to multicentric growth. Spread to the lymph nodes is common but blood-borne metastases are unusual unless the tumour is extrathyroidal. The term extrathyroidal indicates that the primary tumour has infiltrated through the capsule of the thyroid gland, although minimal invasion of the sternothyroid muscle is much less significant than infiltration into the oesophagus or trachea.

Microcarcinoma (occult carcinoma)

The reported prevalence of tiny foci of papillary carcinoma is related to the care with which the thyroid is examined histologically. In an autopsy study from Finland in which the thyroid was examined serially in 2-mm slices, an incidence of up to 36% was reported. Clearly the majority of such tumours never progress to become a clinically significant entity. A small percentage of cancers present with enlarged lymph nodes in the jugular chain or pulmonary metastases with no palpable abnormality of the thyroid. The primary tumour may be no more than a few millimetres in size and is often termed occult. Foci of papillary carcinoma may also be discovered in thyroid tissue resected for other reasons, for example Graves' disease. The term 'occult' was formally applied to all papillary carcinomas of less than 1.5 cm in diameter but the preferred terminology now is microcarcinoma for cancers less

than 1 cm in diameter. These have a uniformly excellent prognosis although those presenting with nodal or distant metastases justify more aggressive therapy.

Follicular carcinoma

These appear to be macroscopically encapsulated but, microscopically, there is invasion of the capsule and of the vascular spaces in the capsular region (Fig. 48.40). Multiple foci are seldom seen and lymph node involvement is much less common than in papillary carcinoma. Blood-borne metastases (Fig. 48.41) are more common and the eventual mortality rate is twice that of papillary cancer.

Hürthle cell tumours are a variant of follicular neoplasm in which oxyphil (Hürthle, Askanazy) cells predominate histologically. Hürthle cell cancers are associated with a poorer prognosis and some hold that all Hürthle cell neoplasms are malignant.

Differences between papillary and follicular carcinoma

The major differences between papillary (including mixed papillary and follicular) and follicular carcinoma were set out by Cady on the basis of an analysis of 40 years' experience at the Lahey Clinic (Table 48.9).

Prognosis in differentiated thyroid carcinoma

Compared with most cancers the prognosis in differentiated thyroid carcinoma is excellent. Although influenced by histological type, prognosis is much more dependent on age at diagnosis, size of the tumour, metastatic disease and the presence of either extrathyroidal spread (in papillary cancer) or major capsular transgression (in follicular carcinoma). There is a multiplicity of

Table 48.9 Major differences between papillary and follicular carcinoma (after Cady)

	Papillary (%)	Follicular (%)
Male incidence	22	35
Lymph node metastases	35	13
Blood vessel invasion	40	60
Recurrence rate	19	29
Overall mortality rate	11	24
Location of recurrent carcinoma		
Distant metastases	45	75
Nodal metastases	34	12
Local recurrence	20	12

scoring systems available, all of which identify patients at high (40% at 20 years) or low (1% at 20 years) risk of death (Table 48.10). All patients should be tumour–node–metastasis (TNM) staged and this classification acknowledges the low risk of patients aged less than 45 years at presentation (Table 48.11). Approximately 80% of patients are at a low risk of dying of thyroid cancer but suboptimal treatment, i.e. failure to eradicate all

Figure 48.41 Follicular carcinoma of the thyroid with skull secondaries.

macroscopic disease at the first operation, may lead to increased recurrence and avoidable death many years after presentation. It is, however, important to avoid iatrogenic morbidity by overzealous treatment in those patients with a normal life expectancy.

Surgical treatment of differentiated thyroid carcinoma

There is agreement that patients with large, locally aggressive or metastatic DTC require total thyroidectomy, with excision of adjacent involved structures if necessary, and appropriate nodal surgery followed by radioiodine ablation with long-term TSH suppression. However, such 'high-risk' patients are in the minority and there is continuing disagreement on the most appropriate operation for 'low-risk' DTC, although contemporary guidelines increasingly recommend total thyroidectomy for virtually all cancers.

Table 48.10 Prognostic scoring in differentiated thyroid cancer

	Age	Sex	Size	Metastases	Nodes	Extrathyroid	Histological grade	Complete excision
AMES	+	+	+	+		+		
AGES	+		+	+		+	+	
MACIS	+		+	+		+		+
EORTC	+			+		+		
TNM	+	+	+	+	+	+		

AMES – age, metastases, extent, size.

AGES – age, grade, extent, size.

MACIS – metastases, age, completeness of excision, invasion, size.

EORTC – European Organisation for Research and Treatment of Cancer.

TNM – tumour, nodes, metastases – American Joint Committee on Cancer.

Table 48.11 Tumour–node–metastasis staging (5th edition) of thyroid cancer

Tumour		
TX	Primary cannot be assessed	
T0	No evidence of primary	
T1	Limited to thyroid, 1 cm or less	
T2	Limited to thyroid, > 1 cm but < 4 cm	
T3	Limited to thyroid, > 4 cm	
T4	Extending beyond capsule, any size	
Nodes		
NX	Cannot be assessed	
N0	No regional node metastases	
N1	Regional node metastases	
Metastases		
MX	Cannot be assessed	
M0	No metastases	
M1	Metastases present	
Stage	Under 45 years	Over 45 years
I	Any T, any N, M0	T1, N0, M0
II	Any T, any N, M1	T2, N0, M0 or T3, N0, M0
III		T4, N0, M0 or any T, N1, M0
IV		Any T, any N, M1

Note the effect of age on stage; only patients older than 45 years can have stage III or IV disease.

The conservative approach reserves total thyroidectomy for specific indications (namely those in which there is a preoperative diagnosis of high-risk cancer, bilateral disease or when there is a clear indication for postoperative radioiodine therapy). ‘Small’ cancers confined to one lobe can be managed by lobectomy and TSH suppression. Unfortunately there is no consistent definition of a small cancer, with arbitrary limits of between 1 and 4 cm in use.

The radical approach advocates routine total thyroidectomy, often necessitating early reoperation and a second lobectomy following a diagnostic first lobectomy. Routine ‘central compartment’ node dissection is also advocated. Total thyroidectomy facilitates the use of radioiodine for postoperative scanning to detect and subsequently ablate metastases. It is unlikely that this policy will improve on the 99% survival rate regardless of primary surgical treatment in low-risk patients. It is argued that this policy will reduce local recurrence but this is based on an imperfect evidence base.

This argument cannot be resolved at present because of the long and changing natural history of DTC, the inherently good prognosis for the great majority of patients, the lack of randomised studies and the paucity of long-term prospective data.

The case for a policy of routine total thyroidectomy is based on large but retrospective studies of patients in whom the risk of local recurrence (particularly) and death was higher if therapy was less than total thyroidectomy with radioiodine ablation. It is argued that the prevalence of multifocality in papillary carcinoma and the risk from occult metastases justifies more radical treatment in all patients because it is not possible to identify low-risk patients reliably. If the low operative morbidity attributable to total thyroidectomy achieved in some expert centres, with negligible rates of hypoparathyroidism and recurrent nerve injury

(Delbridge), was universal, a small possible benefit in the long term would become more attractive. However, there are centres with large practices in thyroid surgery still reporting hypoparathyroidism rates of up to 30% after total thyroidectomy for cancer, particularly when combined with routine and more radical nodal surgery. Total thyroidectomy and permanent hypoparathyroidism requires long-term access to thyroxine, calcium and possibly vitamin D supplements. This may be a consideration in selecting treatment options in some countries. Similarly, there are cultural differences over the liberal use of radioactive iodine, which has become virtually routine in western countries.

Local recurrence in either the thyroid bed or the contralateral lobe should be exceptionally rare after total lobectomy, particularly in low-risk cases. The evidence that the long-term results of routine total thyroidectomy are better than a more conservative policy (selective total thyroidectomy) is based on the prolonged follow-up of cohorts of patients extending back over 50 years. There have been changes in the stage, and possibly the behaviour, of thyroid cancer over that time. In addition, the selection criteria for and the surgical technique of thyroidectomy are now more precise and better documented. A randomised trial would have to recruit several thousand patients and take 30 years to resolve this debate. For the foreseeable future, the risks of iatrogenic morbidity (recurrent nerve injury and hypoparathyroidism) associated with a policy of routine total thyroidectomy must be balanced against the knowledge that this will overtreat 95% of low-risk patients. Unfortunately, there is no reliable method of identifying those who will benefit.

The author’s current practice when a *preoperative diagnosis* of DTC has been made, usually on FNAC, is to image the neck with MRI or CT. Total thyroidectomy is recommended for tumours greater than 2 cm and those with nodal involvement or metastases and lobectomy is recommended for the remainder. Functional selective node dissection (Watkinson) of involved node levels is performed as required. Lateral extension of the normal thyroidectomy incision generally gives adequate access to node levels 2–6. If access to level 2 is difficult, an additional higher skin crease incision or alternatively a J-shaped utility incision may be made.

Routine central compartment node clearance is not recommended for small tumours with negative imaging although a representative node biopsy may be assessed by frozen section histology. Preserving inferior parathyroid function is practically impossible with level 6/7 clearance. Very occasionally it may be necessary to sacrifice the RLN if it is completely encircled and, on even more rare occasions, extrathyroidal spread may require tracheal, oesophageal or laryngeal resection.

When the diagnosis of DTC is made *after diagnostic lobectomy*, TSH suppression and review can be recommended, with reoperation only for a clear indication. Indications for completion total

thyroidectomy are the development of a new swelling or rising thyroglobulin levels. This policy is based on the outcome of thyroid lobectomy in the author's unit in both low- and high-risk patients since 1977.

Additional measures

Thyroxine

On the basis that most tumours are TSH dependent it is standard practice to prescribe thyroxine (0.1–0.2 mg daily) for all patients after operation for differentiated thyroid carcinoma to suppress endogenous TSH production. Suppression of the TSH level should be confirmed by measurement. Failure of suppression to a level of $<0.1 \text{ mU l}^{-1}$ may indicate an inadequate dose of thyroxine or, more usually, that the patient is non-compliant. There is a trend to manage patients with undetectable thyroglobulin after radical treatment with a TSH level in the normal range because of some concern over the impact of long-term TSH suppression.

Thyroid hormone replacement is obviously necessary after total thyroidectomy and in the majority of patients after near-total thyroidectomy, and is usually given in the form of thyroxine. Patients with potential or actual distant metastases, who may require repeated radioiodine administration for scanning and therapy, should be given tri-iodothyronine ($40\text{--}60 \mu\text{g daily}^{-1}$) because it is much shorter acting and, on stopping it, increased TSH secretion and thyroid avidity for iodine recover quickly so that radioiodine may be given after several days. The patient is thereby spared weeks of developing thyroid insufficiency after stopping thyroxine before radioiodine may be given.

Radioiodine

If metastases take up radioiodine they may be detected by scanning and treated with large doses of radioiodine. For effective scanning all normal thyroid tissue must have been ablated, either by surgery or preliminary radioiodine, and the patient must be hypothyroid to improve uptake. Alternatively, synthetic recombinant TSH may be used to stimulate uptake. The indications for scanning after operation for differentiated carcinoma are also disputed, but radioactive iodine is indicated in patients with unresectable disease, local recurrence or metastatic disease, high-risk patients and in those with a rising serum thyroglobulin level. A whole body scan can be carried out 10 days after empirical treatment with high-dose radioactive iodine, to allow decay of activity (Fig. 48.42). Unfortunately, the more aggressive and de-differentiated the cancer, the less likely it is to take up radioactive iodine: those most in need of an effect are least likely to derive a benefit.

If metastases have been treated, the serum thyroglobulin level and local protocols will determine when the scan should be repeated and further therapeutic doses of radioiodine given if necessary. Solitary distant metastases may be treated by external radiotherapy.

Thyroglobulin

The measurement of serum thyroglobulin is of value in the follow-up and detection of metastatic disease in patients who have undergone surgery for DTC. It can be used after lobectomy, as after total thyroidectomy, provided that endogenous TSH production has been completely suppressed by T_4 . This measurement reduces the need for serial radioactive iodine scanning but, when a rise occurs, imaging with neck ultrasound is appropriate.

Figure 48.42 Whole-body scan after total thyroidectomy and high-dose radioiodine for follicular carcinoma showing metastases in the right shoulder, ribs and pelvis (courtesy of Dr M. Brooks, Aberdeen, UK).

Surgery or therapeutic radioiodine is then indicated, with a subsequent whole-body scan once activity has decayed. This will confirm and locate metastatic disease, which is iodine avid. The presence of circulating anti-thyroglobulin antibodies interferes with and invalidates thyroglobulin as a serum marker for recurrence and, occasionally, careful clinical palpation of the neck will be the first indication of local recurrence.

Undifferentiated (anaplastic) carcinoma

This occurs mainly in elderly women and is diagnosed much less often now than in the past, when many thyroid lymphomas were mistakenly classified histologically as anaplastic carcinomas. Local infiltration is an early feature of these tumours, with spread by lymphatics and by the bloodstream. They are extremely lethal tumours and survival is calculated in months. Complete resection is justified if the disease appears confined to the thyroid and possibly the strap muscles and is only possible in a minority of patients. Even then the survival rarely exceeds 6 months and the median is around 3 months for the whole group. Some of these aggressive lesions present in an advanced stage with tracheal obstruction and they require urgent tracheal decompression. The trachea may be decompressed and tissue obtained for histology by isthmusectomy. Tracheostomy is best avoided. Radiotherapy should be given in all cases and may provide a worthwhile period of palliation, but there is little evidence to support the use of chemotherapy.

Medullary carcinoma

These are tumours of the parafollicular cells (C cells) derived from the neural crest and not of cells of the thyroid follicle, as is the case for other primary thyroid carcinomas. The cells are not unlike those of a carcinoid tumour and there is a characteristic amyloid stroma (Fig. 48.43). High levels of serum calcitonin and carcinoembryonic antigen are produced by many medullary tumours. Levels fall after resection and rise again with recurrence making it a valuable tumour marker in the follow-up of patients with this disease. Diarrhoea is a feature in 30% of cases and this

Figure 48.43 Histology of medullary carcinoma showing characteristic 'cell balls' and amyloid (courtesy of Dr S.W.B. Ewen, Aberdeen, UK).

may be due to 5-hydroxytryptamine or prostaglandins produced by the tumour cells.

Some tumours are familial, possibly accounting for 10–20% of all cases. Medullary carcinoma may occur in combination with adrenal phaeochromocytoma and hyperparathyroidism (HPT) (usually due to hyperplasia) in the syndrome known as multiple endocrine neoplasia type 2A (MEN-2A). The familial form of the disease frequently affects children and young adults, whereas sporadic cases occur at any age with no sex predominance. When the familial form is associated with prominent mucosal neuromas involving the lips, tongue and inner aspect of the eyelids, with a marfanoid habitus, the syndrome is referred to as MEN type 2B.

Involvement of lymph nodes occurs in 50–60% of cases of medullary carcinoma and blood-borne metastases are common. As would be expected, tumours are not TSH dependent and do not take up radioactive iodine. The prognosis is variable and depends on the stage at diagnosis. Any nodal involvement virtually eliminates the prospect of cure and, unfortunately, even small tumours confined to the thyroid gland may have spread by the time of diagnosis, particularly in familial cancers. In common with many endocrine tumours the progression of disease may be very slow with a characteristically indolent course and long survival, even in the absence of cure.

Treatment

Treatment is by total thyroidectomy and either prophylactic or therapeutic resection of the central and bilateral cervical lymph nodes.

Familial cases are now detected by genetic screening for *RET* gene mutations, which identifies individuals who will develop medullary cancer later in life (Fig. 48.44). The genetic tests are supplemented by estimating serum calcitonin levels in the basal state and after stimulation by either calcium or pentagastrin. A rise in calcitonin levels in these circumstances should lead to thyroidectomy, but even then the disease may be beyond the pre-invasive C-cell hyperplasia stage (Fig. 48.45). Prophylactic surgery is now recommended for infants with the genetic trait. A

Figure 48.44 Hyperplasia of parafollicular C cells in a child from a family with medullary cancer (courtesy of Dr S.W.B Ewen, Aberdeen, UK).

Figure 48.45 Total thyroidectomy specimen from a young girl undergoing surgery following genetic screening, showing a small medullary cancer in the right lobe.

recent refinement as a result of preoperative genetic differentiation between sporadic and familial cancers suggests that lobectomy might be adequate treatment for sporadic cases.

In all cases, before embarking upon thyroid surgery, phaeochromocytoma must be excluded by measurement of urinary catecholamine levels.

Malignant lymphoma

In the past, many malignant lymphomas were diagnosed as small round-cell anaplastic carcinomas. The response to irradiation is good (Fig. 48.46) and radical surgery is unnecessary once the diagnosis is established by biopsy. Although the diagnosis may be made or suspected on FNAC, sufficient material is seldom available for immunocytochemical classification and large-bore needle (Trucut) or open biopsy is usually necessary. In patients with tracheal compression, isthmusectomy is the most appropriate form of biopsy, although the response to therapy is so rapid that this should rarely be necessary unless there has been difficulty in making a histological diagnosis. The prognosis is good if there is no involvement of cervical lymph nodes. Rarely, the tumour is part of widespread malignant lymphoma disease, and the prognosis in

Bernard Jean Antonin Marfan, 1858–1942, Physician, Hôpital des Enfants-Malades, Paris, France, described this syndrome in 1896.

Figure 48.46 Magnetic resonance imaging scans of extensive malignant lymphoma (a) before and (b) after 7 days of external beam radiotherapy (courtesy of Dr F.W. Smith, Aberdeen, UK).

these cases is worse. Most lymphomas occur against a background of lymphocytic thyroiditis (Summary box 48.6).

THYROIDITIS

Chronic lymphocytic (autoimmune) thyroiditis (Fig. 48.47)

This common condition is usually associated with raised titres of thyroid antibodies. Not infrequently there is a family history of other autoimmune disease. It commonly presents as a goitre, which may be diffuse or nodular with a characteristic ‘bosselated’ feel, or with established or subclinical thyroid failure. The diagnosis often follows investigation of a discrete swelling. Features of chronic lymphocytic (focal) thyroiditis are commonly present on

Figure 48.47 Autoimmune thyroiditis (Hashimoto’s disease; struma lymphomatosa) showing intense lymphocytic plasma cell infiltration, acinar destruction and fibrosis. Compare with the normal histology shown in Figure 48.2, p. 772.

histological examination in association with other thyroid diseases, notably toxic goitre. Primary myxoedema without detectable thyroid enlargement represents the end-stage of the pathological process.

Clinical features

The onset, thyroid status and type of goitre vary profoundly from case to case. The onset may be insidious and asymptomatic or so sudden and painful that it resembles the acute form of granulomatous thyroiditis. Mild hyperthyroidism may be present initially, but hypothyroidism is inevitable and may develop rapidly or extremely slowly. The goitre is usually lobulated and may be diffuse or localised to one lobe. It may be large or small, and soft, rubbery or firm in consistency, depending on the cellularity and degree of fibrosis. The disease is most common in women at the menopause but may occur at any age. Papillary carcinoma and malignant lymphoma are occasionally associated with autoimmune thyroiditis.

Diagnosis

Biochemical tests of thyroid function vary with the thyroid status and are of diagnostic value only if hypothyroidism is present. Significantly, raised serum levels of one or more thyroid antibodies are present in over 85% of cases. Nevertheless, differential diagnosis from nodular goitre, carcinoma and malignant lymphoma of the thyroid is not always easy. FNAC is the most appropriate investigation although abundant lymphocytes may make the cytological distinction between autoimmune thyroiditis and lymphoma difficult. When there is doubt about neoplastic disease, which may coexist with thyroiditis, diagnostic lobectomy may be necessary.

Treatment

Full replacement dosage of thyroxine should be given for hypothyroidism and if the goitre is large or symptomatic because some (under TSH stimulation) may subside with hormone therapy. More minor manifestations of the condition, such as a small goitre with raised antibody titres, or histological evidence of thyroiditis in association with other thyroid disease, do not justify thyroxine replacement if thyroid function is biochemically normal; however, long-term surveillance is necessary because of the risk of late thyroid failure. Occasionally, the goitre increases

in size despite hormone treatment and, in these circumstances, there may be a favourable response to steroid therapy. Thyroidectomy may be necessary if the goitre is large and causes discomfort. An increase in size of a longstanding lymphocytic goitre should be assessed urgently because of the possibility of the development of malignant lymphoma.

Granulomatous thyroiditis (subacute thyroiditis, de Quervain's thyroiditis)

Granulomatous thyroiditis is caused by a viral infection. In a typical subacute presentation there is pain in the neck, fever, malaise and a firm irregular enlargement of one or both thyroid lobes. There is a raised erythrocyte sedimentation rate and absent thyroid antibodies, the serum T_4 is high normal or slightly raised and the ^{123}I uptake of the gland is low. The condition is self-limiting and after a few months the goitre subsides and there may be a period of months of hypothyroidism before eventual recovery. In 10% of cases the onset is acute, the goitre is very painful and tender and there may be symptoms of hyperthyroidism. One-third of cases are asymptomatic but for the presence of the goitre. If diagnosis is in doubt it may be confirmed by FNAC, radioactive iodine uptake and a rapid symptomatic response to prednisone. The specific treatment for the acute case with severe pain is to give prednisone 10–20 mg daily for 7 days, with the dose gradually reduced over the next month. If thyroid failure is prominent, treatment with thyroxine may be required until function recovers.

Riedel's thyroiditis

Riedel's thyroiditis is very rare, accounting for 0.5% of goitres. Thyroid tissue is replaced by cellular fibrous tissue, which infiltrates through the capsule into muscles and adjacent structures, including the parathyroids, recurrent nerves and carotid sheath. It may occur in association with retroperitoneal and mediastinal fibrosis and is most probably a collagen disease. The goitre may be unilateral or bilateral and is very hard and fixed. The differential diagnosis from anaplastic carcinoma can be made with certainty only by biopsy, when a wedge of the isthmus should also be removed to free the trachea. If the condition is unilateral the other lobe is usually involved later and subsequent hypothyroidism is common. Treatment is with high-dose steroids and thyroxine replacement. A reduction in the size of the goitre and long-term improvement in symptoms are to be expected if treatment is commenced early (Summary box 48.7).

Summary box 48.7

Thyroiditis

PARATHYROID HYPERPARATHYROIDISM

Primary hyperparathyroidism

Primary HPT is more commonly sporadic than familial. Hypercalcaemia in the presence of inappropriately raised serum PTH levels is due to enlargement of one or more glands and hypersecretion of PTH. The normal response to hypercalcaemia is PTH suppression.

Epidemiology

The prevalence of sporadic primary HPT increases with age and it affects women more than men. On biochemical screening approximately 1% of adults are hypercalcaemic.

Familial HPT occurs as part of the following genetically determined conditions:

- MEN-1 (multiple endocrine neoplasia type 1; Werner's syndrome)
- MEN-2A (Sipple's syndrome) and rarely MEN-2B.
- familial isolated HPT.

Pathology

The majority (85%) of patients with sporadic primary HPT have a single adenoma, approximately 13% have hyperplasia affecting all four glands and about 1% will have more than one adenoma or a carcinoma. In familial disease, multiple gland enlargement is the norm.

There is a weak correlation between the size of an adenoma and the level of PTH (Fig. 48.48). The histological differentiation between adenoma and hyperplasia can be difficult and the macroscopic findings are an important determinant in making the diagnosis. A single enlarged gland with three small normal glands is characteristic of a single adenoma, regardless of the histology, which may show considerable overlap between a hyperplastic and an adenomatous gland. Multiple adenomas occur more frequently in older patients. Parathyroid hyperplasia by definition affects all four glands (Fig. 48.49a and b).

Parathyroid carcinomas are large tumours and typically much more adherent or even frankly invasive than large adenomas. Histology demonstrates a florid desmoplastic reaction with dense fibrosis and capsular and vascular invasion.

Parathyroid cysts may be secondary to degeneration in nodules or adenomas, or developmental and, although some present as a

Note how the superior gland has migrated posterior and inferior to the inferior thyroid artery (3). (4) Recurrent laryngeal nerve. (b) Total parathyroidectomy specimens.

palpable neck swelling, small cysts are most often noted as incidental findings during neck exploration. If aspirated preoperatively the diagnosis should be suspected from the watery clear fluid aspirated. The diagnosis is confirmed by a high PTH level in the aspirated fluid.

Clinical presentation

The classic quartet of ‘stones, bones, abdominal groans and psychic moans’ is rarely observed in developed countries where the diagnosis is usually made on serum calcium estimation well before the full picture of severe bone disease (von Recklinghausen’s disease), renal calculi and calcinosis, pancreatitis and psychiatric disorder develops. Incidentally detected hypercalcaemia is rarely truly ‘asymptomatic’ and most patients experience an improved sense of well-being after surgery. Careful enquiry into family history is always appropriate and may reveal an index case for familial disease, including familial primary HPT, MEN syndromes and familial hypocalcaemic hypercalcaemia.

Friedrich Daniel von Recklinghausen, 1833–1910, Professor of Pathology, Strasbourg, France, described generalised neurofibromatosis in 1882.

Diagnosis

Although ionised calcium is the physiologically active circulating element, total serum calcium is a satisfactory measure. The effect of calcium binding to serum proteins must be corrected by upward or downward correction to a serum albumin level of 40 g l^{-1} . Inappropriate (elevated or normal) PTH levels in the presence of high serum calcium are diagnostic of primary HPT. Hypophosphataemia and elevated urine calcium excretion are confirmatory.

Other causes of hypercalcaemia must be considered and excluded (Table 48.12). Advanced malignancy is the most common cause of hypercalcaemia in hospital patients, resulting from parathyroid hormone-related peptide (PTHrP) or bone metastases. The PTH level is suppressed.

Familial hypocalcaemic hypercalcaemia is an autosomal dominant disorder characterised by mild elevation of calcium and PTH levels secondary to a missense mutation in the cell membrane calcium receptor. The low urinary excretion of calcium will discriminate this from HPT. Parathyroidectomy is not required. However, neonatal HPT is rare but associated with severe hypercalcaemia in homozygous patients and urgent near-total parathyroidectomy is required.

Treatment of primary hyperparathyroidism

At present, surgery is the only curative option and should be offered to all patients with significant hypercalcaemia provided that they are otherwise fit for the procedure. There are a number of medical strategies and therapies, particularly in mild HPT, including simple expectant treatment until the calcium level or symptoms reach a level at which surgery becomes more attractive, a low-calcium diet, withdrawal of drugs (diuretics and lithium) that aggravate hypercalcaemia and, more recently, calcium-reducing agents such as bisphosphonates and the calcium receptor agonist cinacalcet.

Occasionally, patients present with a parathyroid crisis and severe hypercalcaemia (serum calcium greater than 3.5 mmol l^{-1}). This results in confusion, nausea, abdominal pain, cardiac arrhythmias and hypotension with acute renal failure. Intravenous saline and bisphosphonate therapy (pamidronate) are required to correct the dehydration and hypercalcaemia. This is best done in a high-dependency unit or even an intensive therapy unit setting to monitor the major physiological fluxes that result.

Indications for operation

Conventional indications for operation are shown in Table 48.13; traditionally, endocrine surgeons have had a lower threshold for

Table 48.12 Causes of hypercalcaemia

Endocrine	Primary hyperparathyroidism Thyrotoxicosis Pheochromocytoma Adrenal crisis
Renal failure	Tertiary hyperparathyroidism

recommending operation than physicians. However, the widespread adoption of minimal access techniques for parathyroidectomy has changed many physicians' attitudes because of the perceived reduction in operative morbidity. There remains a cohort of patients with mild primary HPT and those with significant comorbidity in whom the decision for operation remains a matter of clinical judgement.

Preoperative localisation

There has been a paradigm shift in the use of preoperative imaging in primary HPT. Until a few years ago the maxim that the 'only localisation test necessary was to locate a good endocrine surgeon' (Doppman) was apposite when opinion favoured a conventional bilateral neck exploration. Skilled surgeons can achieve cure rates of about 98%, with lack of success the result of an ectopic adenoma not accessible through a cervical incision or occasionally the failure to recognise multiple gland disease. Although there should be minimal morbidity associated with a bilateral neck exploration, an image-guided targeted approach reduces this even further and has become routine in most major centres. Concerns remain that subtle abnormalities will be missed if all glands are not routinely visualised but, to date, these have not been translated into a significant clinical issue. There remains a cohort of patient in whom preoperative imaging does not localise an adenoma and the experience of the surgeon remains paramount in achieving a high cure rate.

High-frequency neck ultrasound is non-invasive and should

Figure 48.50 Ultrasound scan of a parathyroid adenoma at the upper pole of the right thyroid lobe. C, carotid artery; A, parathyroid adenoma; T, right thyroid lobe.

John L. Doppman, Contemporary, Radiologist, Bethesda, USA.

identify 75% of enlarged glands. It gives better resolution but reduced penetration and it cannot visualise the mediastinum (Fig. 48.50). Nodular thyroid disease is a confounding factor.

Technetium-99m (^{99m}Tc)-labelled sestamibi (MIBI) isotope scans (Fig. 48.51) also identify 75% of abnormal parathyroid glands. The area scanned must include the mediastinum to detect ectopic glands. Single-photon emission computerised tomography (SPECT) (Fig. 48.52) gives a three-dimensional image that may influence the surgical approach. Concordance between ultrasound and sestamibi scans permits a targeted approach with confidence. However, the size of the adenoma is important and imaging and concordance decline with glands weighing less than 500 mg.

CT, PET and MRI are not indicated prior to first-time neck exploration.

Figure 48.51 Technetium-99m-labelled sestamibi isotope scans 15 min and 3 hours after injection showing retention of isotope in a left inferior parathyroid adenoma.

Figure 48.52 Technetium-99m-labelled sestamibi isotope scan with single photon emission computerised tomography showing a hot-spot in the anterior mediastinum (arrow) (courtesy of Mr B. Harrison, Sheffield, UK).

The noun *isotope* is derived from the Greek *isos* = equal and *topos* = place, meaning having an equal place on the periodic table.

Operation for primary hyperparathyroidism

Preoperative discussion must include the possibility of:

- persistent HPT (5%);
- recurrent laryngeal nerve injury (1%);
- postoperative haemorrhage (1%);
- permanent hypoparathyroidism;
- recurrent HPT.

There are a number of surgical options available of which a targeted small incision approach and bilateral exploration using a conventional 'thyroidectomy' incision are the most frequently performed. Video-assisted (in which a video endoscope is used to reduce the size of incision and permit bilateral exploration) and totally endoscopic techniques with multiple punctures have not achieved much popularity. Preoperative intravenous infusion of methylene blue (5 mg kg^{-1} body weight in 500 ml of dextrose-saline) is used by some surgeons because it preferentially stains parathyroid tissue. The short serum half-life of PTH means that intraoperative measurements can be used to confirm that the source of excess PTH production has been excised, although this is of more value in reoperations than first-time operations. A gamma probe can be used to guide exploration following preoperative injection of MIBI.

Operative strategy and technique of parathyroidectomy

Targeted approach

General or local anaesthesia may be used. A head light and magnifying loupes are useful. Confident preoperative localisation permits a 2- to 3-cm incision located over the site of the adenoma (Fig. 48.53). This may be placed to permit extension to a formal bilateral exploration incision if the imaging is sub-optimal. The subplatysmal plane is incised and a lateral approach to the strap muscles permits development of the plane between the thyroid capsule and carotid artery and jugular veins. The adenoma is easily identified in the anticipated site when imaging is concordant. It is carefully mobilised, staying close to but avoiding rupture of the capsule. Identification of the RLN is not routine and only bipolar diathermy should be used. Failure to immediately identify the gland may require an extended exploration, which can be accomplished through a unilateral limited incision. Conversion to a formal neck incision and bilateral exploration should rarely be required if preoperative assessment has been rigorous.

Figure 48.53 Targeted parathyroid surgery; a 2-cm incision over a left inferior parathyroid adenoma.

Conventional approach

The patient is positioned in reverse Trendelenburg with a silicone gel pad placed transversely under the shoulders to extend the neck and the head supported in a padded ring. A transverse collar incision is made, the subplatysmal plane is developed superiorly and inferiorly and the deep cervical fascia are incised in the midline between the strap muscles. The thyroid lobes are mobilised with division of the middle thyroid vein when present. It is not normally necessary to divide the superior thyroid vessels unless the exploration proves difficult. Medial rotation of the thyroid lobe exposes the inferior thyroid artery and RLN (see Fig. 48.49). The glands are identified in a systematic manner commencing with the common sites and working sequentially through to the rare locations. The superior gland is sought above the termination of the inferior thyroid artery, then inferiorly behind the inferior thyroid artery and oesophagus. The inferior gland is sought along the thyrothymic axis, on the surface of the inferior pole of the thyroid lobe, the upper horn of the thymus, the mediastinal thymus, then within the carotid sheath and finally within the thyroid lobe, which may require thyroid lobectomy. All abnormal glands are excised and, in the event of sporadic four-gland disease, subtotal parathyroidectomy is carried out, preserving approximately 50 mg of one gland. This must be marked with a non-absorbable suture to facilitate any possible future re-exploration.

In patients with four-gland disease, transcervical thymectomy is recommended to reduce the risk of persistent or recurrent HPT. In patients with MEN-1, total parathyroidectomy reduces the risk of recurrence.

Preoperative imaging will identify the 1% of patients with a mediastinal adenoma and permit a single curative operation (Fig. 48.54). This may be performed thoroscopically rather than by a mediastinotomy.

Secondary hyperparathyroidism

Chronic renal failure results in *secondary HPT*. The kidney cannot convert vitamin D into the physiologically active 1,25-cholecalciferol. Reduced intestinal absorption of calcium resulting in a low serum calcium, and elevated phosphate due to renal failure to excrete phosphate, increases secretion of PTH. Prolonged stimulation results in parathyroid hyperplasia. Initially this is reversible following renal transplantation but when autonomous hyperfunction progresses after transplantation this is termed tertiary HPT.

Secondary HPT also occurs in vitamin D-deficient *rickets*, *malabsorption* and *pseudohypoparathyroidism*.

Clinical and biochemical features

These include bone pain, pruritus, muscle weakness, renal osteodystrophy and soft-tissue calcification (Fig. 48.55). Calciphylaxis (calcific uraemic arteriolopathy) is the end-stage of this condition with arteriolar occlusion resulting in cutaneous ulceration and gangrene. The systemic effects of these changes result in a high mortality rate and urgent parathyroidectomy may be required if the PTH is excessively high.

Friedrich Trendelenburg, 1844–1924, Professor of Surgery, Rostock (1875–1882), Bonn (1882–1895), and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

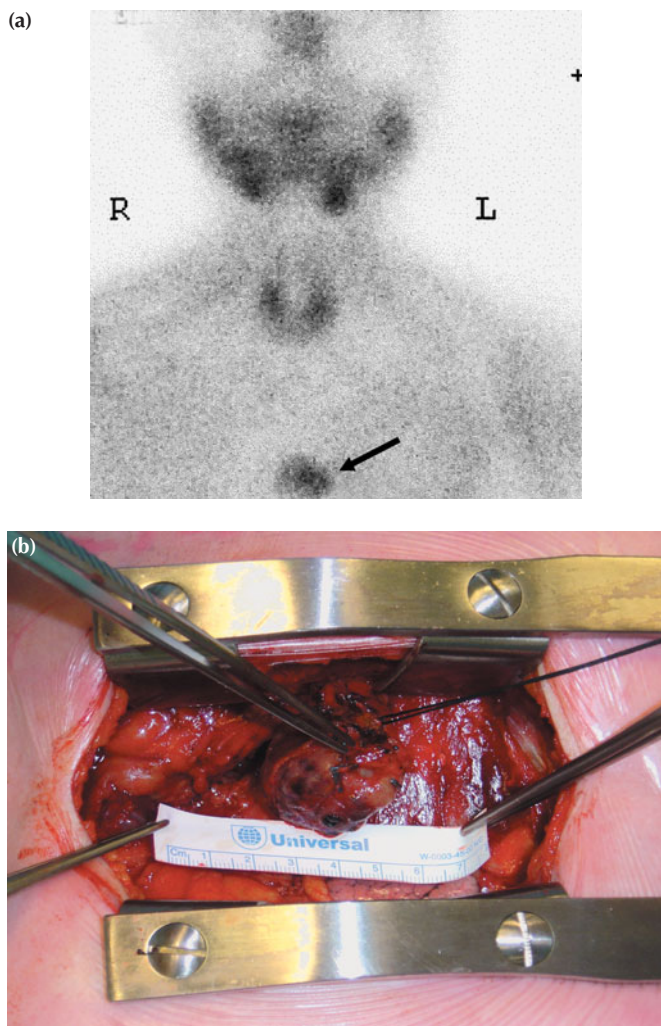

Figure 48.54 Mediastinal parathyroid adenoma (courtesy of Mr K. Buchan, Aberdeen, UK) (a) Preoperative technetium-99m-labelled sestamibi isotope scan with mediastinal adenoma (arrowed). (b) Operative photograph of a median sternotomy showing a 4-cm parathyroid adenoma.

Treatment

Medical treatment of secondary HPT includes dietary phosphate restriction and calcium and vitamin D supplementation. Surgery is indicated when there is an excessive rise in the calcium/phosphate product and serum PTH. Patients are prepared with high-dose vitamin D (calcitriol) to reduce the severity of the profound hypocalcaemia that would otherwise follow parathyroidectomy. Preoperative dialysis is obligatory.

Operative strategy

Multiple-gland disease is usual although occasionally HPT secondary to single-gland disease is the cause rather than the consequence of renal failure. Options for management include total parathyroidectomy (see Fig. 48.49), total parathyroidectomy with autotransplantation of 50 mg of parathyroid tissue into the brachioradialis or subtotal parathyroidectomy. The last strategy is preferred if renal transplantation is likely. Transcervical thymectomy is indicated.

Figure 48.55 Secondary hyperparathyroidism. (a) Radiograph of ectopic calcification. (b) Computerised tomography scan showing ectopic calcification in the chest wall.

Postoperative hypocalcaemia is inevitable even after subtotal parathyroidectomy or autotransplantation. Preoperative preparation and oral vitamin D and calcium are essential. Intravenous calcium and magnesium are often required.

Parathyroid carcinoma

Cancer of the parathyroid is rare, accounting for 1% of cases of HPT. Typical features are very high calcium and PTH levels, often with a palpable neck swelling or occasionally lymphadenopathy. Scanning may support the diagnosis (Fig. 48.56). The diagnosis is rarely known at the time of exploration but, if suspected, operation should include excision of the tumour mass with *en bloc* thyroid lobectomy and node dissection when indicated. The diagnosis is difficult to make histologically and may only become apparent when recurrent disease presents with hypercalcaemia, increased serum PTH and evidence of local recurrence. Adjuvant or palliative radiotherapy may be indicated and overall survival, as in most endocrine cancers, is reasonable with a 5-year survival rate of 85%.

en bloc is French for 'in a block'.

Figure 48.56 Technetium-99m-labelled sestamibi isotope scan at 3 hours showing a left superior parathyroid carcinoma.

Persistent hyperparathyroidism

The first operation is the best opportunity to cure HPT surgically and, when competently performed, should be successful in more than 95% of procedures. If hypercalcaemia persists after a first neck exploration the diagnosis, preoperative investigations, operative findings and pathology must be reviewed carefully. Referral to a specialist centre is prudent. If reoperation is appropriate, further investigation is required to localise the abnormal parathyroid tissue, usually a missed adenoma. This may be readily apparent but can require a combination of ultrasound, sestamibi, CT, MRI, PET, selective angiography (Fig. 48.57) and venous sampling for PTH. The results of this last technique may be difficult to interpret if normal venous drainage has been disrupted by previous operations.

When the site of an ectopic or missed adenoma is accurately identified, a second operation can be straightforward when performed through intact tissue planes. Re-exploration through previously explored tissues is more difficult and increases the risks to the RLNs and the risks of postoperative hypocalcaemia.

Recurrent hyperparathyroidism

Recurrent HPT is diagnosed when hypercalcaemia recurs more than 12 months after an initially curative operation. This may occur because of:

- missed pathology at the first operation;
- (rarely) development of a second adenoma;
- hyperplasia in autotransplanted tissue;
- parathyromatosis (disseminated nodules of parathyroid tissue within the soft tissues of the neck and superior mediastinum caused by rupture of abnormal parathyroid tissue at initial surgery).

Reoperative parathyroid surgery is associated with an increased risk of RLN injury and postoperative hypocalcaemia. Knowledge that surgical cure is achieved when a single gland has been removed obviates the need for further dissection. An intraoperative rapid PTH assay can be used to demonstrate the fall in PTH levels that occurs when all abnormal parathyroid tissue has been excised. If PTH levels fall to < 50% of baseline values at 15 min after specimen excision, the surgeon can terminate the intervention and

Figure 48.57 Selective arteriogram of the internal mammary artery showing parathyroid tumour blush in a patient who had undergone three previous neck explorations for hyperparathyroidism (courtesy of Mr B. Harrison, Sheffield, UK).

reduce the risk of surgical morbidity associated with further exploration of a scarred operative field.

HYPOPARATHYROIDISM

Although there are rare congenital (DiGeorge) and medical (autoimmune polyglandular and Wilson) syndromes causing hypoparathyroidism, for practical purposes, postoperative hypoparathyroidism is the dominant management issue in surgical practice. This results from trauma to or removal or devascularisation of the parathyroid glands, which may be deliberate but is more often inadvertent.

Symptoms and signs

The symptoms and signs of acute hypoparathyroidism are related to the level of serum calcium and range from mild circumoral and digital numbness and paraesthesia to tetanic symptoms with carpopedal or laryngeal spasms, cardiac arrhythmias and fits.

Angelo DiGeorge, B. 1921, Professor of Paediatrics, Temple University, Philadelphia, PA, USA.

Samuel Alexander Kinnier Wilson, 1878–1936, Professor of Neurology, King's College Hospital, London, England.

Chronic hypoparathyroidism can lead to abnormal bone demineralisation, cataracts, calcification in basal ganglia and consequent extrapyramidal disorders.

Percussion of the facial nerve just below the zygoma causes contraction of the ipsilateral facial muscles (Chvostek's sign). Carpopedal spasm can be induced by occlusion of the arm with a blood pressure cuff for 3 min (Trousseau's sign). Electrocardiogram changes include prolonged QT intervals and QRS complex changes.

Treatment

Acute symptomatic hypocalcaemia is a medical emergency and requires urgent correction by intravenous injection of calcium. Magnesium supplements may also be required. Oral calcium (1 g three or four times daily) supplemented by 1–3 µg daily of 1-alpha-vitamin D if necessary should be given with a view to gradual withdrawal over the next 3–12 months (Summary box 48.8).

Summary box 48.8

Management of postoperative hypocalcaemia

- Check serum calcium within 24 hours of total thyroidectomy or earlier if symptomatic
- Medical emergency if the level is $< 1.90 \text{ mmol l}^{-1}$: correct with 10 ml of 10% calcium gluconate intravenously; 10 ml of 10% magnesium sulphate intravenously may also be required
- Give 1 g of oral calcium three or four times daily
- Give 1–3 µg daily of oral 1-alpha-vitamin D if necessary

Frantisek Chvostek, 1835–1884, Physician, The Josefsacademie, Vienna, Austria.
Armand Trousseau, 1801–1867, Physician, Hôtel Dieu, Paris, France.

Adrenal glands and other endocrine disorders

LEARNING OBJECTIVES

To understand:

- The anatomy and function of the adrenal and other endocrine glands
- The diagnosis and management of endocrine disorders
- The role of surgery in the management of endocrine disorders

ADRENAL GLANDS

Anatomy

The weight of a normal adrenal gland is approximately 4 g. There are two distinct components of the gland: the inner adrenal medulla and the outer adrenal cortex (Fig. 49.1). The adrenal glands are situated at the upper poles of the kidneys in the retroperitoneum within Gerota's capsule. The right adrenal gland is located between the right liver lobe and the diaphragm, close to and partly behind the inferior vena cava. The left adrenal gland lies on the upper pole of the left kidney and reaches the renal pedicle. It is covered by the pancreatic tail and the spleen (Fig. 49.2).

The adrenal glands are well supplied by blood vessels. The arterial blood supply branches from the aorta and the diaphragmatic and renal arteries and varies considerably. A large adrenal

Figure 49.1 Cross-section of a normal adrenal gland. The inner, very thin layer between the two dark lines (zona reticularis) is the adrenal medulla.

Dumitru Gerota, 1867–1939, Professor of Surgery, Bucharest, Romania.

Figure 49.2 Position of the adrenal glands (hatched) in the retroperitoneum.

vein drains on the right side into the vena cava and on the left side into the renal vein.

Embryology

The two functional parts, the cortex and the medulla, arise from different blastodermic layers: mesodermal cells form the adrenal cortex and neuroectodermal cells migrate to the cortex during embryogenesis and form the adrenal medulla.

Histology

The adrenal cortex is characterised by a zonal configuration. The outer zona glomerulosa contains small, compact cells. The zona fasciculata can be identified by the larger, lipid cells, which are arranged in radial columns. Compact and pigmented cells characterise the inner zona reticularis. The adrenal medulla consists of a thin layer of large chromaffin cells, which store catecholamine granules.

Function of the adrenal glands

The adrenal glands play a pivotal role in the response to stress. Catecholamines are secreted by the adrenal medulla and corticosteroids, aldosterone and cortisol are synthesised in the adrenal cortex.

Cells of the adrenal medulla synthesise mainly adrenaline (epinephrine) but also noradrenaline (norepinephrine) and dopamine. These catecholamines act as hormones as they are secreted directly into the circulation. Their effects, which are mediated through α and β receptors on target organs, include activation of the cardiovascular system, resulting in an increase in blood pressure and heart rate; vasoconstriction of vessels in the splanchnic system and vasodilatation of vessels in the muscles; broncho-dilatation; and increased glycogenolysis in liver and muscles.

Cells of the zona glomerulosa produce aldosterone, which regulates sodium–potassium homeostasis. The target organs of aldosterone are the kidneys, the sweat and salivary glands and the intestinal mucosa. Aldosterone promotes sodium retention and potassium excretion. The most important regulators of aldosterone secretion are the renin–angiotensin system and the serum potassium concentration. Renin produced by the juxtaglomerular cells in the kidneys acts on its substrate angiotensinogen to generate angiotensin I. Angiotensin I is converted by the angiotensin-converting enzyme (ACE) to the octapeptide angiotensin II, which is modified to angiotensin III. Both stimulate the secretion of aldosterone from the adrenal cortex. A decrease in renal blood flow (haemorrhage, dehydration, salt depletion, orthostasis, renal artery stenosis) or hyponatraemia increases renin secretion and leads to sodium retention, potassium excretion and an increase of plasma volume.

Cells of the zona fasciculata and zona reticularis synthesise cortisol and the adrenal androgens dehydroepiandrosterone (DHEA) and its sulphate DHEAS. DHEA and DHEAS are precursors of androgens and are converted by different peripheral tissues. Cortisol secretion is regulated by adrenocorticotrophic hormone (ACTH), which is produced by the anterior pituitary gland. The hypothalamus controls ACTH secretion by secreting corticotropin-releasing hormone (CRH). The cortisol level inhibits the release of CRH and ACTH via a closed-loop system.

Cortisol is the most important steroid and has numerous metabolic and immunological effects. It increases gluconeogenesis and lipolysis; decreases peripheral glucose utilisation, immunological response and muscular mass; affects fat distribution, wound healing and bone mineralisation; and alters mood (euphoria or, rarely, depression) and cortical awareness.

DISORDERS OF THE ADRENAL CORTEX

Incidentaloma

Definition

A clinically unapparent mass detected incidentally by imaging studies conducted for other reasons.

Incidence

The prevalence of adrenal masses in autopsy studies ranges from 1.4% to 8.7% and increases with age. Incidentalomas may be detected on imaging studies in 4% of patients. More than 75% are non-functioning adenomas but Cushing's adenomas, phaeochromocytomas and even adrenocortical carcinomas may be present (Table 49.1).

Diagnosis

When an incidentaloma is identified, a complete history and clinical examination are required. A biochemical work-up for hormone excess and sometimes additional imaging studies are also needed. The main goal is to exclude a functioning or malignant adrenal tumour.

Hormonal evaluation includes:

- morning and midnight plasma cortisol measurements;
- a 1-mg overnight dexamethasone suppression test;
- 24-hour urinary cortisol excretion (optional);
- 24-hour urinary excretion of catecholamines, metanephrines or plasma-free metanephrines;
- serum potassium, plasma aldosterone and plasma renin activity;
- serum DHEAS, testosterone or 17β -hydroxyestradiol (virilising or feminising tumour).

For evaluation of malignancy, computerised tomography (CT) or magnetic resonance imaging (MRI) should be performed in all patients with adrenal masses, followed by fine-needle aspiration cytology after a phaeochromocytoma has been excluded. The likelihood of an adrenal mass being an adrenocortical carcinoma increases with the size of the mass (25% > 4 cm). Adrenal metastases are likely in patients with a history of cancer elsewhere (Summary box 49.1).

Summary box 49.1

Adrenal gland biopsy

- Never biopsy an adrenal mass until phaeochromocytoma has been biochemically excluded
- The indication for adrenal gland biopsy is to confirm adrenal gland metastasis

Table 49.1 Prevalence of non-functioning and functioning tumours in patients with incidentalomas

Tumour	Prevalence (%)
Non-functioning adenoma	78
Cushing's adenoma	7
Adrenocortical carcinoma	4
Phaeochromocytoma	4
Myelolipoma	2
Cyst	2
Metastases	2
Conn's adenoma	1

Harvey Williams Cushing, 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA.

Treatment

The treatment of functional adrenal tumours is described below. Any non-functioning adrenal tumour greater than 4 cm in diameter and smaller tumours that increase in size over time should undergo surgical resection. Non-functioning tumours smaller than 4 cm should be followed-up after 6, 12 and 24 months by imaging and hormonal evaluation.

Primary hyperaldosteronism

Incidence

Primary hyperaldosteronism (PHA) is defined by hypertension, hypokalaemia and hypersecretion of aldosterone. In PHA, plasma renin activity is suppressed. Among patients with hypertension the incidence of hypokalaemic PHA is approximately 2%. Recent studies have revealed that up to 12% of hypertensive patients have PHA with normal potassium levels.

Pathology

The most frequent cause of PHA with hypokalaemia is a unilateral adrenocortical adenoma (Conn's syndrome) (Fig. 49.3). In 20–40% of cases, bilateral micronodular hyperplasia is causative. Rare causes of PHA are bilateral macronodular hyperplasia, glucocorticoid-suppressible hyperaldosteronism or adrenocortical carcinoma. In the subset of patients with normokalaemic PHA, 70% have hyperplasia and 30% unilateral adenoma.

Clinical features

Most patients are between 30 and 50 years of age with a female predominance. Apart from hypertension and hypokalaemia, patients complain of non-specific symptoms: headache, muscle weakness, cramps, intermittent paralysis, polyuria, polydipsia and nocturia.

Diagnosis

The key feature of the biochemical diagnosis is the assessment of potassium level and the aldosterone to plasma renin activity

Figure 49.3 A Conn's adenoma (arrow) of the left adrenal gland; note the V-shaped normal adrenal tissue.

Jerome William Conn, 1907–1981, Professor of Internal Medicine, The University of Michigan, Michigan, MI, USA.

ratio. Antihypertensive and diuretic therapy, which cause hypokalaemia and influence the renin–angiotensin–aldosterone system, have to be discontinued. Once the biochemical diagnosis is confirmed, MRI or CT should be performed to distinguish unilateral from bilateral disease. Conn's adenomas usually measure between 1 and 2 cm and are detected by CT with a sensitivity of 80–90% (Fig. 49.4). Micronodular changes and small adenomas are often underdiagnosed. An apparent unilateral mass could be a non-functioning tumour in a patient with bilateral micronodular hyperplasia. Therefore, selective adrenal vein catheterisation is warranted before a decision on non-surgical or surgical treatment is made. During selective adrenal vein catheterisation, samples are obtained from the vena cava and from both adrenal veins and the aldosterone to cortisol ratio (ACR) is determined in each sample. A significant difference in the ACR ratio on one side indicates unilateral disease.

Treatment

The first-line therapy for PHA with bilateral hyperplasia is medical treatment with spironolactone. In most cases supplemental antihypertensive medication is necessary.

Unilateral laparoscopic adrenalectomy is an effective therapy in patients with clear evidence of unilateral or asymmetrical bilateral disease. A subtotal resection is favoured in the case of a typical Conn's adenoma. In 10–30% of patients who undergo an adrenalectomy, hypertension persists despite adequate diagnostic work-up and treatment.

Cushing's syndrome

Definition

Hypersecretion of cortisol caused by endogenous production or excessive use of corticosteroids is known as Cushing's syndrome. It can be either ACTH-dependent or ACTH-independent in origin. The most common cause (85%) of ACTH-dependent Cushing's syndrome is Cushing's disease resulting from a pituitary adenoma that secretes an excessive amount of ACTH. Ectopic ACTH-producing tumours (small cell lung cancer, foregut carcinoid) and CRH-producing tumours (medullary thyroid

Figure 49.4 Computerised tomography scan of a Conn's adenoma of the left adrenal gland (arrowheads).

carcinoma, neuroendocrine pancreatic tumour) are more infrequent causes of ACTH-dependent Cushing's syndrome.

In about 15% of patients, an ACTH-independent Cushing's syndrome (low ACTH levels) is caused by a unilateral adrenocortical adenoma. Adrenocortical carcinoma and bilateral macronodular or micronodular hyperplasia represent rare causes of hypercortisolism.

Clinical symptoms

The clinical features of Cushing's syndrome are shown in Summary box 49.2. The typical patient is characterised by a facial plethora, a buffalo hump and a moon face in combination with hypertension, diabetes and central obesity (Figs 49.5 and 49.6). However, clinical signs can be minimal or absent in patients with subclinical Cushing's syndrome.

Summary box 49.2

Clinical features of Cushing's syndrome

- Weight gain/central obesity
- Diabetes
- Hirsutism
- Hypertension
- Skin changes (abdominal striae, facial plethora, ecchymosis, acne)
- Muscle weakness
- Menstrual irregularity/impotence
- Depression/mania
- Osteoporosis
- Hypokalaemia

Diagnosis

- Morning and midnight plasma cortisol levels are elevated, possibly with loss of diurnal rhythm.

Figure 49.5 34-year-old patient with Cushing's syndrome whose symptoms included thickening of the face, weight gain and acne. Today patients with Cushing's syndrome rarely have the full-blown appearance as shown in older textbooks.

Figure 49.6 Discrete central obesity, ecchymosis and fragile skin in a patient with Cushing's syndrome.

- Dexamethasone fails to suppress 24-hour urinary cortisol excretion.
- Serum ACTH levels discriminate ACTH-dependent from ACTH-independent disease.

Elevated or normal ACTH levels provide evidence for an ACTH-producing pituitary tumour (85%) or ectopic ACTH production. Therefore, in patients with elevated ACTH, MRI of the pituitary gland must be performed. If MRI is negative and additional venous sampling from the inferior petrosal sinus has excluded a pituitary microadenoma, a CT scan of the chest and abdomen is warranted to detect an ectopic cortisol-producing tumour. In patients with suppressed ACTH levels, a CT or MRI scan is performed to assess the adrenal glands.

Subclinical Cushing's syndrome is diagnosed if clinical symptoms are absent and urinary cortisol excretion is in the normal range but a basal low ACTH level increases to normal after CRH stimulation.

Treatment

Medical therapy with metyrapone or ketoconazole reduces steroid synthesis and secretion and is used in patients with severe hypercortisolism or if surgery is not possible. ACTH-producing pituitary tumours are treated by trans-sphenoidal resection or radiotherapy. If an ectopic ACTH source is localised, resection will cure hypercortisolism.

A unilateral adenoma is treated by adrenalectomy. In cases of bilateral ACTH-independent disease (Fig. 49.7), bilateral adrenalectomy is the primary treatment. Patients with an ectopic ACTH-dependent Cushing's syndrome and an irresectable or unlocalised primary tumour should be considered for bilateral adrenalectomy as this controls hormone excess. Subclinical Cushing's syndrome caused by unilateral adenoma is treated by unilateral adrenalectomy.

Preoperative management

Patients with Cushing's syndrome are at an increased risk of hospital-acquired infection and thromboembolic and myocardial

Figure 49.7 Bilateral asymmetrical hyperplasia of the adrenal glands (arrows) in a patient with Cushing's syndrome.

complications. Therefore, prophylactic anti-coagulation and the use of prophylactic antibiotics are essential. Cushing-associated diseases (diabetes, hypertension) must be controlled by medical therapy preoperatively.

Postoperative management

Supplemental cortisol should be given after surgery. In total, 15 mg h^{-1} is required parenterally for the first 12 hours followed by a daily dose of 100 mg for 3 days, which is gradually reduced thereafter. After unilateral adrenalectomy, the contralateral suppressed gland needs up to 1 year to recover adequate function. In 10% of patients with Cushing's disease who undergo a bilateral adrenalectomy, the pituitary adenoma converts into an aggressive tumour (Nelson's syndrome).

Adrenal metastases

Adrenal metastases are discovered at autopsy in one-third of patients with malignant disease (less frequently during life). In declining frequency, the most common primary tumours are breast, lung, renal, gastric, pancreatic, ovarian and colorectal cancer. In selected cases an adrenalectomy can be performed.

Adrenocortical carcinoma

Incidence

Adrenocortical carcinoma is a rare malignancy with an incidence of 1–2 cases per 1 000 000 population per year and a variable but generally poor prognosis. A slight female predominance is observed (1.5:1). The age distribution is bimodal with a first peak in childhood and a second between the fourth and fifth decades.

Pathology

The differentiation between benign and malignant adrenal tumours is challenging, even in the hands of an experienced pathologist. Criteria for malignancy are tumour size, the presence of necrosis or haemorrhage and microscopic features such as capsular or vascular invasion. These should be assessed in terms of a

microscopic diagnostic score. Additional information is provided by immunohistochemistry. The macroscopic features are commonly multinodularity and heterogeneous structure (see Fig. 49.8).

Clinical presentation

Approximately 60% of patients present with evidence of steroid hormone excess (Cushing's syndrome). Patients with non-functioning tumours frequently complain of abdominal discomfort or back pain caused by large tumours. However, with increasing use of abdominal imaging, a growing number of adrenocortical carcinomas are detected incidentally.

Diagnosis

The diagnostic work-up should include measurements of DHEAS, cortisol and catecholamines to exclude a pheochromocytoma and a dexamethasone suppression test. MRI and CT are equally effective in distinguishing adrenocortical adenoma from carcinoma (Fig. 49.9). MRI angiography is useful to exclude tumour thrombus in the vena cava, which must be excluded before adrenalectomy. As distant metastases are frequently

Figure 49.8 Adrenocortical carcinoma that caused Cushing's syndrome and virilisation in a female patient.

Figure 49.9 Magnetic resonance imaging of adrenocortical carcinoma (arrow) in a patient with cortisol and testosterone excess.

Don H. Nelson, B. 1925, Professor of Medicine, The University of Utah, Salt Lake City, UT, USA.

present, a CT scan of the lung is recommended. The World Health Organization classification of 2004 is based on the McFarlane classification and defines four stages: tumours < 5 cm (stage I) or > 5 cm (stage II), locally invasive tumours (III) or tumours with distant metastases (IV).

Treatment

Complete tumour resection (R0) is associated with favourable survival and should be attempted whenever possible. In order to prevent tumour spillage and implantation metastases, the capsule must not be damaged. *En bloc* resection with removal of locally involved organs is often required and in case of tumour thrombus in the vena cava the assistance of a cardiac surgeon is sometimes needed. Laparoscopic adrenalectomy is associated with a high incidence of local recurrence and cannot be recommended. Tumour debulking plays a role in functioning tumours to control hormone excess.

Patients should be treated postoperatively with mitotane alone or in combination with etoposide, doxorubicin and cisplatin in 30% and 50% of cases respectively. Adjuvant radiotherapy may reduce the rate of local recurrence. After surgery, restaging every 3 months is required as the risk of tumour relapse is high. Prognosis depends on the stage of disease and complete removal of the tumour. Patients with stage I or II disease have a 5-year survival rate of 25% whereas patients with stage III and stage IV disease have 5-year survival rates of 6% and 0% respectively.

Congenital adrenal hyperplasia (adrenogenital syndrome)

Virilisation and adrenal insufficiency in children are pathognomonic of congenital adrenal hyperplasia (CAH). This is an autosomal recessive disorder caused by a variety of enzymatic defects in the synthetic pathway of cortisol and other steroids from cholesterol. The most frequent defect (95%) is the 21-hydroxylase deficiency, which has an incidence of 1 in 5000 live births. Excessive ACTH secretion is caused by the loss of cortisol and this leads to an increase in androgenic cortisol precursors and to CAH. CAH may present in girls at birth with ambiguous genitalia or as late-onset disease at puberty. Hypertension and short stature, caused by the premature epiphyseal plate closure, are common symptoms. Affected patients are treated by replacement of cortisol and with fludrocortisone.

Adrenal insufficiency

Primary adrenal insufficiency is caused by the loss of function of the adrenal cortex (Summary box 49.3). It was first described by Thomas Addison in 1855. An early diagnosis is a clinical challenge, even today. Symptoms are only evident when about 90% of the adrenal cortex is destroyed. Secondary adrenal insufficiency is defined as a deficiency of pituitary ACTH secretion. Tertiary adrenal deficiency is provoked by a loss of hypothalamic CRH secretion and is caused by therapeutic glucocorticoid administration, a brain tumour or irradiation.

en bloc is French for 'in a block'.

Thomas Addison, 1795–1860, Physician, Guy's Hospital, London, England, described the effects of disease of the suprarenal capsules in 1849.

Summary box 49.3

Diseases associated with adrenal insufficiency

- Polyglandular autoimmune syndrome
- Tuberculosis
- After bilateral adrenalectomy
- Haemorrhage
- Metastases
- Systemic diseases (Boeck's disease, amyloidosis, Wilson's disease)
- Hereditary diseases (e.g. adrenoleukodystrophy, adrenogenital syndrome)
- HIV infection

Acute adrenal insufficiency

Acute adrenal insufficiency usually presents as shock in combination with fever, nausea, vomiting, abdominal pain, hypoglycaemia and electrolyte imbalance. The Waterhouse–Friderichsen syndrome is a bilateral adrenal infarction associated with meningococcal sepsis and is rapidly fatal unless immediately treated. Because of intestinal symptoms and fever, the so called Addisonian crisis is often misdiagnosed as an acute abdominal condition.

Chronic adrenal insufficiency

When symptoms develop over time, patients present with severe anorexia, weakness and nausea. As a result of negative feedback, ACTH and proopiomelanocortin (POMC) levels increase and cause hyperpigmentation of the skin and mucosa. Hypotension, hyponatraemia, hyperkalaemia and hypoglycaemia are commonly observed. The diagnosis of adrenal insufficiency is made using the ACTH stimulation test. Basal ACTH levels are found to be high with cortisol levels decreased.

Treatment

If a patient displays features of adrenal insufficiency, treatment must immediately be commenced, before the biochemical diagnosis. Initial blood samples can be used for later determinations of ACTH and cortisol levels. In addition to intravenous administration of hydrocortisone, 100 mg every 6 hours, 3 litres of saline is given in 6 hours under careful cardiovascular monitoring. Concomitant infections, which are frequently present, require aggressive treatment.

Chronic adrenal insufficiency is treated by replacement therapy with daily oral hydrocortisone (10 mg m⁻² body surface area) and fludrocortisone (0.1 mg). Patients must be advised about the need to take lifelong glucocorticoid and mineralocorticoid replacement therapy. To prevent an Addisonian crisis, patients must be aware of the need to adjust the dose in case of illness or stress. If patients with adrenal insufficiency are scheduled for surgery, appropriate steroid cover must be administered.

Caesar Peter Moller Boeck, 1845–1917, Professor of Medicine, The University of Oslo, Norway.

Samuel Alexander Kinnier Wilson, 1878–1936, Professor of Neurology, King's College Hospital, London, England, described this condition in 1912.

Rupert Waterhouse, 1873–1958, Physician, The Royal United Hospital, Bath, England, described this syndrome in 1911.

Carl Friderichsen, 1886–1979, Medical Superintendent, Sundby Hospital, Copenhagen, Denmark, gave his account of the syndrome in 1918.

DISORDERS OF THE ADRENAL MEDULLA

Phaeochromocytoma (adrenal paraganglioma)

Definition

This is a tumour of the adrenal medulla, which is derived from chromaffin cells and which produces catecholamines.

Aetiology

The prevalence of phaeochromocytoma in patients with hypertension is 0.1–0.6% with an overall prevalence of 0.05% in autopsy series. In total, 4% of incidentalomas are phaeochromocytomas. Sporadic phaeochromocytomas occur after the fourth decade whereas patients with hereditary forms are diagnosed earlier. Phaeochromocytoma is known as the ‘10% tumour’ as 10% of tumours are inherited, 10% are extra-adrenal, 10% are malignant, 10% are bilateral and 10% occur in children. With the recent advent of detailed genetic tests, however, the incidence of hereditary phaeochromocytomas has been shown to be higher.

Hereditary phaeochromocytomas occur in several tumour syndromes:

- *Multiple endocrine neoplasia type 2 (MEN 2)*: an autosomal dominant inherited disorder that is caused by activating germline mutations of the *RET* proto-oncogene.
- *Familial paraganglioma (PG) syndrome*: glomus tumours of the carotid body and extra-adrenal paraganglioma are characteristic in this hereditary tumour syndrome, which is caused by germline mutations within the succinate dehydrogenase complex subunit B (*SDHB*) and *SDHD* genes.
- *von Hippel–Lindau (VHL) syndrome*: those affected can develop early-onset bilateral kidney tumours, phaeochromocytomas, cerebellar and spinal haemangioblastomas and pancreatic tumours. Patients have a germline mutation in the *VHL* gene.
- *Neurofibromatosis (NF) type 1*: phaeochromocytomas in combination with fibromas on the skin and mucosae (‘café-au-lait’ skin spots) are indicative of a germline mutation in the *NF1* gene.

Pathology

Phaeochromocytomas are greyish-pink on the cut surface and are usually highly vascularised. Areas of haemorrhage or necrosis are often observed (Fig. 49.10). Microscopically, tumour cells are polygonal but the configuration varies considerably. The differentiation between malignant and benign tumours is difficult, except if metastases are present. An increased PASS (phaeochromocytoma of the adrenal gland scale score) indicates malignancy as does a high number of Ki-67-positive cells, vascular invasion or a breached capsule.

Phaeochromocytomas may also produce calcitonin, ACTH, vasoactive intestinal polypeptide (VIP) and parathyroid hormone-related protein (PTHrP). In patients with MEN 2, the onset of phaeochromocytoma is preceded by adrenomedullary hyperplasia, usually bilateral. Phaeochromocytoma is rarely malignant in MEN 2.

Clinical features

Symptoms and signs are caused by catecholamine excess and can be continuous or intermittent (Table 49.2). In total, 90% of

Figure 49.10 Gross appearance of a phaeochromocytoma.

Table 49.2 Clinical signs of phaeochromocytoma

Symptoms	Prevalence (%)
Hypertension:	80–90
Paroxysmal	50–60
Continuous	30
Headache	60–90
Sweating	50–70
Palpitation	50–70
Pallor	40–45
Weight loss	20–40
Hyperglycaemia	40
Nausea	20–40
Psychological effects	20–40

patients with the combination of headache, palpitations and sweating have a phaeochromocytoma. Paroxysms may be precipitated by physical training, induction of general anaesthesia and numerous drugs and agents (contrast media, tricyclic antidepressive drugs, metoclopramide and opiates). Hypertension may occur continuously, be intermittent or absent. A subset of patients is asymptomatic. More than 20% of apparently sporadic phaeochromocytomas are caused by germline mutations in the *RET*, *SDHB*, *SDHD* and *NF1* genes; genetic testing for these genes is therefore generally recommended.

Diagnosis

The first step in the diagnosis of a phaeochromocytoma is the determination of adrenaline, noradrenaline, metanephrine and normetanephrine levels in a 24-hour urine collection. Catecholamine levels that exceed the normal range by 2–40 times will be found in affected patients. Determination of plasma-free metanephrine and normetanephrine levels is a recently available test that has a high sensitivity. Biochemical tests should be performed at least twice. The biochemical diagnosis is followed by the localisation of the phaeochromocytoma and/or metastases. MRI is preferred because contrast media used for CT scans can provoke paroxysms. Classically, phaeochromocytomas show a ‘Swiss cheese’ configuration (Fig. 49.11). ¹²³I-MIBG (meta-iodobenzylguanidine) single-photon emission computerised tomography (SPECT) will identify about 90% of primary tumours and is essential for the detection of multiple extra-adrenal tumours and metastases (Fig. 49.12).

Eugen von Hippel, 1867–1939, Professor of Ophthalmology, Göttingen, Germany.
Arvid Lindau, 1892–1958, Professor of Pathology, Lund, Sweden.

Figure 49.11 Magnetic resonance imaging of a sporadic pheochromocytoma of the left adrenal gland (arrowheads).

Figure 49.12 Meta-iodobenzylguanidine (MIBG) single-photon emission computerized tomography scan of a pheochromocytoma of the left adrenal gland (arrow) in the same patient as in Figure 49.11.

Treatment

Laparoscopic resection is now routine in the treatment of pheochromocytoma. If the tumour is larger than 8–10 cm or radiological signs of malignancy are detected an open approach should be considered.

Preoperative

Once a pheochromocytoma has been diagnosed, an α -adrenoreceptor blocker (phenoxybenzamine) is used to block catecholamine excess and its consequences during surgery. With adequate medical pre-treatment, the perioperative mortality rate has decreased from 20–45% to less than 3%. A dose of 20 mg of phenoxybenzamine initially should be increased daily by 10 mg until a daily dose of 100–160 mg is achieved and the patient reports symptomatic postural hypotension. Additional β -blockade is required if tachycardia or arrhythmias develop; this should not be introduced until the patient is α -blocked.

Peroperative

With adequate α -blockade preoperatively, anaesthesia should not differ from that used in patients with a non-functioning adrenal tumour; however, in some patients, dramatic changes in heart

rate and blood pressure may occur and require sudden administration of pressor or vasodilator agents. A central venous catheter and invasive arterial monitoring are essential. Special attention is required when the adrenal vein is ligated as a sudden drop in blood pressure may occur. Rarely, the infusion of large volumes of fluid or even administration of adrenaline can be necessary.

Postoperative

Patients should be observed for 24 hours in the intensive care unit (ICU) as hypovolaemia and hypoglycaemia may occur. Biochemical cure should be confirmed by an assessment of catecholamines 2–3 weeks postoperatively. Lifelong yearly biochemical tests should be performed to identify recurrent, metastatic or metachronous pheochromocytoma (Summary box 49.4).

Summary box 49.4

Pheochromocytoma

- Obtain a secure biochemical diagnosis
- Exclude family history
- Diagnosis confirmed, treat with α -blockers
- Plan surgical excision
- Yearly lifelong follow-up

Malignant pheochromocytoma

Definition

Approximately 10% of pheochromocytomas are malignant. This rate is higher in extra-adrenal tumours (paragangliomas). The diagnosis of malignancy implies metastases of chromaffin tissue, most commonly to lymph nodes, bone and liver. About 8% of patients with an apparently benign pheochromocytoma subsequently develop metastases.

Treatment

Surgical excision is the only chance for cure. Even in patients with metastatic disease, tumour debulking can be considered to reduce the tumour burden and to control the catecholamine excess. Symptomatic treatment can be obtained with α -blockers. Mitotane should be started as adjuvant or palliative treatment. Treatment with ^{131}I -MIBG or combination chemotherapy has resulted in a partial response in 30% and an improvement of symptoms in 80% of patients. The natural history is highly variable with a 5-year survival rate of less than 50%.

Pheochromocytoma in pregnancy

Pheochromocytomas in pregnancy may imitate an amnion infection syndrome or pre-eclampsia. Without adequate α -blockade, mother and unborn child are threatened by hypertensive crisis during vaginal delivery. In the first and second trimesters the patient should be scheduled for laparoscopic adrenalectomy after adequate α -blockade; the risk of a miscarriage during surgery is high. In the third trimester, elective Caesarean with consecutive adrenalectomy should be performed. The maternal mortality rate is 50% when a pheochromocytoma remains undiagnosed.

Neuroblastoma

Definition

A neuroblastoma is a malignant tumour that is derived from the sympathetic nervous system in the adrenal medulla (38%) or

from any site along the sympathetic chain in the paravertebral sites of the abdomen (30%), chest (20%) and, rarely, the neck or pelvis.

Pathology

Neuroblastomas have a pale and grey surface, are encapsulated and show typical areas with calcification. With increased tumour size, necrosis and haemorrhage may be detected. They are characterised by the presence of immature cells derived from the neuroectoderm of the sympathetic nervous system. Mature cells are found only in ganglioneuroblastomas.

Clinical features

Predominantly newborn infants and young children (< 5 years of age) are affected. Symptoms are caused by tumour growth or by bone metastases. Patients present with a mass in the abdomen, neck or chest, proptosis, bone pain, painless bluish skin metastases, weakness or paralysis. Metastatic disease is present in 70% of patients. The catecholamine excess is asymptomatic and an excess of ACTH or VIP may occur.

Diagnosis

Biochemical evaluation should include urinary excretion (24-hour urine) of vanillylmandelic acid (VMA), homovanillic acid (HVA), dopamine and noradrenaline, as increased levels are present in about 80% of patients. Accurate staging requires CT/MRI of the chest and abdomen, a bone scan, bone marrow aspiration and core biopsies as well as an MIBG scan. Staging is established according to the International Neuroblastoma Staging System (INSS).

Treatment

Prognosis can be predicted by the tumour stage and the age at diagnosis. Patients are classified as low, intermediate or high risk. Low-risk patients are treated by surgery alone (the addition of 6–12 weeks of chemotherapy is optional) whereas intermediate-risk patients are treated by surgery with adjuvant multi-agent chemotherapy (carboplatin, cyclophosphamide, etoposide, doxorubicin). High-risk patients receive high-dose multi-agent chemotherapy followed by surgical resection in responding tumours and myeloablative stem cell rescue. Patients assigned to the low-risk, intermediate-risk and high-risk groups have overall 3-year survival rates of 90%, 70–90% and 30% respectively.

Ganglioneuroma

Definition

A ganglioneuroma is a benign adrenal neoplasm that arises from neural crest tissue. Ganglioneuromas occur in the adrenal medulla and are characterised by mature sympathetic ganglion cells and Schwann cells in a fibrous stroma.

Clinical features

Ganglioneuroma is found in all age groups but is more common before the age of 60. Ganglioneuromas occur anywhere along the paravertebral sympathetic plexus and in the adrenal medulla (30%). Most often they are identified incidentally by CT or MRI performed for other indications.

Theodor Schwann, 1810–1882, Professor of Anatomy, Louvain (1839–1848), and later at Liège (1849–1880), described the neurilemma in 1839.

Treatment

Treatment is by surgical excision, laparoscopic when adrenalectomy is indicated.

SURGERY OF THE ADRENAL GLANDS

Since its introduction in the 1990s, laparoscopic or retroperitoneoscopic adrenalectomy has become the ‘gold standard’ in the resection of adrenal tumours, except for tumours with signs of malignancy. The more popular approach is the laparoscopic transperitoneal approach, which offers a better view of the adrenal region and may be easier to learn. The advantage of the retroperitoneoscopic approach is the minimal dissection required by this extra-abdominal procedure. In the case of small, bilateral tumours or in patients with hereditary tumour syndromes a subtotal resection is warranted. The mortality rate ranges from 0 to 2% in specialised centres.

An open approach should be considered if radiological signs, distant metastases, large tumours (> 8–10 cm) or a distinct hormonal pattern suggest malignancy. The surgical access in such cases should be thoracoabdominal.

Laparoscopic adrenalectomy

Knowledge of the anatomy of the adrenal region is essential as anatomical landmarks guide the surgeon during operation. If these landmarks are respected, injury to the vena cava or renal vein, the pancreatic tail or the spleen can be avoided. Careful haemostasis is essential as small amounts of blood can impair the surgeon’s view. To prevent tumour spillage, direct grasping of the adrenal tissue/tumour has to be avoided.

Right adrenalectomy

After mobilisation of the right liver lobe the adrenal vein is identified and divided. The dissection continues at the level of the periadrenal fat using careful coagulation and is finished by the complete or subtotal removal of the adrenal gland.

Left adrenalectomy

With the patient positioned on his or her right side, mobilisation of the spleen will displace the pancreatic tail medially. The incision of Gerota’s fascia is followed by identification of the adrenal vein, which runs into the renal vein in the space between the medial aspect of the kidney and the posterior aspect of the pancreatic tail (Fig. 49.13). The resection is completed by the transection of the adrenal gland at the level of the periadrenal fat.

Retroperitoneoscopic adrenalectomy

The first port is placed at the distal end of the 12th rib with the patient in the prone position. After a digital dissection into the retroperitoneum, Gerota’s fascia is displaced ventrally. The right adrenal vein is covered by the retrocaval posterior aspect of the adrenal gland. The left adrenal vein is usually located at the medial inferior pole of the adrenal gland.

Open adrenalectomy

An open adrenalectomy through a thoracoabdominal approach is almost exclusively performed when a malignant adrenal tumour is suspected. On the right side the hepatic flexure of the colon is mobilised and the right liver lobe is cranially retracted to achieve an optimal exposure of the inferior vena cava and the adrenal

Figure 49.13 Laparoscopic view during a right adrenalectomy. Arrow indicates the adrenal vein. AT, adrenal tumour; VC, vena cava.

gland. On the left side the adrenal gland can be exposed after mobilisation of the splenic flexure of the colon, through the transverse mesocolon or through the gastrocolic ligament. The remaining dissection is the same as in laparoscopic adrenalectomy. A resection of regional lymph nodes is recommended in malignant adrenal tumours and should include resection of the tissue between the renal pedicle and the diaphragm.

PANCREATIC ENDOCRINE TUMOURS

Introduction

Pancreatic endocrine tumours (PETs) represent an important subset of pancreatic neoplasms. They account for 5% of all clinically detected pancreatic tumours. They consist of single or multiple, benign or malignant neoplasms and are associated in 10–20% of cases with multiple endocrine neoplasia type 1 (MEN 1). PETs present as either functional tumours, causing specific hormonal syndromes, or non-functional tumours, with symptoms

similar to those in patients with pancreatic adenocarcinoma. This section focuses on insulinomas, gastrinomas and non-functioning tumours because they represent 90% of all PETs (Table 49.3).

Function of the endocrine pancreas

The endocrine cells of the pancreas are grouped in the islets of Langerhans, which constitute approximately 1–2% of the mass of the pancreas (Fig. 49.14). There are about one million islets in a healthy adult human pancreas and their combined weight is 1–1.5 g. There are four main types of cell in the islets of Langerhans, which can be classified according to their secretions:

- beta cells producing insulin (65–80% of the islet cells);
- alpha cells producing glucagon (15–20%);
- delta cells producing somatostatin (3–10%);
- pancreatic polypeptide (PP) cells containing polypeptide (1%).

Figure 49.14 Immunofluorescent labelling of endocrine [insulin (green)] and exocrine [amylase (red)] pancreatic cells and the nuclear marker DAPI (blue) (courtesy of Dr Esni, Department of Surgery, University of Pittsburgh, USA).

Table 49.3 Neuroendocrine tumours of the pancreas

Tumour (syndrome)	Incidence (%)	Presentation	Malignancy (%)
Insulinoma	70–80	Weakness, sweating, tremor, tachycardia, anxiety, fatigue, dizziness, disorientation, seizures	< 10
Gastrinoma	20–25	Intractable or recurrent peptic ulcer disease (haemorrhage, perforation), complications of peptic ulcer, diarrhoea	60–80
Non-functional tumours	30–50	Obstructive jaundice, pancreatitis, epigastric pain, duodenal obstruction, weight loss, fatigue	60–90
VIPoma	4	Profuse watery diarrhoea, hypotension, abdominal pain	80
Glucagonoma	4	Migratory necrolytic skin rash, glossitis, stomatitis, angular cheilitis, diabetes, severe weight loss, diarrhoea	80
Somatostatinoma	< 5	Cholelithiasis, diarrhoea, neurofibromatosis	50
Carcinoid	< 1	Flushing, sweating, diarrhoea, oedema	90
ACTHoma	< 1	Cushing's syndrome	> 90
GRFoma	< 1	Acromegaly	30

ACTH, adrenocorticotrophic hormone; GRF, growth hormone-releasing factor; VIP, vasoactive intestinal polypeptide.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany.

Insulinoma

Definition

This is an insulin-producing tumour of the pancreas causing Whipple's triad, i.e. symptoms of hypoglycaemia after fasting or exercise, plasma glucose levels $< 2.8 \text{ mmol l}^{-1}$ and relief of symptoms on intravenous administration of glucose.

Incidence

Insulinomas are the most frequent of all the functioning PETs with a reported incidence of 2–4 cases per million population per year. Insulinomas have been diagnosed in all age groups with the highest incidence found in the fourth to the sixth decades. Women seem to be slightly more frequently affected.

Pathology

The aetiology and pathogenesis of insulinomas are unknown. No risk factors have been associated with these tumours. Virtually all insulinomas are located in the pancreas and tumours are equally distributed within the gland. Approximately 90% are solitary and about 10% are multiple and are always associated with MEN 1 syndrome.

Prognosis and predictive factors

No markers are available that reliably predict the biological behaviour of an insulinoma. Approximately 10% are malignant. Insulinomas of $< 2 \text{ cm}$ in diameter without signs of vascular invasion or metastases are considered benign.

Clinical features

Insulinomas are characterised by fasting hypoglycaemia and neuroglycopenic symptoms. The episodic nature of the hypoglycaemic attacks is caused by intermittent insulin secretion by the tumour. This leads to central nervous system symptoms such as diplopia, blurred vision, confusion, abnormal behaviour and amnesia. Some patients develop loss of consciousness and coma. The release of catecholamines produces symptoms such as sweating, weakness, hunger, tremor, nausea, anxiety and palpitations.

Biochemical diagnosis

A fasting test that may last for up to 72 hours is regarded as the most sensitive test. Usually, insulin, proinsulin, C-peptide and blood glucose are measured in 1- to 2-hour intervals to demonstrate inappropriately high secretion of insulin in relation to blood glucose. About 80% of insulinomas are diagnosed by this test, most of them in the first 24 hours. Continuous C-peptide levels demonstrate the endogenous secretion of insulin and exclude factitious hypoglycaemia caused by insulin injection.

Differential diagnosis

The differential diagnosis of hypoglycaemia includes hormonal deficiencies, hepatic insufficiency, medication, drugs and enzyme defects. Occasionally, differentiating insulinoma from other causes of hypoglycaemia can be difficult. Nesidioblastosis is a rare disorder, mainly encountered in children, which is characterised

by replacement of normal pancreatic islets by diffuse hyperplasia of islet cells.

Medical treatment of insulinoma

Medical management is reserved only for patients who are unable or unwilling to undergo surgical treatment or for unresectable metastatic disease. Diazoxide suppresses insulin secretion by direct action on the beta cells and offers reasonably good control of hypoglycaemia in approximately 50% of patients. When surgical options to treat malignant insulinomas cannot be applied, chemotherapeutic options include doxorubicin and streptozotocin.

Surgical treatment of insulinoma

Indications for operation

After a positive fasting test and exclusion of diffuse abdominal metastases by ultrasound or CT scan, all patients should undergo surgical excision of insulinoma.

Preoperative localisation studies

Intraoperative exploration of the pancreas is the best method to use for localisation of insulinoma. The author's experience of preoperative localisation in more than 40 patients has shown that insulinomas are detected in about 65% of cases by endoscopic ultrasound (EUS), 33% of cases by CT scan and abdominal ultrasound, 15% of cases by magnetic resonance tomography and not at all by somatostatin receptor scintigraphy (SRS). On the other hand, all tumours were identified and resected after surgical exploration and intraoperative ultrasound (IOUS) of the pancreas after extensive mobilisation of the gland. For preoperative localisation of an insulinoma, EUS has the highest sensitivity and should be used if laparoscopic resection is considered. If no lesion is identified and one can rely on the biochemical tests for diagnosis, laparotomy should follow.

Benign insulinoma

Surgical cure rates in patients with the biochemical diagnosis of insulinoma range from 90% to 100%. At surgical exploration the abdomen is initially explored for evidence of metastatic disease. Following this, an extended Kocher manoeuvre and mobilisation of the head and then the distal pancreas is performed to explore the whole gland. IOUS should then be used to confirm the presence of a tumour, to find non-palpable lesions and also to identify the relation of the tumour to the pancreatic duct (Fig. 49.15a). Tumour enucleation is the technique of choice (Fig. 49.15b). For superficial tumours, laparoscopic enucleation is undertaken (Fig. 49.16). Tumours located deep in the body or tail of the pancreas and those in close proximity to the pancreatic duct require distal pancreatectomy. Postoperatively, blood sugar levels begin to rise in most patients within the first few hours after removal of the tumour. To preserve pancreatic function and reduce the risk of iatrogenic diabetes mellitus, patients in whom tumour localisation is not successful at operation should not undergo blind resection.

Malignant insulinoma

Aggressive attempts at resection are recommended as these tumours are much less virulent than adenocarcinomas.

George Hoyt Whipple, 1878–1976, Professor of Pathology, The University of Rochester, Rochester, NY, USA, described this disease in 1907. He shared the 1934 Nobel Prize for Physiology or Medicine with George Richards Minot, and William Parry Murphy 'for their discoveries concerning liver therapy against anaemias.'

Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland, was awarded the Nobel Prize for Physiology or Medicine in 1909, 'for his work on the physiology, pathology, and surgery of the thyroid gland.'

Gastrinoma (Zollinger–Ellison syndrome)

Definition

Zollinger–Ellison syndrome (ZES) is a condition that includes (1) fulminating ulcer diathesis in the stomach, duodenum or atypical sites; (2) recurrent ulceration despite adequate therapy; and (3) non-beta islet cell tumours of the pancreas (gastrinoma).

Robert Milton Zollinger, B. 1903, Professor of Surgery, The Ohio State University, Columbus, OH, USA.

Edwin Homer Ellison, 1918–1970, Professor of Surgery, Marquette University, WI, USA. Zollinger and Ellison described this condition in a joint paper in 1955 when they were both working at The Ohio State University.

Incidence

Gastrinomas account for about 20% of PETs, second in frequency to insulinomas. Approximately 0.1% of patients with duodenal ulcers have evidence of ZES. The reported incidence is between 0.5 and 4 cases per million population per year. ZES is more common in males than in females. The mean age at the onset of symptoms is 38 years, and the range 7–83 years.

Pathology

The aetiology and pathogenesis of sporadic gastrinomas are unknown. At the time of diagnosis more than 60% of tumours are malignant. Pancreatic gastrinomas are mainly found in sporadic disease; most are found in the head of the pancreas. More than 70% of the gastrinomas in MEN 1 syndrome and most sporadic gastrinomas are located in the first and second part of the duodenum. Therefore, the anatomical area comprising the head of the pancreas, the superior and descending portion of the duodenum and the relevant lymph nodes has been called the ‘gastrinoma triangle’ because it harbours the vast majority of these tumours (Fig. 49.17).

Prognosis and predictive factors

In general, the progression of gastrinomas is relatively slow with a 5-year survival rate of 65% and a 10-year survival rate of 51%. Patients with complete tumour resection have excellent 5- and 10-year survival rates (90–100%). Patients with pancreatic tumours have a worse prognosis than those with primary tumours in the duodenum. There is no established marker to predict the biological behaviour of gastrinoma.

Clinical and biochemical features

Over 90% of patients with gastrinomas have peptic ulcer disease, often multiple or in unusual sites. Diarrhoea is another common symptom, caused by the large volume of gastric acid secretion. Abdominal pain from either peptic ulcer disease or gastro-oesophageal reflux disease (GORD) remains the most common symptom, occurring in more than 75% of patients.

Biochemical diagnosis

If the patient presents with a gastric pH below 2.5 and a serum gastrin concentration above 1000 pg ml⁻¹ (normal < 100 pg ml⁻¹)

Figure 49.17 The gastrinoma triangle.

then the diagnosis of ZES is confirmed. Unfortunately, the majority of patients have serum gastrin concentrations between 100 and 500 pg ml⁻¹ and in these patients a secretin test should be performed. The secretin test is considered positive if an increase in serum gastrin of > 200 pg ml⁻¹ over the pre-treatment value is obtained; this also rules out other causes of hypergastrinaemia (e.g. atrophic gastritis).

Differential diagnosis

The most common misdiagnoses are idiopathic peptic ulcer disease, chronic idiopathic diarrhoea and GORD. Other reasons for hypergastrinaemia are chronic atrophic gastritis, gastric outlet stenosis and retained antrum after gastric resection.

Medical treatment of gastrinoma

In most patients with ZES, gastric hypersecretion can be treated effectively with proton pump inhibitors. Octreotide can also help to control acid hypersecretion. Systemic chemotherapy is utilised in patients with diffuse metastatic gastrinomas. Streptozotocin in combination with 5-fluorouracil or doxorubicin is the first-line treatment.

Surgical treatment of gastrinoma

Indications for operation

The only chance for cure is surgical resection and routine surgical exploration increases survival. Therefore, surgical exploration should be performed in all patients without diffuse metastases.

Preoperative localisation studies

Pancreatic gastrinomas are often larger than 1 cm in diameter whereas gastrinomas of the duodenum are usually smaller. Therefore, it is nearly impossible to identify duodenal gastrinomas by preoperative imaging. Pancreatic gastrinomas are detected by endoscopic ultrasound in about 80–90% of cases, and by CT in 39% of cases, and by MRI in 46% of cases. In approximately one-third of patients the results of conventional imaging studies are negative. On the basis of recent studies and the author's experience, either endoscopic ultrasound or CT and SRS should be performed preoperatively for staging.

Pancreatic gastrinomas

Most pancreatic gastrinomas are solitary, located in the head of the gland or uncinat process, and can be identified at operation. Enucleation with peripancreatic lymph node dissection is the procedure of choice. Rarely, tumours are situated in the body or tail and should be treated by enucleation or distal resection. Even if a tumour is found in the pancreas, duodenotomy is recommended to detect additional tumours.

Duodenal gastrinomas

The duodenum should be opened with a longitudinal incision and the posterior and anterior walls palpated separately (Fig. 49.18). Duodenal tumours smaller than 5 mm can be enucleated with the overlying mucosa; larger tumours are excised with full-thickness excision of the duodenal wall.

Non-functional endocrine pancreatic tumours

Definition

PETs are clinically classified as non-functioning (NF-PETs) when they do not cause a clinical syndrome.

Figure 49.18 Palpation of a duodenal gastrinoma (arrow) after duodenotomy.

Incidence

NF-PETs account for 30–50% of all PETs. They are most often diagnosed in the fifth to sixth decades of life.

Pathology

NF-PETs cannot be differentiated from functional tumours by immunocytochemistry because they may also express hormones such as gastrin, insulin, etc. They usually stain positively for chromogranin A and synaptophysin. The tumours are usually large (> 5 cm) and unifocal except in MEN 1 syndrome. They are distributed throughout the pancreas with a head to body to tail ratio of 7:1:1.5.

Prognosis and predictive factors

About 70% of all NF-PETs are malignant. Overall 5- and 10-year survival rates of 65% and 49% respectively have been described. When comparing NF-PETs with functioning PETs, the NF-PETs have a worse prognosis.

Clinical features

Patients usually present late because of the lack of a clinical/hormonal marker of tumour activity. Therefore, in contrast to functioning PETs, patients with NF-PETs present with various non-specific symptoms, including jaundice, abdominal pain, weight loss and pancreatitis. In some cases liver metastases are the first presentation.

Biochemical diagnosis

Increased levels of chromogranin A have been reported in 50–80% of NF-PETs; the level of chromogranin A sometimes correlates with the tumour burden. The combination of elevated chromogranin A and PP measurements increases the sensitivity of diagnosis from 84% to 96% in NF-PETs.

Differential diagnosis

Differentiation from the more aggressive pancreatic adenocarcinoma is extremely important (Table 49.4). Recognition of NF-PETs is imperative because of their resectability and excellent long-term survival compared with their exocrine counterparts.

Table 49.4 Differences between pancreatic cancer and non-functioning endocrine pancreatic tumours (NF-PETs)

	Pancreatic cancer	NF-PETs
Tumour size	< 5 cm	> 5 cm
CT scan	Hypodensity No calcifications	Hyperdensity Calcifications possible
Chromogranin A in blood	Negative	Positive
Somatostatin receptor scintigraphy	Negative	Positive

Medical treatment of non-functioning islet cell tumours

When surgical excision is not possible, chemotherapeutic options include streptozotocin, octreotide and interferon.

Surgical treatment of non-functioning islet cell tumours

Indications for operation

An aggressive surgical approach should be considered in malignant NF-PETs, even in the presence of distant metastases.

Preoperative localisation studies

Preoperative ultrasound or CT scan are the procedures of choice as these tumours are relatively large. Also, SRS should be performed to differentiate endocrine from non-endocrine pancreatic tumours.

Operative procedures

The major goal is a potentially curative resection. This may require partial pancreaticoduodenectomy as well as the synchronous or metachronous resection of liver metastases. Using an aggressive approach, curative resections are possible in up to 62% of cases and overall 5-year survival rates of around 65% can be achieved. Repeated resections for resectable recurrences or metastases are justified to improve survival.

NEUROENDOCRINE TUMOURS OF THE BRONCHI, STOMACH AND SMALL BOWEL

Definition and physiology

Neuroendocrine tumours (NET) of the gut and the pancreas arise from the diffuse neuroendocrine cell system, which can be found as single or clustered cells in the mucosa of the bronchi, stomach, gut, biliary tree, urogenital system and in the pancreas (see Chapters 67, 65 and 68 for NET of the appendix, colon and rectum respectively). This cell system was first recognised as the 'clear cell system' by Feyrter in the 1930s and is identical to the APUD (amine precursor uptake and decarboxylation) system described by Pearse in 1970. All cells of the system secrete different neuroendocrine markers, such as synaptophysin, chromogranin A and neurone-specific enolase (NSE), and produce peptide hormones that are stored in granules, e.g. serotonin, somatostatin, PP or gastrin. In clinical practice chromogranin A is utilised as a tumour marker. The main functional test for NET of the jejunum and ileum (the NET that are most often encoun-

tered) is the measurement of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in urine.

Pathology

Neuroendocrine cells can form hyperplasias or tumours. Oberndorfer coined the term 'carcinoids' for tumours arising from these cells in 1907. Although the term carcinoid continues to be used in clinical practice, these tumours do not always grow in a well-differentiated pattern reflecting the rather benign 'carcinoma-like', i.e. 'carcinoid', tumour. They can show different growth patterns, from benign tumours to high-grade undifferentiated carcinomas having a poor prognosis (neuroendocrine carcinomas). Therefore, they should always be addressed as NET, including a description of their histological pattern (benign, low- or high-grade malignant) and their anatomical site (e.g. stomach, ileum) according to the World Health Organization (WHO) classification (2000). The relative distribution of NET in different organs is given in Table 49.5. Another classification based on embryological principles classifies NET as foregut (lung, stomach, pancreas), midgut (small bowel and appendix) and hindgut (colon and rectum) tumours.

Table 49.5 Relative distribution of neuroendocrine tumours in different organs

Site	Distribution (%)
Lung	10
Stomach	5
Duodenum	2
Small bowel	25
Appendix	40
Colon	6
Rectum	15

Neuroendocrine tumours of the bronchi

Aetiology and clinical features

About 1–2% of all lung tumours are NET. Their aetiology is unknown except in those diagnosed in patients with MEN 1 syndrome. In centrally located tumours, symptoms can be coughing, dyspnoea or fever if obstruction and pneumonia occur. NET situated in the peripheral parts of the lung do not cause symptoms for a long time. The WHO classification should be used for these tumours and should replace the former classification of typical or atypical 'carcinoid'.

Diagnosis and treatment

The diagnosis is made by radiography, CT scan, octreotide (SRS) scan and bronchoscopy and biopsy (Fig. 49.19). The treatment of choice is surgical resection. In benign or low-grade malignancy, a parenchyma-sparing resection without regional lymph node dissection should be performed. In highly undifferentiated NET, patients should be treated as in ordinary lung cancer. If there is metastatic disease, treatment with somatostatin analogues or chemotherapy (e.g. cisplatin and etoposide or streptozotocin and doxorubicin) is recommended.

Even in advanced disease and in the presence of liver metastases, patients do not suffer from 'carcinoid' syndrome ('flushing', etc.), as NET of the foregut do not secrete serotonin. This is also the reason why a 5-HIAA urine test cannot be used to help make a diagnosis.

Figure 49.19 (a) Computerised tomography scan and (b) octreotide scan of a pulmonary (bronchial) neuroendocrine tumour.

Neuroendocrine tumours of the stomach

These tumours are rare. They comprise about 5% of all NET of the gastrointestinal tract and have an incidence of approximately 0.2 cases per 100 000 population per year. There are four different types of gastric NET (Table 49.6). Types 1 and 2 are small benign tumours that arise from the enterochromaffin-like (ECL) cells in the gastric mucosa and grow in either a linear or a nodular pattern (Fig. 49.20). Hypergastrinaemia may cause symptoms and the treatment of choice is endoscopic resection. Types 3 and 4 are almost always malignant and surgical resection should be undertaken if possible.

Pathogenesis, diagnosis and treatment

Type 1 tumours (ECLomas) are the most frequent NET of the stomach (approximately 80%); they occur mostly in elderly

Figure 49.20 Immunostaining of chromogranin in micronodular hyperplasia of enterochromaffin-like (ECL) cells of the stomach associated with chronic atrophic gastritis.

women. Chronic hypergastrinaemia is the result of chronic atrophic gastritis and achlorhydria, the alkaline pH being the stimulus for hypersecretion of gastrin. They do not cause symptoms and are usually detected during gastroscopy for other reasons. Endoscopic resection is the treatment of choice. Antrectomy and resection of ECLomas should be undertaken only if there is recurrent disease and multiple (more than six) tumours, with at least one measuring > 1 cm and infiltration of at least one into the submucosa.

The pathogenesis, diagnosis and treatment of type 2 tumours is similar to that of type 1. The only difference is the cause of the hypergastrinaemia, which in type 2 tumours is the result of MEN 1 syndrome, with multiple gastrinomas in the duodenum or, rarely, in the pancreas.

Type 3 tumours are rare, sporadic and solitary tumours of unknown origin. Serum gastrin is normal; upper gastrointestinal bleeding is the usual symptom that leads to endoscopy. Type 3 tumours are usually larger than 2 cm (Fig. 49.21) and often have lymph node and liver metastases at the time of diagnosis. Gastrectomy and lymph node dissection and resection of liver metastases is the treatment of choice. Liver metastases can also be treated by chemoembolisation.

Type 4 tumours present as large ulcerating malignancies similar to adenocarcinomas and should be treated accordingly. The prognosis of types 3 and 4 is poor (Table 49.6).

Table 49.6 Classification of gastric neuroendocrine tumours

Type	Histological pattern	Size and location	Causative factor and prognosis
1	Benign, non-functional, well differentiated	Gastric corpus; < 1 cm; mucosa/submucosa	ECLomas in chronic atrophic gastritis, hypergastrinaemia
2	Benign or low-grade malignant, differentiated	1–2 cm; angio-invasion; mucosa/submucosa	ECLomas with hypergastrinaemia as a result of gastrinoma in MEN 1
3	Low-grade malignant, differentiated	2 cm; invasion beyond submucosa	Sporadic ECLomas not related to hypergastrinaemia
4	Intermediate or small cell type, high-grade malignant (neuroendocrine carcinoma)	Different sizes	Causative factor unknown; prognosis poor

ECL, enterochromaffin-like; MEN, multiple endocrine neoplasia.

Figure 49.21 Type 3 gastric neuroendocrine tumour discovered after upper gastrointestinal bleeding.

Neuroendocrine tumours of the small bowel

Introduction

These are the tumours that are most commonly referred to as ‘carcinoid’ tumours, as most NET of the gastrointestinal tract are found in the small bowel. They are also called ‘midgut’ tumours (together with NET of the appendix and the right colon). These tumours produce serotonin and cause the ‘carcinoid’ syndrome, but only in patients who have a large volume of liver metastases or if there is advanced local tumour growth draining into the inferior vena cava and thereby bypassing the liver. NET of the duodenum (gastrinomas in MEN 1 syndrome, somatostatinomas and others) are very rare and are not discussed further.

Pathology

NET of the jejunum and ileum arise from a sub-group of cells of the diffuse neuroendocrine system, the enterochromaffin (EC) cells, which secrete serotonin and substance P. They are either solitary or more often multiple, are almost always malignant and metastasise early to the regional lymph nodes and the liver depending on the location of the primary tumour(s) (Fig. 49.22).

Clinical symptoms

Symptoms that lead to the diagnosis are caused by either the primary tumour or its lymph node metastases. Acute or chronic, recurrent or persistent abdominal pain, ileus or, rarely, lower gastrointestinal bleeding may occur. Symptoms may be due to liver metastases, such as sudden painful reddening of the face and chest (‘flushing’), diarrhoea or bronchospasm. These symptoms constitute ‘carcinoid’ syndrome. About 60% of patients eventually develop cardiac symptoms because of stenosis and insufficiency of the pulmonary and, more rarely, the tricuspid valve, with enlargement and thickening of the wall of the right atrium. The aetiology is unknown but local effects of serotonin and kinins may contribute.

Abdominal symptoms are caused either by obstruction of the appendix by an appendiceal NET (leading to appendectomy) or

Figure 49.22 Relation of site and diameter of neuroendocrine tumours of the gut to frequency of lymph node metastasis.

by obstruction of the mesentery or the bowel lumen by growth of lymph node metastases in the mesentery near the bowel. Pain is caused by chronic ischaemia of the bowel (Fig. 49.23), resulting not only from mesenteric lymph node metastases but also from constriction of mesenteric arteries and fibrosis of the mesentery by a so-called desmoplastic reaction.

Primary tumours in the jejunum and ileum rarely cause symptoms such as bleeding or intussusception as they usually only measure from a few millimetres up to 1 cm or at the most 2 cm in diameter (Fig. 49.24). A polypoid NET of the terminal ileum may, however, cause ileocaecal intussusception.

Diagnosis

The diagnosis of NET of the small bowel is made by history, physical examination of the abdomen, imaging and an assessment of 5-HIAA in a 24-hour urine sample. It is positive in larger tumours only if metastases are present. Cross-sectional imaging, sonography, CT scan and MRI will not show the primary tumour but will show mesenteric lymph node and liver metastases.

The best method for staging of NET is an octreotide (SRS)

Figure 49.23 Chronic ischaemia of the small bowel caused by desmoplastic reaction and narrowing of vessels in the mesentery in a neuroendocrine tumour of the ileum.

Johann Friedrich Meckel (The Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany.

Figure 49.24 Multiple neuroendocrine tumours in the small bowel causing large lymph node metastases in the mesentery.

scan. This will show tumour deposits in all organs provided that they are large enough and have a high somatostatin receptor density (Fig. 49.25).

Surgical procedure

Surgery should be undertaken as soon as the diagnosis is made, even in the presence of liver metastases. The main goal is resection of the bowel primary tumour(s) and mesenteric lymph node metastases. This may entail resection of large amounts of bowel (100 cm or more), particularly if stage III or IV lymph node masses are found in the mesentery (Fig. 49.26). In the presence of liver metastases, extrahepatic disease should be resected

Figure 49.26 Bulky lymph node metastases can occur at different levels in the mesentery. To resect them completely, long segments of bowel must be resected, the closer to the mesenteric root the metastases are situated [adapted from Akerström, G., Hellman, P. and Öhrvall, U. (2001) Midgut and hindgut carcinoid tumours. In: Doherty, G.M. and Skogseid, B. (eds.). *Surgical Endocrinology*. Lippincott Williams & Wilkins, Philadelphia, PA, by kind permission].

whenever possible. Metastatic disease in the mesenteric root will lead to long-term pain in the abdomen or back and to a poor quality of life, whereas liver metastases can be treated by chemotherapy or embolisation.

Somatostatin and its analogues provide symptomatic treatment of the 'carcinoid' syndrome caused by a large volume of liver metastases. These drugs may also have an antiproliferative effect. Surgery to remove liver metastases is possible in approximately 10% of patients. In others, embolisation, chemoembolisation, SRS using radioactively labelled octreotide, chemotherapy, biotherapy and also liver transplantation can be performed.

MULTIPLE ENDOCRINE NEOPLASIAS

Introduction

Multiple endocrine neoplasias (MEN) are inherited syndromes characterised by a different pattern of benign and malignant tumours in different endocrine glands. There are two main types, type 1 (MEN 1) and type 2 (MEN 2). The mode of inheritance is autosomal dominant in both.

MEN 1 is characterised by the triad of tumours in the anterior pituitary gland, mostly presenting as prolactinomas or non-functioning tumours, hyperplasia of the parathyroids causing primary hyperparathyroidism (pHPT) and pancreaticoduodenal endocrine tumours (PETs). The syndrome was first described by Wermer in 1954 and is therefore also called Wermer's syndrome. It is caused by germline mutations in the *menin* gene, located on chromosome 11.

MEN 2 is divided into three subtypes: familial medullary thyroid carcinoma (FMTC), MEN 2a and MEN 2b. Medullary thyroid carcinoma (MTC) plays the key role in all subtypes. MEN 2 is caused by germline mutations in the *RET* proto-oncogene, located on chromosome 10. MEN 2a is characterised by the combination of MTC, pHPT and mostly bilateral pheochromocytomas. MTC combined with pheochromocytoma alone is called

Figure 49.25 Octreotide scan of a patient with neuroendocrine tumour of the gut and diffuse metastases in different organs.

Paul Wermer, 1898–1975, Physician, The Presbyterian Hospital, New York, NY, USA, described this condition in 1954.

Sipple's syndrome. FMTC is characterised by distinct mutations in *RET* and *MTC* alone as the clinical manifestation. MEN 2b comprises *MTC*, pheochromocytoma and characteristic facial and oral mucosal neurofibromas and intestinal ganglioneuromatosis accompanied by a marfanoid habitus (Fig. 49.27).

The most important difference between MEN 1 and MEN 2, besides the different clinical pictures, is that MEN 2 is characterised by a well-understood genotype–phenotype correlation. This means that depending on the particular mutation in the *RET* proto-oncogene the phenotypic appearance and the onset of endocrine tumours will be different and can be predicted from the type of mutation. This is not the case in MEN 1 syndrome.

Multiple endocrine neoplasia type 1

Epidemiology

The prevalence of the syndrome is estimated to be around 0.04–0.2 cases per 1000 population per year. The penetrance is high with almost 100% of mutation carriers developing the syndrome. The disease is equally distributed between men and women.

Clinical presentation

The clinical presentation depends on the affected organs. Often tumours occur synchronously (Table 49.7). Most of the mutation carriers identified in screening programmes are asymptomatic.

Parathyroids

In total, 90–100% of patients suffering from MEN 1 develop pHPT and it is usually the first manifestation of the disease. MEN 1 pHPT is characterised by multiglandular disease so that all four parathyroids become hyperplastic in the course of the disease. The clinical presentation of MEN 1 pHPT is similar to that of the sporadic disease. Few patients have asymptomatic disease; most common in symptomatic disease is nephrolithiasis. Diagnosis is

Figure 49.27 Neurofibromas of the tongue in a patient with multiple endocrine neoplasia type 2b.

established by determination of parathyroid hormone (PTH) and calcium in serum.

Endocrine pancreas

PETs occur in around 50–60% of MEN 1 patients. In patients taking part in screening programmes, 70–90% are found to have non-functioning and functioning PETs. This high rate of detection of PETs is the result of the improvement in diagnostic procedures in the last decade, including EUS. MEN 1 PETs are the most common syndrome-associated cause of death. They are mostly multiple and often recur after surgery. Although most patients have multiple tumours, one hormone syndrome is usually dominant. The most common functional tumour is gastrinoma followed by insulinoma. VIPomas, glucagonomas and somatostatinomas are extremely rare. Non-functioning tumours can be asymptomatic for many years.

Table 49.7 Affected organs in multiple endocrine neoplasia type 1

Endocrine gland affected	Frequency (%)	Hormone	Clinical syndrome
Parathyroids	90	PTH	pHPT
Pancreas, duodenum (mostly multiple):	50–80		
Gastrinoma		Gastrin	Zollinger–Ellison syndrome
Insulinoma		Insulin	Hypoglycaemia syndrome
Non-functioning tumours		PP	–
VIPoma		VIP	Verner–Morrison syndrome
Glucagonoma		Glucagon	Glucagonoma syndrome
Anterior pituitary gland:	30–60		
Prolactinoma		Prolactin	Galactorrhea
Non-functioning adenoma		–	Non-specific
Other manifestations			
Adrenals	40–50	Cortisol?	Mostly non-functioning
NET in lung, thymus, stomach	3–10	–	–
Lipoma	5–10	–	–

NET, neuroendocrine tumours; pHPT, primary hyperparathyroidism; PP, pancreatic polypeptide; PTH, parathormone; VIP, vasoactive intestinal polypeptide.

John Sipple, B. 1930, Physician, The State University of New York, New York, NY, USA.
John V. Verner, B. 1927, an American Physician.
A.B. Morrison, B. 1921, an American Physician.

The diagnostic work-up is similar to that for sporadic PETs and includes laboratory tests, such as different hormone measurements, e.g. gastrin, insulin, PP, etc., and imaging.

Anterior pituitary gland

Tumours of the anterior pituitary gland are found in 30–60% of patients with MEN 1. These are mostly microadenomas that present as prolactinomas or non-functioning tumours. Most prolactinomas can be treated with anti-hormone medication.

Adrenal tumours and other organ manifestations

Adrenal involvement is common in MEN 1 patients and affects nearly 40–50% of patients. Mostly non-functioning bilateral adenomas are found. Very rarely adrenocortical carcinomas or pheochromocytomas may develop.

Although very rare, manifestations of MEN 1 include NET of the lung, thymus, stomach, duodenum and small bowel. It is important to check for NETs of the thymus, as they are mostly malignant and are the main cause of death in MEN 1 patients.

Genetic screening

Identification of the MEN 1 (*menin*) gene in 1997 formed the basis for direct mutational analysis of the gene and for family screening. After genetic counselling of the index patient, family members can be screened. Mutation carriers can then be included in screening programmes that make early detection of endocrine tumours possible. Screening programmes should follow the consensus guidelines published by Brandi *et al.* in 2001. In cases of obviously sporadic endocrine tumours in patients younger than 40 years, genetic testing for MEN 1 seems to be useful.

Operative therapy

Parathyroids

The indications for surgery in MEN 1 pHPT follow the same criteria as in sporadic disease but the choice of procedure is different. As multiglandular disease is present in all cases, resection follows the same rules as in secondary HPT. Therefore, the most common procedures are total parathyroidectomy, including cervical thymectomy and autotransplantation of parathyroid tissue in the forearm, or 3½-gland resection, leaving approximately 50 mg of parathyroid tissue behind, and cervical thymectomy. Selective resection of enlarged glands is obsolete because of the high rates of recurrence.

Endocrine pancreas

Indications for surgery and its extent are controversial. Most experts agree that MEN 1 gastrinoma and insulinoma have to be operated on to prevent liver metastases and to control hormonal excess, provided that diffuse liver metastases are not present. MEN 1 gastrinomas are more often located in the duodenum as multiple small tumours than in the pancreas. For gastrinomas

located in the duodenum or pancreatic head (gastrinoma triangle, Fig. 49.17), pylorus-preserving partial pancreaticoduodenectomy is recommended. In rare cases the gastrinoma is located in the body or tail of the pancreas. In such cases distal pancreatectomy with excision of tumours in the pancreatic head is the procedure of choice. In MEN 1 insulinoma the standard operative procedure is distal pancreatectomy with enucleation of tumours in the pancreatic head. Non-functioning PETs are operated on if they reach a size of 1 cm. Careful palpation and IOUS are essential in every pancreatic procedure for MEN 1 PETs.

Anterior pituitary gland

The indications for surgery in tumours of the anterior pituitary gland are the presence of symptomatic non-functional tumours or if medical therapy of prolactinoma fails. Most procedures can be performed through a trans-sphenoidal approach.

Adrenal tumours

Functional adrenal tumours in MEN 1 are rare and have to be operated on. Non-functioning tumours should be resected if they reach a size of 4 cm. Pre- and perioperative management follows the same rules as in sporadic adrenal tumours; therefore, pheochromocytoma has to be ruled out in every patient. In most cases a laparoscopic or retroperitoneoscopic approach can be used. If there is evidence for a malignant tumour, open surgery is preferred.

Multiple endocrine neoplasia type 2

In most patients with MEN 2a, the disease is caused by mutations of the *RET* proto-oncogene in codon 634. MTC is almost always the first manifestation of the syndrome. If pheochromocytoma and pHPT do not occur, one must suspect the presence of the FMTC subtype. Patients with MEN 2b do not develop pHPT and in 95% of cases mutations in codon 918 of the *RET* proto-oncogene are causative (Table 49.8).

Medullary thyroid carcinoma

MTC is characterised by multicentricity and is often accompanied by C-cell hyperplasia. These characteristics should lead to molecular diagnostic work-up (mutational analysis of the *RET* proto-oncogene) in patients with 'sporadic' MTC. In contrast to sporadic MTC, the diagnosis in families with known mutation of the *RET* gene is mostly made much earlier, possibly as the result of mutational screening and calcitonin measurements. MTC is most aggressive in MEN 2b. It occurs in early childhood, much earlier than in MEN 2a, with lymph node metastases present in the early stages.

Primary hyperparathyroidism

pHPT in MEN 2a is less common and has a milder clinical course than MEN 1 pHPT. It occurs in about 20–30% of patients with

Table 49.8 Frequency of diseases in multiple endocrine neoplasia type 2 related to mutation in different codons

Syndrome	Frequently affected codons in <i>RET</i>	MTC	pHPT	PCC
FMTC	533, 630, 768, 844	90–100%	–	–
MEN 2a	609, 634, 790, 804	90–100%	20–30%	10–50%
MEN 2b	883, 918	100%	–	10–50%

FMTC, familial medullary thyroid cancer; MEN 2a, multiple endocrine neoplasia type 2a; MEN 2b, multiple endocrine neoplasia type 2b; MTC, medullary thyroid cancer; PCC, pheochromocytoma; pHPT, primary hyperparathyroidism; *RET*, *RET* proto-oncogene (*RET* = rearranged during transfection).

Table 49.9 Prophylactic thyroidectomy for medullary thyroid cancer depending on the site of mutation of the *RET* proto-oncogene in multiple endocrine neoplasia type 2 patients with normal calcitonin levels

	High	Risk group Medium	Low
Codon	883, 918, 922	609, 611, 618, 620, 634	768, 790, 791, 804, 891
Thyroidectomy at age (years)	< 1	6	< 20

MEN 2a. Most patients are asymptomatic but all parathyroid glands become hyperplastic, mostly metachronously. The disease develops after the third decade of life.

Phaeochromocytoma

The frequency of phaeochromocytoma in MEN 2 is around 10–50% and most tumours are bilateral. This can occur synchronously or metachronously. The tumours are almost always benign. Diagnostic work-up includes measurement of urinary catecholamines, abdominal CT or MRI, and ¹³¹I-MIBG scintigraphy (see above).

Operative therapy

Medullary thyroid carcinoma

Operative therapy for MEN 2 MTC in patients detected by genetic screening is a good example of efficient prophylactic surgery, as the likelihood of developing MTC is 100% for most mutations. The mutation carriers can be operated on with no evidence of tumour in the thyroid, protecting them from MTC for the rest of their lives. Different *RET* mutations are associated with early or late onset of the disease. Risk groups have been defined to determine the appropriate age for thyroidectomy (Table 49.9).

Phaeochromocytoma

The operative approach is open surgery or laparoscopy or retroperitoneoscopy, depending on the manifestation of the disease in a given patient. Unilateral or bilateral subtotal resection may be feasible, which retains the healthy part of the gland and prevents postoperative dependence on cortisol and mineralocorticoid supplementation (see above) (Fig. 49.28).

Primary hyperparathyroidism

The clinical situation in MEN 2 pHPT is even more difficult than in MEN 1 pHPT because of the association with MTC in MEN 2. During neck surgery for MTC in a eucalcaemic patient, enlarged parathyroid glands should be removed. In cases in which neck surgery has already been performed for MTC, the surgical approach to MEN 2a pHPT should be more tailored to the individual patient. For example, in an older patient after thyroidectomy for MTC with mild asymptomatic hypercalcaemia, localisation procedures and a targeted approach with intraoperative parathormone measurement may be worthwhile, if possible.

The breast

LEARNING OBJECTIVES

To understand:

- Appropriate investigation of breast disease
- Breast anomalies and the complexity of benign breast disease
- The in-depth modern management of breast cancer

COMPARATIVE AND SURGICAL ANATOMY

The protuberant part of the human breast is generally described as overlying the second to the sixth ribs and extending from the lateral border of the sternum to the anterior axillary line. Actually, a thin layer of mammary tissue extends considerably further, from the clavicle above to the seventh or eighth ribs below and from the midline to the edge of the latissimus dorsi posteriorly. This fact is important when performing a mastectomy, the aim of which is to remove the whole breast. The anatomy of the breast is illustrated in Fig. 50.1.

The *axillary tail* of the breast is of surgical importance. In some normal subjects it is palpable and, in a few, it can be seen premenstrually or during lactation. A well-developed axillary tail is sometimes mistaken for a mass of enlarged lymph nodes or a lipoma.

The *lobule* is the basic structural unit of the mammary gland. The number and size of the lobules vary enormously: they are most numerous in young women. From 10 to over 100 lobules empty via ductules into a lactiferous duct, of which there are 15–20. Each lactiferous duct is lined with a spiral arrangement of contractile myoepithelial cells and is provided with a terminal ampulla, a reservoir for milk or abnormal discharges.

Figure 50.1 Cross-sectional anatomy of the breast.

The *ligaments of Cooper* are hollow conical projections of fibrous tissue filled with breast tissue; the apices of the cones are attached firmly to the superficial fascia and thereby to the skin overlying the breast. These ligaments account for the dimpling of the skin overlying a carcinoma.

The *areola* contains involuntary muscle arranged in concentric rings as well as radially in the subcutaneous tissue. The areolar epithelium contains numerous sweat glands and sebaceous glands, the latter of which enlarge during pregnancy and serve to lubricate the nipple during lactation (Montgomery's tubercles).

The *nipple* is covered by thick skin with corrugations. Near its apex lie the orifices of the lactiferous ducts. The nipple contains smooth muscle fibres arranged concentrically and longitudinally; thus, it is an erectile structure, which points outwards.

The *lymphatics* of the breast drain predominantly into the axillary and internal mammary lymph nodes. The axillary nodes receive approximately 85% of the drainage and are arranged in the following groups:

- *lateral*, along the axillary vein;
- *anterior*, along the lateral thoracic vessels;
- *posterior*, along the subscapular vessels;
- *central*, embedded in fat in the centre of the axilla;
- *interpectoral*, a few nodes lying between the pectoralis major and minor muscles;
- *apical*, which lie above the level of the pectoralis minor tendon in continuity with the lateral nodes and which receive the efferents of all the other groups.

The apical nodes are also in continuity with the supraclavicular nodes and drain into the subclavian lymph trunk, which enters the great veins directly or via the thoracic duct or jugular trunk. The *sentinel node* is defined as the first lymph node draining the tumour-bearing area of the breast. The importance of the sentinel node is described later.

Sir Astley Paston Cooper, 1768–1841, Surgeon, Guy's Hospital, London, England, described these ligaments in 1845.
William Fetherston Montgomery, 1797–1859, Obstetrician, Dublin, Ireland, described these tubercles in 1837.

The internal mammary nodes are fewer in number. They lie along the internal mammary vessels deep to the plane of the costal cartilages, drain the posterior third of the breast and are not routinely dissected although they were at one time biopsied for staging.

INVESTIGATION OF BREAST SYMPTOMS

Although an accurate history and clinical examination are important methods of detecting breast disease, there are a number of investigations that can assist in the diagnosis. Examination precedes palpation and requires careful observation of the patient both with the arms at rest and also elevated to lift the breast. Small lesions may betray their presence by dimpling or minor distortions when the patient moves.

Mammography

Soft tissue radiographs are taken by placing the breast in direct contact with ultrasensitive film and exposing it to low-voltage, high-amperage X-rays (Fig. 50.2). The dose of radiation is approximately 0.1 cGy and, therefore, mammography is a very safe investigation.

Figure 50.2 Mammogram showing a carcinoma.

Cy is short for Gray, the SI unit for the absorbed dose of ionizing radiation. Louis Harold Gray, 1905–1965, Director, The British Empire Cancer Campaign Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, Middlesex, England.

The sensitivity of this investigation increases with age as the breast becomes less dense. In total, 5% of breast cancers are missed by population-based mammographic screening programmes; even in retrospect, such carcinomas are not apparent. Thus, a normal mammogram does not exclude the presence of carcinoma. Digital mammography is being introduced, which allows manipulation of the images and computer-aided diagnosis. Tomo-mammography is also being assessed as a more sensitive diagnostic modality.

Ultrasound

Ultrasound is particularly useful in young women with dense breasts in whom mammograms are difficult to interpret, and in distinguishing cysts from solid lesions (Figs 50.3 and 50.4). It can also be used to localise impalpable areas of breast pathology. It is not useful as a screening tool and remains operator dependent. Increasingly, ultrasound of the axillary tissue is performed when a cancer is diagnosed and guided percutaneous biopsy of any suspicious glands may be performed.

Figure 50.3 Ultrasound of the breast showing a cyst (arrow).

Figure 50.4 Ultrasound of the breast showing a carcinoma (arrow).

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is of increasing interest to breast surgeons in a number of settings:

- It can be useful to distinguish scar from recurrence in women who have had previous breast conservation therapy for cancer (although it is not accurate within 9 months of radiotherapy because of abnormal enhancement).
- It is the best imaging modality for the breasts of women with implants.
- It has proven to be useful as a screening tool in high-risk women (because of family history).
- It is less useful than ultrasound in the management of the axilla in both primary breast cancer and recurrent disease (Fig. 50.5).

Although biopsies can be performed with MRI guidance this is complicated because of the configuration of the imaging system. With improved ultrasound equipment, an MRI-detected lesion can often be found on a second-look ultrasound and biopsied using this modality.

Needle biopsy/cytology

Histology can be obtained under local anaesthesia using a spring-loaded core needle biopsy device (Fig. 50.6). Cytology is obtained using a 21G or 23G needle and 10-ml syringe with multiple passes through the lump with negative pressure in the syringe. The aspirate is then smeared on to a slide, which is air dried or fixed (Fig. 50.7). Fine-needle aspiration cytology (FNAC) is the least invasive technique of obtaining a cell diagnosis and is rapid

Figure 50.6 Corecut biopsy of breast.

and very accurate if both operator and cytologist are experienced. However, false negatives do occur, mainly through sampling error, and invasive cancer cannot be distinguished from *in situ* disease. A histological specimen taken by core biopsy allows a definitive preoperative diagnosis, differentiates between duct carcinoma *in situ* (DCIS) and invasive disease and also allows the tumour to be stained for receptor status. This is important before commencing neoadjuvant therapy.

Large-needle biopsy with vacuum systems

The sampling error decreases as the biopsy volume increases and using 8G or 11G needles allows more extensive biopsies to be taken. This is useful in the management of microcalcifications or in the complete excision of benign lesions such as fibroadenomas.

Triple assessment

In any patient who presents with a breast lump or other symptoms suspicious of carcinoma, the diagnosis should be made by a combination of clinical assessment, radiological imaging and a tissue sample taken for either cytological or histological analysis (Fig. 50.8), the so called triple assessment. The positive predictive value (PPV) of this combination should exceed 99.9%.

Figure 50.7 Fine-needle aspiration cytology (FNAC) showing grade III ductal carcinoma cells.

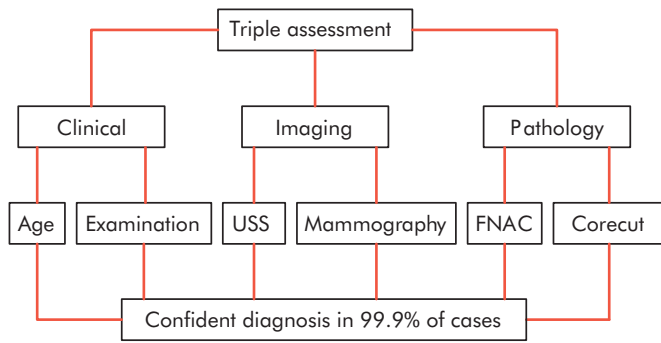

Figure 50.8 Triple assessment of breast symptoms. USS, ultrasound scan.

THE NIPPLE

Absence of the nipple is rare and is usually associated with amazia (congenital absence of the breast).

Supernumerary nipples not uncommonly occur along a line extending from the anterior fold of the axilla to the fold of the groin (Fig. 50.9). This constitutes the milk line of lower mammals.

Nipple retraction

This may occur at puberty or later in life. Retraction occurring at puberty, also known as *simple nipple inversion*, is of unknown aetiology (benign horizontal inversion). In about 25% of cases it is bilateral. It may cause problems with breast-feeding and infection can occur, especially during lactation, because of retention of secretions. Recent retraction of the nipple may be of considerable pathological significance. A slit-like retraction of the nipple may be caused by duct ectasia and chronic periductal mastitis (Fig. 50.10a), but circumferential retraction, with or without an underlying lump, may well indicate an underlying carcinoma (Fig. 50.10b).

Figure 50.9 Accessory nipple with congenital retraction of the normal nipple.

Figure 50.10 Recent nipple retraction. (a) Slit-like retraction of duct ectasia with mammary duct fistula. (b) Circumferential retraction with underlying carcinoma.

Treatment

Treatment is usually unnecessary and the condition may spontaneously resolve during pregnancy or lactation.

Simple cosmetic surgery can produce an adequate correction but has the drawback of dividing the underlying ducts. Mechanical suction devices have been used to evert the nipple, with some effect.

Cracked nipple

This may occur during lactation and be the forerunner of acute infective mastitis. If the nipple becomes cracked during lactation, it should be rested for 24–48 hours and the breast should be emptied with a breast pump. Feeding should be resumed as soon as possible.

Papilloma of the nipple

Papilloma of the nipple has the same features as any cutaneous papilloma and should be excised with a tiny disc of skin. Alternatively, the base may be tied with a ligature and the papilloma will spontaneously fall off.

Retention cyst of a gland of Montgomery

These glands, situated in the areola, secrete sebum and if they become blocked a sebaceous cyst forms.

Eczema

Eczema of the nipples is a rare condition and is often bilateral; it is usually associated with eczema elsewhere on the body. It is treated with 0.5% hydrocortisone (not a stronger steroid preparation).

Paget's disease

Paget's disease of the nipple must be distinguished from eczema. The former is caused by malignant cells in the subdermal layer. Eczema tends to occur in younger people who have signs of eczema elsewhere (look at the antecubital fossae).

Discharges from the nipple

Discharge can occur from one or more lactiferous ducts. Management depends on the presence of a lump (which should always be given priority in diagnosis and treatment) and the presence of blood in the discharge or discharge from a single duct. Mammography is rarely useful except to exclude an underlying impalpable mass. Cytology may reveal malignant cells but a negative result does not exclude a carcinoma.

- A *clear, serous discharge* may be 'physiological' in a parous woman or may be associated with a duct papilloma or mammary dysplasia. Multiduct, multicoloured discharge is physiological and the patient may be reassured.
- A *blood-stained discharge* may be caused by duct ectasia, a duct papilloma or carcinoma. A duct papilloma is usually single and situated in one of the larger lactiferous ducts; it is sometimes associated with a cystic swelling beneath the areola.
- A *black or green discharge* is usually the result of duct ectasia and its complications (Summary box 50.1).

Summary box 50.1

Discharges from the nipple (the principal causes are italicised)

Discharge from the surface

- Paget's disease
- Skin diseases (eczema, psoriasis)
- Rare causes (e.g. chancre)

Discharge from a single duct

Blood-stained:

- *Intraduct papilloma*
- *Intraduct carcinoma*
- Duct ectasia

Serous (any colour):

- *Fibrocystic disease*
- *Duct ectasia*
- Carcinoma

Discharge from more than one duct

Blood-stained:

- *Carcinoma*
- Ectasia
- Fibrocystic disease

Black or green:

- *Duct ectasia*

Purulent:

- *Infection*

Serous:

- *Fibrocystic disease*
- Duct ectasia
- Carcinoma

Milk:

- *Lactation*
- Rare causes (hypothyroidism, pituitary tumour)

Sir James Paget, 1814–1899, Surgeon, St. Bartholomew's Hospital, London, England, described this disease of the nipple in 1874.

Treatment

Treatment must firstly be to exclude a carcinoma by occult blood test and cytology. Simple reassurance may then be sufficient but, if the discharge is proving intolerable, an operation to remove the affected duct or ducts can be performed (microdochectomy).

Microdochectomy

It is important not to express the blood before the operation as it may then be difficult to identify the duct in theatre. A lacrimal probe or length of stiff nylon suture is inserted into the duct from which the discharge is emerging. A tennis racquet incision can be made to encompass the entire duct or a periareolar incision used and the nipple flap dissected to reach the duct. The duct is then excised. A papilloma is nearly always situated within 4–5 cm of the nipple orifice.

Ductoscopy (inspection of the internal structure of the duct system) using microendoscopes is technically feasible but generally disappointing. The affected duct may not be visualised and biopsy systems are currently rudimentary.

Cone excision of the major ducts (after Hadfield)

When the duct of origin of nipple bleeding is uncertain or when there is bleeding or discharge from multiple ducts, the entire major duct system can be excised for histological examination without sacrifice of the breast form. A periareolar incision is made and a cone of tissue is removed with its apex just deep to the surface of the nipple and its base on the pectoral fascia. The resulting defect may be obliterated by a series of purse-string sutures although a temporary suction drain will reduce the chance of long-term deformity. It is vital to warn the patient that she will be unable to breast-feed after this and may experience altered nipple sensation.

BENIGN BREAST DISEASE

This is the most common cause of breast problems; up to 30% of women will suffer from a benign breast disorder requiring treatment at some time in their lives. The most common symptoms are pain, lumpiness or a lump. The aim of treatment is to exclude cancer and, once this has been done, to treat any remaining symptoms.

Congenital abnormalities

Amazia

Congenital absence of the breast may occur on one (Fig. 50.11) or both sides. It is sometimes associated with absence of the sternal portion of the pectoralis major (Poland's syndrome). It is more common in males.

Polymazia

Accessory breasts (Fig. 50.12) have been recorded in the axilla (the most frequent site), groin, buttock and thigh. They have been known to function during lactation.

Mastitis of infants

Mastitis of infants is at least as common in boys as in girls. On the third or fourth day of life, if the breast of an infant is pressed

Geoffrey John Hadfield, Surgeon, Stoke Mandeville Hospital, Aylesbury, Buckinghamshire, England.

Alfred Poland, 1822–1872, Surgeon, Guy's Hospital, London, England described this condition in 1841.

Figure 50.11 Congenital absence of the right breast.

Figure 50.12 Bilateral accessory breasts.

lightly, a drop of colourless fluid can be expressed; a few days later, there is often a slight milky secretion, which disappears during the third week. This is popularly known as 'witch's milk' and is seen only in full-term infants. It is caused by stimulation of the fetal breast by prolactin in response to the drop in maternal oestrogens and is essentially physiological. True mastitis is uncommon and is predominately caused by *Staphylococcus aureus*.

Diffuse hypertrophy

Diffuse hypertrophy of the breasts occurs sporadically in otherwise healthy girls at puberty (benign virginal hypertrophy) and, much less often, during the first pregnancy. The breasts attain enormous dimensions and may reach the knees when the patient is sitting. The condition is rarely unilateral. This tremendous overgrowth is apparently caused by an alteration in the normal sensitivity of the breast to oestrogenic hormones and some success in treating it with anti-oestrogens has been reported. Treatment is otherwise by reduction mammoplasty.

Injuries of the breast

Haematoma

Haematoma, particularly a resolving haematoma, gives rise to a lump, which, in the absence of overlying bruising, is difficult to diagnose correctly unless it is biopsied.

Traumatic fat necrosis

Traumatic fat necrosis may be acute or chronic and usually occurs in stout, middle-aged women. Following a blow, or even indirect violence (e.g. contraction of the pectoralis major), a lump, often painless, appears. This may mimic a carcinoma, even displaying skin tethering and nipple retraction, and biopsy is required for diagnosis. A history of trauma is not diagnostic as this may merely have drawn the patient's attention to a pre-existing lump. A seatbelt may transect the breast with a sudden deceleration injury, as in a road traffic accident.

Acute and subacute inflammations of the breast

Bacterial mastitis

Bacterial mastitis is the most common variety of mastitis and is associated with lactation in the majority of cases.

Aetiology

Lactational mastitis is seen far less frequently than in former years. Most cases are caused by *Staphylococcus aureus* and, if hospital acquired, are likely to be penicillin resistant. The intermediary is usually the infant; after the second day of life, 50% of infants harbour staphylococci in the nasopharynx.

Although ascending infection from a sore and cracked nipple may initiate the mastitis, in many cases the lactiferous ducts will first become blocked by epithelial debris leading to stasis; this theory is supported by the relatively high incidence of mastitis in women with a retracted nipple. Once within the ampulla of the duct, staphylococci cause clotting of milk and, within this clot, organisms multiply.

Clinical features

The affected breast, or more usually a segment of it, presents the classical signs of acute inflammation. Early on this is a generalised cellulitis but later an abscess will form.

Treatment

During the cellulitic stage the patient should be treated with an appropriate antibiotic, for example flucloxacillin or co-amoxiclav. Feeding from the affected side may continue if the patient can manage. Support of the breast, local heat and analgesia will help to relieve pain.

If an antibiotic is used in the presence of undrained pus, an 'antibioma' may form. This is a large, sterile, brawny oedematous swelling that takes many weeks to resolve.

It used to be recommended that the breast should be incised and drained if the infection did not resolve within 48 hours or if after being emptied of milk there was an area of tense induration or other evidence of an underlying abscess. This advice has been replaced with the recommendation that repeated aspirations under antibiotic cover (if necessary using ultrasound) be performed. This often allows resolution without the need for an incision scar and will also allow the patient to carry on breast-feeding.

The presence of pus can be confirmed with needle aspiration and the pus sent for bacteriological culture. In contrast to the

majority of localised infections, fluctuation is a late sign. Usually, the area of induration is sector shaped and, in early cases, about one-quarter of the breast is involved (Fig. 50.13); in many late cases the area is more extensive (Fig. 50.14). When in doubt an ultrasound scan may clearly define an area suitable for drainage.

Operative drainage of a breast abscess

This is less commonly needed as prompt commencement of antibiotics and repeated aspiration is usually successful. Incision of a lactational abscess is necessary if there is marked skin thinning and can usually be performed under local anaesthesia if an analgesic cream such as EMLA (lidocaine) is applied 30 min before surgery.

The usual incision is sited in a radial direction over the affected segment, although if a circumareolar incision will allow adequate access to the affected area this is preferred because it gives a better cosmetic result. The incision passes through the skin and the superficial fascia. A long artery forceps is then inserted into the abscess cavity. Every part of the abscess is palpated against the point of the artery forceps and its jaws are opened. All loculi that can be felt are entered.

Finally, the artery forceps having been withdrawn, a finger is introduced and any remaining septa are disrupted. The wound may then be lightly packed with ribbon gauze or a drain inserted to allow dependent drainage.

Figure 50.13 Intramammary breast abscess.

Figure 50.14 Large breast abscess.

Chronic intramammary abscess

A chronic intramammary abscess, which may follow inadequate drainage or injudicious antibiotic treatment, is often a very difficult condition to diagnose. When encapsulated within a thick wall of fibrous tissue the condition cannot be distinguished from a carcinoma without the histological evidence from a biopsy.

Tuberculosis of the breast

Tuberculosis of the breast, which is comparatively rare, is usually associated with active pulmonary tuberculosis or tuberculous cervical adenitis.

Tuberculosis of the breast (Fig. 50.15) occurs more often in parous women and usually presents with multiple chronic abscesses and sinuses and a typical bluish, attenuated appearance of the surrounding skin. The diagnosis rests on bacteriological and histological examination. Treatment is with anti-tuberculous chemotherapy. Healing is usual, although often delayed, and mastectomy should be restricted to patients with persistent residual infection.

Actinomycosis

Actinomycosis of the breast is rarer still. The lesions present the essential characteristics of faciocervical actinomycosis.

Mondor's disease

Mondor's disease is thrombophlebitis of the superficial veins of the breast and anterior chest wall (Fig. 50.16), although it has also been encountered in the arm.

In the absence of injury or infection, the cause of thrombophlebitis (like that of spontaneous thrombophlebitis in other sites) is obscure. The pathognomonic feature is a thrombosed subcutaneous cord, usually attached to the skin. When the skin over the breast is stretched by raising the arm, a narrow, shallow subcutaneous groove alongside the cord becomes apparent. The differential diagnosis is lymphatic permeation from an occult

Figure 50.15 Tuberculosis of the breast with secondary suppurating axillary lymph nodes (courtesy of Professor A.K. Toufeeq, Lahore, Pakistan).

Henri Mondor, 1885–1962, Professor of Surgery, Paris, France.

Figure 50.16 Mondor's disease under the right breast (arrow).

carcinoma of the breast. The only treatment required is restricted arm movements and, in any case, the condition subsides within a few months without recurrence, complications or deformity. There are case reports of Mondor's disease being associated with subsequent development of malignancy although this has been unsubstantiated by others and is thought to be coincidental.

Duct ectasia/periductal mastitis

Pathology

This is a dilatation of the breast ducts, which is often associated with periductal inflammation. The pathogenesis is obscure and almost certainly not uniform in all cases, although the disease is much more common in smokers.

The classical description of the pathogenesis of duct ectasia asserts that the first stage in the disorder is a dilatation in one or more of the larger lactiferous ducts, which fill with a stagnant brown or green secretion. This may discharge. These fluids then set up an irritant reaction in surrounding tissue leading to periductal mastitis or even abscess and fistula formation (Figs 50.17 and 50.18). In some cases, a chronic indurated mass forms beneath the areola, which mimics a carcinoma. Fibrosis eventually develops, which may cause slit-like nipple retraction.

An alternative theory suggests that periductal inflammation is the primary condition and, indeed, anaerobic bacterial infection is found in some cases. A marked association between recurrent

Figure 50.17 Subareolar abscess in duct ectasia.

Figure 50.18 Mammary fistula originating in a chronic subareolar abscess.

periductal inflammation and smoking has been demonstrated. This was thought by some to indicate that arteriopathy is a contributing factor in its aetiology although others believe that smoking increases the virulence of the commensal bacteria. It is certainly clear that cessation of smoking increases the chance of a long-term cure.

Clinical features

Nipple discharge (of any colour), a subareolar mass, abscess, mammary duct fistula and/or nipple retraction are the most common symptoms.

Treatment

In the case of a mass or nipple retraction, a carcinoma must be excluded by obtaining a mammogram and negative cytology or histology. If any suspicion remains the mass should be excised.

Antibiotic therapy may be tried, the most appropriate agents being co-amoxiclav or flucloxacillin and metronidazole. However, surgery is often the only option likely to bring about cure of this notoriously difficult condition; this consists of excision of all of the major ducts (Hadfield's operation). It is particularly important to shave the back of the nipple to ensure that all terminal ducts are removed. Failure to do so will lead to recurrence.

Aberrations of normal development and involution

Nomenclature

The nomenclature of benign breast disease is confusing. This is because over the last century a variety of clinicians and pathologists have chosen to describe a mixture of physiological changes and disease processes according to a variety of clinical, pathological and aetiological terminology. As well as leading to confusion, patients were often unduly alarmed or overtreated by ascribing a pathological name to a variant of physiological development. To sort out this confusion, a new system [Aberrations of Normal Development and Involution (ANDI)] has been developed and described by the Cardiff Breast Clinic. (Many alternative terms have been applied to this condition, including fibrocystic disease, fibroadenosis, chronic mastitis and mastopathy.)

Aetiology

The breast is a dynamic structure that undergoes changes throughout a woman's reproductive life and, superimposed upon this, cyclical changes throughout the menstrual cycle. This is illustrated in Fig. 50.19. The pathogenesis of ANDI involves disturbances in the breast physiology extending from a perturbation of normality to well-defined disease processes. There is often little correlation between the histological appearance of the breast tissue and the symptoms.

Pathology

The disease consists essentially of four features that may vary in extent and degree in any one breast.

- *Cyst formation.* Cysts are almost inevitable and very variable in size.
- *Fibrosis.* Fat and elastic tissues disappear and are replaced with dense white fibrous trabeculae. The interstitial tissue is infiltrated with chronic inflammatory cells.
- *Hyperplasia* of epithelium in the lining of the ducts and acini may occur, with or without atypia.
- *Papillomatosis.* The epithelial hyperplasia may be so extensive that it results in papillomatous overgrowth within the ducts.

Clinical features

The symptoms of ANDI are many as the term is used to encompass a wide range of benign conditions, but often include an area of lumpiness (seldom discrete) and/or breast pain (mastalgia).

- A benign discrete lump in the breast is commonly a cyst or fibroadenoma. True lipomas occur rarely.
- Lumpiness may be bilateral, commonly in the upper outer quadrant or, less commonly, confined to one quadrant of one breast. The changes may be cyclical, with an increase in both lumpiness and often tenderness before a menstrual period.
- Non-cyclical mastalgia is more common in peri-menopausal than post-menopausal women. It may be associated with ANDI or with periductal mastitis. It should be distinguished from referred pain, for example a musculoskeletal disorder. 'Breast' pain in post-menopausal women not taking hormone-replacement therapy (HRT) is usually derived from the chest wall.

About 5% of breast cancers exhibit pain at presentation.

Treatment of lumpy breasts

If the clinician is confident that he or she is not dealing with a discrete abnormality (and clinical confidence is supported by mammography and/or ultrasound scanning if appropriate), then initially the woman can be offered firm reassurance. It is perhaps

Figure 50.19 Normal breast changes throughout life. UK National Health Service Breast Screening Programme data.

worthwhile reviewing the patient at a different point in the menstrual cycle, for example 6 weeks after the initial visit, and often the clinical signs will have resolved by that time. There is a tendency for women with lumpy breasts to be rendered unnecessarily anxious and to be submitted to multiple random biopsies because the clinician lacks the courage of his or her convictions.

Treatment of mastalgia

Pronounced cyclical mastalgia may become a significant clinical problem if the pain and tenderness interfere with the woman's life, disturb her sleep and impair sexual activity. Initially, firm reassurance that the symptoms are not associated with cancer will help the majority of women. Acknowledgement that this is a real symptom, a non-dismissive attitude and an explanation of the aetiology are all helpful in managing this condition.

In the first instance, an appropriately fitting and supportive bra should be worn throughout the day and a soft bra (such as a sports bra) worn at night. Avoiding caffeine drinks is said to help, although the author remains unconvinced.

A patient symptom diary will help her to chart the pattern of pain throughout the month and thus determine whether this is cyclical mastalgia. This allows the majority of patients to adjust to the concept of a cyclical nature of their problem but, if reassurance is inadequate, then a planned escalation of treatment (Table 50.1) could be advised. Oil of evening primrose, in adequate doses given over 3 months, will help more than half of these women. It appears to achieve higher response rates in those over 40 years of age rather than younger women. For those with intractable symptoms, an anti-gonadotrophin, such as danazol, or a prolactin inhibitor, such as bromocriptine, may be tried. Very rarely it is necessary to prescribe an anti-oestrogen, for example

Table 50.1 Treatment of breast pain

Exclude cancer	
Reassure	Use pain chart if unsure if cyclical or non-cyclical. Also allows time for reassurance to become active!
Adequate support	Firm bra during the day and a softer bra at night
Exclude caffeine	Works for some although not very efficacious in author's practice
Consider medication	
Evening primrose oil (GLA)	Better effect in women over 40 years old than in younger women
Danazol, 100 mg t.d.s.	Start at 100 mg per day and increase (seldom used these days)
Tamoxifen	Not licensed for this indication but occasionally very helpful

tamoxifen, or a luteinising hormone-releasing hormone (LHRH) agonist to deprive the breast epithelium of oestrogenic drive. Ablative surgery should never be contemplated for breast pain and any patient seeking this treatment should be referred to a psychiatrist.

For non-cyclical mastalgia it is important to exclude extramammary causes such as chest wall pain. This is common in postmenopausal women who are not on HRT and the neck and shoulders are common sites of referred pain. It is seldom necessary these days to carry out a biopsy on a very localised tender area that might be harbouring a subclinical cancer as imaging is so much better. Treatment may be with non-steroidal analgesics or by injection with local anaesthetic on a 'trigger spot'.

Breast cysts

These occur most commonly in the last decade of reproductive life as a result of a non-integrated involution of stroma and epithelium. They are often multiple, may be bilateral and can mimic malignancy. Diagnosis can be confirmed by aspiration and/or ultrasound. They typically present suddenly and cause great alarm; prompt diagnosis and drainage provides immediate relief.

Treatment

A solitary cyst or small collection of cysts can be aspirated. If they resolve completely, and if the fluid is not blood-stained, no further treatment is required. However, 30% will recur and require reaspiration. Cytological examination of cyst fluid is no longer practised routinely. If there is a residual lump or if the fluid is blood-stained, a core biopsy or local excision for histological diagnosis is advisable, which is also the case if the cyst reforms repeatedly. This will exclude cystadenocarcinoma, which is more common in elderly women.

Galactocele

Galactocele, which is rare, usually presents as a solitary, subareolar cyst and always dates from lactation. It contains milk and in longstanding cases its walls tend to calcify.

Fibroadenoma

These usually arise in the fully developed breast between the ages of 15 and 25 years, although occasionally they occur in much older women. They arise from hyperplasia of a single lobule and usually grow up to 2–3 cm in size. They are surrounded by a well-marked capsule and can thus be enucleated through a cosmetically appropriate incision. A fibroadenoma does not require excision unless associated with suspicious cytology, it becomes very large or the patient expressly desires the lump to be removed.

Giant fibroadenomas occasionally occur during puberty. They are over 5 cm in diameter and are often rapidly growing but, in other respects, are similar to smaller fibroadenomas and can be enucleated through a submammary incision. They are more common in the Afro-Caribbean population.

Phyllodes tumour

These benign tumours, previously sometimes known as serocystic disease of Brodie or cystosarcoma phyllodes, usually occur in women over the age of 40 years but can appear in younger

women. They present as a large, sometimes massive, tumour with an unevenly bosselated surface. Occasionally, ulceration of overlying skin occurs because of pressure necrosis. Despite their size they remain mobile on the chest wall. Histologically, there is a wide variation in their appearance, with some of low malignant potential resembling a fibroadenoma and others having a higher mitotic index, which are histologically worrying. The latter may recur locally but, despite the name of cystosarcoma phyllodes, they are rarely cystic and only very rarely develop features of a sarcomatous tumour. These may metastasise via the bloodstream.

Treatment

Treatment for the benign type is enucleation in young women or wide local excision. Massive tumours, recurrent tumours and those of the malignant type will require mastectomy (Summary box 50.2).

Summary box 50.2

Benign breast disorder classification

Congenital disorders

- Inverted nipple
- Supernumerary breasts/nipples
- Non-breast disorders
- Tietze's disease (costochondritis)
- Sebaceous cysts and other skin conditions

Injury

Inflammation/infection

ANDI (aberations of normal differentiation and involution):

- Cyclical nodularity and mastalgia
- Cysts
- Fibroadenoma
- Duct ectasia/periductal mastitis

Pregnancy-related:

- Galactocele
- Puerperal abscess

When the diagnosis of carcinoma is in doubt

There will always be cases when the clinician cannot be sure whether a particular lump in the breast is an area of mammary dysplasia, a benign tumour or an early carcinoma.

If there is doubt on clinical, cytological or radiological examination, it is essential to obtain a tissue diagnosis. This is often possible by needle biopsy. In the event of a negative result, open biopsy of the mass is necessary. Because of the possibility of reporting errors and because the histology is likely to be more difficult (if a diagnosis has not already been made), the author suggests that frozen-section reporting should be used rarely and certainly should not form the basis for a decision to undertake a mastectomy. Table 50.2 gives an algorithm for investigating any breast lump.

Risk of malignancy developing in association with benign breast pathology

The relative risks of malignancy developing according to different histological features found at biopsy are illustrated in Table 50.3.

Sir Benjamin Collins Brodie, 1783–1862, Surgeon, St. George's Hospital, London, England, described serocystic disease of the breast in 1840.

Alexander Tietze, 1864–1927, Professor of Surgery, Breslau, Germany (now Wrocław, Poland), described this condition in 1921.

Table 50.2 Investigation of a breast lump (after imaging performed) using fine-needle aspiration with cytology

Cystic	Lump disappears; clear fluid (many colours) Residual thickening; blood-stained fluid	Discharge patient Investigate – ?core biopsy
Solid	Benign Atypical Malignant	Offer excision or observe Investigate – ?core biopsy Treat for cancer

These were elucidated 30 years ago but remain pertinent and a recent single-centre review reinforces the conclusion that the histological classification of the benign lesion in combination with a family history of breast cancer are important predictors of risk.

CARCINOMA OF THE BREAST

Breast cancer is the most common cause of death in middle-aged women in western countries. In 2004 approximately one and a half million new cases were diagnosed worldwide. In England and Wales, 1 in 12 women will develop the disease during their lifetime.

Aetiological factors

Geographical

Carcinoma of the breast occurs commonly in the western world, accounting for 3–5% of all deaths in women. In developing countries it accounts for 1–3% of deaths.

Age

Carcinoma of the breast is extremely rare below the age of 20 years but, thereafter, the incidence steadily rises so that by the age of 90 years nearly 20% of women are affected.

Gender

Less than 0.5% of patients with breast cancer are male.

Genetic

It occurs more commonly in women with a family history of breast cancer than in the general population. Breast cancer

related to a specific mutation accounts for about 5% of breast cancers yet has far-reaching repercussions in terms of counselling and tumour prevention in these women. This will be discussed more fully in a subsequent section.

Diet

Because breast cancer so commonly affects women in the ‘developed’ world, dietary factors may play a part in its causation. There is some evidence that there is a link with diets low in phytoestrogens. A high intake of alcohol is associated with an increased risk of developing breast cancer.

Endocrine

Breast cancer is more common in nulliparous women and breast-feeding in particular appears to be protective. Also protective is having a first child at an early age, especially if associated with late menarche and early menopause. It is known that in post-menopausal women, breast cancer is more common in the obese. This is thought to be because of an increased conversion of steroid hormones to oestradiol in the body fat. Recent studies have clarified the role of exogenous hormones, in particular the oral contraceptive pill and HRT, in the development of breast cancer. For most women the benefits of these treatments will far outweigh the small putative risk; however, long-term exposure to the combined preparation of HRT does significantly increase the risk of developing breast cancer.

Previous radiation

This was considered to be of historical interest, with the majority of women exposed to the atomic bombs at Hiroshima and

Table 50.3 Relative risk of invasive breast carcinoma based on pathological examination of benign breast tissue (American College of Pathologists Consensus Statement)^a

No increased risk	Adenosis, sclerosing or florid Apocrine metaplasia Cysts, macro and/or micro Duct ectasia Fibroadenoma Fibrosis Hyperplasia Mastitis (inflammation) Periductal mastitis Squamous metaplasia
Slightly increased risk (1.5–2 times)	Hyperplasia, moderate or florid, solid or papillary Papilloma with a fibrovascular core
Moderately increased risk (5 times)	Atypical hyperplasia (ductal or lobular)
Insufficient data to assign a risk	Solitary papilloma of lactiferous sinus Radial scar lesion

After Page and Dupont (1978) by kind permission of the *Journal of the National Cancer Institute*, USA.

^a A combination with positive family history significantly increases the risks shown above.

Nagasaki having died. It is, however, a real problem in women who have been treated with mantle radiotherapy as part of the management of Hodgkin's disease, in which significant doses of radiation to the breast are received. The risk appears about a decade after treatment and is higher if radiotherapy occurred during breast development. A surveillance programme has been organised in the UK with MRI and mammographic screening.

Pathology

Breast cancer may arise from the epithelium of the duct system anywhere from the nipple end of the major lactiferous ducts to the terminal duct unit, which is in the breast lobule. The disease may be entirely *in situ*, an increasingly common finding with the advent of breast cancer screening, or may be invasive cancer. The degree of differentiation of the tumour is usually described using three grades: well differentiated, moderately differentiated or poorly differentiated. Commonly, a numerical grading system based on the scoring of three individual factors (nuclear pleomorphism, tubule formation and mitotic rate) is used, with grade III cancers roughly equating to the poorly differentiated group.

Previously, descriptive terms were used to classify breast cancer ('scirrhous', meaning woody, or 'medullary', meaning brain-like). More recently, histological descriptions have been used. These have been shown to have clinical correlations in the way that the tumour behaves and are likely to be used for the near future. However, with the increasing application of molecular markers there will be a change in the way that breast cancers are classified and it is likely that much more information about an individual tumour will be routinely reported, such as its likelihood of metastasis and to which therapeutic agents it will be susceptible. Gene array analysis of breast cancers has identified five subtypes. Some of these correlate with known markers such as oestrogen receptor status. There are specific gene signatures that are said to correlate with response to chemotherapy or poor prognosis; trials based upon these differences are planned. A typical result of a multigene array is shown in Fig. 50. 20.

Current nomenclature

Ductal carcinoma is the most common variant with *lobular carcinoma* occurring in up to 15% of cases. There are subtypes of lobular cancer including the classical type, which carries a better prognosis than the pleomorphic type. Occasionally, the

Figure 50.20 Gene array heat map of breast cancers.

Thomas Hodgkin, 1798–1866, Curator of the Museum, and Demonstrator of Morbid Anatomy, Guy's Hospital, London, England.

picture may be mixed with both ductal and lobular features. There are different patterns of spread depending on histological type. If there is doubt whether a tumour is predominantly lobular in type, immunohistochemical analysis using the e-cadherin antibody, which reacts positively in lobular cancer, will help in diagnosis.

Rarer histological variants, usually carrying a better prognosis, include *colloid carcinoma*, whose cells produce abundant mucin, *medullary carcinoma*, with solid sheets of large cells often associated with a marked lymphocytic reaction, and *tubular carcinoma*. Invasive lobular carcinoma is commonly multifocal and/or bilateral. Cases detected via the screening programme are often smaller and better differentiated than those presenting to the symptomatic service and are of a special type.

Inflammatory carcinoma is a fortunately rare, highly aggressive cancer that presents as a painful, swollen breast, which is warm with cutaneous oedema. This is the result of blockage of the subdermal lymphatics with carcinoma cells. Inflammatory cancer usually involves at least one-third of the breast and may mimic a breast abscess. A biopsy will confirm the diagnosis and show undifferentiated carcinoma cells. It used to be rapidly fatal but with aggressive chemotherapy and radiotherapy and with salvage surgery the prognosis has improved considerably.

In situ carcinoma is pre-invasive cancer that has not breached the epithelial basement membrane. This was previously a rare, usually asymptomatic, finding in breast biopsy specimens but is becoming increasingly common because of the advent of mammographic screening; it now accounts for over 20% of cancers detected by screening in the UK. *In situ carcinoma* may be ductal (DCIS) or lobular (LCIS), the latter often being multifocal and bilateral. Both are markers for the later development of invasive cancer, which will develop in at least 20% of patients. Although mastectomy is curative, this constitutes overtreatment in many cases. The best treatment for *in situ carcinoma* is the subject of a number of on-going clinical trials. DCIS may be classified using the Van Nuys system, which combines the patient's age, type of DCIS and presence of microcalcification, extent of resection margin and size of disease. Patients with a high score benefit from radiotherapy after excision, whereas those of low grade, whose tumour is completely excised, need no further treatment.

Staining for oestrogen and progesterone receptors is now considered routine, as their presence will indicate the use of adjuvant hormonal therapy with tamoxifen or the newer aromatase inhibitors (Fig 50.21). Tumours are also stained for c-erbB2 (a growth factor receptor) as patients who are positive can be treated with the monoclonal antibody trastuzumab (Herceptin), either in the adjuvant or relapse setting.

The pathologist is an important member of the breast cancer team and will increasingly help decide which adjuvant therapies will be appropriate.

Paget's disease of the nipple

Paget's disease of the nipple (Fig. 50.22a and b) is a superficial manifestation of an underlying breast carcinoma. It presents as an eczema-like condition of the nipple and areola, which persists despite local treatment. The nipple is eroded slowly and eventually disappears. If left, the underlying carcinoma will sooner or later become clinically evident. Nipple eczema should be biopsied if there is any doubt about its cause. Microscopically, Paget's disease is characterised by the presence of large, ovoid cells with

Figure 50.21 Immunohistochemical staining for oestrogen receptors.

abundant, clear, pale-staining cytoplasm in the Malpighian layer of the epidermis.

The spread of breast cancer

Local spread

The tumour increases in size and invades other portions of the breast. It tends to involve the skin and to penetrate the pectoral muscles and even the chest wall if diagnosed late.

Lymphatic metastasis

Lymphatic metastasis occurs primarily to the axillary and the internal mammary lymph nodes. Tumours in the posterior one-third of the breast are more likely to drain to the internal mammary nodes. The involvement of lymph nodes has both biological and chronological significance. It represents not only an evolutionary event in the spread of the carcinoma but is also a marker for the metastatic potential of that tumour. Involvement of supraclavicular nodes and of any contralateral lymph nodes represents advanced disease.

Spread by the bloodstream

It is by this route that skeletal metastases occur, although the initial spread may be via the lymphatic system. In order of frequency the lumbar vertebrae, femur, thoracic vertebrae, rib and skull are affected and these deposits are generally osteolytic. Metastases may also commonly occur in the liver, lungs and brain and, occasionally, the adrenal glands and ovaries; they have, in fact, been described in most body sites.

Clinical presentation

Although any portion of the breast, including the axillary tail, may be involved, breast cancer is found most frequently in the upper outer quadrant (Figs 50.23 and 50.24). Most breast cancers will present as a hard lump, which may be associated with indrawing of the nipple. As the disease advances locally there may be skin involvement with peau d'orange (Fig. 50.25) or frank

Marcello Malpighi, 1628–1694, Professor of Physic successively at Bologna, Pisa and Messina, and in 1691 Physician to the Papal Court in Rome, Italy. *peau d'orange* is French for 'orange skin'.

Figure 50.25 Peau d'orange of the breast.

ulceration and fixation to the chest wall (Fig. 50.26). This is described as cancer-en-cuirasse when the disease progresses around the chest wall. About 5% of breast cancers in the UK will present with either locally advanced disease or symptoms of metastatic disease. This figure is much higher in the developing world. These patients must then undergo a staging evaluation so that the full extent of their disease can be ascertained. This will include a careful clinical examination, chest radiograph, computerised tomography (CT) of the chest and abdomen and an isotope bone scan (Fig. 50.27). This is important for both progn-

Figure 50.26 Ulcerated carcinoma of the right breast.

Figure 50.27 Skeletal isotope bone scan showing multiple 'hot spots' due to metastases.

sis and treatment; a patient with widespread visceral metastases may obtain an increased length and quality of survival from systemic hormone therapy or chemotherapy but is unlikely to benefit from surgery as she will die from her metastases before local disease becomes a problem. In contrast, patients with relatively small tumours (< 5 cm in diameter) confined to the breast and ipsilateral lymph nodes rarely need staging beyond a good clinical examination as the pick-up rate for distant metastases is so low. Currently, a chest radiograph, full blood count and liver function tests are all that are recommended for screening of patients with early-stage breast cancer.

Staging of breast cancer

Classical staging of breast cancer by means of the TNM (tumour–node–metastasis) or UICC (Union Internationale Contre le Cancer) criteria is used less often as we gain more knowledge of the biological variables that affect prognosis. It is becoming increasingly clear that it is these factors (discussed in more detail below) rather than anatomical mapping that influence outcome and treatment. Perhaps a more pragmatic approach would be to classify patients according to the treatment that they require (Table 50.4). Treatment recommendations are summarised in consensus statements such as those from the American Society of Clinical Oncology (ASCO) and the St Gallen Conference.

Prognosis of breast cancer

The best indicators of likely prognosis in breast cancer remain tumour size and lymph node status; however, it is realised that some large tumours will remain confined to the breast for decades whereas some very small tumours are incurable at diagnosis. Hence, the prognosis of a cancer depends not on its chronological age but on its invasive and metastatic potential. In an attempt to define which tumours will behave aggressively, and thus require early systemic treatment, a host of prognostic factors have been described. These include the histological grade of the tumour, hormone receptor status, measures of tumour proliferation such as S-phase fraction, growth factor analysis and oncogene or oncogene product measurements. Many others are under investigation but have proved of little practical value in patient management. Prognostic indices (such as the Nottingham prognostic index) have combined these factors to allow subdivision of patients into discrete prognostic groups. More recently, a computer-aided program (adjuvant online; www.adjuvantonline.com) has been developed, which incorporates the putative benefits of treatment allowing oncologist and patient to visualise the benefits of therapy. There are commercial enterprises that are trying to combine a gene profile with classical prognostic indicators to give a recurrence score but these must be viewed as unproven at the moment. Other groups have developed ‘gene signatures’ said to be able to detect cancers of good or poor prognosis but there is little consistency between the various signatures developed by different groups and these approaches have not yet been translated into clinical practice.

Treatment of cancer of the breast

The two basic principles of treatment are to reduce the chance of local recurrence and the risk of metastatic spread. Treatment of early breast cancer will usually involve surgery with or without radiotherapy. Systemic therapy such as chemotherapy or hormone

therapy is added if there are adverse prognostic factors such as lymph node involvement, indicating a high likelihood of metastatic relapse. At the other end of the spectrum, locally advanced or metastatic disease is usually treated by systemic therapy to palliate symptoms, with surgery playing a much smaller role. An algorithm for the management of breast cancer is shown in Summary box 50.3.

Summary box 50.3

Algorithm for management of operable breast cancer

Achieve local control

Appropriate surgery

- Wide local excision (clear margins) and radiotherapy, or
- Mastectomy ± radiotherapy (offer reconstruction – immediate or delayed)
- Combined with axillary procedure (see text)
- Await pathology and receptor measurements
- Use risk assessment tool; stage if appropriate

Treat risk of systemic disease

- Offer chemotherapy if prognostic factors poor; include Herceptin if Her-2 positive
- Radiotherapy as decided above
- Hormone therapy if oestrogen receptor or progesterone receptor positive

The multidisciplinary team approach

As in all branches of medicine, good doctor–patient communication plays a vital role in helping to alleviate patient anxiety. Participation of the patient in treatment decisions is of particular importance in breast cancer when there may be uncertainty as to the best therapeutic option and the desire to treat the patient within the protocol of a controlled clinical trial. As part of the preoperative and postoperative management of the patient it is often useful to employ the skills of a trained breast counsellor and also to have available advice on breast prostheses, psychological support and physiotherapy, when appropriate.

In many specialist centres the care of breast cancer patients is undertaken as a joint venture between the surgeon, medical oncologist, radiotherapist and allied health professionals such as the clinical nurse specialist. This has been shown to be good for the patient, to lead to higher trial entry and to improve the mental health of the professionals in the breast team. There are published guidelines for the optimal management of patients with breast cancer such as SIGN 84 (Scottish Intercollegiate Guidelines Network).

Table 50.4 A pragmatic classification of breast cancer

Group	Approximate 5-year survival rate	Example	Treatment
‘Very low-risk’ primary breast cancer	> 90%	Screen-detected DCIS, tubular or special types	Local
‘Low-risk’ primary breast cancer	70–90%	Node negative with favourable histology	Locoregional with/without systemic
‘High-risk’ primary breast cancer	< 70%	Node positive or unfavourable histology	Locoregional with systemic
Locally advanced	< 30%	Large primary or inflammatory	Primary systemic
Metastatic	–	–	Primary systemic

DCIS, duct carcinoma *in situ*.

Local treatment of early breast cancer

Local control is achieved through surgery and/or radiotherapy (Summary box 50.4).

Summary box 50.4

Treatment of early breast cancer

The aims of treatment are:

- 'Cure': likely in some patients but late recurrence is possible
- Control of local disease in the breast and axilla
- Conservation of local form and function
- Prevention or delay of the occurrence of distant metastases

Surgery

Surgery still has a central role to play in the management of breast cancer but there has been a gradual shift towards more conservative techniques, backed up by clinical trials that have shown equal efficacy between mastectomy and local excision followed by radiotherapy.

It was initially hoped that avoiding mastectomy would help to alleviate the considerable psychological morbidity associated with breast cancer but recent studies have shown that over 30% of women develop significant anxiety and depression following both radical and conservative surgery. After mastectomy women tend

to worry about the effect of the operation on their appearance and relationships, whereas after conservative surgery they may remain fearful of a recurrence.

Mastectomy is indicated for large tumours (in relation to the size of the breast), central tumours beneath or involving the nipple, multifocal disease, local recurrence or patient preference. The radical Halsted mastectomy, which included excision of the breast, axillary lymph nodes and pectoralis major and minor muscles, is no longer indicated as it causes excessive morbidity with no survival benefit. The modified radical (Patey) mastectomy is more commonly performed and is thus described below. Simple mastectomy involves removal of only the breast with no dissection of the axilla, except for the region of the axillary tail of the breast, which usually has attached to it a few nodes low in the anterior group.

Patey mastectomy The breast and associated structures are dissected *en bloc* (Fig. 50.28) and the excised mass is composed of:

- the whole breast;
- a large portion of skin, the centre of which overlies the tumour but which always includes the nipple;
- all of the fat, fascia and lymph nodes of the axilla.

The pectoralis minor muscle is either divided or retracted to gain access to the upper two-thirds of the axilla. The axillary vein and nerves to the serratus anterior and latissimus dorsi (the thoraco-dorsal trunk) should be preserved. The intercostal brachial nerves are usually divided in this operation and the

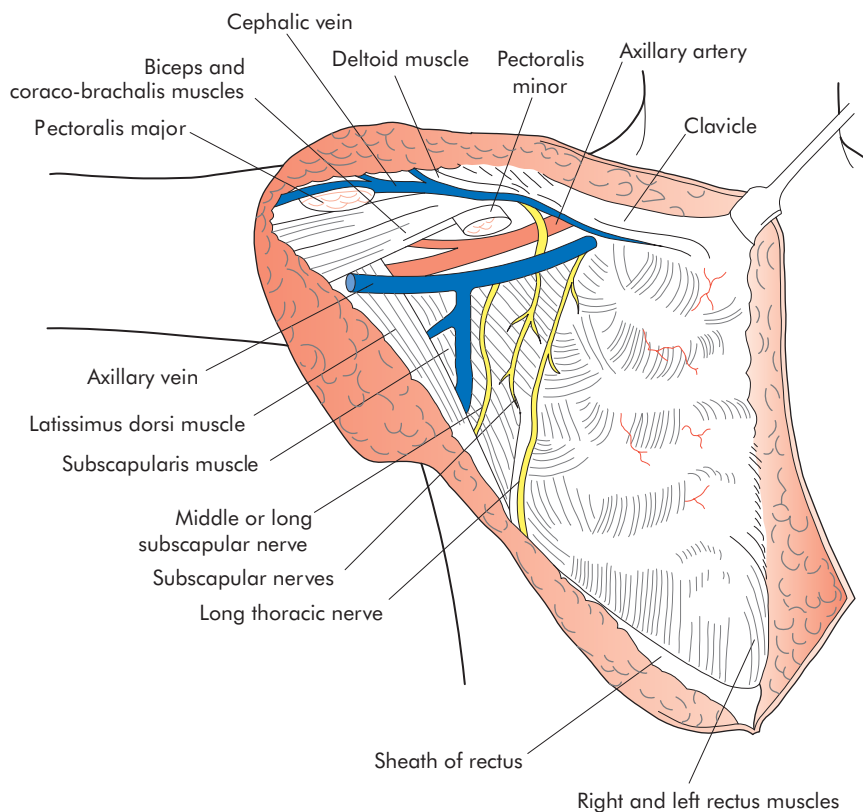

Figure 50.28 Radical mastectomy with pectoralis removed; the modified radical approach leaves the pectoralis major muscle intact.

William Stewart Halsted, 1852–1922, Professor of Surgery, Johns Hopkins Medical School, Baltimore, MD, USA.
David Howard Patey, 1899–1976, Surgeon, The Middlesex Hospital, London, England.

patient should be warned about sensation changes postoperatively.

The wound is drained using a wide-bore suction tube. Early mobilisation of the arm is encouraged and physiotherapy helps normal function to return very quickly; most patients are able to resume light work or housework within a few weeks.

Conservative breast cancer surgery This is aimed at removing the tumour plus a rim of at least 1 cm of normal breast tissue. This is commonly referred to as a wide local excision. The term lumpectomy should be reserved for an operation in which a benign tumour is excised and in which a large amount of normal breast tissue is not resected. A quadrantectomy involves removing the entire segment of the breast that contains the tumour. Both of these operations are usually combined with axillary surgery, usually via a separate incision in the axilla. There are various options that can be used to deal with the axilla, including sentinel node biopsy, sampling, removal of the nodes behind and lateral to the pectoralis minor (level II) or a full axillary dissection (level III).

There is a somewhat higher rate of local recurrence following conservative surgery, even if combined with radiotherapy, but the long-term outlook in terms of survival is unchanged. Local recurrence is more common in younger women and in those with high-grade tumours and involved resection margins. Patients whose margins are involved should have a further local excision (or a mastectomy) before going on to radiotherapy. Excision of a breast cancer without radiotherapy leads to an unacceptable local recurrence rate.

The role of axillary surgery is to stage the patient and to treat the axilla. The presence of metastatic disease within the axillary lymph nodes remains the best single marker for prognosis; however, treatment of the axilla does not affect long-term survival, suggesting that the axillary nodes act not as a 'reservoir' for disease but as a marker for metastatic potential. It used to be accepted that only pre-menopausal women should have their axilla staged by operation as there was a good case for giving chemotherapy to lymph node-positive patients; however, it is now clear that post-menopausal women also benefit from chemotherapy and so all patients require axillary surgery. In post-menopausal patients, tamoxifen was once given regardless of axillary lymph node status, but it is now known that all hormone receptor-positive patients, irrespective of age, benefit from this. If mastectomy is performed it is reasonable to clear the axilla as part of the operation, but if a wide local excision is planned the surgeon should dissect the axilla through a separate incision.

Axillary surgery should not be combined with radiotherapy to the axilla because of excess morbidity. Removal of the internal mammary lymph nodes is unnecessary.

Sentinel node biopsy This technique is currently becoming the standard of care in the management of the axilla in patients with clinically node-negative disease. The sentinel node is localised preoperatively by the injection of patent blue dye (Fig. 50.29) and radioisotope-labelled albumin in the breast. The recommended site of injection is in the subdermal plexus around the nipple although some still inject on the axillary side of the cancer. The marker passes to the primary node draining the area and is detected visually and with a hand-held gamma camera. The excised node can be sent for frozen-section histological analysis or touch imprint cytology (TIC) if preoperative diagnosis is sought. In some cases

Figure 50.29 Sentinel node biopsy.

there are only subcapsular micrometastases that are missed at frozen section. In patients in whom there is no tumour involvement of the sentinel node, further axillary dissection can be avoided. A normogram outlining the chances of further axillary node positivity has been developed by the group at Memorial Sloan Kettering Hospital, New York, and is available on their website (www.mskcc.org/mskcc/html/15938.cfm).

Radiotherapy

Radiotherapy to the chest wall after mastectomy is indicated in selected patients in whom the risks of local recurrence are high. This includes patients with large tumours and those with large numbers of positive nodes or extensive lymphovascular invasion. There is some evidence that postoperative chest wall radiotherapy improves survival in women with node-positive breast cancer.

It is conventional to combine conservative surgery with radiotherapy to the remaining breast tissue. Recurrence rates are too high for treatment by local excision alone except in special cases (small node-negative tumours of a special type). Trials are under way to investigate whether radiotherapy can be given intraoperatively at one sitting or as an accelerated postoperative course. This would have considerable advantages in making conservative surgery available in areas where radiotherapy is not currently used. It would also relieve the burden of the current demand for radiotherapy, which accounts for up to 40% of activity in some departments.

Extrapolation from the Oxford overviews of systemic therapy (carried out every 5 years) suggests that for every four local recurrences one additional life will be spared at 15 years. This means that it is important to get the first treatments right and avoid local recurrence.

Adjuvant systemic therapy

Over the last 25 years there has been a revolution in our understanding of the biological nature of carcinoma of the breast. It is now widely accepted that the outcomes of treatment are predetermined by the extent of micrometastatic disease at the time of diagnosis. Variations in the radical extent of local therapy might influence local relapse but probably do not alter long-term mortality from the disease. However, systemic therapy targeted at these putative micrometastases might be expected to delay relapse and

prolong survival. As a result of many international clinical trials and recent world overview analyses it can be stated with statistical confidence that the appropriate use of adjuvant chemotherapy or hormone therapy will improve relapse-free survival by approximately 30%, which ultimately translates into an absolute improvement in survival of the order of 10% at 15 years. Bearing in mind how common the disease is in northern Europe and the USA, these figures are of major public health importance.

Who to treat and with what are still questions for which absolute answers have yet to be found, but the data from the overviews of recent trials show that lymph node-positive and many higher risk node-negative women should be recommended adjuvant combined chemotherapy. Women with hormone receptor-positive tumours will obtain a worthwhile benefit from about 5 years of endocrine therapy, either 20 mg daily of tamoxifen if pre-menopausal or the newer aromatase inhibitors (anastrozole, letrozole and exemestane) if post-menopausal. It is no longer appropriate to give hormone therapy to women who do not have oestrogen or progesterone receptor-positive disease.

Hormone therapy

Tamoxifen has been the most widely used 'hormonal' treatment in breast cancer. Its efficacy as an adjuvant therapy was first reported in 1983 and it has now been shown to reduce the annual rate of recurrence by 25%, with a 17% reduction in the annual rate of death. The beneficial effects of tamoxifen in reducing the risk of tumours in the contralateral breast have also been observed, as has its role as a preventative agent (IBIS-I and NSABP-P1 trials). Trials studying the optimal duration of treatment suggest that 5 years of treatment is preferable to 2 years.

Other hormonal agents that are also beneficial as adjuvant therapy have been developed. These include the LHRH agonists, which induce a reversible ovarian suppression and thus have the same beneficial effects as surgical or radiation-induced ovarian ablation in pre-menopausal receptor-positive women, and the oral aromatase inhibitors for post-menopausal women. The latter group of compounds are now licensed for treatment of recurrent disease, in which they have been shown to be superior to tamoxifen. A large trial comparing anastrozole to tamoxifen in the adjuvant setting has shown a beneficial effect for the aromatase inhibitor in terms of relapse-free survival, although the data are still immature for overall survival. There is an additional reduction in contralateral disease, which makes this drug suitable for a study of prevention, and the side-effect profile is different from that of tamoxifen. However, it is currently considerably more expensive.

Chemotherapy

Chemotherapy using a first-generation regimen such as a 6-monthly cycle of cyclophosphamide, methotrexate and 5-fluorouracil (CMF) will achieve a 25% reduction in the risk of relapse over a 10- to 15-year period. It is important to understand that this 25% reduction refers to the likelihood of an event happening. For example, a woman with a 96% chance of survival at, say, 5 years only has a 4% chance of death over this time and the absolute benefit from chemotherapy would be an increase in survival rate of 1%, to 97%. This would not be a sufficient gain to offset the side-effects of this potentially toxic therapy. However, for a woman with a 60% chance of dying (40% survival rate) a 25% reduction in risk would increase her likelihood of survival to 55% and thus treatment would be worthwhile. CMF is no longer

considered adequate adjuvant chemotherapy and modern regimens include an anthracycline (doxorubicin or epirubicin) and the newer agents such as the taxanes.

Chemotherapy was once confined to pre-menopausal women with a poor prognosis (in whom its effects are likely to be the result, in part, of a chemical castration effect) but is being increasingly offered to post-menopausal women with poor-prognosis disease as well. Chemotherapy may be considered in node-negative patients if other prognostic factors, such as tumour grade, imply a high risk of recurrence. The effect of combining hormone and chemotherapy is additive although hormone therapy is started after completion of chemotherapy to reduce side-effects.

High-dose chemotherapy with stem cell rescue for patients with heavy lymph node involvement has now been shown in controlled trials to offer no advantage and has been abandoned.

Primary chemotherapy (neoadjuvant) is being used in many centres for large but operable tumours that would traditionally require a mastectomy (and almost certainly postoperative adjuvant chemotherapy). The aim of this treatment is to shrink the tumour to enable breast-conserving surgery to be performed. This approach is successful in up to 80% of cases but is not associated with improvements in survival compared with conventionally timed chemotherapy. For older patients with breast cancers strongly positive for hormone receptors a similar effect can be seen with 3 months of endocrine treatment.

Newer 'biological' agents will be used more frequently as molecular targets are identified – the first of these, trastuzumab (Herceptin), is active against tumours containing the growth factor receptor c-erbB2. Other agents currently available include bevacizumab, a vascular growth factor receptor inhibitor, and lapatinib, a combined growth factor receptor inhibitor. It is unclear how and when these agents will be used, whether in combination or instead of standard chemotherapy agents.

Follow-up of breast cancer

Patients with breast cancer used to be followed for life to detect recurrence and dissemination. This led to large clinics with little value for either patient or doctor. It is current practice to arrange yearly or 2-yearly mammography of the treated and contralateral breast. There is a move to return the patient early to the care of the general practitioner with fast-track access back to the breast clinic if suspicious symptoms appear. There is currently no routine role for repeated measurements of tumour markers or imaging other than mammography.

Phenomena resulting from lymphatic obstruction in advanced breast cancer

Peau d'orange

Peau d'orange is caused by cutaneous lymphatic oedema. Where the infiltrated skin is tethered by the sweat ducts it cannot swell, leading to an appearance like orange skin. Occasionally, the same phenomenon is seen over a chronic abscess.

Late oedema of the arm is a troublesome complication of breast cancer treatment, fortunately seen less often now that radical axillary dissection and radiotherapy are rarely combined. However, it does still occur occasionally after either mode of treatment alone and appears at any time from months to years after treatment. There is usually no precipitating cause but recurrent tumour should be excluded because neoplastic infiltration of

the axilla can cause arm swelling as a result of both lymphatic and venous blockage. This neoplastic infiltration is often painful because of brachial plexus nerve involvement.

An oedematous limb is susceptible to bacterial infections following quite minor trauma and these require vigorous antibiotic treatment. Antibiotics may need to be given for much longer than is normal and patients at risk of infection should have antibiotics readily available to enable treatment to be started promptly. Treatment of late oedema is difficult but limb elevation, elastic arm stockings and pneumatic compression devices can be useful.

Cancer-en-cuirasse

The skin of the chest is infiltrated with carcinoma and has been likened to a coat. It may be associated with a grossly swollen arm. This usually occurs in cases with local recurrence after mastectomy and is occasionally seen to follow the distribution of irradiation to the chest wall. The condition may respond to palliative systemic treatment but prognosis in terms of survival is poor.

Lymphangiosarcoma

Lymphangiosarcoma is a rare complication of lymphoedema with an onset many years after the original treatment. It takes the form of multiple subcutaneous nodules in the upper limb and must be distinguished from recurrent carcinoma of the breast. The prognosis is poor but some cases respond to cytotoxic therapy or irradiation. Interscapulothoracic (forequarter) amputation is rarely indicated.

Breast reconstruction

Despite an increasing trend towards conservative surgery, up to 50% of women still require, or want, a mastectomy. These women can now be offered immediate or delayed reconstruction of the breast. Few contraindications to breast reconstruction exist. Even those with a limited life expectancy may benefit from the improved quality of life; however, patients do require counselling before this procedure so that their expectations of cosmetic outcome are not unrealistic.

The easiest type of reconstruction is using a silicone gel implant under the pectoralis major muscle. This may be combined with prior tissue expansion using an expandable saline prosthesis first (or a combined device), which creates some ptosis of the new breast. If the skin at the mastectomy site is poor (e.g. following radiotherapy) or if a larger volume of tissue is required, a musculocutaneous flap can be constructed either from the latissimus dorsi muscle (an LD flap) (Fig. 50.30) or using the transversus abdominis muscle (a TRAM flap as shown in Fig. 50.31). The latter gives an excellent cosmetic result in experienced hands but is a lengthy procedure and requires careful patient selection. It is now usually performed as a free transfer using microvascular anastomosis, although the pedicled TRAM from the contralateral side is still used. Variations on the TRAM flap requiring less muscle harvesting, such as the DIEP flap (based on deep inferior epigastric vessels), are increasingly being used.

The timing of reconstruction is difficult. Impediments to immediate reconstruction include insufficient theatre time and a lack of experienced reconstructive surgeons. In addition, if a patient is likely to need postoperative radiotherapy then a delayed reconstruction using a flap often gives a better result.

Figure 50.30 Reconstruction with latissimus dorsi flap.

Figure 50.31 Transversus abdominis muscle flap.

Radiotherapy onto a prosthesis often leads to a high incidence of capsular contracture and unacceptable results.

Nipple reconstruction is a relatively simple procedure that can be performed under a local anaesthetic. Many different types of nipple reconstruction are described but the majority lose height with time. Tattooing of the reconstructed nipple is often required. Alternatively, the patient can be fitted with a prosthetic nipple. To achieve symmetry the opposite breast may require a cosmetic procedure such as reduction or augmentation mammoplasty, or mastopexy. A breast reconstructive service can be offered by a suitably trained breast surgeon, a plastic surgeon or, ideally, using a combined oncoplastic approach. The patient needs to be

warned that breast reconstruction is seldom, if ever, one operation.

External breast prostheses that fit within the bra are the most common method of restoring volume fill and should be available for all women who do not have an immediate reconstruction.

Screening for breast cancer

Because the prognosis of breast cancer is closely related to stage at diagnosis it would seem reasonable to hope that a population screening programme that could detect tumours before they come to the patient's notice might reduce mortality from breast cancer. Indeed, a number of studies have shown that breast screening by mammography in women over the age of 50 years will reduce cause-specific mortality by up to 30%. Following the publication in 1987 of the Forrest report, the National Health Service in the UK launched a programme of 3-yearly mammographic screening for women between the ages of 50 and 64 years (now increased to 70 years). The introduction of this programme has undoubtedly improved the quality of breast cancer services but a number of questions remain unanswered, including the value of screening women under 50 years and the ideal interval between screenings. The psychological consequences of false alarms or false reassurances still need to be addressed and self-examination programmes that have failed to show any benefit for the population in terms of earlier detection of or decreased mortality from breast cancer remain controversial.

Familial breast cancer

Recent developments in molecular genetics and the identification of a number of breast cancer predisposition genes (*BRCA1*, *BRCA2* and *p53*) have done much to stimulate interest in this area. Yet women whose breast cancer is due to an inherited genetic change actually account for less than 5% of all cases of breast cancer, that is about 1250 cases per year in the UK and 9000 cases in the USA. A much larger number of women will have a risk that is elevated above normal because of an as yet unspecified familial inheritance. These women have a risk of developing breast cancer that is 2–10 times above baseline. The risks associated with family history are summarised in Table 50.5.

The *BRCA1* gene has been cloned and is located on the long arm of chromosome 17 (17q). The gene frequency in the population is approximately 0.0006. It does, however, occur with greater frequency in certain populations such as Ashkenazi Jews, in

Table 50.5 Likelihood of genetic mutation with family history

No. of family cases < 50 years old	<i>BRCA1</i> (%) ^a	<i>BRCA2</i> (%) ^b
2	4	3
3	17	13
4	41	33
5	55	44

^a *BRCA1* is also associated with ovarian and, to a lesser extent, colorectal and prostate cancer.

^b *BRCA2* is associated with familial male breast cancer.

Sir Andrew Patrick McEwen Forrest, Regius Professor of Clinical Surgery, The University of Edinburgh, Edinburgh, Scotland.
Ashkenazi Jews are Jews of Eastern or Central European descent.

whom there is often a common (founder) mutation. *BRCA2* is located on chromosome 13q and there is an association with male breast cancer. Women who are thought to be gene carriers may be offered breast screening (and ovarian screening in the case of *BRCA1*, which is known to impart a 50% lifetime risk of ovarian cancer), usually as part of a research programme, or genetic counselling and mutation analysis. Those who prove to be 'gene positive' have a 50–80% risk of developing breast cancer, predominantly while pre-menopausal. Many will opt for prophylactic mastectomy. Although this does not completely eliminate the risk, it does reduce it considerably. This work should be carried out in specialist centres.

For the great majority of women with a positive family history, who are unlikely to be carriers of a breast cancer gene, there are no currently proven breast cancer screening manoeuvres, although this is under investigation. Tamoxifen given for 5 years appears to reduce the risk of breast cancer by 30–50% and newer agents are currently under trial. Thus, these women are best served by being assessed and followed-up, preferably in a properly organised family history clinic.

Pregnancy

The effects of pregnancy on breast cancer are not well studied but it is thought that breast cancer presenting during pregnancy or lactation tends to be at a later stage, presumably because the symptoms are masked by the pregnancy; however, in other respects it behaves in a similar way to breast cancer in a non-pregnant young woman and should be treated accordingly. Thus, treatment is similar with some provisos: radiotherapy should be avoided during pregnancy, making mastectomy a more frequent option than breast conservation surgery; chemotherapy should be avoided during the first trimester but appears safe subsequently; most tumours are hormone receptor negative and so hormone treatment, which is potentially teratogenic, is not required. Becoming pregnant subsequent to a diagnosis of breast cancer appears not to alter the likely outcome, but women are usually advised to wait at least 2 years as it is within this time that recurrence most often occurs. The risk of developing breast cancer with oral contraceptive use is only slight, and disappears 10 years after stopping the oral contraceptive pill.

Hormone replacement therapy

HRT does increase the risk of developing breast cancer if taken for prolonged periods and in certain high-risk groups. HRT may also prolong symptoms of benign breast disorders such as cysts and mastalgia and make mammographic appearances more difficult to interpret.

Patients who develop breast cancer while on HRT appear to have a more favourable prognosis. The consequences in terms of recurrence in women using HRT following breast cancer are unknown.

Treatment of advanced breast cancer

Breast cancer may occasionally present as metastatic disease without evidence of a primary tumour (that is with an occult primary). The diagnosis is made partly by exclusion of another site for the primary tumour and may be confirmed by histology with special immunohistological stains of the metastatic lesions. Management should be aimed at palliation of the symptoms and treatment of the breast cancer, usually by endocrine manipulation with or without radiotherapy.

Locally advanced inoperable breast cancer

Locally advanced inoperable breast cancer, including inflammatory breast cancer, is usually treated with systemic therapy, either chemotherapy or hormone therapy.

Occasionally, 'toilet mastectomy' or radiotherapy is required to control a fungating tumour but often incision through microscopically permeated tissues results in a worse outcome.

Metastatic carcinoma of the breast

Metastatic carcinoma of the breast will also require palliative systemic therapy to alleviate symptoms. Hormone manipulation is often the first-line treatment because of its minimal side-effects. It is particularly useful for bony metastases. However, only about 30% of these tumours will be hormone responsive and, unfortunately, in time even these will become resistant to treatment. First-line hormone therapy for post-menopausal women is now anastrozole or one of the other third-generation aromatase inhibitors. Tamoxifen, ovarian suppression by surgery (for premenopausal women), radiotherapy and medical treatment are all in common use. When resistance to these has developed, other hormonal agents can prove useful, with about one-half of the response rate seen in the first-line therapy. The newer agents such as anti-progestins, pure anti-oestrogens and growth factor tyrosine kinase inhibitors are all candidates for this role.

Cytotoxic therapy is used particularly in younger women or those with visceral metastases and rapidly growing tumours. A variety of regimens is available and, although none prolongs survival, contrary to expectations, quality of life and symptom control is often better with more aggressive treatments, with responses being seen in up to 70% of patients.

Local treatment may also prove useful for some metastatic disease such as radiotherapy for painful bony deposits and internal fixation of pathological fractures.

THE MALE BREAST

Gynaecomastia

Idiopathic

Hypertrophy of the male breast may be unilateral or bilateral. The breasts enlarge at puberty and sometimes present the characteristics of female breasts (Fig. 50.32).

Hormonal

Enlargement of the breasts often accompanied stilbestrol therapy for prostate cancer, now rarely used. It may also occur as a result of a teratoma of the testis, in anorchism and after castration. Rarely, it may be a feature of ectopic hormonal production in bronchial carcinoma and in adrenal and pituitary disease. Body builders may use steroids to improve their physique, which may cause gynaecomastia. Some even go so far as to take tamoxifen to mask this symptom.

Associated with leprosy

Gynaecomastia is very common in men suffering from leprosy. This is possibly because of bilateral testicular atrophy, which is a frequent accompaniment of leprosy.

Associated with liver failure

Gynaecomastia sometimes occurs in patients with cirrhosis as a result of failure of the liver to metabolise oestrogens. It is

Figure 50.32 Chief Chengwayo, from a photograph by Schujelot.

associated with drugs that interfere with the hepatic metabolism of oestrogens. It is also seen with certain drugs such as cimetidine, digitalis and spironolactone.

Associated with Klinefelter syndrome

Gynaecomastia may occur in patients with Klinefelter's syndrome, a sex chromosome anomaly having 47XXY trisomy.

Treatment

Provided that the patient is healthy and comparatively young, reassurance may be sufficient. If not, mastectomy with

Figure 50.33 Carcinoma of the male breast.

Harry Fitch Klinefelter, Jr., B. 1912, Physician of Baltimore, MD, USA, described this syndrome in 1942.

preservation of the areola and nipple can be performed. The patient must be warned about the side-effects of this procedure, which are common and a cause of many medico-legal complaints in the UK.

Carcinoma of the male breast

Carcinoma of the male breast (Fig. 50.33) accounts for less than 0.5% of all cases of breast cancer. The known predisposing causes include gynaecomastia and excess endogenous or exogenous oestrogen. As in the female it tends to present as a lump and is most commonly an infiltrating ductal carcinoma.

Treatment

Stage for stage the treatment is the same as for carcinoma in the female breast and prognosis depends upon stage at presentation. Adequate local excision, because of the small size of the breast, should always be with a 'mastectomy'.

OTHER TUMOURS OF THE BREAST

Lipoma

A true lipoma is very rare.

Sarcoma of the breast

Sarcoma of the breast is usually of the spindle-cell variety and accounts for 0.5% of malignant tumours of the breast. Some of

these growths arise in an intracanalicular fibroadenoma or may follow previous radiotherapy, e.g. for Hodgkin's lymphoma, many years previously. It may be impossible to distinguish clinically a sarcoma of the breast from a medullary carcinoma, but areas of cystic degeneration suggest a sarcoma and on incising the neoplasm it is pale and friable. Sarcoma tends to occur in younger women between the ages of 30 and 40 years. Treatment is by simple mastectomy followed by radiotherapy. The prognosis depends on the stage and histological type.

Metastases

On rare occasions cancer elsewhere may present with a metastasis in the breast. The breast is also occasionally infiltrated by Hodgkin's disease and other lymphomas.

Cardiac surgery

LEARNING OBJECTIVES

To understand:

- The important role of surgery in cardiac disease
- The role of investigation in planning surgery
- The management of coronary heart disease
- The role of surgery in valvular heart disease
- The special role of surgery in congenital heart disease
- The management of aortic vascular and pericardial disease

INTRODUCTION

In 1925 Sir Henry Souttar reported the first mitral commissurotomy in the *British Medical Journal*. He wrote that the heart should be as amenable to surgery as any other organ and that many of the problems in heart disease were, to a large extent, mechanical. He saw the main problem as being maintenance of blood flow, particularly to the brain, while surgery was being performed. The first real advances occurred in the late 1940s and early 1950s, driven by surgeons who had gained confidence and experience under the pressures and opportunities provided by war. Further progress waited upon the development of cardiopulmonary bypass in the mid-1950s. Now the number, range and technical complexity of heart operations are remarkable; with the heart restored to good working order, the well-being and lifespan of patients with congenital, valvular and degenerative heart disease can be very much improved.

CARDIOPULMONARY BYPASS

Introduction

Cardiopulmonary bypass (CPB) was first used successfully in 1953 by Gibbon and has revolutionised cardiac surgical practice. It can be employed in any procedure in which the heart and lungs need to be stopped temporarily and their function replaced by artificial means (Box 51.1). Before Gibbon's work, valve surgery under direct vision would not have been possible nor would the precise reconstructions needed to treat extensive coronary artery disease. Much of the success of modern CPB is attributable to the development of new biomaterials and sophisticated oxygenating devices as well as a greater understanding of the pathophysiological consequences of CPB (Summary box 15.1).

Sir Henry Sessions Souttar, 1875–1964, Surgeon, The London Hospital, London, England.
John Heysham Gibbon, 1903–1973, worked at Jefferson University, Philadelphia, PA, USA.

Summary box 51.1

Alternative uses of CPB

- Rewarming from profound hypothermia
- Resuscitation in severe respiratory failure
- As an adjunct in pulmonary embolectomy
- In single- and double-lung transplantation
- In cardiopulmonary trauma
- In certain non-cardiac surgical procedures:
 - Resection of highly vascular tumours
 - Large complex arteriovenous malformations
 - Tumours invading large blood vessels (e.g. renal or hepatic tumours extending into the inferior vena cava, right atrium or even pulmonary arteries)

Surgical approach to the heart

For most operations, the heart is approached by a median sternotomy. An incision is made from the jugular or suprasternal notch to the lower end of the xiphisternum. The sternum is divided and retracted to expose the thymus superiorly and the pericardium inferiorly. The thymus, although atrophic in adults, often remains relatively vascular. The thymus and pleurae are dissected from the pericardium, and the pericardium is opened. Before cannulation for CPB, the patient is fully heparinised.

Initiating cardiopulmonary bypass

Arterial cannulation

Conventionally, the great vessels are exposed and an aortic perfusion cannula is inserted into the ascending aorta, held in place by the purse-string suture. Air is excluded and the cannula connected to the bypass circuit. Alternatively, when it is inadvisable (aortic dissection), impractical (aortic root surgery) or impossible (severe adhesions) to cannulate the aorta, femorofemoral bypass can be employed. Arterial return is via the femoral artery.

Venous cannulation

A second purse-string suture is inserted into the right atrium by

the appendage. A single 'two-stage' venous cannula placed in the right atrium establishes venous drainage. The venous pipe has end holes that sit in the inferior vena cava and side holes that sit in the right atrium (to take the drainage from the superior vena cava). Alternatively, the superior and inferior vena cavae may be cannulated separately to gain better control over the venous return and to facilitate surgery within the right atrium. Femorofemoral bypass with venous drainage from the femoral vein offers an alternative, particularly during thoracic aortic procedures.

Cardiopulmonary bypass circuit

Once the circuit is connected (Fig. 51.1) the CPB machine (the 'pump') takes over circulation and ventilation. Blood is pumped from a venous reservoir and oxygenated with a membrane oxygenator that allows gas exchange across a silicone membrane. To reduce the metabolic demands of the tissues the core systemic temperature may be lowered by passing the returning blood through a heat exchanger. The degree of cooling is according to the severity and complexity of the surgical procedure, as well as the surgeon's preference. The blood is also filtered to remove particulate emboli and infused back into the systemic arterial circulation via a roller pump. This returns blood to the patient at an even arterial perfusion pressure. The surgeon can now isolate the heart from the rest of the circulation with suction pumps to keep the area around the heart clear of blood. A vent suction pump may be used to decompress the heart.

Figure 51.1 Components of the cardiopulmonary bypass (CPB) circuit. [Reproduced from Abraham, J.K. (2000) Cardiopulmonary bypass. *Surgery* 18: 11, with permission from The Medical Publishing Company.]

Myocardial protection

To obtain a bloodless operative field, the ascending aorta is usually cross-clamped once CPB has been established and blood is diverted away from the heart. The heart ceases to eject and, as a result of inhibition of coronary blood flow, becomes anoxic. Permanent myocardial damage will develop within 30–45 min. Therefore, most cardiac operations require some form of myocardial protection. Techniques of myocardial protection and the operative management of the myocardium have had a significant impact on the complexity of cardiac surgery. The methods of myocardial protection include intracoronary infusion of a cardioplegic solution, intermittent cross-clamp fibrillation and total circulatory arrest.

Cardioplegic solutions vary in terms of temperature, pH, arresting agent, osmolality, presence of red cells and other factors. Most solutions contain potassium as the arresting agent. Potassium arrests the heart in diastole by depolarisation of the membrane. Cold (4–10°C) isotonic crystalloid or chilled blood solutions aid myocardial protection by reducing metabolic requirements through local hypothermia.

Intermittent cross-clamp fibrillation is a technique in which intermittent ventricular fibrillation is induced by a small electrical charge. The heart does not eject and is relatively still but not bloodless. The aorta is cross-clamped to render the heart ischaemic. The heart can tolerate short periods (10–20 min) of intermittent ischaemia, providing the heart is reperfused when the cross-clamp is released and allowed to beat following cardioversion for short periods during the operation.

Total circulatory arrest becomes a necessity when visibility and clarity of the operative area is crucial, as in paediatric surgery or in surgery of the ascending aorta and arch of the aorta. CPB is instituted and core systemic temperature reduced to 15–18°C (profound hypothermia). The metabolic rate of all organs of the body is reduced by 50% with every 7°C drop in temperature. So, with the pump switched off at 18°C, circulatory arrest can be tolerated for 20–30 min. Additional cerebral protection can be provided with ice packs placed around the head. Retrograde and antegrade cerebral perfusion techniques can also be used.

Discontinuing cardiopulmonary bypass

At the end of the procedure, air must be meticulously excluded from the cardiac chambers. Once perfusion is restored to the coronary arteries the heart may beat spontaneously or, if ventricular fibrillation is present, it may require a shock by a direct current (DC). Epicardial pacing wires may be placed to treat postoperative bradycardia or heart block. The patient is rewarmed, acidosis or hypokalaemia is corrected, and ventilation is restarted. The heart gradually takes over the circulation while the arterial flow from the CPB machine is reduced. When the blood pressure is acceptable and the surgeon is confident that the heart function is adequate, CPB is discontinued.

Complications of cardiopulmonary bypass

CPB is a complex technique and, as such, there are many potentially serious complications (Summary box 51.2). Increasingly, 'off-pump' coronary artery surgery is being used to avoid such complications.

Summary box 51.2

Potential complications of CPB

- Air embolism
- Bleeding disorders
- Cholecystitis
- Constrictive pericarditis
- Infection
- Intestinal ischaemia/infarction
- Mediastinal tamponade
- Microembolisation
- Myocardial depression
- Neurological dysfunction
- Pancreatitis
- Post-cardiotomy syndrome
- Pulmonary injury
- Systemic organ dysfunction
- Vascular injury

CORONARY ARTERY BYPASS SURGERY

Introduction

Before the 1950s, surgical attempts to treat coronary artery disease (CAD) through augmentation of non-coronary flow to the myocardium via the creation of pericardial or omental adhesions met with limited success. By the 1960s, the importance of aortocoronary saphenous vein grafts and the value of the internal mammary or internal thoracic artery were increasingly recognised. From the start, the results of coronary artery bypass graft (CABG) surgery were carefully monitored. By the 1970s, three large, prospectively randomised, multicentre trials were being conducted. All of these studies showed that a subset of patients had improved survival after surgery. With the advent of percuta-

neous coronary intervention (PCI) in the 1980s, the patient population undergoing CABG has changed, becoming progressively sicker but often with the most to gain (Summary box 51.3).

Summary box 51.3

Coronary artery surgery

- Randomised controlled trials have confirmed improvement in survival following CABG for certain groups of patients

Coronary artery anatomy

The coronary arteries are branches of the ascending aorta, arising from ostia in the aortic sinuses above the aortic valve, the right from the anterior sinus and the left from the left posterior sinus (Fig. 51.2).

Left coronary artery

The left main coronary artery, which arises from the aortic root, can be the site of significant stenosis ('left main stem disease') and carries the worst prognosis in terms of survival without surgery. The artery is inaccessible at its origin and therefore grafts are anastomosed to its branches, the left anterior descending artery (LAD) or anterior interventricular artery and obtuse/marginal (OM) branches of the circumflex artery. The LAD is the most frequently diseased coronary artery and most often bypassed during CABG surgery.

Right coronary artery

The right coronary artery (RCA) passes from its origin anteriorly between the right atrial appendage and the pulmonary trunk and courses in the atrioventricular groove around the margin of the right ventricle. It usually forms an anastomosis with the circumflex artery at the junction of the right and left atria and the

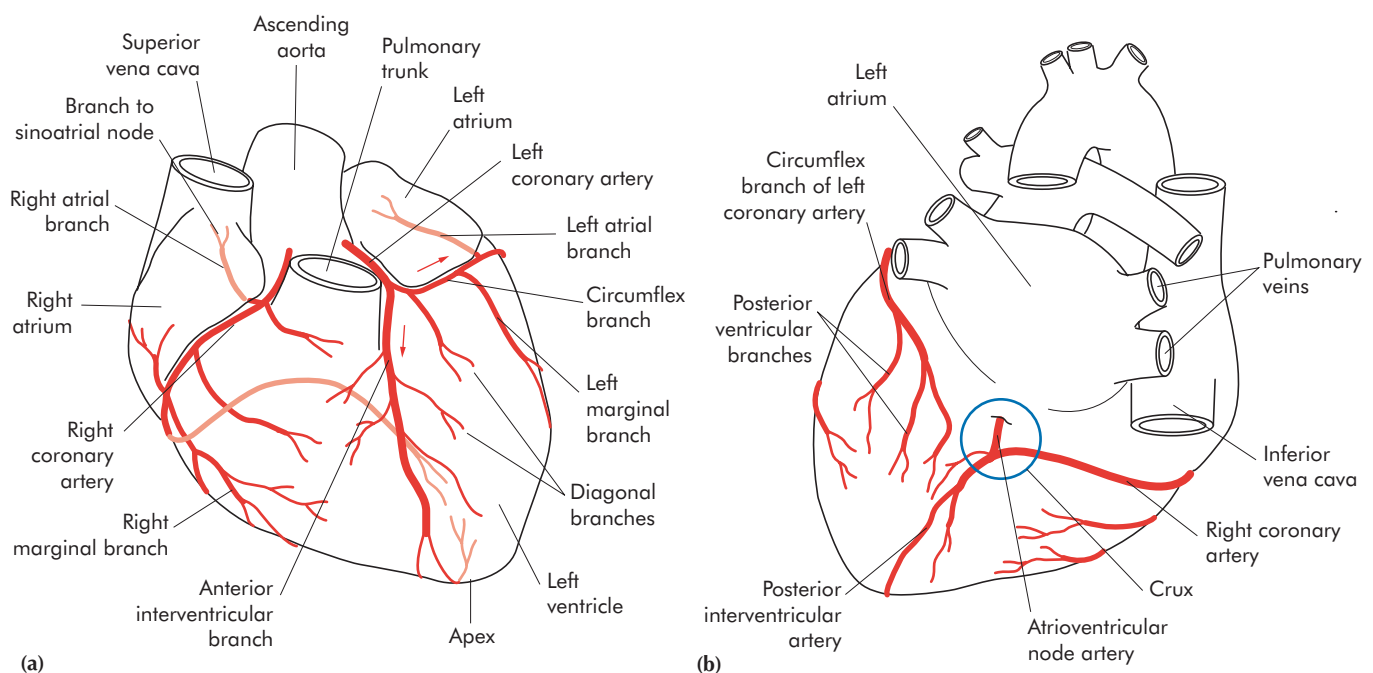

Figure 51.2 The heart, showing the distribution of the left and right coronary arteries. (a) Anterior surface of the heart and (b) base and diaphragmatic surface of the heart.

interventricular septum (the crux). It continues as the posterior descending artery or interventricular artery. Common sites of stenosis of the RCA are in its proximal portion or at the bifurcation or crux. In the presence of disease at the bifurcation, a graft can be placed distally to the posterior descending artery.

The question of anatomical dominance is determined by the artery that supplies the posterior descending artery. In approximately 90% of cases the posterior descending artery arises from the RCA, a pattern referred to as right dominance. The posterior descending artery can also arise from the circumflex artery, a pattern referred to as left dominance, which occurs in approximately 10% of cases. A balanced pattern is one in which two posterior descending arteries, one arising from the right coronary artery and one from the circumflex artery, can exist (Fig. 51.2).

Ischaemic heart disease

Ischaemic heart disease (IHD) is a major cause of morbidity and mortality in developed countries. The underlying pathology is usually atherosclerosis of the coronary arteries.

Pathophysiology

Atherosclerosis is the process underlying the formation of focal obstructions or plaques in large- and medium-sized arteries. It is characterised by the presence of focal intimal thickening, these intimal elevations being made up of accumulations of cholesterol-rich 'gruel' (atherosis) and a proliferation of connective tissue (sclerosis). An essential component of atherogenesis is inflammation involving monocytes/macrophages, T lymphocytes and mast cells. Four stages are described in the pathogenesis of atherosclerosis:

- Initiation with deposition of foam cells to form fatty streaks.
- Progression into mature atherosclerotic or fibrolipid plaques.
- Destabilisation with rupture of the plaque, exposure of thrombogenic atheroma, and deposition of platelets and fibrin. This may lead to subsequent ischaemia, infarction or narrowing of the vessel through plaque repair.
- Plaque repair: many coronary thrombi eventually undergo a process of recanalisation with a degree of reperfusion.

Clinical manifestations

The principal symptoms of IHD are chest pain or angina, breathlessness, fatigue, swelling, palpitations and syncope. Severity of symptoms and the extent to which the symptoms interfere with everyday activities form a significant part of the clinical history. An assessment of risk factors should be included (Summary box 51.4). Clinical examination follows and, although often normal, any evidence of myocardial ischaemia or stigmata of associated disease such as diabetes or peripheral vascular disease should be noted.

Summary box 51.4

Risk factors for IHD

- Advancing age
- Male gender
- Hyperlipidaemia
- Diabetes mellitus
- Hypertension

Investigations

Non-invasive methods of diagnosis

Resting electrocardiography

As a baseline test, a 12-lead resting electrocardiogram (ECG) often provides the first indication of ischaemic cardiac disease and is essential in the acute clinical setting. However, it is not necessarily abnormal even in the presence of severe multivessel coronary heart disease. Evidence of previous myocardial infarction is seen commonly, as Q waves and/or non-specific ST and T-wave changes.

Cardiac isoenzymes and troponins

These are useful in assessing patients with an acute coronary syndrome (ACS) when the diagnosis is in doubt. Standard enzyme measurement such as creatine kinase MB and lactate dehydrogenase usually take too long and may delay thrombolytic therapy. Troponin T and I, markers of myocardial damage, appear to be more specific and may aid rapid diagnosis as well as having prognostic implications.

Exercise tolerance testing

Exercise tolerance testing (ETT) is a valuable technique for assessing myocardial ischaemia, both for diagnostic purposes and as a prognostic tool. However, an abnormal exercise test must be interpreted in the light of the probability of coronary artery disease and the physiological response to exercise as measured by the percentage of the maximum predicted heart rate achieved. A positive test with evidence of ischaemia on the ECG (ST depression of ≤ 2 mm) does not always indicate IHD, and a negative test does not always exclude its presence.

Echocardiography

Performed either through a transthoracic or transoesophageal approach, it is valuable for the evaluation of ventricular function and regional wall motion abnormalities, as well as valvular lesions.

Stress echocardiography can detect regional wall motion abnormalities brought on by exercise or the use of dobutamine or dipyridamole. It is a reliable method of identifying viable myocardium. Impaired but recoverable myocardium possesses a functional reserve that allows it to be temporarily recruited into action, whereas scar tissue does not.

Radionuclide studies and cardiac magnetic resonance imaging

The two main types of radionuclide study available are perfusion and blood pool studies. They allow an assessment of the perfusion and cellular integrity of viable myocardium. Cardiac magnetic resonance imaging (MRI) can be performed to evaluate the structure and function of the heart and blood vessels and offers an alternative to angiography.

Positron emission tomography

Positron emission tomography (PET) provides information on myocardial perfusion, metabolism and cell membrane function. Positron-emitting isotopes are used to label physiological substances, after which the regional distribution of these substances can be measured. PET is valuable in the diagnosis of coronary artery disease, particularly when the more widely available imaging modalities are inconclusive. It can identify injured but viable myocardium that is potentially salvageable by revascularisation.

Computerised tomography

With the development of the latest computerised tomography (CT) scanners, which have the ability to correct for respiratory and cardiac movements, multislice high-resolution CT scanning may become an alternative to coronary angiography. It allows for the assessment of coronary disease, particularly proximal coronary artery disease, and gives some information about the degree of coronary artery calcification.

Invasive methods of diagnosis

Coronary angiography

Selective coronary angiography provides the means of accurately diagnosing the presence and extent of coronary artery disease and remains the 'gold standard' diagnostic technique (Fig. 51.3). In spite of the availability of newer imaging techniques such as cardiac MRI, selective coronary angiography provides high image quality, demonstrating the extent, severity and location of coronary artery stenoses and the quality and size of the distal coronary arteries. Any stenosis in an artery of > 70% of the diameter (90% reduction on cross-sectional area) is considered 'severe'. In addition, it allows assessment of ventricular function and provides the cardiac surgeon with information to determine operability, operative risk and probability of operative result. This test only outlines the coronary anatomy, does not demonstrate ischaemia and carries an overall complication rate of less than 1% (Summary box 51.5).

Summary box 51.5

Coronary angiography

- 'Gold standard' for imaging of anatomy
- Demonstrates extent, severity and location of stenoses
- Reduction in diameter of > 70% is considered severe (90% reduction in cross-sectional area)
- Demonstrates quality and size of distal arterial tree
- Aids diagnosis of ischaemia
- Evaluates suitability for surgery
- Aids in prognostic assessment

Figure 51.3 Coronary angiogram demonstrating severe stenosis in the left main stem prior to bifurcation of the left anterior descending and circumflex arteries.

Indications for surgery

Surgery for coronary artery disease may be indicated for *symptomatic* or *prognostic* reasons. The decision to advise CABG is based on the balance between the expected benefit and the risks that the patient faces. Studies have identified a subset of patients with certain angiographic features who have improved survival after surgery (Summary box 51.6).

Summary box 51.6

Survival is improved through surgery in patients with:

- > 50% stenosis of the left main stem ('critical left main stem disease')
- > 70% stenosis of the proximal left anterior interventricular artery
- All three main coronary arteries diseased ('triple-vessel disease')
- Poor ventricular function associated with coronary artery disease

Chronic stable angina

A common indication is for the relief of symptoms of angina despite adequate medical therapy. Percutaneous coronary angioplasty (PTCA) and coronary stents are increasingly used for treatment. In the presence of certain angiographic features, surgical revascularisation offers a better survival. Angina can be relieved by surgical revascularisation in most patients and symptomatic improvement can be expected for over 10 years.

Acute coronary syndromes

The majority of patients who are hospitalised with *unstable angina* become asymptomatic within 48 hours of the initiation of anti-anginal therapy, and ECG signs of transient ischaemia disappear. If, however, the patient develops recurrent angina and/or ECG changes despite medical therapy, surgical revascularisation has largely been superseded by thrombolysis and primary PTCA. If following an uncomplicated acute myocardial infarction (MI), the patient is a suitable candidate for surgical revascularisation, elective CABG should be carried out at least 6 weeks after the infarction to reduce the higher complication rate associated with recent acute MI.

Surgery for the complications of myocardial infarction

MI leads to myocyte necrosis, which may heal to form scar tissue or rupture if the ventricular wall gives way. Free rupture of the ventricle is usually fatal despite treatment. *Ventricular septal rupture* typically presents 3–7 days after infarction with pulmonary oedema, a pansystolic murmur and hypotension. The diagnosis is usually confirmed with echocardiography. Repair is with a pericardial or artificial Dacron patch.

Papillary muscle necrosis causes acute mitral regurgitation, a pansystolic murmur and pulmonary oedema. Diagnosis is made by echocardiography and right heart catheterisation (showing large V waves). Mitral valve replacement is usually necessary, but the mortality rate is higher than in valve replacement for rheumatic heart disease as a result of the associated coronary artery disease.

Ventricular aneurysm occurs following partial-thickness necrosis of the ventricular wall if the free wall is replaced with non-contractile fibrous tissue. Left ventricular function is affected because the fibrous wall balloons out during systole and reduces

the actual stroke volume. Repair is undertaken using CPB, and CABG is undertaken at the same time if necessary.

Combined with valve replacement

Patients undergoing valve replacement usually have coronary bypass surgery to any significant coronary lesions. However, several variables need to be carefully evaluated when considering the choice of a combined procedure and the overall operative risk: these include age > 70 years, female sex and poor left ventricular function, as well as what the underlying valve pathology is and which valve is to be replaced.

Acute failure of percutaneous coronary angioplasty

Since the advent of intracoronary stents, the need for emergency CABG following complications of PTCA is low at < 1%. The mortality rate in this group is significantly higher than for elective CABG.

Contraindications to surgery

Few absolute contraindications exist, although the presence of significant cerebrovascular disease may require modification of surgical strategy. Other relative contraindications are recognised (Summary box 51.7).

Summary box 51.7

Contraindications for coronary artery bypass surgery

- Small, diffusely diseased arteries
- Diffuse disease and heart failure
- Acute myocardial infarction over 6 hours old
- Moribund patients after resuscitation

Preparation for surgery

Clinical assessment

Before CABG, the severity and stability of the patient's IHD, the presence of significant valvular disease and the status of left ventricular function should be properly evaluated.

Any comorbid risk factors for IHD should be documented and, in particular, the state of coexisting diseases assessed. Attention is paid to the presence of carotid artery disease, peripheral vascular disease, respiratory status, preoperative diabetic control and presence of associated diabetic complications, significant renal dysfunction or coagulopathy. All medications taken by the patient are noted. Ideally, some should be stopped before surgery, in particular any anti-platelet agents, including aspirin and anticoagulants, as well as oral hypoglycaemics. Others drugs, such as diuretics and angiotensin-converting enzyme (ACE) inhibitors, are stopped on the discretion of the surgeon. However, apart from the exceptions noted, as a general rule all cardiac and antihypertensive medications should be taken preoperatively.

Risk assessment

Risk assessment or stratification can be calculated using various scoring systems developed for cardiac surgery, including the EuroSCORE and PARSONNET. The common scoring systems

The Parsonnet score was developed by V. Parsonnet and others, at the Newark Beth Israel Medical Center, New Jersey, NJ, USA, and is based on the publication 'A Method of Uniform Stratification of Risk for Evaluating the Results of Surgery in Acquired Adult Heart Disease', (1989).

stratify risk factors that are recognised to be associated with poor outcome following surgery. An estimate of operative mortality can be calculated and allows informed consent by the patient.

Selection of conduit

Venous grafts

The long saphenous vein is the most common vein used as a conduit as it is straightforward to harvest, provides good length and is easy to handle.

The 10-year patency rate for long saphenous vein grafts is reported to be 50–60%, with 10–15% occluding in 1 year. Strategies to improve vein graft patency include smoking cessation following CABG, the use of lipid-lowering agents and the early use of anti-platelet agents such as low-dose aspirin. In assessing the patient preoperatively, the legs should be checked for varicose veins. Alternative vein conduits include the short saphenous vein or upper limb veins such as the cephalic vein.

Arterial grafts

The left internal mammary artery (LIMA), or internal thoracic artery, has become the conduit of choice for the LAD. Since the mid-1980s, 10-year patency rates of 90% have been reported, with improved long-term survival and fewer reoperations. As LIMA–LAD anastomosis avoids the late complication of vein graft atherosclerosis, particular interest has focused on the use of bilateral internal mammary artery (BIMA) grafts. It does have limitations, however, and may be particularly inappropriate in certain sub-groups of patients, such as the obese diabetic in whom sternal wound complications appear higher.

The use of the radial artery as a second or alternative arterial bypass graft has enjoyed a revival. This has been driven to some extent by the developing concept of total arterial revascularisation and the belief that this will help improve long-term results of coronary surgery. Patency rates appear at least as good if not better than for long saphenous vein grafts. In assessing a patient in whom a radial artery harvest is planned, an Allen's test is performed (Summary box 51.8).

Summary box 51.8

Allen's test

- The patient makes a tight fist while the surgeon compresses both distal and ulnar arteries digitally; this squeezes blood from the hand
- The hand is then relaxed and compression of the ulnar artery is released; the speed of returning colour to the hand is assessed
- If colour returns in 5–7 s, patency and collateral flow from the ulnar artery is confirmed

Alternative arterial bypass grafts include the gastroepiploic artery and the inferior epigastric artery.

The operation

Intraoperative monitoring includes monitoring of continuous central venous pressure and blood pressure (via a central line in

Edgar van Nuys Allen, 1900–1961, Professor of Medicine, The Mayo Clinic, Rochester, MN, USA.

the internal jugular or subclavian vein and radial artery line respectively), urine output via a urinary catheter, temperature using a probe positioned at the nasal septum, and the ECG.

The operation commences with harvesting of the long saphenous vein from the leg (Fig. 51.4) while the chest is opened via a median sternotomy and the LIMA is dissected from the chest wall (Fig. 51.5). The patient is typically placed on CPB after heparinising, the aorta is cross-clamped and the heart arrested with cardioplegia. The grafts are anastomosed to coronary arteries distal to the stenosis (Fig. 51.6).

The aortic cross-clamp is removed and the heart is reperfused with oxygenated blood. A side-biting clamp is applied to the ascending aorta and the proximal anastomoses are completed. The patient is warmed and weaned from CPB. The heparin is reversed and the patient is returned to the intensive care unit (ICU).

Figure 51.4 The long saphenous vein is exposed at the ankle, anterior to the medial malleolus, as far as the saphenofemoral junction (if required). The side branches are tied carefully and divided, and the vein is excised. Gentle distension of the vein through a cannula at its distal end allows inspection for leaks.

Figure 51.5 A pedicled left internal mammary artery is dissected off the chest wall and divided distally after systemic heparinisation. It is left attached to the subclavian artery proximally.

Figure 51.6 Completed coronary artery bypass grafts

Postoperative recovery

The majority of patients are extubated a few hours after returning from surgery and remain in the ICU for 24 hours or so. In some centres, 'fast tracking' appropriate patients allows for an earlier transfer to a recovery area or high-dependency unit (HDU). Discharge is routinely 5–8 days after surgery.

Postoperative complications

Bleeding

Significant bleeding occurs in approximately 3–5% of patients. Rarely, acute cardiac tamponade or profound hypotension may occur in the early postoperative period and requires emergency re-sternotomy.

Arrhythmias

The most common postoperative arrhythmia is sinus tachycardia, closely followed by atrial fibrillation (AF). It occurs in around 30% of patients undergoing CABG and often spontaneously reverts to sinus rhythm. Treatment includes correction of potassium ($> 4.5 \text{ mmol l}^{-1}$), the use of amiodarone or digoxin and, if necessary, cardioversion. Bradycardia is seldom seen, but temporary pacing via epicardial pacing wires inserted intraoperatively may be required in the postoperative period.

Poor cardiac output state

Myocardial function typically declines in the first few hours following cardiac surgery, presumably in response to an ischaemia/reperfusion-type injury. Often, inotropic agents are required at this time to support the heart and circulation. Occasionally, the patient develops a persistent low cardiac output state. The clinical manifestations of such a situation include poor peripheral perfusion, with poor urine output, a developing metabolic acidosis and low blood pressure.

There are several mechanisms that account for this complication in the early postoperative period, including depressed

myocardial contractility, reduced preload, increased afterload and a disturbance in heart rate or rhythm.

Treatment is aimed at the underlying cause but generally includes oxygenation, optimising preload, reducing afterload, managing any rhythm disturbances and improving contractility. If the low cardiac output state persists, the heart may require pharmacological or mechanical support.

Pharmacological support

Inotropic drugs act in a variety of ways to alter the systemic vascular resistance, increase the heart rate and increase the force of myocardial contractility. Commonly used inotropes include isoprenaline, dopamine, dobutamine, adrenaline (epinephrine) and noradrenaline (norepine); they are often used in conjunction with vasodilating agents that decrease the afterload.

Mechanical support

If low cardiac output persists despite inotropic support, the heart may require mechanical support while it recovers its function. The intra-aortic balloon pump (IABP) is a device that is inserted, either percutaneously or under direct vision, into the common femoral artery. It is threaded into the aorta until its tip lies just distal to the arch vessels (Fig. 51.7). The balloon is triggered by the ECG, deflating during ventricular systole (thus reducing afterload) and inflating in diastole (displacing blood that perfuses the coronary arteries retrogradely). When the heart has recovered sufficiently, the balloon is removed.

Figure 51.7 Intra-aortic balloon pump counterpulsation. (a) The balloon deflates during systole and thereby lowers systemic resistance. It inflates during diastole and increases coronary perfusion in addition to augmenting the systemic blood pressure. (b) The pressure changes and phases of the electrocardiogram (ECG) are shown.

Neurological dysfunction

Stroke leading to a focal neurological deficit occurs in approximately 2% of patients following CABG. Embolisation, probably originating from the aortic arch or heart chambers, is the most common mechanism for territorial infarcts, with hypoperfusion leading to watershed infarcts. Diffuse neurological injury may occur leading to more subtle cognitive abnormalities in memory, concentration and attention.

Wound infection

Significant deep wound infection resulting in sternal dehiscence and mediastinitis occurs in around 0.5–2% of patients. This can be associated with significant morbidity with a prolonged hospital stay and further surgical interventions for debridement and/or rewiring of the sternum. It still has a significant mortality rate of as high as 40%. Wound infections are more common in diabetics and the obese.

Mortality

In the UK, the overall mortality rate for patients undergoing CABG is 2–3%. Multiple factors have been demonstrated to affect mortality after CABG, including age, gender, left ventricular function, use of LIMA and complete revascularisation.

Surgical outcome

Relief of symptoms

If revascularisation is complete, CABG alleviates or improves anginal symptoms in more than 90% of patients at 1 year; this falls to 80% at 5 years and 60% at 10 years. This symptomatic deterioration usually reflects progression of atherosclerotic disease in vein grafts and native coronary arteries.

Survival

Early surgical versus medical studies have reported survival rates to be 95% at 1 year, 90% at 5 years, 75% at 10 years and 60% at 15 years. Through changes in surgical practice, such as an increased use of arterial conduits and the widespread use of aspirin and lipid-lowering statins, post-CABG survival may well improve in the future (Summary box 51.9).

Summary box 51.9

Coronary artery bypass surgery outcome

Mortality

- 2–3%

Peroperative infarct

- 2–3%

Angina

- Better in 90% at 1 year
- 80% at 5 years
- 60% at 10 years

Survival

- 95% at 1 year
- 90% at 5 years
- 75% at 10 years
- 60% at 15 years

Off-pump coronary artery surgery

CABG without the use of CPB is a well established and increasingly popular method that may be combined with a minimally invasive approach or carried out through a conventional sternotomy. It offers the advantages that it avoids the physiological stress associated with CPB and, to some extent, the aortic manipulation that can lead to neurological injury through atherosclerotic embolisation. Since the introduction of cardiac stabilising devices such as the Octopus (Fig. 51.8), off-pump coronary artery bypass (OPCAB) grafting has become widespread.

Minimal access surgery

Minimally invasive direct coronary artery bypass (MIDCAB) grafting is performed through a strategically placed minimal access incision and so avoids all invasive aspects of conventional CABG. Through an anterior submammary incision the LIMA can be dissected down with the aid of a thoracoscope and grafted to the LAD. More lateral MIDCAB incisions allow access to other coronary vessels including branches of the circumflex artery. Patient selection remains, at least at present, a restriction to the ever-increasing minimally invasive methods being developed. Although not yet critically evaluated, one particular approach is to combine MIDCAB (typically LIMA to LAD) with PCI to other less accessible coronary arteries ('hybrid' coronary revascularisation).

VALVULAR HEART DISEASE

Introduction

Early surgical management of valvular heart disease concentrated on valvular repair. The heroic early procedures for valve stenosis were closed and therefore 'blind' commissurotomies. They were replaced by open procedures with full visualisation allowing precise repair and replacement. The first prosthetic valve replacement was performed by Harken in 1960 replacing the aortic valve, followed by a mitral valve replacement by Starr

Figure 51.8 Off-pump coronary artery bypass using an Octopus stabiliser to perform the distal anastomosis.

Dwight Emary Harken, B. 1910, formerly Chief of Thoracic Surgery, The Peter Bent Brigham Hospital, Boston, MA, USA.
Albert Starr, B. 1926, formerly Professor of Surgery, The University of Oregon, Portland, OR, USA.

a year later. Continued improvements in perioperative care, myocardial protection and, in particular, the development of prosthetic heart valves have improved long-term haemodynamic effects, provided symptom relief and prolonged survival. The majority of valvular operations involve surgery on the aortic or mitral valve; tricuspid and pulmonary valve surgery is rarely undertaken.

Surgical anatomy

Heart valves function to maintain pressure gradients between cardiac chambers and so ensure unidirectional flow of blood without reflux through the heart. The aortic valve is tricuspid with semilunar leaflets attached to the aortic wall at the annulus with the aortic sinuses occurring above the base of each leaflet, two of which form the origin or ostium of the coronary arteries. The intrinsic shape of the aortic semilunar valve allows blood to leave the ventricle during systole and prevents its regurgitation during diastole. If disease leads to disruption of the leaflets or the annulus, valve function will be affected.

The mitral valve is bicuspid; the more anterior cusp is larger and lies between the orifices of the mitral and aortic valves. The leaflets, like those of the aortic valve, are attached to an annulus. The leaflets join at two commissures and are supported by a sub-valvular apparatus consisting of chordae tendinae and papillary muscles. The papillary muscles contract in ventricular systole, pulling the cusps towards the atrioventricular orifice and holding blood within the ventricle. The proper functioning of the mitral valve depends on the integrity of the annulus, leaflets, chordae and papillary muscles. If surgical correction is required, emphasis is on the preservation of these structures when possible (Fig. 51.9).

Surgical options for heart valve disease

The decision of whether to repair or replace the diseased valve depends on the underlying pathology, the severity of disease, and quality and/or involvement of the surrounding supporting structures. Generally, repair is increasingly favoured when possible in mitral valve disease, particularly in mitral regurgitation in which it has been shown to have good long-term outcomes. Repair is the operation of choice in tricuspid valve disease, but aortic valve surgery generally involves replacing the diseased valve (Table 51.1).

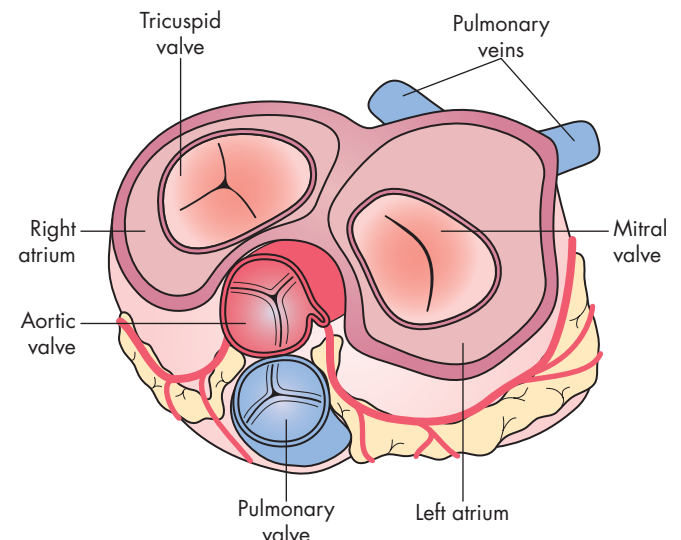

Figure 51.9 Four valves of the heart.

Table 51.1 Comparing options for heart valve surgery

	Advantages	Disadvantages
Valve repair	Preservation of integral structures Improved haemodynamics Avoids long-term anticoagulation	Technical difficulties Variable failure rate
Valve replacement		
Mechanical	Readily available Extensive experience of use Used in any age group Durability, lifelong	Needs lifelong anticoagulation Susceptibility to infection
Biological		
Stented	Readily available Short period of anticoagulation	Limited lifespan
Stentless	Readily available Probably better haemodynamics with less outflow tract obstruction Short period of anticoagulation	Limited lifespan More difficult to insert
Homograft	No anticoagulation Improved haemodynamics Long-term outcome uncertain	Not readily available Technical difficulties

Table adapted from Sharpe, D.A.C. and Das, S.R. (2000) Heart valve surgery. *Surgery* **18**: 265–9.

Important factors in selecting the type of procedure and prosthesis include the age of the patient and the need for anticoagulation. Because of uncertainties about its lifespan, there is debate about when a bioprosthetic valve should be used, with most accepting its use in those over 65 years. The need for anticoagulation may have an impact on choice of valve, particularly in women of childbearing age, in the elderly, in the presence of congenital or acquired bleeding diathesis and when there is the need for further major surgery.

Types of prosthetic valves

Mechanical valves

Mechanical valves can be used in any age group to replace any valve (Fig. 51.10). They are extremely durable but the components

Figure 51.10 Bileaflet mechanical valve.

of the valve are thrombogenic and therefore the patient requires systemic anticoagulation, usually with warfarin. This subjects the patients to a lifetime of blood tests, medication and the constant threat of haemorrhagic complications (intracerebral, epistaxis, gastrointestinal bleed).

Biological valves

Biological valves include *homograft* (or *allograft*) valves, removed from cadavers; *autografts*, a patient's own valve; and, most commonly, *heterografts* (or *xenografts*) prepared from animal tissues. All share the basic design of three semilunar leaflets with central flow, so decreasing pressure gradients and minimising turbulence (Fig. 51.11). Heterograft 'tissue' valves are the most commonly used valves and can be stented with a limited durability of 10–15 years, whereas stentless (or frameless) valves are expected to have less late calcific degeneration but are more technically difficult to insert.

Figure 51.11 Porcine heterograft stented valve.

Prosthetic valve dysfunction and complications

Structural valve failure

Bioprosthetic valves are vulnerable to degenerative changes. Structural failure rates for biological valves, although rare in those over 70 years of age, can reach 60% after 15 years. Structural failure of a mechanical valve is generally uncommon.

Paravalvular leak

Early-onset paravalvular leaks usually result from technical difficulties at insertion. Late-onset leaks can occur and may be related to an episode of endocarditis or, in the presence of bioprostheses, leaflet degeneration. The leak can cause haemolytic anaemia or haemodynamic compromise and the valve may need replacement.

Thrombosis and thromboembolism

Thrombus formation on a prosthetic valve remains the most common complication of mechanical and biological valves (Fig. 51.12). The risk of thromboembolism is greater with a valve in the mitral position (mechanical or biological) than with one in the aortic position. Improved haemodynamic function lowers the probability of thromboembolism. The incidence of thromboembolism in current mechanical valves is 0.5–3% per patient-year.

Prosthetic valve endocarditis

The incidence of prosthetic valve endocarditis (PVE) is 2–4%. The risk is lifelong and at its greatest in the first 15 weeks after surgery. The incidence of PVE is higher with mechanical and bioprosthetic valves and lowest with homograft and autograft valves. The diagnosis is made by symptoms of septicaemia, appearance of a new murmur or a septic embolus. It is confirmed with echocardiography, which may show vegetations and even abscess formation. A high index of suspicion is required and early multiple blood cultures are needed to confirm the diagnosis, identify the infective organism and choose appropriate antibiotic therapy. The most common organisms that can lead to PVE are the *Staphylococcus* species, particularly *Staphylococcus epidermidis* in early PVE and *Staphylococcus aureus* (at least 50% of cases); the *Streptococcus* species, usually

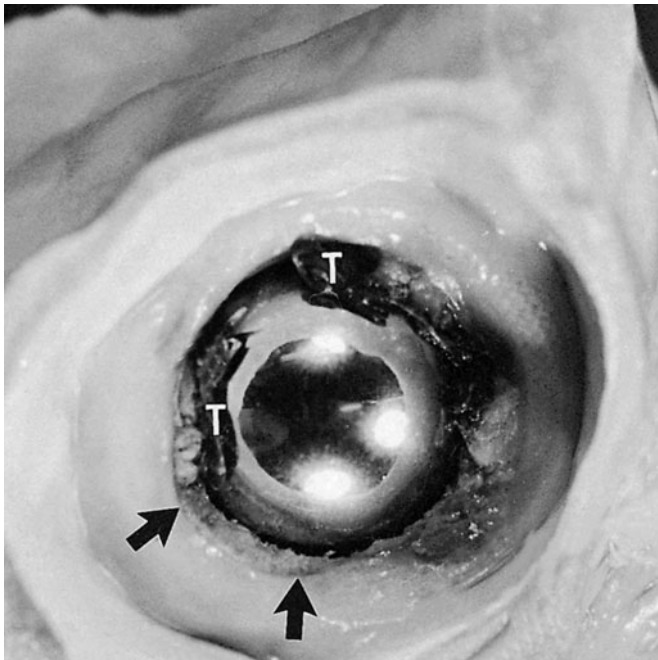

Figure 51.12 Thrombus (marked T and illustrated with the arrows) on the moving components of a ball-and-cage valve.

Streptococcus viridans but also *Streptococcus pneumoniae*; and, less commonly, Gram-negative bacilli, as well as fungal organisms.

The treatment of choice is early aggressive intravenous antibiotic therapy. Serial echocardiography to assess extent of infection into surrounding myocardial tissue as well as functional assessment of the infected valve may help in optimising decisions on timing of surgical intervention. The prognosis of PVE remains poor with an overall mortality rate of over 50%.

Postoperative management

Antibiotic prophylaxis

Valve surgery, like all cardiac procedures, requires perioperative and immediate postoperative antibiotic prophylaxis. If prosthetic infective endocarditis is to be avoided, further prophylaxis with appropriate antibiotics is required during dental and minor surgical procedures in all patients with prosthetic heart valves.

Anti-thrombotic therapy

All patients with mechanical valves require warfarin, usually started on the second postoperative day. The use of anticoagulation or anti-platelet therapy with biological valves is variable and depends on the patient's underlying rhythm postoperatively.

Mitral valve disease

Approximately one-third of all valve surgery performed in the UK is for mitral valve disease, with increasing emphasis on valve repair as the importance of preserving the mitral valve apparatus has become apparent.

Mitral regurgitation

Any pathological process affecting the mitral valve apparatus will lead to mitral regurgitation. As such, there are many causes of regurgitation and they can be broadly classified into five headings (Summary box 51.10).

Summary box 51.10

Causes of mitral regurgitation and likely pathology

Degenerative

- Mitral valve prolapse
- Floppy valve: degeneration of the leaflets with/without chordal rupture
- Senile calcification: calcified annulus
- Connective tissue disorders (e.g. Marfan's syndrome, Ehlers–Danlos' syndrome): disruption of mitral valve apparatus

Ischaemic

- Papillary muscle rupture: following myocardial infarction
- Dynamic mitral regurgitation: as a result of transient ischaemia
- Poor left ventricular function: most common 'functional' cause secondary to myocardial ischaemia

Rheumatic

- Previous acute rheumatic fever: stiffened leaflets unable to coapt

Infective

- Endocarditis: leaflet destruction

Functional

- Presence of reduced left ventricular function with increased ventricular size

Adapted from Hall, R. (1997) Mitral valve disease. *Medicine* 25: 27.

Pathophysiology

There is an important distinction between acute and chronic mitral regurgitation. The former is compared with chronic mitral regurgitation, usually as a result of ischaemic papillary muscle rupture or following infective endocarditis, whereas the latter is a result of myxomatous degeneration of the leaflets leading to a floppy valve.

In *acute mitral regurgitation*, the left ventricle ejects blood back into a small poorly compliant left atrium, imposing a sudden volume load on the left atrium during ventricular systole. This leads to an abrupt rise in left atrial pressure followed by a rise in pulmonary venous pressure and pulmonary oedema.

In *chronic mitral regurgitation*, the process is sufficiently slow to allow compensatory left ventricular dilatation and hypertrophy, and dilatation of the left atrium without any significant increase in pressure, so protecting the pulmonary circulation. As the disease advances and the left atrial dilatation can no longer cope, left atrial pressure begins to rise, leading to a rise in pulmonary venous pressure and progressive pulmonary congestion, and eventual congestive cardiac failure.

Clinical features

In acute mitral regurgitation, the patient is usually unwell, presenting with clinical and radiological evidence of acute pulmonary oedema and a loud apical pansystolic murmur. Patients with mild chronic mitral regurgitation are usually asymptomatic. With progressive pulmonary congestion and left ventricular failure, the patient develops fatigue, dyspnoea on exertion and orthopnoea. The development of atrial fibrillation with left atrial dilatation is common. The enlarged left ventricle leads to a heaving apical impulse and a pansystolic murmur.

Investigations

- ECG may show only left atrial hypertrophy (bifid P waves), left ventricular hypertrophy and atrial fibrillation.
- *Chest radiography*. There may be cardiomegaly with prominent pulmonary vasculature.
- *Echocardiography* is often combined with colour flow Doppler imaging, which shows the severity of the regurgitant jet of mitral regurgitation.

Indications for surgery

Indications for surgery include severe symptoms as assessed by the New York Heart Association (NYHA) functional classification system, a progressive increase in left ventricular volume leading to ventricular dysfunction, uncontrolled endocarditis and severe acute mitral regurgitation (Fig. 51.13). Timing of surgery is crucial, as surgery performed too late in the natural history of the condition does not benefit the patient because of the damage already done.

Mitral stenosis

The most common cause of mitral stenosis remains rheumatic fever, although the incidence of overt rheumatic fever in the developed world has decreased. During the healing phase of acute rheumatic fever, the valve leaflets become adherent to each other at their free border so that the commissures become

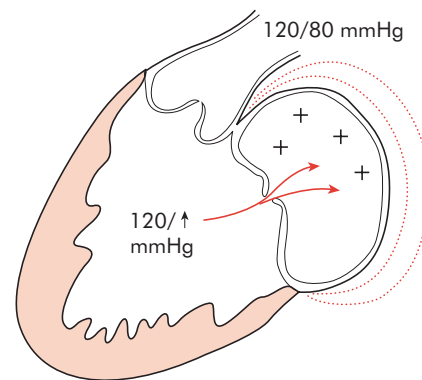

Figure 51.13 Features and pathophysiology of mitral regurgitation. There is a loud parasystolic murmur and the left atrium enlarges. The left ventricle enlarges as a consequence of volume overload.

obliterated and the valve orifice narrows. Symptoms from mitral stenosis usually develop more than 10 years after the acute attack.

Pathophysiology

Mitral stenosis slows ventricular filling during diastole and the pressure in the left atrium rises to maintain cardiac output. This leads to atrial hypertrophy and dilatation. Pulmonary congestion results from the rise in left atrial pressure but, with time, the lungs are protected against pulmonary oedema by constriction of the pulmonary vessels. However, this adaptive response, along with the passive 'back pressure' generated by the rise in left atrial pressure, leads to pulmonary hypertension. This leads to an increased demand on the right ventricle with eventual right heart failure and tricuspid regurgitation. The development of atrial fibrillation is common and can lead to a significant reduction in cardiac output. Atrial fibrillation predisposes to thrombi forming in the left atrium, which may embolise.

Clinical features

Patients may remain asymptomatic for years and then present with symptoms when the heart is stressed by an event such as pregnancy, fever or a chest infection, or with the onset of atrial fibrillation. The common symptoms are fatigue and dyspnoea on exertion, which result from the combination of reduced forward flow and increased back pressure. The resulting pulmonary congestion adds to the breathlessness and may produce a cough or haemoptysis. If mitral stenosis is advanced, there may also be a right ventricular heave due to right ventricular hypertrophy in response to pulmonary hypertension. Auscultation reveals an opening snap soon after the second heart sound, as the diseased valve is opened forcibly by the high pressure in the left atrium. The reverse happens when the valve closes and there is a loud 'tapping' first heart sound. In addition, a rumbling mid-diastolic murmur can be heard. The duration of the murmur is related to the severity of the mitral stenosis, increasing in length as the mitral stenosis becomes more severe.

Investigations

- ECG may show left atrial enlargement (P-mitrale) or AF. Right axis deviation and other ECG signs of right ventricular

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

hypertrophy (tall QRS complexes in the right ventricular leads V_{1-3}) may also be present.

- **Chest radiography.** There is a small aortic outline and a prominent pulmonary artery. The left atrium is enlarged (sometimes to an enormous degree) along with upper lobe diversion as a result of the raised pulmonary venous pressure. The right ventricle also appears enlarged (Fig. 51.14).
- **Echocardiography,** in combination with colour flow Doppler imaging, allows assessment of the flow across the valve and, therefore, the degree of stenosis. Transoesophageal echocardiography (TOE) may be better at assessing valve morphology in detail and excluding the presence of an atrial clot.

Indications for surgery

Medical management includes the use of anticoagulation in patients with AF or left atrial enlargement. Prophylactic antibiotics for endocarditis should be administered before invasive procedures. Tachyarrhythmias, including fast AF, which may lead to decompensation and cardiac failure, should be avoided. Digoxin is the mainstay of treatment but other rate-controlling agents are increasingly used. Diuretics may provide some benefit.

Surgery is indicated for severe symptoms (NYHA class III or IV), moderate or severe mitral stenosis (mitral valve area $\leq 1.5 \text{ cm}^2$) or systemic emboli. Prognosis is determined by the severity of the stenosis, the size of the atrium, the onset of AF, rising pulmonary artery pressure and the unpredictable risk of embolism from a large, fibrillating atrium (Fig. 51.15). Surgical options include commissurotomy or valvotomy, which may be closed or open, mitral valve repair or mitral valve replacement. Since the 1980s, percutaneous mitral balloon valvotomy (PMBV), a catheter-based approach, has become an accepted alternative to surgical approaches in selected patients (Summary box 51.11).

Figure 51.14 Chest radiograph of longstanding mitral stenosis, showing a massive left atrium.

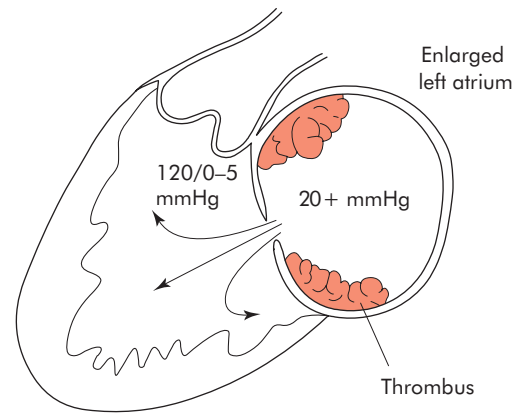

Figure 51.15 Features and pathophysiology of mitral stenosis. The aorta and left ventricle are relatively small because of chronically reduced cardiac output. The atrium is enlarged and may fibrillate, become stagnant and contain a thrombus. The ventricle fills with a turbulent jet that may be detected as a diastolic murmur or a thrill at the apex.

Summary box 51.11

Causes of mitral valve disease

Stenosis

- Rheumatic heart disease (common)
- Calcification of valve or chordae
- Congenital (rare)

Regurgitation

- Rheumatic heart disease
- Valve prolapse
- Left ventricular dilatation or hypertrophy
- Ischaemia
- Bacterial endocarditis

Mitral valve operations

Depending on the type of procedure and approach to the mitral valve, a median sternotomy or, occasionally, a left or right thoracotomy is completed. The mitral valve can be approached directly through the left atrium in the interatrial groove, through the right atrium and then the interatrial septum, or through the left atrial appendage.

Closed mitral valvotomy

Closed mitral valvotomy (or commissurotomy) was first carried out in the 1920s and by the 1950s was an accepted clinical procedure for the surgical treatment of mitral stenosis. The heart is approached through a left thoracotomy and purse-string sutures are placed at the apex of the left ventricle and in the left atrial appendage. A finger is introduced into the left atrial appendage and the mitral valve is assessed by direct palpation. A special dilator ('the Tubbs dilator') is inserted through the left ventricular apex and across the mitral valve. The dilator is opened and the fused commissures are split. Some regurgitation may occur and the process may have to be repeated after 10–15 years. In

Oswald Sydney Tubbs, 1908–1993, Cardiothoracic Surgeon, St. Bartholomew's Hospital, London, England.

experienced hands, the mortality rate is < 1%. It is now uncommonly performed in developed countries as similar results can be achieved with PMBV.

Open mitral valvotomy

With the development of CPB in the 1960s, open mitral valvotomy (or commissurotomy) became accepted practice. It allows direct inspection of the mitral valve apparatus and, under direct vision, division of the commissures, splitting of fused chordae tendinae and papillary muscles, and debridement of calcium deposits. Amputation of the left atrial appendage may reduce the chance of subsequent thromboembolic events.

It has become clear that restoration of normal valve function is preferable to replacement and, as experience in open valvotomy has increased, there have been improvements in the complexity and variety of reconstructive mitral repair techniques available, particularly those to deal with mitral regurgitation.

Mitral valve repair

The functional classification system developed by Carpentier serves as a guideline in valve reconstruction. It allows classification of any mitral insufficiency into one of three groups according to the amplitude of the leaflet motion and provides a useful framework for the mechanisms of failure of the mitral valve. As a rule, several valvular lesions or abnormalities are involved in a functional abnormality, with specific techniques developed to correct each lesion.

At surgery, the anatomy of the valvular apparatus and subvalvular structures has to be carefully inspected. In particular, the extent of annular dilatation, leaflet prolapse and chordal dysfunction are assessed. The mitral valve reconstruction is completed using various techniques, including insertion of a prosthetic ring annuloplasty (Fig 51.16); quadrangular resection of the leaflet; use of a sliding plasty; chordal shortening; chordal transposition; and use of an Alfieri stitch.

The results of valve repair are better for regurgitant lesions than for stenotic lesions and repair is more likely with degenerative

Figure 51.16 Operative view of the completed repair of a mitral valve using a Carpentier–Edwards annuloplasty ring (courtesy of A. Murday, FRCS).

Alain Carpentier, Cardiothoracic Surgeon, Hôpital European Georges Pompidou, Paris, France.

mitral lesions as opposed to rheumatic lesions or endocarditis. The operative mortality is 1–3%. Complication-free survival at 5 years ranges from 80 to 95%. Valve repair, although not conclusively demonstrated, offers better preservation of ventricular function and avoids the need for prolonged anticoagulation as well as avoiding valve-related complications such as PVE or structural dysfunction.

Mitral valve replacement

When valve repair is not possible mitral valve replacement is necessary. This usually involves a median sternotomy and access to the left atrium on CPB. The diseased valve is exposed, excised and a suitably sized mechanical or bioprosthetic valve is implanted. The atriotomy is closed following de-airing of the left heart. Intraoperative TOE can be used to assess adequate valve function.

The operative mortality rate for elective mitral valve replacement is approximately 5–6%. This depends largely on the state of the myocardium and the general condition (including age) of the patient. Common serious in-hospital complications include stroke (< 4%) and renal failure (3%), although any complication of heart surgery is possible. The longer-term prognosis for patients following mitral valve replacement is generally good in comparison with the natural history of mitral valve disease.

Aortic valve disease

Approximately two-thirds of all valve surgery performed in the UK is for aortic valve disease, which remains common despite a reduction in the incidence of rheumatic fever in the developed world.

Aortic stenosis

Aortic stenosis, as opposed to aortic sclerosis, is when a pressure gradient can be demonstrated across the valve. Therefore, the difference is not absolute, as sclerosis can progress to stenosis. The common cause of aortic stenosis in adults is an acquired, degenerative, calcific process that produces an immobilisation of the aortic valve cusps. Progressive fibrosis and calcification of a congenitally abnormal valve can mimic this degenerative process. The usual congenital abnormality is commissural fusion, leading to a bicuspid aortic valve, which occurs in approximately 1% of the population (Fig. 51.17).

Pathophysiology

A pressure gradient develops between the left ventricle and the aorta, with the left ventricle adapting to this systolic pressure overload by an increase in left ventricular wall thickness or hypertrophy. This adaptive response is an attempt to normalise left ventricular wall stress in the face of increased left ventricular systolic pressure, and may maintain a normal cardiac output, prevent left ventricular dilatation and avoid significant symptoms for a number of years. Eventually, myocardial function is affected and, together with insufficient left ventricular hypertrophy to normalise wall stress (load mismatch), ventricular contractility is reduced.

When aortic stenosis is severe and cardiac output is normal, a > 50 mmHg gradient between peak systolic left ventricular and aortic pressure exists. As aortic stenosis worsens, cardiac output cannot increase with exertion and eventually becomes insufficient at rest. The reduction in ventricular contractility leads to an irreversible decline in left ventricular function, with dilatation

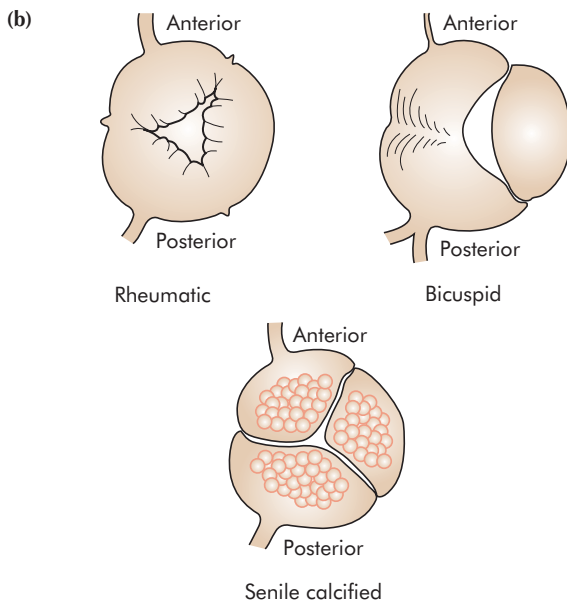

Figure 51.17 (a) Formaldehyde-treated aortic valve (normal tricuspid configuration). (b) Aortic stenosis, different pathologies.

and a rise in left ventricular end-diastolic pressure, to the point of overt left heart failure.

Clinical features

Patients are often asymptomatic until decompensation occurs, typically presenting with dyspnoea and angina, which is due to increased oxygen needs of the hypertrophied left ventricle, reduced coronary filling and inadequate cardiac output during exertion. Patients often describe a feeling of light-headedness or 'near' syncope on effort. Cardiac arrhythmias can also occur. Auscultation of the heart demonstrates a murmur that is typically harsh, ejection in nature and best heard over the aortic area with radiation to the carotids. With critical aortic stenosis and a fall in cardiac output, the murmur may become quieter. The apex beat may be displaced in late disease along with signs of cardiac congestion (Fig. 51.18).

Figure 51.18 Features and pathophysiology of aortic stenosis. Haemodynamic changes in aortic stenosis. Aorta with post-stenotic dilatation.

Investigations

- **ECG.** There is left ventricular hypertrophy with tall R waves in the lateral leads and sometimes a 'strain pattern' (S-T depression with inverted T waves in the lateral leads).
- **Chest radiography.** May be normal. Cardiomegaly and pulmonary congestion can be seen in the presence of left ventricular failure. Post-stenotic dilatation of the aorta is occasionally seen (Fig. 51.19).
- **Echocardiography** confirms the diagnosis and, together with colour flow Doppler imaging, allows assessment of the aortic valve gradient, calculation of valve area, and evaluation of left ventricular dimensions and wall thickness.

Indications for surgery

Medical management focuses on the avoidance of systemic hypotension and arterial vasodilatation, which may reduce myocardial perfusion pressure and therefore provoke ischaemia.

The natural history of symptomatic patients with aortic stenosis is dismal, with a 10-year mortality rate of 80–90%. The patient is at risk of sudden death related to the severity of the stenosis.

Figure 51.19 Chest radiograph in aortic stenosis.

An estimated or actual peak systolic gradient of > 6.7 kPa (50 mmHg) with left ventricular function is sufficient indication for aortic valve replacement.

Indications for surgery in asymptomatic patients with severe aortic stenosis are controversial. Most would consider surgery in patients with left ventricular dysfunction, concomitant coronary artery disease, in patients over 60–65 years, severe left ventricular hypertrophy, arrhythmias and silent ischaemia.

Aortic regurgitation

The causes of aortic regurgitation can be classified according to the speed of development of the regurgitant jet (acute or chronic) or according to the anatomical location of pathology (valve leaflet or aortic wall). The causes of acute aortic regurgitation include infective endocarditis, aortic dissection and trauma. The common causes of chronic aortic regurgitation include degeneration leading to aortic root and/or annular dilatation, congenital bicuspid valve and previous rheumatic fever or endocarditis (Summary box 51.12).

Summary box 51.12

Causes of aortic regurgitation according to predominant anatomical location of pathology

Valve leaflet disease

- Congenital, e.g. bicuspid valve leading to degenerative changes, with ventricular septal defect
- Rheumatic heart disease
- Infective endocarditis

Aortic wall pathology

- Inflammatory, e.g. connective tissue disorders such as ankylosing spondylitis, systemic lupus erythematosus, rheumatoid arthritis
- Systemic disease, e.g. tertiary syphilis
- Degenerative, e.g. Marfan's syndrome, aortic root dissection, senile aortopathy, leading to aortic root/annular dilatation

Adapted from Petch, M. (1997) Aortic valve disease. *Medicine* 25: 31.

Pathophysiology

Acute aortic regurgitation imposes a volume load on the left ventricle because of backflow. It causes a sharp rise in left ventricular end-diastolic pressure, premature closure of the mitral valve and inadequate forward left ventricular filling. The result is sudden haemodynamic deterioration and acute respiratory compromise.

In chronic aortic regurgitation, volume load and left ventricular end-diastolic pressure increase gradually, leading to compensatory left ventricular dilatation and eccentric hypertrophy to maintain adequate cardiac output. Systolic and diastolic function is abnormal, and sudden deterioration can occur.

Clinical features

Longstanding aortic regurgitation is asymptomatic until the left ventricle begins to fail, when exertional dyspnoea may be the only symptom. Angina can also develop. A wide pulse pressure due to

a reduction in diastolic pressure and collapsing pulse (water-hammer pulse) are commonly seen. Other manifestations of the wide pulse pressure include visible capillary pulsation of the nail bed (Quincke's sign), pulsatile head bobbing (de Musset's sign), visible arterial pulsation in the neck (Corrigan's sign), a 'pistol-shot' sound on auscultating over the femoral artery (Traube's sign) and uvular pulsation (Müller's sign). The apex is displaced laterally, often visible and hyperdynamic or 'thrusting' in nature because of the left ventricular hypertrophy. Auscultation reveals a high-pitched early diastolic murmur best heard at the left sternal edge (Fig. 51.20).

Investigations

- ECG. There is left ventricular hypertrophy and sometimes a 'strain pattern'.
- Chest radiography. Cardiomegaly can be seen if the left ventricle is dilating; sometimes, the aortic shadow may also indicate dilatation.
- Echocardiography. This allows assessment of the underlying cause and severity of aortic regurgitation and enables the diameter of the aortic root as well as left ventricular dimensions to be determined. Colour flow Doppler imaging quantifies the size of the regurgitant jet.

Indications for surgery

Medical therapy with vasodilator drugs for the relief of dyspnoea or angina is designed to improve forward stroke volume and reduce regurgitant volume. However, symptomatic relief does not alter the need for valve surgery.

The indications for surgery are the onset of symptoms of NYHA class III or IV. Minor degrees of aortic regurgitation are well tolerated but if the left ventricle deteriorates and dilates it may be too late for surgery. An end-diastolic pressure of > 70 mmHg, an end-systolic pressure of > 50 mmHg, an end-systolic dimension of > 50 mm and an end-diastolic dimension of > 70 mm indicate severe pathology warranting surgical intervention, even in patients with mild symptoms (NYHA class II). Asymptomatic patients with left ventricular dysfunction during

Aortic valve surgery

Unlike mitral valve surgery, there are few occasions when the aortic valve can be repaired and usually the valve requires replacement. However, in neonates and children, aortic valve repair or valvotomy is well established. Percutaneous aortic balloon valvotomy has a role in children, but appears to offer no benefits in adult aortic valve disease.

Aortic valve replacement

This is performed through a median sternotomy on CPB. The aorta is cross-clamped and opened proximally to reveal the diseased valve. Cardioplegic solution is infused into the coronary arteries to arrest the heart in diastole. The valve is then excised leaving the annulus *in situ* but removing as much calcific debris as possible. The annulus is sized and the mechanical or biological valve is then sutured into position at the level of the native annulus and the aortotomy is closed.

The operative mortality rate for elective aortic valve surgery is < 5%, but is higher in emergency surgery, in surgery for endocarditis and in older patients. The common serious in-hospital complications include stroke (2%), perioperative myocardial infarction (2%), renal failure requiring dialysis (0.7%) and heart block requiring a permanent pacemaker (< 1%). The major determinant of late survival after aortic valve surgery is preoperative left ventricular function. The 5-year survival rate is approximately 75–85%, with the majority of late deaths related to myocardial factors.

CONGENITAL HEART DISEASE

Introduction

Congenital heart diseases are abnormalities of cardiac structure that are present from birth. Such abnormalities in the development of the heart typically arise in the third to eighth week of

gestation. The first operation for congenital heart disease was the ligation of a patent ductus arteriosus (PDA) by Gross in 1938. With the development of neonatal CPB, improved methods of myocardial protection and microsurgical techniques, an increasing number of corrective and palliative operations are possible.

Development of the heart and fetal circulation

By 12 weeks of fetal life the primitive vascular tube is fully developed. The fetal circulation differs from that of the adult in that the right and left ventricles pump blood in parallel rather than in series. Such an arrangement allows the heart and head to receive more highly oxygenated blood. In the fetus this is possible because of the presence of three structural shunts: the ductus venosus, the foramen ovale and the ductus arteriosus (Fig. 51.21).

Circulatory changes at birth

Soon after birth, pulmonary vascular resistance falls because of the action of breathing and the resulting pulmonary vasodilatation. In addition, within 30 min of delivery, the ductus arteriosus constricts in response to an increase in blood oxygen levels. The result is a reversal of the pulmonary–systemic pressure gradient and termination of blood flow from the pulmonary artery into the aorta.

After birth, the act of cutting and tying the umbilical cord stops venous blood flow from the placenta. This lowers the pressure in the inferior vena cava and, with the fall in pulmonary vascular resistance, right atrial pressure falls. The result is closure of the foramen ovale. The abolition of venous return from the placenta also causes the ductus venosus to close.

The closure of the fetal circulatory shunts in the few hours following birth is functional, with complete structural closure typically taking several months. In 20% of adults the structural closure of the foramen ovale remains incomplete, but is of no cardiovascular significance.

Figure 51.21 Fetal circulation.

Abnormalities of cardiac structure may arise from the persistence of normal fetal channels (PDA, patent foramen ovale), failure of septation (atrial septal defect, ventricular septal defect, tetralogy of Fallot), stenosis (intracardiac–supravalvular, valvular, infravalvular or extracardiac–coarctation of the aorta), atresia or abnormal connections (transposition of the great arteries, total anomalous venous drainage). Fetal echocardiography is now sufficiently sensitive to detect intracardiac lesions in the second trimester.

Incidence

Congenital heart disease is the most common congenital abnormality in the UK; the incidence of significant cardiac abnormalities is 8 cases per 1000 live births. Many spontaneous abortions or stillbirths have cardiac malformations or chromosomal abnormalities associated with structural heart defects. In neonates and children with congenital heart disease, 15% will have more than one cardiac abnormality and 15% will have another extracardiac abnormality.

Aetiology

There is often no obvious aetiology; most abnormalities appear to be multifactorial with both genetic and environmental influences. There are well-recognised associations (Summary box 51.14).

Summary box 51.14

Recognised associations with congenital heart disease

Maternal (environmental) factors

- Infection: rubella
- Disease: systemic lupus erythematosus, diabetes mellitus
- Drugs/medications: alcohol abuse, warfarin, phenytoin

Genetic factors

- Single gene defects: Marfan's, Noonan's and Holt–Oram's syndromes
- Chromosomal defects: trisomy 21 (Down's syndrome), trisomy 18 (Edwards' syndrome), trisomy 13 (Patau's syndrome), Turner's syndrome
- Deletions: DiGeorge's and Williams' syndromes

Diagnosis

Occasionally an antenatal diagnosis is possible, with severe congenital heart disease detected *in utero* at 16–18 weeks. If an infant is suspected of having a congenital heart disease, a diagnostic evaluation begins with an accurate history from the parents and specific questions about maternal health and drug intake during

Etienne Arthur Louis Fallot, 1850–1911, Professor of Medicine, Marseilles, France.
 Jacqueline Anne Noonan, B. 1921, Pediatric Cardiologist, The University of Kentucky College of Medicine, Lexington, KY, USA, described this condition in 1963.
 Mary Clayton Holt, 1924–1993, Cardiologist, The London Hospital for Women and Children, London, England.
 Samuel Oram, 1913–1991, Cardiologist, King's College Hospital, London, England. Holt and Oram described this syndrome in a joint paper in 1960.

 Angelo M. DiGeorge, B. 1921, Professor of Pediatrics, Temple University, Philadelphia, PA, USA.

pregnancy. A detailed family history is important because some defects are familial. Clinical examination may reveal a murmur, evidence of heart failure, failure to thrive and cyanosis. In addition, congenital heart disease can present with hypertension, an arrhythmia, evidence of polycythaemia or a thromboembolic event. Investigation is much the same as for the adult patient and, with fetal echocardiography available, cardiac catheterisation is now avoided whenever possible.

Classification

Congenital heart disease can be broadly classified according to the presence or absence of cyanosis, although the distinction is not always clear-cut. The presence of central cyanosis, blueness of the trunk and mucous membranes, results from levels of deoxygenated haemoglobin of $> 3\text{--}5\text{ g dl}^{-1}$ in the arterial circulation.

Cyanotic congenital heart diseases make up one-third of cases and are usually more complex, although they do include simple defects. Cyanotic congenital cardiac lesions can involve:

- A right-to-left shunt resulting in decreased pulmonary blood flow. Many of these lesions consist of a septal defect in conjunction with a right-sided obstructive lesion, producing an obligatory right-to-left shunt. The most common cause of this is tetralogy of Fallot.
- Parallel systemic and pulmonary blood flow rather than in series. If there is no mixing this is incompatible with life, so typically neonates have a patent foramen ovale that allows some mixing of the two circulations at this level. The most common example of this is transposition of the great vessels (TGV).
- Defects in the connections of the heart in which there is mixing of the systemic and pulmonary flows. An example of such a complex lesion is total anomalous pulmonary venous drainage.

Acyanotic congenital heart diseases represent the other two-thirds of cases and are usually less complex. Such defects result in an increase in the work imposed on the heart because of either:

- A left-to-right shunt with increased pulmonary blood flow, which causes an increase in volume work of the heart. Examples include PDA, atrial septal defect (ASD) and ventricular septal defect (VSD).
- Obstruction of the blood flow across a heart valve on the left side of the heart, such as aortic stenosis, or in the aorta itself, as occurs with coarctation of the aorta, leading to an increase in pressure and work of the heart.

Typically, acyanotic congenital heart disease presents as heart failure in infancy because of pulmonary congestion caused by increased pulmonary blood flow or increased pulmonary venous blood pressure resulting from an obstructive lesion. The common acyanotic cardiac defects can also present as a murmur in infancy or later.

Cyanotic congenital heart disease

Fallot's tetralogy

This is the most common cyanotic congenital heart disease found in children surviving to 1 year and accounts for about 4–6% of all congenital heart diseases. The four intracardiac lesions originally described (Fig. 51.22) were:

- VSD
- overriding aorta

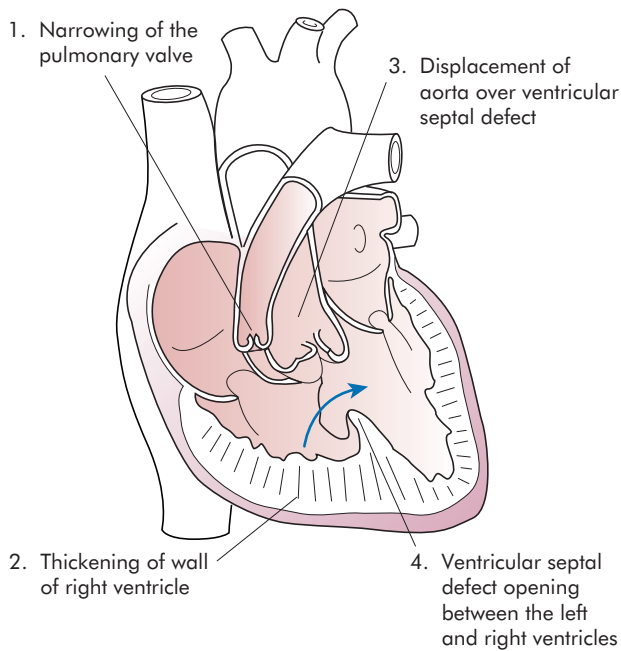

Figure 51.22 Fallot's tetralogy. Four abnormalities that result in insufficiently oxygenated blood being pumped to the body.

- pulmonary (typically infundibular or subpulmonary) stenosis
- right ventricular hypertrophy.

Clinically, there may be no signs initially but, as pulmonary stenosis progresses, cyanosis typically develops within the first year of life. Squatting is an adaptation by the child to hypoxic spells. This increases systemic vascular resistance and the venous return to the heart and consequently blood is diverted into the pulmonary circulation with increased oxygenation. Lethargy and tiredness are also common. Classically the chest radiograph demonstrates a 'boot-shaped' heart with poorly developed lung vasculature. The diagnosis is confirmed with echocardiography. Surgery to correct the tetralogy can be performed early as a single complete primary repair or later following an initial palliative shunt, which diverts systemic blood into the pulmonary circulation and may be used to improve oxygenation. The results of surgery are good, with a late survival rate at 5–10 years following correction of tetralogy of 95%, an operative mortality rate for a repair of between 5% and 10%, and an incidence of reoperation following tetralogy repair of 5–10%.

Transposition of the great vessels

The condition, first described by Morgagni, is the second most common cyanotic congenital heart disease and is the most common cause of cyanosis from a congenital cardiac defect discovered in the newborn period. TGV results from abnormal development and typically occurs when the aorta arises from the right ventricle and the pulmonary artery from the left ventricle (Fig. 51.23). The resulting transposition causes the pulmonary and systemic circulations to run in parallel rather than in series, so that oxygenated pulmonary venous blood returns back to the lungs and desaturated systemic venous blood is pumped around the body. The situation is incompatible with life and mixing of the blood must occur through associated shunts such as a patent foramen ovale or associated VSD. The most obvious presentation is severe central cyanosis occurring in the first 48 hours of life.

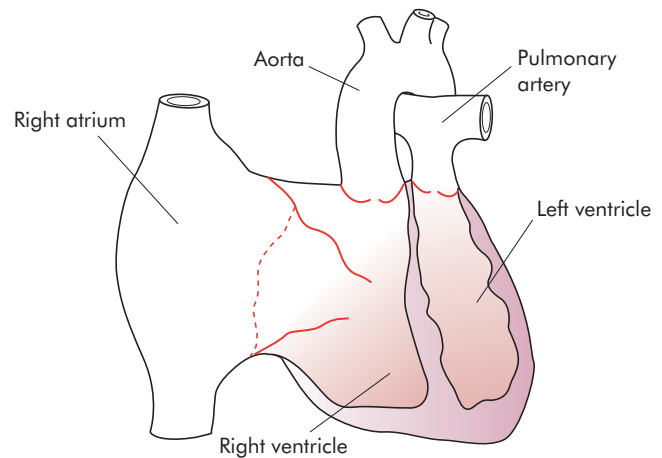

Figure 51.23 Transposition of the great vessels.

However, if there is a large ASD or VSD there may be minimal cyanosis initially. Typically, progress is poor and, as pulmonary vascular resistance declines in the neonatal period, high pulmonary flow develops, with cardiac enlargement and left ventricular failure.

The chest radiograph shows pulmonary plethora, with the heart having an 'egg on its side' appearance, with a small pedicle (aorta in front of pulmonary artery). Cardiac catheterisation and echocardiography confirm the diagnosis and delineate the anatomy. Initial palliation is by percutaneous (Rashkind) balloon atrial septostomy or, alternatively, intravenous prostaglandin to keep the ductus open. Definitive repair is usually by the arterial switch procedure, mostly carried out as a two-stage procedure, whereby the pulmonary artery is first banded to 'tone up' the left ventricle. However, the arterial switch procedure without prior pulmonary artery banding is increasingly being carried out in the newborn with TGV and an intact ventricular septum. The long-term results are impressive and it has replaced the atrial switch or baffle (Mustard or Senning) operations.

Total anomalous pulmonary venous drainage

Total anomalous pulmonary venous drainage (TAPVD) accounts for only 1–2% of congenital heart disease. In this condition the pulmonary venous drainage has become disconnected from the left atrium and drains into the systemic venous circulation at some other point (inferior vena cava, superior vena cava, coronary sinus or right atrium). Typically, TAPVD presents after the first week of life with cyanosis that is mild to moderate depending on pulmonary flow. Infants with high pulmonary flow develop cardiac failure, recurrent chest infections, failure to thrive and feeding difficulties. If high pulmonary flow is associated with a large ASD, cyanosis is often minimal and the lesion is tolerated well. If there is additional venous obstruction, cyanosis presents at birth with dyspnoea and pulmonary oedema. Echocardiography and cardiac (pulmonary) angiography are necessary to

William Jacobson Rashkind, B. 1922, Surgeon, The Children's Hospital, Philadelphia, PA, USA.

William T. Mustard, formerly Associate Professor of Surgery, The Hospital for Sick Children, Toronto, Ontario, Canada.

Ake Senning, 1915–2000, Professor of Surgery, The University Hospital, Zurich, Switzerland.

confirm the diagnosis and establish the location of the anomalous drainage.

The surgical principle is to re-establish the pulmonary venous drainage into the left atrium. The exact operative technique depends on the anatomy and type of TAPVD. The long-term results for survivors of the operation are generally good. Late death following repair is uncommon but, when it occurs, it is often caused by intimal fibroplasia of the pulmonary veins away from the anastomosis.

Eisenmenger's syndrome

Eisenmenger's syndrome is becoming less common as corrective surgery is undertaken increasingly early and fewer patients develop a fixed increase in their pulmonary vascular resistance. It occurs following the reversal of a left-to-right shunt across a previous left-to-right shunt, such as with an ASD, VSD or posterior interventricular artery. These congenital anomalies cause an increase in flow and higher right-sided pressures, which lead to compensatory right ventricular hypertrophy and a subsequent rise in pulmonary artery pressure. Increasing pulmonary hypertension leads to equalisation of pressures either side of the shunt but, at some point, the right-sided pressures will exceed those on the left side, resulting in shunt reversal and desaturated blood entering the left side of the circulation. Cyanosis and dyspnoea are the most common clinical features. Closure of the shunt is contraindicated if pulmonary hypertension is irreversible because the right-to-left shunt now serves to decompress the pulmonary circulation.

Acyanotic congenital heart disease

Patent ductus arteriosus

The ductus arteriosus, a normal fetal communication, facilitates the transfer of oxygenated blood from the pulmonary artery to the aorta, shunting blood away from the lungs. Normally, functional closure of the ductus occurs within a few hours of birth; it is abnormal if it persists beyond the neonatal period. The ductus closes in response to an increase in peripheral oxygen saturation and a drop in the resistance of the pulmonary circulation as the lungs expand; this causes the ductal tissue to contract through a prostaglandin inhibition mechanism. Prostaglandins, such as indomethacin, may be used therapeutically to close the ductus in the first few weeks of life. In premature babies the ductus is more likely to remain patent for longer or permanently. In the isolated case of PDA, there is a left-to-right shunt of blood, resulting in a high pulmonary blood flow. Small shunts usually cause few symptoms and signs apart from the continuous machinery murmur in the left second intercostal space. Larger ducts cause cardiac failure and can uncommonly lead to shunt reversal with cyanosis and clubbing. The diagnosis is best confirmed by echocardiography with colour flow Doppler imaging. Cardiac catheterisation is performed only if additional lesions are suspected.

After 6 months of age, spontaneous closure of a PDA is rare. Most should be closed by preschool age, regardless of the absence of symptoms, if the risks of infective endocarditis, developing left ventricular failure or, rarely, Eisenmenger's syndrome are to be avoided. In the adult, surgical treatment is indicated if there is a persistent left-to-right shunt, even in the presence of pulmonary hypertension. In the premature infant, if medical treatment to

close the ductus is unsuccessful, the lesion may be treated by interventional cardiology using an umbrella or coil duct occlusion device inserted percutaneously. If the lesion is very large or the patient very small, surgical closure via a left thoracotomy is preferred. This can be accomplished by either ligation or division of the PDA. The operative mortality rate is low and outcome generally very good.

Coarctation of the aorta

This accounts for 6–7% of congenital heart disease and is defined as a haemodynamically significant narrowing of the aorta, usually in the descending aorta just distal to the left subclavian artery, around the area of the ductus arteriosus (Fig. 51.24). The coarctation typically puts a pressure load on the left ventricle, which can ultimately fail. The upper body is well perfused but the lower body, including the kidneys, is poorly perfused, leading to fluid overload, excess renin secretion and acidosis. Coarctation usually affects boys and, if it occurs in girls, it is suggestive of Turner's syndrome.

In the neonatal period, coarctation, often referred to as 'infantile' or preductal coarctation, presents with symptoms of heart failure. The child may appear well in the first few days of life because the coarctation is bypassed by the ductus arteriosus and oxygenated blood reaches the entire systemic circulation. As the ductus closes, the child becomes progressively more unwell. In adult-type coarctation, which is often juxtaductal or slightly postductal, obstruction is gradual with complications developing in adolescence or early adulthood. Hypertension is a common presenting problem in older children, often upper body hypertension only with development of enormous collateral vessels that may cause rib-notching and flow murmurs over the scapula. Other

Figure 51.24 Coarctation of the aorta. Coarctation causes severe obstruction of blood flow in the descending thoracic aorta. The descending aorta and its branches are perfused by collateral channels from the axillary and internal thoracic arteries through the intercostal arteries (arrows).

Victor Eisenmenger, 1864–1932, German Physician.

Henry Hubert Turner, 1892–1970, Professor of Medicine, The University of Oklahoma, Oklahoma City, OK, USA.

symptoms include prominent pulsation in the neck, tired legs or intermittent claudication on exercise. Clinical examination of the pulses may demonstrate a radiofemoral delay and a murmur that is continuous and heard best over the thoracic spine or below the left clavicle.

The chest radiograph classically demonstrates rib-notching from the age of 6–8 years because of dilated posterior intercostal vessels. The heart is usually of normal size in the older child and shows a classical ‘three sign’ replacing the typical aortic knuckle. The upper part of the three sign is the dilated left subclavian, the middle part is the narrowing at the coarctation site, and the lower part is the post-stenotic dilatation of the descending aorta. Echocardiography is diagnostic, with cardiac catheterisation performed if other anomalies are present. Infant coarctation typically presents with cardiac failure, often requiring vigorous medical treatment, including the administration of indomethacin to reopen the ductus and general resuscitation, before corrective surgery. Definitive treatment is usually surgical repair via a left thoracotomy. Coarctation presenting in the child or later typically requires surgical repair, as most patients die before the age of 40 years because of the associated complications. Percutaneous balloon dilatation is an alternative procedure in older children and adults and, in particular, for re-coarctation. Without correction, the majority of deaths are caused by heart failure, infective endocarditis, rupture of the aorta or haemorrhagic stroke. The pre-operative hypertension may not resolve despite surgical repair.

Atrial septal defects

An ASD is a defect in the septum between the left and right atria leading to a left-to-right shunt, the significance of which is determined by the size of the defect and the relative compliance of the ventricles. The development of the atrial septum is complex and abnormalities of development lead to three commonly recognised ASDs (Fig. 51.25).

The most common type is an *ostium secundum* ASD. The anomaly is caused by a defect in the floor of the fossa ovalis,

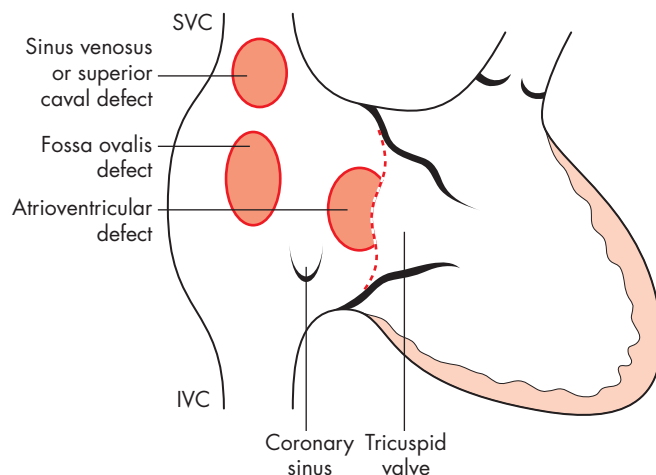

Figure 51.25 Atrial septum viewed from the right. The fossa ovalis is a useful reference point; the most common defect is in this area and is called a fossa ovalis (or ostium secundum) defect. A defect near the atrioventricular junction may be part of the spectrum of atrioventricular septal defects; if the defect is near the entry of the superior vena cava (SVC) it is commonly associated with anomalies of venous drainage into the atria. IVC, inferior vena cava.

resulting in failure of the septum secundum to develop completely and cover the foramen ovale. Secundum defects are usually asymptomatic in childhood, with symptoms developing insidiously, typically presenting in middle age with congestive cardiac failure secondary to pulmonary hypertension or with atrial arrhythmias.

In *ostium primum* ASD the anomaly is a form of partial atrioventricular canal defect or endocardial cushion defect. The abnormalities are confined to the atrial septum and are caused by the endocardial cushions failing to develop and so close the ostium primum part of the interatrial septum. The defect is associated with abnormalities of the mitral valve, leading to mitral regurgitation. There is a relatively high incidence of this abnormality in trisomy 21 (Down’s syndrome). Typically, the primum defect presents earlier than ostium secundum in childhood, with dyspnoea, recurrent chest infections and, if pulmonary hypertension develops, cyanosis.

A *sinus venosus* ASD is a rare defect and is the result of failure of partition of the pulmonary and systemic venous circulations. These defects are most commonly located high in the atrial septum at the junction of the superior vena cava and the right atrium. They are frequently associated with anomalous pulmonary venous drainage with right superior pulmonary veins draining into the superior vena cava or right atrium directly (Summary box 51.15).

Summary box 51.15

ASDs

Common defects

- Ostium secundum: fossa ovalis defect (approximately 70% of ASDs)
- Ostium primum: atrioventricular septal defect (approximately 20% of ASDs)
- Sinus venosus defect: often associated with anomalous pulmonary venous drainage (approximately 10% of ASDs)
- Patent foramen ovale: common in isolation, usually no left-to-right shunt (not strictly an ASD)

Rarer defects

- Inferior vena cava defects: a low sinus venosus defect and may allow shunting of blood into the left atrium
- Coronary sinus septal defect: also known as unroofed coronary sinus with the left superior vena cava draining to the left atrium as part of a more complex lesion

Closure is performed during the first decade of life, even in the absence of symptoms, to avoid late-onset right ventricular failure, endocarditis and paradoxical emboli. In adults, closure is still appropriate for symptomatic improvement and avoidance of complications. The traditional method of closure involves open-heart surgery with CPB and closure of the defect either directly with sutures, as with most secundum defects, or, if the defect is large, using a pericardial or synthetic patch. Closure of small to moderate ASDs using percutaneous catheter-delivered devices in the cardiology catheter laboratory is increasingly common. Primum atrioventricular defect repairs may require additional mitral

John Langdon Haydon Down (sometimes given as Langdon-Down), 1828–1896, Physician, The London Hospital, London, England.

valve repair. The operative mortality rate for isolated atrioventricular defect repairs is < 1%, with an excellent prognosis. Surgical correction of complete atrioventricular canal defects, with closure of the ASD and ventricular septal components and mitral valve repair, is possible with a higher surgical mortality rate.

Ventricular septal defects

A VSD is a defect in the interventricular septum that allows a left-to-right shunting of blood. VSDs account for 20–30% of congenital heart disease and affect approximately 2 in 1000 live births. They may occur in isolation or as part of a more complex set of cardiac abnormalities (e.g. tetralogy of Fallot, complete atrioventricular canal defect). Four major anatomical types of VSD are described, based on the anatomical subsections of the interventricular septum (Summary box 51.16 and Fig. 51.26).

Summary box 51.16

Types of VSD

Perimembranous defect

- Also called conoventricular VSD; the most common defect (70–80%), usually located within the membranous septum and may extend to the tricuspid valve annulus or base of the aortic valve

Muscular defect

- Also called trabecular VSD; occurs in 10% of cases and is located within the membranous septum and often multiple

Atrioventricular defect

- Also called atrioventricular canal-type defect; occurs in 5% of cases and is located in the atrioventricular canal beneath the tricuspid valve

Subarterial defect

- Also called infundibular or subarterial VSD; occurs in 5–10% of cases and lies within the conal septum immediately subaortic

The VSD permits a left-to-right shunt at the ventricular level, with subsequent right ventricular volume overload and increased pulmonary blood flow. This may lead to progressive pulmonary oedema and congestive cardiac failure. Persistently elevated pulmonary blood flow and pulmonary vascular resistance also lead to irreversible pulmonary hypertension. They may eventually result

Figure 51.26 Ventricular septum viewed from the right, showing the characteristic sites of ventricular septal defects.

in reversal of flow across the defect and Eisenmenger's syndrome. The clinical presentation reflects the magnitude of the left-to-right shunt, which in turn depends on the size of the VSD and the pulmonary and systemic vascular resistances. Small defects may close or cause little systemic disturbance (maladie de Roger); infants are asymptomatic with normal development. In the first 5 years, up to 30–50% of VSDs close spontaneously. Clinically, a loud pansystolic murmur can be detected at the left sternal border because of high pressure flow between the ventricles. Large defects typically present with congestive cardiac failure in the first 2 months of life. Because of the size of the VSD, ventricular pressures are equalised and often only a soft systolic murmur is detected. If left untreated, pulmonary hypertensive changes start from about 1 year of age. Eisenmenger's syndrome, secondary to shunt reversal in such cases, may become evident in the second decade of life.

Echocardiography confirms the diagnosis and can estimate the degree of shunting across the defect. Cardiac catheterisation can quantify the various pressures within the cardiac chambers and so assess the degree of pulmonary hypertension, as well as demonstrating a step-up in oxygen saturation between left and right ventricles. Generally, surgical closure is indicated for large defects, when there is failure to respond to medical therapy, for left-to-right shunts of > 2:1, when there are signs of increasing pulmonary vascular resistance and in the presence of complications of VSD. These include (1) aortic regurgitation, which occurs in about 5% of defects; (2) infundibular stenosis, which tends to be progressive and leads to shunt reversal; and (3) infective endocarditis, often presenting with pneumonia or pleurisy as the infected 'emboli' in a VSD with a typical left-to-right shunt flows into the pulmonary circulation.

THE THORACIC AORTA

The most common pathology affecting the thoracic aorta is aneurysm formation or dissection.

Thoracic aortic aneurysms

A true aneurysm is a localised dilatation of a blood vessel involving all layers of the vessel, whereas a false aneurysm has compressed supporting tissue as its wall and is usually the result of a defect in the vessel intima (from trauma, dissection or previous surgery). Aneurysms are described as fusiform when the whole circumference is affected or saccular when only part of the circumference is involved.

Aortic aneurysms can develop anywhere along its length, but thoracic aortic aneurysms, including those that extend into the upper abdomen (thoracoabdominal aneurysms), account for 25%, typically occurring in men in the fifth to seventh decade or younger in those with connective tissue disorders.

Aetiology

The most common aetiology is atherosclerosis, but connective tissue disorders account for many aneurysms in the aortic root and ascending aorta now that tertiary syphilis is rare. Marfan's syndrome is associated with cystic medial degeneration involving the vessel wall and causes widening of the proximal aorta and aortic root, leading to aortic valve insufficiency. Other disorders

Henri Louis Roger, 1809–1891, Physician, Hôpital Sainte-Eugene, Paris, France.

associated with aneurysm formation and dissection include Ehlers–Danlos's syndrome and osteogenesis imperfecta.

Trauma, typically following blunt chest injury, can lead to aneurysm formation, usually involving the descending aorta. However, these are usually false aneurysms containing haematoma from injury to the aortic vessel wall.

Clinical features

Many aneurysms are asymptomatic and are discovered incidentally on routine chest radiographs. Others present as a space-occupying lesion in the thorax with pain caused by pressure on adjacent structures (vertebra), hoarseness (left recurrent laryngeal nerve), dysphagia (oesophagus) and respiratory symptoms (left main bronchus). Aortic root aneurysms may lead to dilatation of the aortic root annulus and aortic regurgitation.

Rupture can lead to cardiac tamponade or haemorrhage into the left pleural space, leading to dyspnoea and, if the tracheo-bronchial airway or oesophagus is involved, haemoptysis or haematemesis respectively.

Investigations

The diagnosis is confirmed by CT or MRI. Arteriography is not necessary for diagnosis but is often required to demonstrate the relation of the arch vessels to the aneurysm.

Indications for surgery

Without treatment the aneurysm is likely to expand and ultimately rupture. Important factors to consider when planning treatment are age, comorbidity and coexisting coronary disease.

In ascending aneurysms, the presence of progressive aortic valve insufficiency is an important indication for surgery. Other indications in this group, including Marfan-related aneurysms, are a diameter of 5–6 cm and the presence of symptoms. In descending aneurysms, indications for surgery include symptoms, acute enlargement and a diameter of approximately 6 cm.

Surgical options

The approach adopted for surgical treatment depends on the location of the aneurysm, but typically involves a median sternotomy, CPB and cooling the patient to 18°C before cross-clamping the aorta above the aneurysm (Fig. 51.27). If the *aortic root* is involved, the aorta, together with its annulus and valve, is resected and a composite graft is sutured to the aortic root. The circulation is arrested and, after removal of the aortic cross-clamp, the distal anastomosis is completed. The coronary ostia require reimplantation into the graft (Bentall's operation). If the *ascending aorta* is involved, it is resected and replaced with a tube graft. For *aortic arch* aneurysms, surgery on this section of the aorta is a formidable undertaking because the cerebral and subclavian vessels have to be anastomosed to the graft, either separately or *en bloc*. Typically, it involves a period of circulatory arrest and some form of cerebral protection. Excision of a *descending aortic aneurysm* is with graft replacement under CPB with exposure via a left thoracotomy or

Figure 51.27 A large thoracic aortic aneurysm.

with a heparin-bonded shunt. Increasingly, thoracic aneurysms at the aortic arch or more distal are repaired using a percutaneous approach via the femoral artery with insertion of an endovascular stent under radiological guidance.

Surgical outcome

The operative mortality rate is variable depending on the location and type of repair required but electively is between 5% and 15%. An emergency repair has a considerably higher operative mortality rate. Long-term survival depends on underlying pathology but, for ascending aneurysm repairs, the 5-year survival rate is approximately 65%. The major complications of descending aneurysm repairs include paraplegia, renal failure and ventricular dysfunction.

Aortic dissection

This occurs when there is a defect or flap in the intima of the aorta, resulting in blood tracking into the aortic tissues splitting the medial layer and creating a false lumen. It most commonly occurs in the ascending aorta or less often just distal to the left subclavian artery. It is also more common in men, typically those aged 50–70 years, and in Afro-Caribbeans.

Aetiology

It usually occurs as a spontaneous or sporadic event, although very often a history of hypertension is noted. Other important associations include Marfan's syndrome and pregnancy (Summary box 51.17).

Summary box 51.17

Predisposing factors for aortic dissection

- Age
- Hypertension
- Marfan's syndrome
- Pregnancy
- Other connective tissue disorders, for example Ehlers–Danlos's syndrome, giant cell arteritis, systemic lupus erythematosus
- Coarctation of the aorta
- Turner's or Noonan's syndromes
- Aortotomy site

Edvard Ehlers, 1863–1937, Professor of Clinical Dermatology, Copenhagen, Denmark.

Henri Alexandre Danlos, 1844–1912, Dermatologist, Hôpital St. Louis, Paris, France, gave his account of this condition in 1908.

Hugh Henry Bentall, formerly Professor of Cardiac Surgery, The Royal Postgraduate Hospital, Hammersmith, London, England.

Clinical features

The presentation is often a tearing intrascapular pain not unlike the pain of myocardial ischaemia, and it may be difficult to distinguish between the two. The extent of arterial dissection may produce widespread symptoms and signs.

The dissection can extend distally down the aorta to involve:

- the renal arteries (renal pain and renal failure)
- the mesenteric arteries (abdominal pain and bowel ischaemia)
- the spinal arteries (paraplegia)
- the iliac arteries (leg pain, pallor, loss or reduced pulses and limb ischaemia).

The dissection may track proximally to involve:

- the head and neck vessels (symptoms and signs of a stroke or transient ischaemic attack)
- the coronary vessels (myocardial infarction)
- the aortic root (aortic regurgitation).

The aneurysm may rupture back into the lumen or externally into the pericardium (cardiac tamponade) or mediastinum (left haemothorax).

Classification

There are two classifications, both of which are limited in their application but widely used. The DeBakey classification is based on the pattern of dissection whereas the Stanford classification is based on whether the ascending aorta is involved (Fig. 51.28).

Investigations

The diagnosis is suspected when chest radiography demonstrates a widened mediastinum, often associated with fluid in the left costophrenic angle. Diagnosis is confirmed by whatever method is most readily at hand and includes echocardiography, ideally TOE, CT of the thorax or MRI (Fig. 51.29). Traditionally, aortography was the 'gold standard' technique and it still provides excellent information before surgery but, increasingly, advanced three-dimensional CT angiography and MRI are used when available.

Management

In the emergency situation, before further imaging, blood pressure (which is usually high at presentation) should be brought under control to prevent extension of the dissection.

Figure 51.28 Stanford classification of aortic dissections according to whether the ascending aorta is involved (type A) or not (type B). This is simpler than the DeBakey classification (types I, II and III).

Figure 51.29 Computerised tomography scan showing acute dissection of the descending thoracic aorta. F, false lumen; T, true lumen.

Surgical options

Type A (or type I and II) dissections

Those involving the ascending aorta usually require surgical intervention. The chest is opened through a median sternotomy and CPB is started with core cooling down to 18°C. The aorta is cross-clamped as high as possible and opened. Cardioplegia solution is infused into the coronary ostia to arrest the heart in diastole. If the intimal tear is present and localised, the ascending aorta is excised with the tear and replaced with a synthetic graft. The distal anastomosis is performed with circulatory arrest.

Type B (or type III) dissections

Initially, these are best managed medically with antihypertensive drugs. Surgery is indicated if the pain increases (signalling impending rupture), the aneurysm is expanding on serial chest radiographs or complications, such as organ, limb or neurological symptoms, develop. The operation may be performed with a heparin-bonded shunt or under CPB. There is a real risk of paraplegia from this operation, which should be mentioned specifically to the patient before operation. Use of percutaneously placed endovascular stents is likely to increase in the future, although currently its role in the acute setting remains to be established.

Surgical outcome

If dissection is untreated, the mortality rate is 50% within 48 hours and 75% within 1–2 weeks. Almost all patients with type A dissections will die if not operated on, whereas patients with type B dissections have a better prognosis. The surgical mortality rate is variable but is around 15% for proximal aortic dissection. The overall survival rate for patients leaving hospital, regardless of the type of dissection, is around 80% at 5 years and 40% at 10 years.

PERICARDIAL DISEASE

There is a fibrous envelope covering the heart and separating it from the mediastinal structures. This fibrous structure includes a parietal layer and allows the heart to move with each beat. It is not essential for life because it can be left wide open after cardiac

surgery without any ill-effects; however, there are a number of conditions affecting the pericardium that may present to the surgeon.

Pericardial effusion

There is a continuous production and resorption of pericardial fluid. If a disease process disturbs this balance a pericardial effusion may develop. If the pressure exceeds the pressure in the atria, compression will occur, venous return will fall and the circulation will be compromised. This state of affairs is called 'tamponade'. A gradual build-up of fluid (e.g. malignant infiltration) may be well tolerated for a long period before tamponade occurs, and the pericardial cavity may contain 2 litres of fluid. Acute tamponade (from penetrating trauma, during coronary angiography or post-operatively) may occur in minutes with small volumes of blood. The clinical features are low blood pressure with a raised jugular venous pressure and paradoxical pulse. Kussmaul's sign is a characteristic pattern that is seen when the jugular venous pressure rises with inspiration as a result of the impaired venous return to the heart.

Emergency treatment of pericardial tamponade is aspiration of

Figure 51.30 (a) Pericardial aspiration through the subxiphoid region. (b) Site of needle insertion for pericardial aspiration.

Adolf Kussmaul, 1822–1902, successively Professor of Medicine at Heidelberg, Erlangen, Freiburg and Strasbourg, Germany.

the pericardial space. A wide-bore needle is inserted under local anaesthesia to the left of the xiphisternum, between the angle of the xiphisternum and the ribcage (Fig. 51.30). The needle is advanced towards the tip of the scapula into the pericardial space. An ECG electrode attached to the needle will indicate when the heart has been touched. This will relieve the situation temporarily until the cause of the tamponade is established. Penetrating wounds of the heart usually require exploration through a median sternotomy. Emergency room thoracotomy is rarely required. Chronic tamponade is usually a result of malignant infiltration of the pericardium (usually secondary carcinoma from breast or bronchus) or, very occasionally, uraemia or connective tissue disease. Treatment sometimes requires a pericardial window between the pericardial space and the pleural or peritoneal space.

Pericarditis

Infection and inflammation may also affect the pericardium. Acute pericarditis usually occurs following a viral illness. Treatment is with non-steroidal anti-inflammatory drugs and bed rest (in case there is an underlying myocarditis). Acute purulent pericarditis is uncommon but requires urgent drainage and intravenous antibiotics with attention to the underlying cause.

Chronic pericarditis is an uncommon condition in which the pericardium becomes thickened and non-compliant. The heart cannot move freely and the stroke volume is reduced by the constrictive process. The central venous pressure is raised and the liver becomes congested. Peripheral oedema and ascites are also a feature. Treatment is aimed at relieving the constriction.

LEARNING OBJECTIVES

To understand:

- The anatomy and physiology of the thorax

- Investigation of chest pathology
- Surgical oncology as applied to chest surgery

INTRODUCTION

Anatomical development of the lungs

The lungs are derived from an outpouching of the primitive foregut during the fourth week of intrauterine life. This bud becomes a two-lobed structure, the ends of which ultimately become the lungs. The lobar arrangement is defined early and is fairly constant but anomalies of fissures and segments are common.

The primitive lungs drain into the cardinal veins, which ultimately become the pulmonary veins draining into the left atrium. Variability in venous drainage is very common and is usually of little functional significance. At the most severe end of the spectrum is total anomalous drainage, which presents in early infant life because oxygenated blood is all directed back to the right heart.

Anatomy of the lungs

The left lung is divided by the oblique fissure, which lies nearer vertical than horizontal, so the upper and lower lobes could also be called anterior and posterior. On the right, the equivalent of the upper lobe is further divided to give the middle lobe. Each lobe is composed of segments, with anatomically defined and named bronchial, pulmonary arterial and venous connections (Fig. 52.1).

The right main bronchus is shorter, wider and nearly vertical compared with the left. As a consequence, inhaled foreign bodies are more likely to enter the right main bronchus than the left (Fig. 52.2). The trachea and bronchi have a systemic arterial blood supply delivered by the bronchial arteries, which arise directly from the nearby thoracic aorta.

Lymphatic drainage tends to follow the bronchi. Lymph nodes are both named and identified by numbered 'stations', which are of importance in staging of lung cancer (Fig. 52.3).

Mechanics of breathing

The intercostal muscles contract, causing the ribs to move upwards and outwards, thereby increasing the transverse and anteroposterior dimensions of the chest wall. The diaphragm contracts simultaneously and flattens, increasing the vertical dimension of the chest cavity. As the volume increases, the intrathoracic pressure falls and air flows in until the alveolar pressure is the same

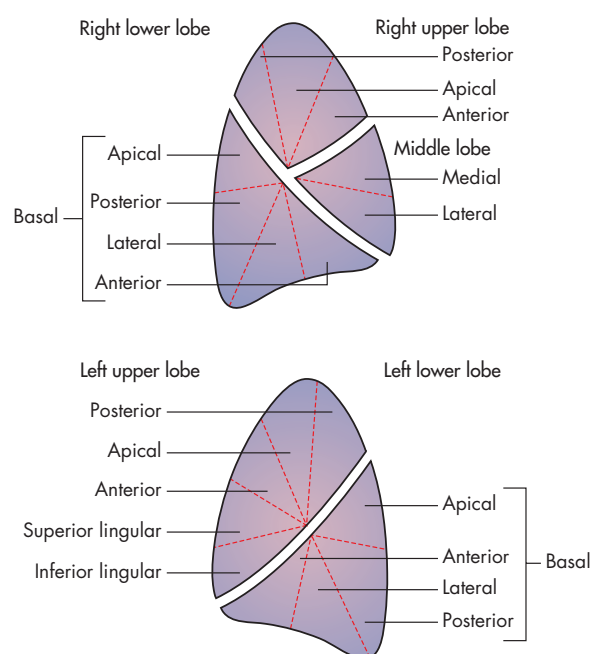

Figure 52.1 The lobar and segmental divisions of the lungs, right lung above and left lung below as if viewed from the side.

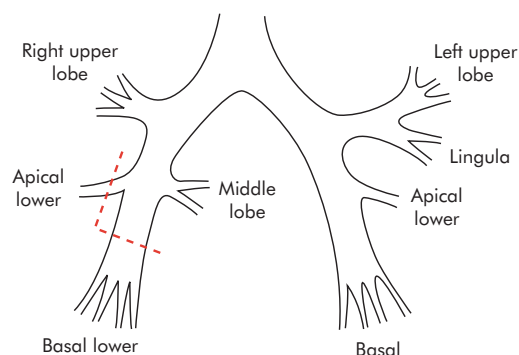

Figure 52.2 Surgical anatomy of the bronchial tree. To surgically remove the right lower lobe and conserve the middle lobe, the surgeon must be prepared to dissect and separately divide the apical bronchial segment (red line).

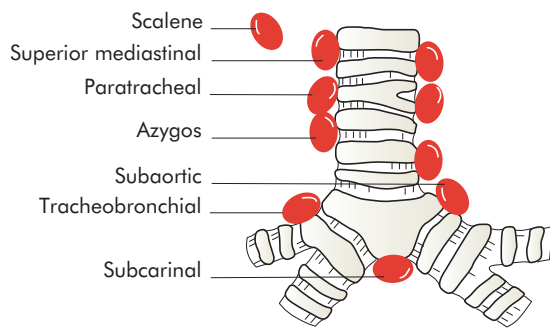

Figure 52.3 Lymph nodes related to the bronchial tree.

as the atmospheric pressure. The only force used in normal expiration is the elastic recoil of the lung.

Coughing to clear sputum is an essential part of recovery from surgery. In a vigorous cough, probably the only muscle in the body that is relaxed is the diaphragm; as the abdomen and chest wall muscles contract, the limbs are braced and the sphincters are tightened. When the intrathoracic and abdominal pressure is built up, the glottis is opened and the diaphragm is forced up as a piston, or like the plunger of a syringe, to expel air at high velocity.

Investigation of the respiratory system

Any patient undergoing general anaesthesia requires some assessment of respiratory function. This may be a clinical appraisal of fitness but more detail is necessary for patients who are undergoing thoracotomy and lung resection.

Pulmonary function tests are useful in determining the functional capacity of the patient and the severity of pulmonary disease, and in predicting the response to various treatments. The tests range from simple clinic or bedside measurements to those only available in specialist centres. The simpler tests are listed below (Table 52.1).

Peak expiratory flow rate

Peak expiratory flow rate (PEFR) is measured by a Wright peak flow meter or a peak flow gauge. This is a reliable and reproducible test but has the disadvantage of being effort dependent, and it may therefore be affected by abdominal or thoracic wound pain.

Forced expiratory volume in 1 second

The forced expiratory volume in 1 s (FEV_1) is the amount of air forcibly expired in 1 s. It is low in obstructive lung disease and may be normal in patients with poor gas exchange.

Table 52.1 Respiratory values in lung disease

	Obstructive pattern	Restrictive pattern
PEFR	↓↓	Normal or ↓
FEV_1	↓↓	Normal or ↓
FVC	Normal or ↓	↓↓
FEV_1/FVC	< 70	> 80

FEV_1 , forced expiratory volume in 1 s; FVC, forced vital capacity; PEFR, peak expiratory flow rate.

Basil Martin Wright, 1912–2001, Member of the Scientific Staff of the Medical Research Council Research Centre, Northwick Park Hospital, Harrow, Middlesex, England.

Forced vital capacity

The forced vital capacity (FVC) is the volume of air forcibly displaced following maximal inspiration to maximal expiration. The FEV_1 and the FVC can be measured using a Vitalograph and a ratio (FEV_1/FVC) can be calculated (Fig. 52.4). A low ratio indicates obstruction and the test should be repeated after bronchodilators. A normal ratio (FVC and FEV_1 reduced to the same extent) indicates a restrictive pathology.

Blood gases

Oxygen saturation can be measured non-invasively. The oxygen content of blood falls precipitously when saturation is less than 90% as an effect of the oxygen dissociation curve. Arterial blood gases provide a great deal of information (Table 52.2).

Fitness for lung resection

A patient with an $FEV_1 > 1.5$ litres is fit enough to undergo lobectomy; an $FEV_1 > 2.0$ litres is required for pneumonectomy. If the measurements are less than these they should be quoted as percentage predicted and further tests should be done.

The pleura

The key to many aspects of practical chest surgery is an understanding of the pleura and of the mechanics of breathing. Management of the essentially healthy pleural space is logical and simple and needs minimal technology. On the other hand, when pleural disease is advanced, for example when there is gross pleural sepsis surrounding a leaking and trapped lung, management is difficult and the patient may require prolonged care with repeated interventions.

The physiology of pleural fluid

The turnover of fluid in the human pleural space is about 1–2 litres in 24 hours, with only 5–10 ml of fluid present at any one time as a film, about 20 μm thick, between the visceral and parietal pleura. The quantities can only be measured indirectly because the very act of instrumenting the pleura to obtain a sample or measure the volume or pressure of fluid interferes with the physiological mechanisms that govern the flux of pleural fluid. For example, if there is a tube in the normal healthy pleural space it will drain 100–200 ml or more of fluid each day, which is simply part of the normal turnover; without the tube, the fluid would be absorbed.

Gray (1993) Pulmonary embolism. *Medicine International* 21: 477, by kind permission of the Medicine Group (Journals) Ltd.]

The mechanisms and equations given are simplifications but serve to explain the clinical conditions encountered. The fluid is produced from the capillaries of the parietal pleura as a transudate, according to the Starling capillary loop pressures. However, there is a further negative force in the pleura. The elastic content of the lung causes it to recoil and collapse if not held open by the negative pressure in the pleura. This elastic recoil exerts about 4 mmHg negative pressure and favours accumulation of fluid. The secreting forces add up to about 11 mmHg in health. Pleural fluid is mainly reabsorbed (about 90%) by the visceral pleura, whose capillaries are part of the pulmonary circulation. The principal force in absorption of pleural fluid is oncotic pressure (approximately 25 mmHg) less the difference in mean capillary hydrostatic pressure of the pulmonary capillary (8 mmHg). Thus, the overall absorbing pressure is $25 - 8 = 17$ mmHg, producing a net drying effect ($17 - 11$) of about 6 mmHg (Fig. 52.5).

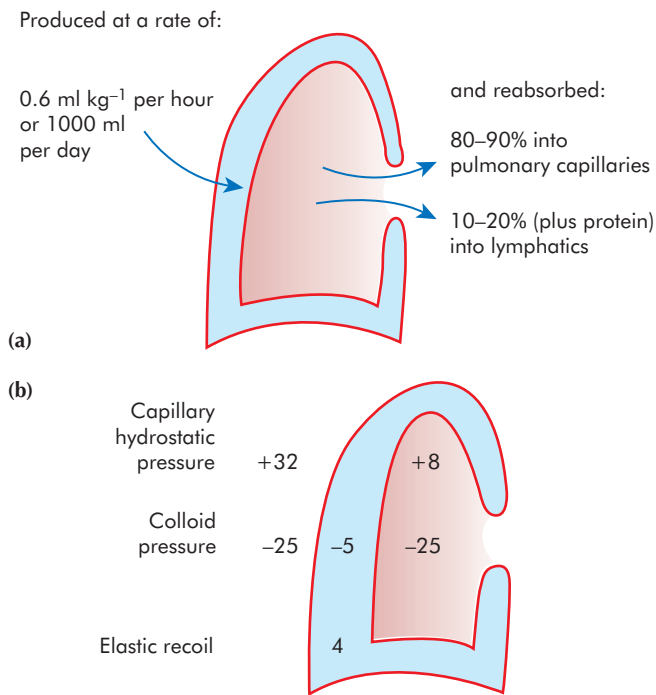

Gas in the pleural space

There is normally no free gas in the pleural space because the same physiological mechanism that absorbs air from a pneumothorax prevents any gas accumulating.

The partial pressures (water as saturated vapour pressure) of the gases in venous/end-capillary blood are:

• P_{O_2}	40 mmHg	5.3 kPa
• P_{CO_2}	46 mmHg	6.1 kPa
• P_{N_2}	573 mmHg	76.4 kPa
• P_{H_2O}	47 mmHg	6.3 kPa

These partial pressures add up to less than atmospheric pressure (760 mmHg). Free gas is therefore absorbed into the blood and lost to the atmosphere through the lungs, with the gases moving in relation to their solubility (carbon dioxide quickest and nitrogen slowest) and relative concentrations in the pleural space and the blood. This does not favour nitrogen, which constitutes about 80% of atmospheric air. Breathing oxygen accelerates nitrogen removal by reducing the content of nitrogen in the blood and increasing the gradient for its absorption. Nitrous oxide anaesthesia is dangerous

Net drying effect 6 mmHg

Figure 52.5 (a) Production and absorption of pleural fluid. (b) Normal pleural physiology. (See the text for an explanation of this simplistic physiological model.)

in the presence of a pneumothorax; nitrous oxide is very soluble and, although not normally present in the pleural space, it will be rapidly transported into the space if the patient is given nitrous oxide to breathe.

PLEURAL DISEASE

Pneumothorax

Pneumothorax is the presence of air outside the lung, within the pleural space. It must be distinguished from bullae or air cysts within the lung. Bullae can be the cause of an air leak from the lung and can therefore coexist with pneumothorax.

Spontaneous pneumothorax occurs when the visceral pleura ruptures without an external traumatic or iatrogenic cause.

- Primary spontaneous pneumothorax is a disease in its own right.
- Secondary spontaneous pneumothorax occurs when the visceral pleura leaks as part of an underlying lung disease; any disease that involves the pleura may cause pneumothorax, including tuberculosis, any degenerative or cavitating lung disease and necrotising tumours.

Tension pneumothorax is when (independent of aetiology) there is a build-up of positive pressure within the hemithorax, to the extent that the lung is completely collapsed, the diaphragm is flattened and the mediastinum is distorted and, eventually, the venous return to the heart is compromised. Any pleural breach is inherently valve-like because air will find its way out through the alveoli but cannot be drawn back in because the lung tissue collapses around the hole in the pleura. Patients

being mechanically ventilated following trauma are at particular risk.

Surgical emphysema is the presence of air in the tissues. It requires a breach of an air-containing viscus in communication with soft tissues, and the generation of positive pressure to push the air along tissue planes. The most serious cause is a ruptured oesophagus. Mediastinal surgical emphysema can also occur with asthma or barotrauma from positive pressure ventilation. A poorly managed chest drain with intermittent build-up of pressure allows air to track into the chest wall through the point where the drain breaches the parietal pleura.

Primary spontaneous pneumothorax

This is a common disease characteristically seen in young people from their mid-teens to late-20s. About 75% of cases are in young men, who tend to be tall, and the condition runs in families. It is due to leaks from small blebs, vesicles or bullae, which may become pedunculated, typically at the apex of the upper lobe or on the upper border of the lower or middle lobes.

Usually, pneumothorax presents with sharp pleuritic pain and breathlessness. The pleura is exquisitely sensitive and the movement of the lung on and off the parietal pleura causes severe discomfort. As a result it is mild cases that are more painful, whereas complete collapse is usually painless but causes more breathlessness. Bleeding and tension pneumothorax can occur. They are usually self-limiting; careful observation is wiser than too-ready resort to a chest drain. If the patient is not in respiratory distress or hypoxic there is no urgency. Tension pneumothorax should be immediately relieved by inserting a cannula into the hemithorax in as safe a position as possible (Summary box 52.1).

Summary box 52.1

Pneumothorax

- Patient comfortable:
 - watch
 - PO₂ monitoring
- Pneumothorax complete or patient breathless:
 - aspirate
- Aspiration fails or patient hypoxic:
 - insert chest drain
- Patient ill:
 - immediate drainage

The best estimates of recurrence rates are:

- of patients who experience a first event, only about one-third experience recurrence;
- of those who have a second episode, about one-half go on to experience a third episode;
- those who have had three episodes will probably go on to have repeated recurrences.

Inserting and managing a chest drain

An intercostal tube connected to an underwater seal is central to the management of chest disease; however, the management of the pleura and of chest drains can be troublesome, even in experienced hands.

The safest site for insertion of a drain (Fig. 52.6) is in the triangle that lies:

- anterior to the mid-axillary line;
- above the level of the nipple;
- below and lateral to the pectoralis major muscle.

This will ideally find the fifth space. The technique includes the following:

- Meticulous attention to sterility throughout.
- Adequate local anaesthesia to include the pleura.
- Sharp dissection only to cut the skin.
- Blunt dissection with artery forceps down through the muscle layers; these should only be the serratus anterior and the intercostals.
- An oblique tract, so that the skin incision and the hole in the parietal pleura do not overlie each other and the drain is in a short tunnel, which reduces the chance of entraining air.

Figure 52.6 Insertion of chest drain: (a) triangle of safety; (b) penetration of the skin, muscle and pleura; (c) blunt dissection of the parietal pleura; (d) suture placement; (e) gauging the distance of insertion; (f) digital examination along the tract into the pleural space; (g) withdrawal of central trochar and positioning of drain; (h) underwater seal chest drain bottle.

- A drain for pneumothorax and haemothorax should aim towards the apex of the lung. A drain for pleural effusion or empyema should be nearer the base. The drain should pass over the upper edge of the rib to avoid the neurovascular bundle that lies beneath the rib.
- The retaining stitch should be secure but not obliterate the drain.
- A vertical mattress suture is inserted for later wound closure. This is vital for pneumothorax management but should be omitted if the drain is for empyema (provided there is adherence of the pleura) because that tract should lie open.
- After completion, check that the drain has achieved its objective by taking a chest radiograph.

It is preferable not to apply suction to the drain or to clamp it. The danger is that the clamp may be applied for transport and forgotten. Dangers of disconnection and siphoning are small or best averted in other ways apart from clamping. A bubbling drain should (almost) never be clamped. Remove the drain when it no longer has a function (Summary box 52.2).

Summary box 52.2

Suction on a pleural tube

- Beware! Inserting the drain, and not the suction, is the life-saving manoeuvre
- If the lung is reluctant to expand, the suction deviates the mediastinum
- If the lung is fragile, it may worsen an air leak

Definitive management of pneumothorax

Pleurectomy and pleurodesis

Surgery for pneumothorax is best performed by video-assisted thoracoscopic surgery (VATS).

The object of the exercise is threefold:

- 1 to deal with any leaks from the lung;
- 2 to search for and obliterate any blebs and bullae;
- 3 to make the visceral pleura adherent to the parietal pleura so that any subsequent leaks are contained and the lung cannot completely collapse.

Pleural adhesion is achieved in one of three ways:

- 1 *Pleurectomy*. The conventional approach through thoracotomy is to systematically strip the parietal pleura from the chest wall. However, the intercostal veins are at risk, the subclavian vein can be torn at the apex and the sympathetic chain can be damaged, causing Horner's syndrome.
- 2 *Pleural abrasion*. A scourer is used to scrape off the slick surface of the parietal pleura. This has the same effect as pleurectomy, although it may not be as reliable.
- 3 *Chemical pleurodesis*. Talc insufflation is the preferred method. It carries much less risk and may well be as effective.

Pleural disease

Pleural effusion can be readily understood with reference to the physiological mechanisms governing the flux of pleural fluid given

Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.

above. Pleural effusions are divided into exudates and transudates, depending on protein content (more or less than 30 g l^{-1}), and characterised further according to glucose content, pH and lactate dehydrogenase content. The following are the most common ways in which the pleural fluid balance is disturbed:

- *Elevated pulmonary capillary pressure.* If left atrial pressure rises, the pulmonary capillary pressure must rise with it, whether as a result of impaired cardiac performance or an overloaded circulation.
- *Reduced intravascular oncotic pressure.* If the plasma proteins fall because of renal or hepatic disease or malnutrition, the absorption mechanism fails.
- *Accumulation of pleural protein* due to obstruction of the mediastinal lymphatics secondary to lymphoma or cancers that invade the lymphatic system.
- *Excessive permeability of the capillaries to fluid and protein* as in inflammatory diseases, particularly the collagen vascular diseases. Of particular importance to the surgeon is the fluid associated with pneumonia, which may result in empyema.

Malignant pleural effusion

Pleural effusion is a common complication of cancer. This may be due to:

- lung cancer;
- pleural involvement with primary or secondary malignancy;
- mediastinal lymphatic involvement.

Lung cancer

There may be direct involvement of the parietal and/or visceral pleura, collapse of the lung parenchyma and spread to the mediastinal lymphatics, or a combination of these, causing pleural fluid accumulation. It is usually regarded as a feature that puts lung cancer beyond surgical cure.

Pleural malignancy The only primary malignancy of the pleura seen with any regularity is malignant mesothelioma. This is a consequence of asbestos exposure with few exceptions. The peak of asbestos imports into the UK was from 1960 to 1975 and the incidence of mesothelioma is rising and is expected to peak in around 2010–20. Mesothelioma commonly presents with breathlessness because of pleural effusions, pain and systemic features of malignancy. Diffuse seeding of the parietal and visceral pleura is a common pattern of dissemination of cancers, particularly adenocarcinoma of any origin.

Mediastinal lymphatic involvement

In many instances, particularly in breast cancer, there is no evident disease in the pleura. The disease is in the mediastinal lymphatics, which are obstructed, and this upsets the balance of physiological forces that control pleural fluid.

Surgery for patients with malignant pleural effusion

The surgeon has two roles:

- to make the diagnosis;
- to achieve effective palliation by pleurodesis.

Diagnosis

Pleural biopsy can be obtained by a range of techniques. An unequivocally positive biopsy is useful but a negative biopsy may be a sampling error (Summary box 52.3).

Summary box 52.3

Biopsy of the pleura

- Cytological examination of the pleural fluid (low yield)
- Abrams' needle (low yield in malignancy)
- Computerised tomography (CT)-guided needle biopsy of a suspicious area
- VATS biopsy
- Open surgical biopsy

VATS is the preferred technique for mesothelioma but CT-guided biopsy is increasingly used and is effective.

Thoracoscopy or video-assisted thoracoscopic surgery

The direct-vision thoracoscope has been used for many years, but its use was limited mainly to performing biopsies. The instrument had a limited view and was uncomfortable to use for any length of time. All this has changed since the advent of video-assisted thoracoscopy (Fig. 52.7); the surgeon's hands are freed because the camera is attached to the thoracoscope, which can be operated by an assistant with the image displayed on a television screen. The surgeon is able to manipulate instruments with both hands to perform an impressive variety of procedures.

Pneumonectomy, lobectomy and empyema drainage are all possible, but thoracoscopic procedures for common, more minor problems is the area providing clear justification for this technique. Lung biopsy and the treatment of recurrent pneumothorax are the most frequent indications. The principal advantage is that a large incision is not required and therefore less postoperative pain and a more rapid recovery should result. Once mastered, the surgeon benefits from a better, well-lit and magnified view, and access to all parts of the chest cavity.

Empyema

Empyema is the end-stage of pleural infection from any cause; the pathological diagnosis requires the presence of thick pus with a thick cortex of fibrin and coagulum over the lung. It can occur as a complication of any thoracic operation. It is seen if a traumatic haemothorax becomes infected or in the course of management of pneumothorax or pleural effusions. It may be associated with pus under the diaphragm (Table 52.3).

Figure 52.7 Video-assisted thoracoscopic surgery. In general, three ports are used: one camera and two operating.

Leon David Abrams, formerly Cardiothoracic Surgeon, The United Birmingham Hospitals, Birmingham, England.

Table 52.3 Conditions that predispose to empyema formation

Pulmonary infection	Unresolved pneumonia
	Bronchiectasis
	Tuberculosis
	Fungal infections
	Lung abscess
Aspiration of pleural effusion	Any aetiology
Trauma	Penetrating injury
	Surgery
	Oesophageal perforation
Extrapulmonary sources	Subphrenic abscess
Bone infections	Osteomyelitis of ribs or vertebrae

When empyema presents *de novo* it usually follows pneumonia and three phases are described:

- 1 In the exudative phase, there is protein-rich ($> 30 \text{ g l}^{-1}$) effusion. If this becomes infected with the organisms from the lung (typically *Streptococcus milleri* and *Haemophilus influenzae* in children), the scene is set for empyema. At this stage antibiotics may be all that is required. Aspiration or drainage to dryness in addition is preferred.
- 2 Over the next days, the fluid thickens to what is known as the fibrinopurulent phase. Drainage at this stage is prudent.
- 3 The organising phase causes the lung to be trapped by a thick peel or 'cortex' for which surgical management may be required.

Rib resection and video-assisted thoracoscopic surgical biopsy

This method is used for open pleural biopsy and in the surgical treatment of empyema. To perform this procedure satisfactorily, a double-lumen tube (endotracheobronchial) is required. The patient is positioned with the diseased side uppermost. The presence of fluid at the site to be operated on is confirmed by needle aspiration.

- For malignant effusion, an approach via the fifth, sixth or seventh rib laterally is preferred.
- For empyema, a more posterior approach aiming for the lowest part of the empyema cavity as shown by ultrasound or computerised tomography (CT) is preferred.

A 3-cm incision over the selected rib is made and using diathermy it is deepened through the latissimus dorsi to the periosteum. The intercostal muscle is stripped off the upper surface of the rib. Care is required to free the periosteum from the groove in the lower border of the rib so that the nerve, artery and vein of the intercostal bundle come away uninjured with the intercostal muscle. The rib is divided with a ring-shaped rib cutter (costotome) that divides the rib easily without damage to other structures (Fig. 52.8).

- All fluid can be aspirated under direct vision or videothoracoscopy.
- In the case of malignant effusion, a substantial full-thickness piece of parietal pleura is sent for histological examination (Fig. 52.9).

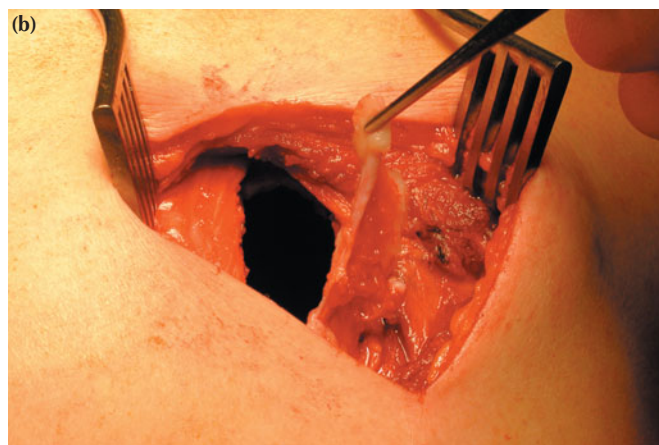

Figure 52.8 Resection of a short segment of rib to allow open pleural biopsy.

Figure 52.9 Full-thickness open pleural biopsy.

- In empyema, adequate specimens of pus, coagulum and pleura are sent for microbiological examination.
- In malignant effusion, talc is insufflated as a dry powder so that it coats the moist pleural surfaces.

Drainage

- A drain is inserted, which must lie in the bottom of the cavity.

- It should lie obliquely in its course through the skin and chest wall and into the pleura, or it will kink.
- The drain must exit the skin anterior to the mid-axillary line otherwise the patient will have to lie on it, causing pain and obstructing the tube.

Decortication

If the lung is trapped, there is space left and drainage is insufficient, the more radical operation of decortication is performed.

PRESENTATION OF LUNG DISEASE

Haemoptysis

Diseases causing repeated haemoptysis include carcinoma, bronchiectasis, carcinoid tumours and some infections. Severe mitral stenosis is now a rare cause. Patients with repeated haemoptysis should be investigated, at the very least by chest radiography and bronchoscopy. Haemoptysis following trauma may be from a lung contusion or injury to a major airway. Treatment depends on the underlying cause.

Common associated chest symptoms include cough with or without sputum, pain, breathlessness, hoarseness and more general symptoms of systemic upset, including fatigue and loss of weight. Occasionally, chest disease may cause palpitation due to atrial fibrillation. Any of these symptoms in association with haemoptysis requires urgent investigation.

Investigation

Bronchoscopy (Table 52.4)

Flexible bronchoscopy may be performed with the patient awake and the oropharynx anaesthetised with topical lignocaine (Fig. 52.10). The bronchoscope is passed into the nose and through the vocal folds under direct vision. As the scope is flexible, its tip can be directed into the segmental bronchi with ease. Tissue and sputum samples may be obtained for diagnostic purposes. There is a greater range of movement with this instrument, but the biopsies are relatively small and suction limited.

Rigid bronchoscopy requires general anaesthesia in most instances. It is ideal for therapeutic manoeuvres, such as removal of foreign bodies, aspiration of blood and thick secretions, and intraluminal surgery (laser resection or stent placement). The surgeon and the anaesthetist share control of the airway. Continuous electrocardiography (ECG) and pulse oximetry monitoring are now essential. The technique involves the operator standing

Table 52.4 Uses of bronchoscopy

Diagnostic	Confirmation of disease: carcinoma of the bronchus; inflammatory process; infective process
Investigative	Tissue biopsy
Preoperative assessment	Before lung resection Before oesophageal resection Persistent haemoptysis
Therapeutic	Removal of secretions Removal of foreign bodies Stent placement, endobronchial resection, etc.

Figure 52.10 (a) Rigid and flexible bronchoscopes. (b) View past the carina into the left main bronchus with a tumour seen in the bronchial lumen.

behind the patient and lifting the maxilla by the upper teeth, using the middle finger and forefinger of the left hand. The bronchoscope rests on the left thumb as it is introduced over the tongue in the midline. Care must be taken not to trap the lips or tongue between the teeth and the bronchoscope, and the fulcrum should be the left thumb and not the teeth. The bronchoscope is passed under direct vision into the oropharynx, behind the epiglottis, until the vocal folds are seen. Turning the instrument through 90° will help to negotiate the vocal folds; only then should the neck be extended.

The tracheal rings and the carina should be easily seen. Advancing the bronchoscope into the right and left main bronchus reveals the orifices of the more peripheral bronchi. Operability is determined by the proximity of a lesion to the carina and whether or not the carina is widened (indicating inoperability from subcarinal lymph node involvement). Complications are rare but include bleeding, pneumothorax, laryngospasm and arrhythmia (Summary box 52.4).

Summary box 52.4

Biopsy hazards

- Bleeding disorders
- Systemic anticoagulation
- Pulmonary hypertension

Other techniques of biopsy of intrathoracic lesions are often necessary to confirm diagnosis, stage disease and plan treatment. The options range from percutaneous needle biopsy under radiological control to open-lung biopsy. However, high-quality, contrast-enhanced, multislice helical CT scanning will reduce the requirement for invasive assessment.

Airway obstruction

Tracheal obstruction may present acutely as a life-threatening emergency or insidiously with little in the way of symptoms until critical narrowing and stridor occur. The more common causes of airway narrowing are outlined in Table 52.5.

Treatment depends on the underlying cause. Tracheostomy may be required to overcome the obstruction, but there are few indications to do this as an emergency. Tracheal replacement with artificial substitutes has so far been unsuccessful, but resection of up to 6 cm of trachea is now possible. Sleeve resections of the major bronchi are also possible.

Inhaled foreign bodies

This is a fairly common occurrence in small children and is often marked by a choking incident that then apparently passes. Surprisingly large objects can be inhaled and become lodged in the wider-calibre and more vertically placed right main bronchus. There are three possible presentations:

- 1 asymptomatic;
- 2 wheezing (from airway narrowing) with a persistent cough and signs of obstructive emphysema;
- 3 pyrexia with a productive cough from pulmonary suppuration.

A chest radiograph is vital; even if the object is not radio-opaque there may be other changes. An experienced anaesthetist is required. The procedure may be very difficult if there is a severe inflammatory reaction.

MALIGNANT TUMOURS

Primary lung cancer

Lung cancer is one of the most common cancers throughout the world. In the UK, there are 40 000 cases a year, making it the most common single cancer. From the time of diagnosis, 80% of patients are dead within 1 year and only 5% survive for 5 years.

Surgical resection has a limited role in curative treatment because at the time of presentation many cases are locally advanced or widely disseminated and are beyond surgical cure. The proportion of lung cancers in which resection is attempted varies from fewer than 10% in the UK to about 25% in the USA. However, the thoracic surgeon working in a cancer team has a role in diagnosis, staging and palliation apart from resection in

Table 52.5 Causes of airway narrowing

Intraluminal	Inhaled foreign body Neoplasm
Intramural	Congenital stenosis Fibrous stricture (post-intubation or tuberculosis)
Extramural	Neoplasm (thyroid cancer, secondary deposits) Aortic arch aneurysm

appropriate cases. The disease is so common that surgeons of all disciplines will encounter cases of lung cancer presenting with various manifestations.

Cigarette smoking is undoubtedly the major risk factor for developing bronchial carcinoma and accounts for 85–95% of all cases. To a lesser extent, atmospheric pollution and certain occupations (radioactive ore and chromium mining) contribute. The risk is related to the lifetime burden of cigarette smoking, which is commonly quoted as 'pack-years' (a 'pack' being 20 cigarettes): the number of packs smoked per day multiplied by the number of years of exposure. In the UK, the mortality rate from lung cancer for individuals smoking more than 40 cigarettes per day is over 210 deaths per 100 000 population per year. This compares with a mortality rate of less than 4 deaths per 100 000 population per year in non-smokers.

Pathological types

For practical purposes, lung cancers are divided into small cell and non-small cell lung cancer (NSCLC), which are seen in a ratio of about 1:4.

- The pattern of disease, the prognosis and the results of treatment for small cell (also known as oat cell) carcinoma differ from all other types sufficiently for these to be managed differently from the outset on the basis of the histological classification.
- Subdivisions of NSCLC according to histological characteristics are much less important, but pathological staging is critical to treatment and outcome.

Histological classification of lung cancer

Small cell lung cancers were known as oat cell cancers because of the packed nature of small dense cells. These represent about 20% of all lung cancer. They tend to metastasise early to lymph nodes and by blood-borne spread. The median survival is measured in months. The tumours are very responsive to chemotherapy such that median survival may be doubled (but is still short), but they are rarely, if ever, cured. Surgery has little place.

Adenocarcinoma is now the most common of the NSCLC types, having overtaken squamous cancer. The increasing incidence is partly due to an increasing incidence in women and may be the result, in part, of a move towards lower-tar cigarettes that are inhaled more deeply to get the same effect.

Squamous carcinoma typically appears as a cavitating tumour.

Large cell undifferentiated is a discrete histological type of NSCLC and is included within neuroendocrine tumours.

Bronchioalveolar carcinoma has a distinct pattern of growth following the pre-existing pulmonary architecture and is thus much less dense; it appears as a patchy diffuse shadow ('ground glass') on the radiograph rather than a solid mass and has a histological appearance to match. After resection, it can appear in another lobe or the other side.

Accurate diagnosis and staging of the tumour are vital if surgery is to be considered.

Clinical features

Clinical features of lung carcinoma depend on:

- the site of the lesion;
- the invasion of neighbouring structures;
- the extent of metastases.

Common symptoms include a persistent cough, weight loss, dyspnoea and non-specific chest pain.

- Haemoptysis occurs in fewer than 50% of patients presenting for the first time.
- Cough, or a changed cough, is a common presentation but non-specific in this population.
- Severe localised pain suggests chest wall invasion with the infiltration of an intercostal nerve. Invasion of the apical area may involve the brachial plexus, leading to Pancoast's syndrome.
- Dyspnoea may come from loss of functioning lung tissue, lymphatic invasion or the development of a large pleural effusion.
- Pleural fluid is an ominous feature and the presence of blood in a pleural effusion suggests that the pleura has been directly invaded.
- Clubbing (Fig. 52.11) and hypertrophic pulmonary osteoarthropathy accompany some lung cancers and may resolve with excision of the primary lesion.
- Invasion of the mediastinum may result in hoarseness (because of recurrent laryngeal nerve involvement), dysphagia (because of the involvement of, or extrinsic pressure on, the oesophagus) and superior vena caval obstruction.
- Small cell carcinoma is associated with the development of myopathies including the Eaton–Lambert syndrome, which is similar to myasthenia gravis (Summary box 52.5).

Figure 52.11 Example of finger clubbing in a patient with bronchogenic carcinoma.

Summary box 52.5

Symptoms of lung cancer

- Haemoptysis < 50% of patients
- Cough, new or changed pattern
- Pain
- Dyspnoea
- Clubbing
- Hoarseness
- Myopathies

Table 52.6 The international tumour–node–metastasis (TNM) staging system

Primary tumour (T)

- TX Tumour proven by the presence of malignant cells and bronchial secretions, but not visualised by radiography or bronchoscopy
- T0 No evidence of primary tumour
- TIS Carcinoma *in situ*
- T1 A tumour that is 3 cm or less in greatest dimension, surrounded by lung or visceral pleura and without evidence of invasion proximal to a lobar bronchus at bronchoscopy
- T2 A tumour of more than 3 cm in greatest dimension or a tumour of any size that either invades the visceral pleura or has associated atelectasis or obstructive pneumonitis, which extends to the hilar region, but does not involve an entire lung; at bronchoscopy, the proximal extent of demonstrable tumour must be within a lobar bronchus or at least 2 cm distal to the carina
- T3 A tumour of any size, with direct extension into the chest wall (including superior sulcus tumours), diaphragm, mediastinal pleura or pericardium, without involving the heart, great vessels, trachea, oesophagus or vertebral body, or a tumour in the main bronchus within 2 cm of the carina without involving the carina
- T4 A tumour of any size, with invasion of the mediastinum or involving the heart, great vessels, trachea, oesophagus, vertebral body or carina, or the presence of malignant pleural effusion

Nodal involvement (N)

- N0 No demonstrable metastasis or regional lymph node
- N1 Metastasis to lymph nodes in the peribronchial or the ipsilateral hilar region, or both, including direct extension
- N2 Metastasis to the ipsilateral, mediastinal and subcarinal lymph nodes
- N3 Metastasis to the contralateral mediastinal lymph nodes, contralateral hilar lymph nodes, ipsilateral or contralateral scalene or supraclavicular lymph nodes

Distant metastasis (M)

- M0 No known distant metastasis
- M1 Distant metastasis present

Henry Khunrath Pancoast, 1875–1939, Professor of Radiology, The University of Pennsylvania, Philadelphia, PA, USA, described this condition in 1932.

Lee M. Eaton, 1905–1958, a Neurologist who was a Professor at The Mayo Clinic, Rochester, MN, USA.

Edward H. Lambert, B. 1915, Professor of Physiology, The University of Minnesota, MN, USA. Eaton and Lambert described this condition in a joint paper in 1956.

Treatment of lung cancer

Careful investigation is required to determine which tumours are operable and will benefit from a major thoracic resection. The internationally agreed tumour–node–metastasis (TNM) staging system gives prognostic information on the natural history of the disease. Tumours graded up to T2, N1, M0 can be encompassed within an anatomical surgical resection and have a much improved prognosis when treated surgically so the tumour must be staged accurately before resection (Table 52.6). A number of non-tumour factors, including the general fitness of the patient and the results of lung function tests, help to determine the appropriate treatment. In patients with incurable disease, treatment is palliative to maximise quality of life and disease-free survival.

Survival

Carcinoma of the bronchus generally has a low survival rate after diagnosis (Table 52.7). Important factors in determining prognosis are the histological type of the tumour, the spread (stage) and the general condition of the patient. Early detection and surgical resection offer the best hope for cure.

Diagnosis and staging

There are three keys to diagnosis:

- 1 detecting the primary lesion;
- 2 tissue diagnosis;
- 3 staging (Table 52.8).

Table 52.7 Survival table following operation for carcinoma of the bronchus

5-year survival according to presurgical staging (%)	
Stage I	56–67
Stage II	39–55
Stage IIIa	23
Stage IIIb	< 10
5-year survival according to cell type (%)	
Squamous cell carcinoma	35–50
Adenocarcinoma	25–45
Adenosquamous carcinoma	20–35
Undifferentiated carcinoma	15–25
Small cell carcinoma	0–5

Table 52.8 Staging of carcinoma of the lung

Stage	Tumour	Nodal involvement	Distant metastasis	Operable/inoperable
Occult carcinoma	TX	N0	M0	Operable
Stage 0	TIS			
Stage I	T1	N0	M0	Operable
Stage II	T1	N1	M0	Operable
	T2	N1	M0	Operable
Stage IIIa	T3	N0	M0	Inoperable
	T3	N1	M0	Inoperable
	T1–3	N2	M0	Inoperable
Stage IIIb	Any T	N3	M0	Inoperable
	T4	Any N	M0	Inoperable
Stage IV	Any T	Any N	M1	Inoperable

Detection of the primary lesion

Chest radiography

A chest radiograph will detect most lung cancers but some, particularly early curable tumours, are hidden by other structures. Secondary effects such as pleural effusion, distal collapse and raised hemidiaphragm may be evident (Fig 52.12).

Computerised tomography

This is the first investigation in suspected lung cancer. The surgeon needs to know if the primary is resectable (T stage) and which if any lymph nodes are involved (N stage) (Fig. 52.13). Lymph nodes of more than 2 cm in diameter are likely to be

Figure 52.12 Chest radiographs of carcinoma of the lung. (a) This patient has a large mass in the right upper lobe, causing Horner's syndrome. (b) This patient has a left hilar mass and presented with haemoptysis.

Figure 52.13 An FDG-avid bronchial carcinoma without metastases shown on a positron emission tomography/computerised tomography scan (courtesy of Dr Sally Barrington).

involved in the disease (70%) (Fig. 52.14) and those less than 1 cm in the shorter axis are very unlikely to be involved. If the presence of cancer in the nodes is critical to management, further evidence from positron emission tomography with fluorodeoxyglucose (FDG-PET) or biopsy (see below) is essential. Remote metastases to the liver, adrenals or elsewhere may be detected.

Figure 52.14 Paratracheal lymphadenopathy shown on a computerised tomography scan (courtesy of Dr Sheila Rankin).

Figure 52.15 Multiple FDG-avid mediastinal lymph nodes shown on a positron emission tomography/computerised tomography scan (courtesy of Dr Sally Barrington).

Positron emission tomography

The patient is given radiolabelled FDG, which is taken up by all metabolising cells but more avidly by cancer cells. The FDG enters the Krebs's cycle but cannot complete it and accumulates in proportion to the glucose avidity of the cells. High accumulation is associated with lung cancers and secondaries. Infection or other inflammation, and lymphadenopathy secondary to it, are also FDG avid (Figs 52.13, 52.15 and 52.16).

Sputum cytology

Sputum cytology may reveal malignant cells but the false-negative rate is high.

Invasive procedures

Computerised tomography-guided biopsy

Percutaneous CT-guided fine-needle aspiration (FNA) may give a good yield of cells for cytological examination.

Alternatively, a core of tissue can be obtained for formal histology. These techniques are best for larger and more peripheral lesions. Pneumothorax is common (30%) but rarely requires intercostal tube drainage. The contraindications include poor respiratory reserve when even a small pneumothorax would be hazardous.

Thoracoscopy, mediastinoscopy, mediastinotomy and open-lung biopsy are aimed at establishing a tissue diagnosis and

Figure 52.16 Bilateral mediastinal FDG-avid lymphadenopathy seen on a positron emission tomography/computerised tomography scan (courtesy of Dr Sally Barrington).

assessing the degree of spread (staging), which determines resectability. Histological proof of the status of mediastinal nodes may be important to avoid unavailing thoracotomy for incurable cancers and, conversely, to not deny surgery when the nodes are enlarged but not involved with cancer.

Mediastinoscopy

This procedure is performed under general anaesthesia with the patient supine and his or her neck extended (Fig. 52.17). A transverse incision is made 2 cm above the sternal notch and deepened until the strap muscles are reached. These are retracted laterally and the thyroid isthmus is retracted superiorly to reveal the pretracheal fascia. Careful blunt dissection in this plane allows access to the paratracheal and subcarinal nodes. A mediastinoscope is introduced for direct visualisation and biopsy. Great caution should be used in the presence of superior vena caval obstruction. Complications include pneumothorax and haemorrhage.

Mediastinotomy

An incision is made through the second intercostal space to gain access to some of the mediastinal lymph nodes on the affected side (Fig. 52.18; see also Fig. 52.3, page 877). Damage to the internal mammary artery and the phrenic nerve must be avoided. Mediastinal extension of tumour can also be assessed.

Figure 52.17 Mediastinoscopy. The mediastinoscope slides down immediately in front of the trachea, behind the aortic arch and behind and between the great vessels of the head and neck.

These techniques may also be used in the diagnosis of other mediastinal conditions, including:

- lymphoma;
- anterior mediastinal tumours;
- thymoma;
- sarcoid, tuberculosis or any other cause of lymphadenopathy.

Thoracotomy

Although the most frequent reason for thoracotomy is lung cancer, all surgeons dealing with trauma should be able to perform a thoracotomy if required. The standard route into the thoracic cavity is through a posterolateral thoracotomy. The incision is used for access to the:

- lung and major bronchi;
- thoracic aorta;
- oesophagus;
- posterior mediastinum.

A double-lumen endotracheal tube is used to allow ventilation of one lung while the other is collapsed, to facilitate surgery and to protect the non-operated lung and retain control of ventilation (Fig. 52.19).

The patient is turned to the lateral position with the affected

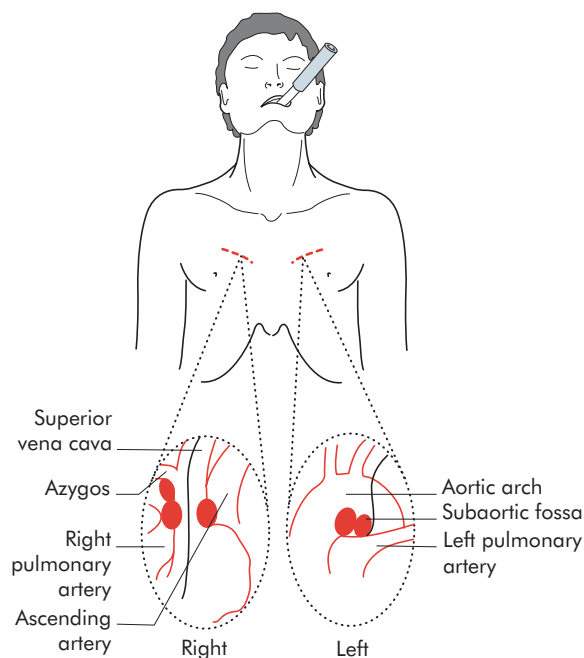

Figure 52.18 Mediastinotomy: structures accessible through anterior mediastinotomy.

Figure 52.19 The double-lumen tube permits separate ventilation of the right and left lungs.

side up (Fig. 52.20). The lower leg is flexed at the hip and the knee, with a pillow between the legs. Table supports are used to maintain the position and additional strapping is used at the hips for stability. The upper arm may be supported by a bracket in a position of 90° flexion. The lower arm is flexed and positioned by the head. It is important for both the surgeon and the anaesthetist to be completely satisfied with the position of the patient and the tube and lines at this stage.

- The incision passes 1–2 cm below the tip of the scapula, and extends posteriorly and superiorly between the medial border of the scapula and the spine.
- The incision is deepened through the subcutaneous tissues to the latissimus dorsi. This muscle is divided with coagulating diathermy, taking care over haemostasis.
- A plane of dissection is developed by hand deep to the scapula and serratus anterior. The ribs can be counted down from the highest palpable rib (which is usually the second) and the sixth rib periosteum is scored with the diathermy near its upper border. A periosteal elevator is used to lift the periosteum off the superior border of the rib (Fig. 52.21).
- This reveals the pleura, which may be entered by blunt dissection. A rib spreader is inserted between the ribs and opened gently to prevent fracture.

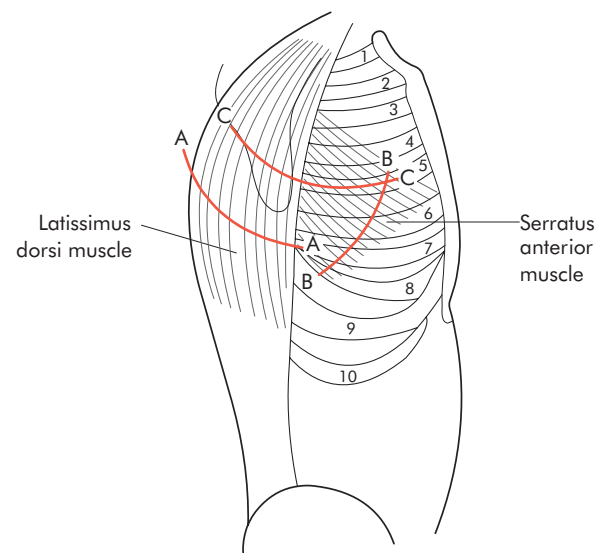

Figure 52.20 Correct positioning for thoracotomy.

- A–A The latissimus dorsi is divided in line with the skin incision
- B–B If the serratus anterior is divided, it should be close to its attachment to ribs 6, 7 and 8. It can be left intact and mobilised along its inferior border.
- C–C The intercostal muscles are stripped off the upper border of the rib

Figure 52.21 Incision and layers encountered during anterolateral thoracotomy.

- Exposure may be facilitated by dividing the rib at the costal angle or by dividing the costotransverse ligament. Resection of a rib is not usually required.
- The anaesthetist is now able to deflate the affected lung to allow a better view of the intrathoracic structures.
- In an emergency thoracotomy for penetrating wounds of the heart, a more anterior approach is used and no specialised supporting equipment is required (Fig. 52.22).

Chest drains

Large-calibre (24–28F) intercostal drains are usually inserted at the end of the procedure. It is best to make the exit site through the seventh or eighth intercostal space, anterior to the mid-axillary line, so that the patient does not lie on them. Even if the site to be drained is posterior, as in empyema, the drains are tunnelled to come out more anteriorly for easier management. The more anteriorly sited drain goes to the apex (the 'A' drain: anterior and apical for air) and the posteriorly placed drain goes to the lung base (the 'B' drain: basal and towards the back, for blood). A rib approximator is used to realign the ribs and the stripped periosteum and intercostal muscle are sutured to the intercostal muscle below the stripped rib with a continuous absorbable suture. The fascia and muscle layer are closed in layers using an absorbable suture. Skin closure is a matter of personal preference.

Analgesia is an important aspect of postoperative care and the process may be started intraoperatively by infiltrating the intercostal nerves in the region of the incision with a long-acting local anaesthetic. Various strategies have been developed to deliver analgesics postoperatively to facilitate a normal breathing pattern.

Surgical management

The principle of surgery is to remove all cancer (the primary and the regional lymph nodes) but to conserve as much lung as possible.

Figure 52.22 Emergency left anterior thoracotomy for access to the heart. Requires no special supports or devices.

Lobectomy

Following dissection of the fissure and hilar structures, the branches of the pulmonary artery and veins to the lobe are isolated and ligated. The bronchus is sewn or stapled according to preference.

At the completion of the operation, the remaining lung is reinflated. Some air leak is common (about 60% of cases) and usually settles within a few days. Intercostal drains are inserted to the base and apex of the space (see above). The patient does not need intensive care and postoperative ventilation is best avoided. The perioperative mortality rate is 2–3%.

Pneumonectomy

Pneumonectomy is removal of a whole lung and has a higher mortality rate (5–10%). The surgeon must be satisfied that the patient is fit to tolerate this procedure from the preoperative work-up. This procedure is reserved for either centrally placed tumours involving the main bronchus or those that straddle the fissure. At thoracotomy, an inspection of the lung and direct palpation of the mass will determine resectability and lymph node spread. Fixation of the tumour to the aorta, heart or oesophagus implies irresectability. Involvement of the mediastinal lymph chain is associated with a poor prognosis. With modern preoperative imaging, resection is abandoned in only about 3% of cases.

Pneumonectomy is anatomically more straightforward than lobectomy:

- The pulmonary artery is first dissected, divided and sutured.
- The pulmonary veins are then isolated, divided and sutured.
- The main bronchus is divided so that no blind stump remains (Fig. 52.23). The technique of stump closure is important if a bronchopleural fistula is to be avoided. The tissues are carefully handled and the stump is usually stapled.

Drainage of the space is a matter of debate. Most use a water-seal drain and either leave it unclamped or unclamp it for 1 min every hour until the drainage ceases; others prefer not to drain. The critical point is that no suction should be applied as there is now a sealed space with the mobile mediastinum on one side of it. The air in the pneumonectomy space is gradually absorbed and the fluid level within the space rises (Fig. 52.24).

Thoracoscopic lung resection

Minimally invasive surgery has become fashionable in recent years in all forms of surgery but, in reality, only a few per cent of all resections are performed this way.

Complications of lung resection

Bleeding Bleeding should be avoidable by the use of a careful surgical technique, but may be severe in the presence of dense adhesions.

Figure 52.23 Mediastinal structures after removal of right lung.

Figure 52.24 Chest radiographs (a) pre- and (b) post-pneumonectomy, with rising fluid level (c) in the left haemothorax.

Respiratory infection Many of these patients are ex-smokers and so basal collapse and hypoxaemia are common postoperatively.

Persistent air leak Chest drains are placed at the time of surgery to deal with the air leak. Rarely, the air leak persists and the remaining lung does not expand. Re-thoracotomy may then be necessary to seal the leak.

Bronchopleural fistula Bronchopleural fistula is a serious complication. Following pneumonectomy the space left behind is initially filled with air. This is slowly reabsorbed and the space fills with tissue fluid. The fluid level rises until the air is finally reabsorbed. Dehiscence of the bronchial stump leads to the development of a bronchopleural fistula and the fluid in the space (which is almost inevitably infected) is expectorated in large quantities. This complication has a high morbidity and mortality rate.

The patient is nursed sitting up and turned so that the affected space is dependent, to prevent infected fluid from entering the remaining lung while arrangements are made to site a pleural drain. This should be connected to an underwater seal but not suction. Bronchopleural fistulas are unlikely to resolve spontaneously and management is highly specialised.

Postoperative care

Patients have limited respiratory reserve following lung resection, so infection and fluid overload are to be avoided. Once air leaks have settled, the drains are removed. Mobilisation, breathing exercises and regular physiotherapy are begun as soon as the patient's condition permits.

Postoperative pain

It is important to deal with post-thoracotomy pain effectively so that a normal breathing pattern and gas exchange are achieved in the early postoperative period. Three strategies are routinely used in combination:

- patient-controlled analgesia (PCA) with intravenous boluses of opiates;
- paravertebral, extrapleural catheter-delivered local anaesthetic;
- background oral analgesia with paracetamol.

Long-term post-thoracotomy pain can be reduced by careful attention to detail during the operation. Sources of avoidable chronic pain include rib fracture and the entrapment of intercostal nerves during wound closure.

Benign tumours

Benign tumours of the lung are uncommon and account for fewer than 15% of solitary lesions seen on chest radiographs. A peripheral tumour usually causes no symptoms until it is large; a central tumour may present with haemoptysis and signs of bronchial obstruction while small. A tumour is likely to be benign if it has not increased in size on chest radiographs for more than 2 years or it has some degree of calcification; however, a tissue diagnosis is usually pursued.

Most benign nodules are *granulomas* (tuberculosis or histoplasmosis). The most common benign tumour is a *hamartoma*, a developmental abnormality containing mesothelial and endothelial elements. Diagnosis (and definitive treatment) is achieved by excision of the lesion. Any of the mesodermal elements of the

lung may form a mesodermal tumour (chondroma, lipoma, leiomyoma). Deposits of amyloid may give similar radiographic appearances of a nodule (pseudotumour).

Bronchopulmonary carcinoid tumours

These carcinoid tumours are derived from the neuroendocrine cells of bronchial glands. Most (80%) are found in the major bronchi and are characteristically slow growing and highly vascular. They are currently classified within a spectrum of neuroendocrine tumours. Most behave in a benign way; however, approximately 15% metastasise. Surgical excision is preferred.

The mediastinum

Primary tumours of the mediastinum

Thymoma, neurogenic tumours, germ cell tumours and lymphoma are the usual primary tumours of the mediastinum (Fig. 52.25).

Thymoma This is the most common mediastinal tumour, accounting for 25% of the total (Fig. 52.26). Thymomas vary in behaviour from benign to aggressively invasive. The only reliable indicator of malignancy is capsular invasion. Diagnosis and treatment are best achieved by complete thymectomy.

Germ cell tumour Germ cell tumours account for 13% of all mediastinal masses and cysts and are usually found in the anterior mediastinum (Fig. 52.27). They contain elements from all three cell types (mesoderm, endoderm and ectoderm). They tend to present in young adults and 75% are benign and cystic, although they may cause compression of neighbouring structures; hence, dermoid cysts are best excised. Malignancy is suspected if elevated levels of serum alpha-fetoprotein, human chorionic gonadotrophin and carcinoembryonic antigen are detected.

Lymphoma Lymphoma is a common cause of a mediastinal mass lesion, particularly the anterior mediastinum, leading to obstruction of the superior vena cava.

Mesenchymal tumours Lipomas are common in the anterior mediastinum. Other mesenchymal tumours are very rare.

Thyroid Ectopic thyroid tissue (and parathyroid) may be found in the anterior mediastinum but usually the mass is an extension of a thyroid lesion.

Neural tumours These may derive from the sympathetic nervous system or the peripheral nerves and are more prevalent in the posterior mediastinum. They may be painful but are more often discovered accidentally on routine chest radiography (Fig. 52.28). They include neuroblastoma in childhood, and Schwannomas and neurofibromas in adults. Pheochromocytoma arises from the sympathetic chain and produces the characteristic endocrine syndrome.

The mediastinal lymph nodes are commonly involved by metastatic tumour mimicking a primary mediastinal lesion. Symptoms are generally secondary to compression or invasion of a structure within the mediastinum.

MEDICAL CONDITIONS FOR WHICH SURGERY MAY BE REQUIRED

Bronchiectasis

This is chronic irreversible dilatation of the medium-sized bronchi, which may occur following a suppurative pneumonia or bronchial obstruction. It is the pathological end-stage of a range of conditions. If generalised it is almost never considered for surgical resection. Cases caused by whooping cough and measles are decreasing in frequency in developed countries.

Treatment

Removal of the bronchiectatic part of the lung for symptoms of bleeding, recurrent infection or copious symptoms can be very effective when the disease is localised.

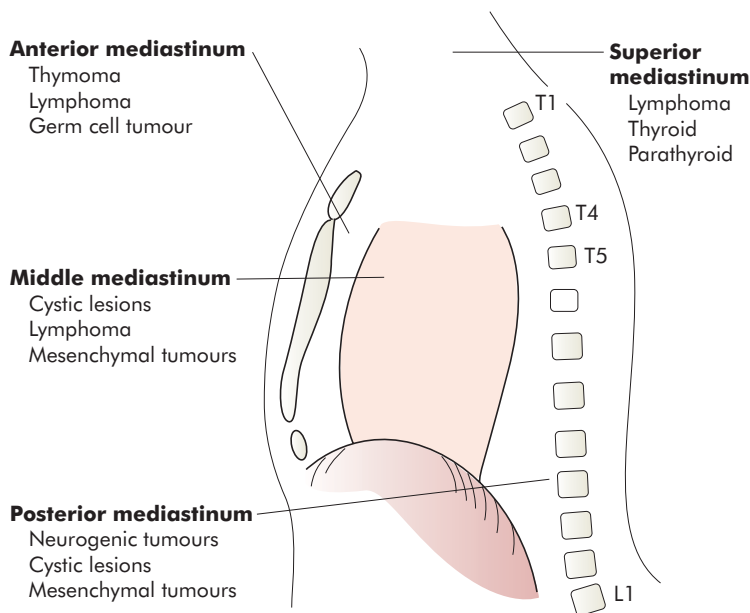

Figure 52.25 Mediastinal pathology. Subdivisions of the mediastinum with the most common mediastinal masses.

Figure 52.26 Computerised tomography scan showing a thymoma presenting as a mediastinal mass.

Figure 52.28 CT showing a right-sided paravertebral neural tumour.

Figure 52.27 Lateral (a) and posteroanterior (b) radiographs of a patient with a mediastinal teratoma. The tumour lies anteriorly and extends into the right hemithorax.

Lung abscess

The causes of lung abscess are shown in Table 52.9. The chest radiograph shows a cavity with a fluid level or in mycetoma a fungal ball. Most acute abscesses resolve with appropriate antibiotic therapy and postural drainage. Surgery is avoided. Small radiologically sited drains are used sometimes in the intensive care unit.

Tuberculosis

Surgery is rarely indicated for tuberculosis in developed countries but, when it is, it must be combined with adequate anti-tubercular chemotherapy or the benefit of surgery will be lost (Summary box 52.6).

Table 52.9 Causes of lung abscess

Specific pneumonia	Streptococcal Staphylococcal Pneumococcal <i>Klebsiella</i> spp. Anaerobic
Bronchial obstruction	Carcinoma Carcinoid Foreign body Postoperative atelectasis
Chronic respiratory sepsis	Sinusitis Tonsillitis Dental infection
Septicaemia	
Penetrating lung injury

Summary box 52.6

Tuberculosis: indications for surgery

- Suspicious lesion on chest radiograph in which neoplasia cannot be excluded
- Chronic tuberculous abscess, resistant to chemotherapy
- Aspergilloma within a tuberculous cavity
- Life-threatening haemoptysis

Diagnosis

Surgical procedures may be necessary to establish the diagnosis if suspected clinically but sputum or pus cultures are persistently negative.

Complications such as an aspergilloma in a chronic cavity causing life-threatening haemoptysis may require lobectomy.

Pulmonary sequestration

This describes a section of lung separated from the normal bronchial connection with other abnormalities of development, which often include a direct systemic arterial supply from the aorta. The segment becomes cystic and infected. Interlobar sequestration occurs within the lung substance. It may present with recurrent chest infections and/or haemoptysis.

Lung cysts

Developmental lung cysts have a tendency to become infected. Acquired lung cysts may contain air or fluid and may be single or multiple. Pulmonary hydatid disease is a cause in endemic areas. Air cysts (bullae) may be spontaneous but may be secondary to emphysematous degeneration (Fig. 52.29).

LUNG TRANSPLANTATION

Lung transplantation is an established therapy for those with end-stage parenchymal or pulmonary vascular disease, which is limited by the number of donor lungs available.

CHEST TRAUMA

The approach to trauma must be methodical and exact, because the signs, particularly in the presence of other injury, may easily be missed. The general principles of resuscitation and ATLS (Advanced Trauma and Life Support) must be followed. Thoracic trauma is responsible for over 70% of all deaths following road traffic accidents. Blunt trauma to the chest in isolation is fatal in 10% of cases, rising to 30% if other injuries are present. Penetrating thoracic wounds vary according to the prevalence of civil violence, with a mortality rate of 3% for simple stabbing to 15% for gunshot wounds.

Early deaths after thoracic trauma are caused by hypoxaemia, hypovolaemia and tamponade. The first steps in treating such patients should be to diagnose and treat these problems as early as possible because they may be readily corrected. Young patients have a large physiological reserve, and serious injury may be overlooked until this reserve is used up, by which time the situation is critical and may be irretrievable. The best approach is to remain highly suspicious if life-threatening conditions are to be anticipated and treated. Early consultation with a regional thoracic centre is advised in cases of

Figure 52.29 (a) A large solitary bulla seen on videothoracoscopy. (b) The bulla deflated and rolled in preparation for staple resection.

doubt. In an emergency it is essential that experienced help is summoned.

Management of chest trauma is covered in detail in Chapter 26.

THE DIAPHRAGM

The diaphragm is the fibromuscular structure separating the thorax from the abdomen (Fig. 52.30). There are two well-recognised congenital sites where abdominal viscera can herniate into the chest (Fig. 52.31):

- *the foramen of Morgagni*: a hernia in the anterior part of the diaphragm with a defect between the sternal and costal attachments. The most commonly involved viscus is the transverse colon.
- *the foramen of Bochdalek*: through the dome of the diaphragm posteriorly.

Traumatic rupture of the diaphragm may occur with blunt trauma. Unless there is severe bleeding or strangulation of the viscera it is best managed at an interval. In a severely injured

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, Padua, Italy for 59 years. He is regarded as ‘The Founder of Morbid Anatomy’.

Figure 52.30 Diagram of sites of hernias. The usual sites of congenital diaphragmatic hernia: 1, foramen of Morgagni; 2, oesophageal hiatus; 3, foramen of Bochdalek (pleuroperitoneal hernia); and 4, dome.

patient being ventilated it can wait until other injuries are dealt with and weaning from the ventilator is being considered.

THE CHEST WALL

Tumours of the chest wall

These can be tumours of any component of the chest wall, i.e. bone, cartilage and soft tissue. They are treated similarly to those that occur in other sites and require specialist surgical input only if major resection and chest wall reconstruction are contemplated.

Other diseases of the chest wall

Congenital abnormalities are often incidental findings on chest radiography (bifid rib), but there are some important exceptions.

Cervical rib and thoracic outlet syndrome

This rib is usually represented by a fibrous band originating from the seventh cervical vertebra and inserting onto the first thoracic rib. It may be asymptomatic, but because the subclavian artery and brachial plexus course over it a variety of symptoms may occur. The lower trunk of the plexus (mainly T1) is compressed, leading to wasting of the interossei and altered sensation in the T1 distribution. Compression of the subclavian artery may result in a post-stenotic dilatation with thrombus and embolus formation. The diagnosis, assessment and surgery are fraught with uncertainties and are best left to those with a well-developed interest in this problem.

Pectus excavatum

The sternum is depressed, with a dish-shaped deformity of the anterior portions of the ribs on one or both sides. It is never a cause of respiratory problems.

Pectus carinatum (pigeon chest)

In this condition the sternum is elevated above the level of the ribs and treatment is offered for cosmetic reasons. The sternum is mobilised and allowed to fall back into place.

Figure 52.31 Chest radiograph of congenital diaphragmatic hernia. (a) Colon occupying a Morgagni hernia (courtesy of Dr Oliver Smith, Birmingham). (b) Foramen of Bochdalek hernia on the left side in an infant. The left pleural cavity is occupied by intestine, the mediastinum is displaced to the right and the right lung is aerated very little.

It often comes to light during the growth spurt at adolescence when, of course, the teenager is particularly sensitive about appearance. Most patients are asymptomatic and the only justification for treatment is on cosmetic grounds. Some surgeons make a very good case for this but the risk of morbidity and of a less than perfect result must be clearly spelt out to the patients and their parents. Surgery involves mobilising the sternum with the costal cartilages and holding this central panel anteriorly with a steel bar. Surgery is best left until the late teens, when further growth of the chest wall is unlikely.

Arterial disorders

LEARNING OBJECTIVES

To understand:

- The nature and associated features of occlusive arterial disease
- The investigative and treatment options for occlusive arterial disease
- The nature and principles of management of the severely ischaemic limb
- The nature and presentation of aneurysmal disease, particularly of the abdominal aorta
- The investigative and treatment options for aneurysmal disease
- The arteritides and vasospastic disorders

INTRODUCTION

Arterial disorders represent the most common cause of morbidity and death in western societies. Much of this is due to the effects of atheroma on the arteries supplying the heart muscle (coronary thrombosis and myocardial infarction) and brain (stroke), although atheroma is also common at other sites. This chapter addresses diseases that are typically the province of the vascular surgeon, namely those affecting the arteries of the body, excluding those of the heart and those within the cranium.

ARTERIAL STENOSIS AND OCCLUSION

Cause and effect

Arterial stenosis or occlusion is commonly caused by atheroma but can occur acutely as a result of emboli or trauma. Stenosis or occlusion produces symptoms and signs that are related to the organ supplied by the artery: e.g. lower limb – claudication, rest pain and gangrene; brain – transient ischaemic attacks and stroke; myocardium – angina and myocardial infarction; kidney – hypertension and renal failure (Fig. 53.1); intestine – abdominal pain and infarction. The severity of the symptoms is related to the size of the vessel occluded and the alternative routes (collaterals) available for blood flow (Fig. 53.2).

Features of arterial stenosis or occlusion in the leg

Intermittent claudication

Intermittent claudication is a cramp-like pain felt in the muscles that is:

- brought on by walking;
- not present on taking the first step (unlike osteoarthritis);

Claudication from the Latin *claudicare* – to limp. The Roman emperor Claudius, (10 BC to 54 AD) walked with a limp, which was possibly due to poliomyelitis.

Figure 53.1 Renal artery stenosis. Angiogram by retrograde femoral catheterisation. Note the post-stenotic dilatation.

- relieved by standing still (unlike lumbar intervertebral disc nerve compression).

The distance that a patient is able to walk without stopping varies only slightly from day to day. It is altered by walking up hill, the speed of walking and changes in general health, such as anaemia or heart failure.

The pain of claudication is most commonly felt in the calf but it can affect the thigh or buttock. Buttock claudication plus sexual impotence resulting from arterial insufficiency is eponymously called Leriche's syndrome. Arm claudication is unusual

Rene Leriche, 1879–1955, Professor of Surgery, Strasbourg, France, described this syndrome.

Figure 53.2 Right superficial femoral stenosis. Left superficial femoral occlusion with collateral vessels present, causing claudication.

but may be caused by subclavian, axillary or brachial artery obstruction.

Rest pain

Rest pain occurs with the limb (usually the leg) at rest; it is exacerbated by lying down or elevation of the foot. Characteristically, the pain is worse at night and it may be lessened by hanging the foot out of bed or by sleeping in a chair.

Coldness, numbness, paraesthesia and colour change

Coldness, numbness and paraesthesia are common in moderate and severe ischaemia but, in the absence of colour change (Fig. 53.3), a neurological cause should be excluded. Affected legs blanch on elevation and develop a purple discoloration on dependency.

Ulceration and gangrene

Ulceration occurs with severe arterial insufficiency and may present as a painful erosion between toes or as shallow, non-healing ulcers on the dorsum of the feet, on the shins and especially around the malleoli. The blackened mummified tissues of frank gangrene are unmistakable (Fig. 53.4).

Temperature sensation and movement

A severely ischaemic foot is usually cold, but an ischaemic limb tends to equilibrate with the temperature of its surroundings and may feel quite warm under the bedclothes. The acutely ischaemic limb is frequently paralysed and insensate; such a limb has a poor prognosis without treatment. Severe chronic ischaemia does not produce paralysis and is sensate. Ischaemic limbs must be handled gently.

Arterial pulsations

Pulsation distal to an arterial occlusion is usually absent or, in the presence of good collaterals, diminished. It is standard practice to feel for pulsation in the radial, carotid, common femoral, popliteal, posterior tibial and dorsalis pedis arteries and in the abdominal aorta. Diminution of a pulse can often be appreciated by comparing it with its opposite number. Expansile pulsation

Figure 53.3 Colour changes with elevation (a) and dependency (b).

may indicate an aneurysm. Stenosis, or occlusion with a highly developed collateral circulation, may allow distal pulses to be normal to palpation. In this case, the sign of the 'disappearing pulse' may prove useful; after exercise to the point of claudication a previously palpable pulse disappears, reappearing after rest. The explanation is that exercise produces vasodilatation below the obstructing lesion and the arterial inflow cannot keep pace with the increasing vascular space; pressure falls and the pulse disappears.

Figure 53.4 Severe chronic ischaemia with dry gangrene.

Arterial bruits

Examination should include auscultation of the subclavian, carotid and femoral (at the groin and adductor canal) arteries and the abdominal aorta. A bruit indicates turbulence, suggesting stenosis, and is conducted distally. Bruits may occur at unusual sites; the patient with renal artery stenosis (see Fig. 53.1, page 899) had a bruit over the affected vessel. A continuous 'machinery' murmur over an artery usually indicates an arteriovenous fistula.

Venous refilling

The limb is elevated for 30 s and then laid flat. Normal venous refilling occurs within seconds and slow refilling indicates arterial insufficiency. Fast refilling and varicose veins suggest an arteriovenous fistula (Summary box 53.1).

Summary box 53.1

Features of lower limb arterial stenosis or occlusion

- Intermittent claudication
- Rest pain
- Cold, numb, paraesthesia, colour change
- Ulceration
- Gangrene
- Assumes ambient temperature
- Sensation decreased
- Movement diminished or lost
- Arterial pulsation diminished or absent
- Arterial bruit
- Slow venous refilling

Relationship of clinical findings to site of disease

Consideration of symptoms and signs should determine the site of any major arterial obstruction (Table 53.1). Furthermore, the presence of an additional obstruction can usually be inferred. For

Table 53.1 Relationship of clinical findings to site of disease

Aortoiliac obstruction	Claudication in both buttocks, thighs and calves Femoral and distal pulses absent in both limbs Bruit over aortoiliac region Impotence common (Leriche)
Iliac obstruction	Unilateral claudication in the thigh and calf and sometimes the buttock Bruit over the iliac region Unilateral absence of femoral and distal pulses
Femoropopliteal obstruction	Unilateral claudication in the calf Femoral pulse palpable with absent unilateral distal pulses
Distal obstruction	Femoral and popliteal pulses palpable Ankle pulses absent Claudication in calf and foot

The best results from surgery are obtained by operation on the larger vessels, which allows a high volume of blood flow through bypass grafts. For instance, aorto-iliac bypass is longer lasting than femorotibial bypass.

example, signs of iliac artery obstruction and ulceration of the foot suggest an additional obstruction, as collateral circulation around an isolated iliac artery obstruction is usually excellent. Such severe features indicate a second obstruction, typically in the femoral or popliteal artery.

Investigation of arterial occlusive disease

Most patients with symptoms of arterial disease do not need active treatment, such as angioplasty or surgical reconstruction, and the decision whether or not to intervene can often be made without recourse to special investigations.

General investigation

Patients with arterial disease tend to be elderly and atherosclerosis is a generalised disease; if active intervention is contemplated, full assessment is essential. Tests relevant to diabetes, abnormal lipid metabolism, anaemia and conditions causing high blood viscosity (e.g. polycythaemia and thrombocythaemia) include a full blood count (including platelets), plasma fibrinogen, blood and urine glucose, and a blood lipid profile (triglycerides, total cholesterol, and high- and low-density lipoprotein cholesterol). Cardiac failure, myocardial ischaemia, hypertension and age-related diseases such as chronic obstructive pulmonary disease and neoplasia should also be considered.

Although a normal electrocardiogram (ECG) does not exclude severe coronary artery disease, a grossly abnormal ECG may influence decision making. An exercise ECG gives a more accurate assessment but many patients are limited in their ability to exercise. In such circumstances radioisotope ventriculography or echocardiography may be attractive as a non-invasive method of assessing left ventricular function. Patients must also be assessed for lung disease by chest radiograph and, if necessary, pulmonary function tests. Tests for renal function (serum creatinine) are also required, especially if contrast agents are to be used at angiography, as they may adversely affect kidney function.

Doppler ultrasound blood flow detection

A hand-held Doppler ultrasound probe is most useful in the assessment of occlusive arterial disease; many consider it essential (Figs 53.5 and 53.6). A continuous-wave ultrasound signal is transmitted from the probe at an artery and the reflected beam is picked up by a receiver within the probe itself. The change in frequency in the reflected beam compared with that of the transmitted beam is due to the Doppler shift, resulting from the reflection of the beam by moving blood cells. The frequency change may be converted into an audio signal that is typically pulsatile. Doppler ultrasound equipment can be used as a very sensitive type of stethoscope in conjunction with a sphygmomanometer to assess systolic pressure in small vessels. This is possible even when the arterial pulse cannot be palpated. It is of the greatest importance to appreciate that, although a 'Doppler signal' indicates moving blood, it does not necessarily indicate that the blood flow detected is sufficient to prevent limb loss, i.e. a Doppler signal does not indicate viability.

The ankle-brachial pressure index (ABPI) is the ratio of systolic pressure at the ankle to that in the arm. The higher of the pressures in the dorsalis pedis and posterior tibial arteries serves as the numerator, with the higher systolic pressure between the brachials serving as the denominator. Resting ABPI is normally about 1.0; values below 0.9 indicate some degree of arterial obstruction and less than 0.3 suggests imminent necrosis. It must

Figure 53.6 Hand-held Doppler probe and sphygmomanometer used to determine systolic pressure in the dorsalis pedis artery, as part of assessing the ankle-brachial pressure index.

be appreciated, however, that values approaching normality at rest may still be associated with intermittent claudication. Retesting after exercise is useful in this context as ABPI normally rises but occlusive disease may result in reduction. Artefacts are due especially to calcified arteries, which are often incompressible and lead to a falsely high pressure or ABPI result, especially in diabetics.

Duplex imaging

This is a major investigative technique in vascular disease. A duplex scanner uses B-mode ultrasound to provide an image of vessels (Figs 53.7 and 53.8). This image is created through the

Figure 53.5 Simple hand-held Doppler ultrasound probe.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

Figure 53.7 Colour duplex scanner.

Figure 53.8 Colour duplex scan of carotid vessels in neck showing stenosis at common carotid bifurcation (courtesy of Dr Paul Allan, Royal Infirmary, Edinburgh, Scotland).

different abilities of different tissues to reflect the ultrasound beam. A second type of ultrasound, namely Doppler ultrasound, is then used to insonate the imaged vessels and the Doppler shift obtained is analysed by a computer in the duplex scanner. Such shifts can give detailed knowledge of vessel blood flow, turbulence, etc. Many scanners have the added sophistication of colour coding, which allows visualisation of blood flow on the image. The various colours indicate change in direction and velocity of flow; points of high flow generally indicate a stenosis (consider that rivers flow fast where they are narrow). Duplex scanning is at least as accurate as angiography in many circumstances. In terms of cost-effectiveness and safety, it is generally to be preferred to any type of angiography if the two tests are considered to be equally useful in any given clinical context.

Treadmill

Patients themselves are poor at assessing claudicating distance and it might be thought that a treadmill assessment would provide a useful objective measurement of distance to onset of pain. However, a simple measured walk along a hospital corridor is even more reliable. A good use for the treadmill (with a slight incline) is the detection of a fall in ABPI after exercise, indicating occult arterial stenosis (see above).

Angiography (synonym: arteriography)

In lower limb disease, symptoms and their severity determine whether intervention is needed. Angiography is only appropriate if intervention is being contemplated. Even then, it is often advisable to have a duplex scan first.

Classical angiography involves the injection of a radio-opaque solution into the arterial tree, generally by a retrograde percutaneous catheter method (Seldinger technique) usually involving the femoral artery (Figs. 53.9 and 53.10). Hazards include thrombosis, arterial dissection, haematoma, renal dysfunction and allergic reaction. Rather than taking simple films, nowadays a computer system digitises the images, allowing the image before injection of contrast agent to be subtracted from the contrast

Figure 53.9 Arterial occlusion just above the knee causing claudication of the calf; good collateral circulation (arteriogram by the Seldinger technique).

image, thereby removing extraneous background and providing great clarity. Such digital subtraction angiography (DSA) may be carried out by arterial or venous injection of contrast agent. The former allows the use of fine catheters and relatively small amounts of contrast agent; although the latter avoids the need for arterial puncture completely, a high volume of contrast agent must be used.

The new millennium has seen the introduction of magnetic resonance angiography, which offers the prospect of multiplanar imaging without the need for ionising radiation or direct arterial puncture (Fig. 53.11). Although image quality is not as good as that of DSA, it is satisfactory for most purposes. Computerised tomography (CT) angiography is another recently introduced method that is gaining in popularity and, taken together, these two new techniques are gradually replacing DSA.

Sven Ivar Seldinger, 1921–1998, Radiologist, Karolinska Institute, Stockholm, Sweden, introduced percutaneous arterial catheterisation in 1953.

Non-surgical management of arterial stenosis or occlusion

General

When told that walking is not doing harm, many claudicants are content to live within the limitations imposed by their condition. Spontaneous improvement occurs in many patients over the first 6 months after an occlusive episode as collateral vessels develop. Lifestyle advice should be offered. Exercise is encouraged, particularly walking within the limits of the disability; supervised exercise programmes are ideal. Stopping smoking is essential. Dietary advice is required for those who are overweight and for those with high blood lipids. Care of the ischaemic foot is often required, especially in diabetics.

Drugs

Medication may be required for diseases associated with arterial disorders, such as hypertension and diabetes; some antihypertensives (particularly β -blockers) may exacerbate claudication. Raised blood lipids require active drug treatment but even when the lipid profile is normal a statin should be prescribed (e.g. 40 mg/day of pravastatin). An antiplatelet agent is also necessary, usually 75 mg day⁻¹ of aspirin, with 75 mg day⁻¹ of clopidogrel as an alternative for those who are aspirin intolerant. Other agents, such as vasodilators, are unlikely to prove beneficial.

Transluminal angioplasty and stenting

Arterial occlusive disease may be treated by inserting a balloon catheter into an artery and inflating it within a narrowed or blocked area (Figs 53.12 and 53.13). This is usually done percutaneously in the radiology department (Figs 53.14 and 53.15). Percutaneous transluminal angioplasty (PTA) has proved very successful in dilating the iliac arteries and, to a lesser extent, the arteries of the leg itself. The technique is also applicable at other sites (upper limb vessels, renal arteries, gastrointestinal arteries, carotid arteries) with variable outcomes. The basic method involves a (usually) femoral angiogram during which a guidewire is inserted through any stenosis or short occlusion to be treated. A balloon catheter is then inserted over the guidewire and the balloon positioned within the lesion, its position being confirmed by angiography. The balloon is then inflated for approximately 1 minute and deflated. This is repeated before withdrawal of the catheter.

Figure 53.12 Balloon catheter for percutaneous transluminal angioplasty.

Figure 53.13 (a) Catheter balloon deflated; (b) balloon inflated.

Figure 53.14 Narrowed superficial femoral artery before and after transluminal angioplasty (courtesy of J. McIvor, FRCR, London). The advantage of this technique is that it can be carried out under local anaesthesia using the Seldinger technique of percutaneous arterial puncture, and is therefore especially useful in the treatment of patients who are medically unfit for major surgery.

Should the vessel fail to stay adequately dilated, it may be possible to hold the lumen open using a metal stent (Figs 53.16 and 53.17). Such a device may be introduced on a balloon catheter, the balloon itself when inflated expanding the stent; the balloon is then deflated and the catheter removed. An alternative type of stent is held compressed by a sheath of plastic in a delivery system. The stent is positioned at the site of arterial dilatation and its sheath withdrawn to allow the device to self-expand and so hold the lumen open.

PTA of the carotid artery is currently topical. At this site the matter of microemboli at the time of dilatation as a cause of iatrogenic stroke cannot be ignored. Several techniques have been developed to try to reduce this problem, including umbrella-style catheters capable of trapping debris released at the point of balloon expansion. Whether or not carotid PTA will prove a sound alternative to carotid endarterectomy remains to be determined through randomised controlled trials.

Operations for arterial stenosis or occlusion

Site of disease and type of operation

Aortoiliac occlusion responds well to aortofemoral bypass (Fig. 53.18a, page 908), but this operation carries a mortality rate of about 5%. Today, PTA is usually a better alternative if technically possible. In a patient who is unable to withstand major surgery, who has pronounced ischaemia and who has no PTA option, a femorofemoral or iliofemoral crossover bypass may be considered (if only one iliac system is involved with disease) or an axillo-bifemoral bypass may be done (if both iliac segments are diseased).

Superficial femoral artery occlusive disease often produces unilateral symptoms. For claudication, conservative treatment is almost always the best plan but, if the block is short and favourably sited, PTA may be a reasonable option. If the lesion is not favourable for PTA and the patient fully understands the risks and benefits of intervention, a femoropopliteal bypass may be considered (Fig. 53.18b, page 908); long-term graft patency is related to the quality of inflow and outflow, and graft length (common femoral to above-knee or below-knee popliteal). It is also related to the material used for the bypass. Autogenous saphenous vein gives the best results when used either as a reversed conduit or *in situ* after valve disruption. Some patients have a profunda femoris origin stenosis that can be overcome by a small vein or prosthetic patch angioplasty.

Occlusive disease below the popliteal artery may require bypass to a tibial vessel, even down to ankle level. Success is fair but the risk of early failure with limb loss is such that this femorotibial bypass is only appropriate for limb salvage or severe rest pain. The most successful conduit is the long saphenous vein used in the *in situ* fashion after disrupting the valves with a valvulotome. If the long saphenous vein is not available from either leg, short saphenous or arm veins may be used. A polytetrafluoroethylene (PTFE) graft may even be employed; many surgeons construct the lower anastomosis using a small collar of vein (Miller cuff) between the PTFE and the recipient artery, which may improve patency.

Prosthetic materials

Dacron is the favoured material for aortoiliac work (Fig. 53.19a); it gives excellent results. For bypass in the femoropopliteal region,

Justin H. Miller, Vascular Surgeon, Royal Adelaide Hospital, Adelaide, SA, Australia.

Figure 53.15 Before (a) and after (b) balloon dilatation of a severely stenosed left renal artery in a 20-year-old woman with uncontrollable hypertension. The blood pressure fell to normal after the procedure. The stenosis was probably due to fibromuscular hyperplasia, but no tissue was available for histological diagnosis.

Shaw, Ninewells Hospital, Dundee, Scotland).

aorta it is usual to use 2/0 or 3/0 sutures and in the femoral artery at the groin 4/0 or 5/0 sutures. Finer sutures, up to 7/0, may be needed further down the limb.

Technical details

For aortofemoral bypass the aorta is approached through a mid-line or transverse abdominal incision. The common femoral arteries and their branches are exposed through vertical groin incisions. The small bowel is retracted to the right and the posterior peritoneum opened. Retroperitoneal tunnels are made from the aorta to the groins. Heparin (5000 U) is given intravenously and the vessels clamped. A vertical incision is made in the anterior aspect of the aorta to which an obliquely cut, bifurcated Dacron graft is sutured end-to-side. The graft limbs are then fed down to the groins where they are anastomosed end-to-side to the common femoral arteries or, if there is evidence of profunda stenosis, to an arteriotomy running from the common femoral vessel down into the profunda. The posterior peritoneum is closed over the Dacron to prevent adhesion of the graft to bowel. The abdomen and groin wounds are closed without drainage.

For femoropopliteal bypass the popliteal artery above or below the knee is exposed through a medial incision. The common femoral artery is exposed at groin level. The long saphenous vein may be treated in two different ways. First, it may be excised, and its tributaries tied, reversed and sutured into the limb as a bypass. Second, it may be left in place (*in situ*) and the valves disrupted with a valvulotome. The graft is then sutured to the femoral artery

if autogenous vein is not available, PTFE (Fig. 53.19b) or glutaraldehyde-tanned, Dacron-supported, human umbilical vein (Fig. 53.19c) may be employed. In general, any vein used requires a diameter of at least 3 mm. Monofilament sutures are used for vascular surgery; polypropylene is particularly popular. In the

proximally and to the popliteal vessel distally. If no suitable vein is available, a prosthetic material (usually PTFE) may be used, with or without a small vein collar (Miller cuff) at its distal end (Fig. 53.20a). Suction drains are rarely necessary. Femorodistal bypass is usually carried out using the long saphenous vein in the *in situ* mode (Fig. 53.20b). For profundaplasty the common femoral artery and its branches are exposed and, after giving heparin and clamping the

Figure 53.19 (a) Dacron bifurcation graft; (b) polytetrafluoroethylene graft; (c) human umbilical vein graft.

vessels in the usual way, an incision is made into the common femoral artery and carried down into the profunda, effectively dividing the stenotic profunda origin. The arteriotomy is then closed with a vein or prosthetic patch to widen the narrowed segment.

A femorofemoral crossover graft is useful for relieving an iliac artery occlusion when the other iliac artery is patent. A prosthetic graft is tunnelled subcutaneously above the pubis and anastomosed end-to-side to the common femoral arteries on each side. Blood from the patent iliac runs through the graft to the ischaemic limb. An axillofemoral graft is useful for salvaging a threatened limb in a poor-risk patient with bilateral iliac obstruction. A long prosthetic graft is tunnelled subcutaneously, from an end-to-side anastomosis with the axillary artery proximally, to reach the femoral artery of the involved limb in the groin where the distal anastomosis is made. The axillary artery will carry sufficient blood to maintain the circulation in both arm and leg. Short-term results are good; in these comorbid patients long-term patency is rarely important. An axillo-bifemoral bypass carries twice as much blood flow through its long limb as an axillo(uni)femoral bypass; the former is said to have a correspondingly improved patency rate. These axillary artery-based salvage operations should not be performed for intermittent claudication alone as limb loss may result if the operation fails.

Results of operation

Long-term results of aortoiliac reconstructive surgery are good, usually marred only by progressive infrainguinal disease. Femoropopliteal surgery is less successful. Immediate postoperative success for vein bypass exceeds 90% but many fail in the first 18 months after operation and, at the end of 5 years, the success rate is about 60%. PTFE bypass gives a poorer result than vein bypass, with 5-year success rates of less than 50%. Although the results of femorotibial bypass are even less satisfactory, such surgery can ensure limb salvage in patients who are generally debilitated and whose expected lifespan is limited; however, they are never appropriate for claudication.

Other sites of atheromatous occlusive disease

The principles of arterial surgery outlined above can be applied at other arterial sites. Carotid stenosis may cause transient ischaemic attacks (TIAs). These are recurrent and, by definition, short-lived mini-strokes. Resolution occurs within 24 hours (usually within minutes) but TIAs are a warning of impending major stroke. Patients should have a duplex scan and, if carotid occlusive disease of appropriate severity and at an appropriate site is confirmed (classically at the internal carotid artery origin) (Fig. 53.21), carotid endarterectomy should be offered. This involves clamping the vessels, an arteriotomy in the common carotid artery continued up into the internal carotid artery through the diseased segment, removal of the occlusive disease (endarterectomy) and closure of the arteriotomy, often with a patch. During clamping, some patients will have inadequate cerebral blood flow. Such a situation may be recognised by recording a low pressure in the distal internal carotid artery above the level of the clamp if general anaesthesia has been employed, or by a temporary neurological deficit if local anaesthesia has been used. It is necessary in such circumstances to insert a temporary silicone shunt over the arterial field being worked upon.

Subclavian artery stenosis may cause claudication in an arm or artery-to-artery embolisation, leading to digital ischaemia. It

Figure 53.20 (a) Completion angiogram of femoropopliteal bypass graft (with Miller cuff). (b) Completion angiogram of femorodistal bypass graft *in situ*.

may be treated by endarterectomy or bypass, but nowadays PTA is the treatment of choice. Sometimes subclavian artery lesions are associated with neck pathology, such as a cervical rib. Any underlying pathology must be corrected at the time of arterial repair. Subclavian steal syndrome may occur if it is the first part of the subclavian artery that is obstructed, with the vertebral artery providing a collateral circulation into the arm by reversing its direction of flow. This may cause periods of cerebral ischaemia. However, the classic syndrome of syncopal attack and visual disturbance associated with arm exercise and a diminished blood pressure in the affected limb is rare; asymptomatic reversal of flow in the vertebral artery is much more common. In symptomatic patients, PTA or operation is indicated.

Enteric artery occlusive disease may cause pain after eating that has no obvious diagnosis in a patient with known atherosclerotic disease and weight loss. In general, two of the three enteric vessels (coeliac axis, superior mesenteric artery, inferior mesenteric artery) must be occluded to produce 'intestinal claudication'. Great care must be taken to exclude all other diagnoses before contemplating PTA, endarterectomy or bypass.

Renal artery stenosis may cause hypertension and, eventually, loss of renal function. It is usually possible to control hypertension with drugs but, if renal failure seems likely, direct intervention is indicated. PTA is the method of choice, if feasible. Otherwise, a variety of operations are available (endarterectomy, aortorenal bypass, renal artery revascularisation using another vessel such as the splenic artery, renal autotransplantation).

ACUTE ARTERIAL OCCLUSION

Sudden occlusion of an artery is commonly caused by emboli. It may also happen when thrombosis occurs on a plaque of pre-existing atheroma, but in this case collaterals are likely to have built up in the face of chronic arterial stenosis, making the effect of the eventual occlusion less dramatic; such effects have been considered in the preceding section.

Embollic occlusion

An embolus is a body that is foreign to the bloodstream and which may become lodged in a vessel and cause obstruction. It is often a thrombus that has become detached from the heart or a more proximal vessel. Sources are the left atrium in cardiac arrhythmia (particularly atrial fibrillation) and a mural thrombus following myocardial infarction; less common sources are aneurysms and thrombi formed on atherosclerotic plaques (so called artery-to-artery embolism). Emboli may lodge in any organ and cause ischaemic symptoms.

- *Leg* – pain, pallor, paresthesia, pulselessness and paraesthesia (Fig. 53.22). Acute arterial occlusion due to an embolus differs from occlusion due to thrombosis on a pre-existing atheroma; in the latter case a collateral circulation has often built up over time (Figs 53.23 and 53.24). It is essential to differentiate between the two as they require different management.
- *Brain* – the middle cerebral artery (or its branches) is most commonly affected, resulting in major or minor (TIA) stroke.

Figure 53.21 Carotid stenosis. A unilateral localised stenosis suitable for operation. CC, common carotid; EC, external carotid; IC, internal carotid.

- *Retina* – amaurosis fugax is fleeting blindness caused by a minute thrombus emanating from an atheromatous plaque in the carotid artery passing into the central retinal artery. Lasting obstruction causes permanent blindness.
- *Mesenteric vessels* – possible gangrene of the corresponding loop of intestine.
- *Spleen* – causing local pain.
- *Kidneys* – causing loin pain and haematuria.

Clinical features

Embolic arterial occlusion is an emergency that requires immediate treatment. The leg is often affected, with pain, pallor, paresis, loss of pulsation and paraesthesia (or anaesthesia) (see Fig. 53.22). The limb is cold and the toes cannot be moved, which contrasts with venous occlusion when muscle function is not affected. The diagnosis can be made clinically in a patient who has no history of claudication and has a source of emboli, who suddenly develops severe pain or numbness of the limb, which becomes cold and mottled. Movement becomes progressively more difficult and sensation is lost. Pulses are absent distally but the femoral pulse may be palpable, even thrusting, as distal occlusion results in forceful expansion of the artery with each pressure wave despite the lack of flow.

Figure 53.22 The symptoms and signs of embolism (four Ps). The fifth feature, anaesthesia, is often stated to be paraesthesia (the fifth P) but, in truth, complete loss of sensation in the toes and feet is characteristic.

Figure 53.23 Aortic bifurcation embolus. Source of embolus is a recent myocardial infarct or atrial fibrillation. This causes severe, dramatic symptoms.

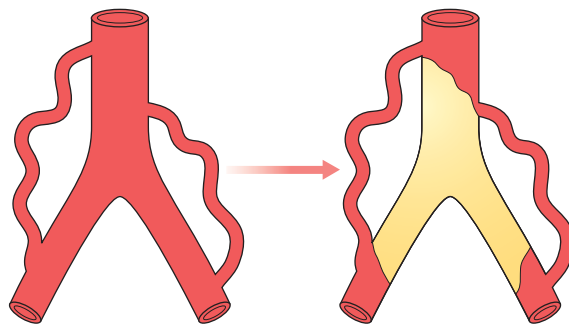

Figure 53.24 Aortic bifurcation thrombosis. No source of embolus but previous claudication. Claudication worse but no dramatic event.

Treatment

Because of the ensuing stasis, a thrombus can extend distally and proximally to the embolus. The immediate administration of 5000 U of heparin intravenously can reduce this extension and maintain patency of the surrounding (particularly the distal) vessels until the embolus can be treated. The relief of pain is

essential because it is severe and constant. Embolectomy and thrombolysis are the treatments available for patients with limb emboli.

Embolectomy

Local or general anaesthesia may be used. The artery (usually the femoral), bulging with clot, is exposed and held in slings. Through a longitudinal or transverse incision the clot begins to extrude and is removed, together with the embolus (Fig. 53.25), with the help of a Fogarty balloon catheter. The catheter, with its balloon tip, is introduced both proximally and distally until it is deemed to have passed the limit of the clot. The balloon is inflated and the catheter withdrawn slowly, together with any obstructing material (Fig. 53.26). The procedure is repeated until bleeding occurs. Postoperatively, heparin therapy is continued until long-term anticoagulation with warfarin is established to reduce the chance of further embolism.

Figure 53.25 Embolic material removed from the common femoral artery, along with a long distal extension thrombus.

Figure 53.26 (a) A Fogarty catheter is inserted through an arteriotomy in the common femoral artery and fed distally down the superficial femoral artery and through the embolus. (b) The balloon is inflated and the catheter withdrawn, removing the embolus; the deep femoral and iliac arteries are similarly treated.

Thomas J. Fogarty, Surgeon, University of Oregon Medical School, Portland, Oregon, USA.

Compartment syndrome

In limbs that have been subject to sudden ischaemia followed by revascularisation, oedema is likely. Muscles swell within fixed fascial compartments and this can itself be a cause of ischaemia, with both local muscle necrosis and nerve damage due to pressure, and distal effects such as renal failure secondary to the liberation of myocyte breakdown products. The treatment is urgent fasciotomy to release the compression. The usual site at which such surgery is necessary is the calf (especially the anterior tibial compartment), but compartment syndrome may occasionally affect the thigh and the arm.

Intra-arterial thrombolysis

If ischaemia is not so severe that immediate operation is essential, it may be possible to treat either embolus or thrombosis by intra-arterial thrombolysis (Fig. 53.27). At arteriography of the ischaemic limb (usually via the common femoral artery) a narrow catheter is passed into the occluded vessel and left embedded within the clot. Tissue plasminogen activator (TPA) is infused through the catheter and regular arteriograms are carried out to check on the extent of lysis, which, in successful cases, is achieved within 24 hours. The method should be abandoned if there is no progression of dissolution of clot with time. There are several contraindications to thrombolysis, the most important of which are recent stroke, bleeding diathesis and pregnancy, and results in those over 80 years old are poor.

Mesenteric artery occlusion

Acute mesenteric occlusion may be either thrombotic (following atheromatous narrowing) or embolic. Thrombotic occlusion follows progressive narrowing and so the symptoms also tend to be progressive with weight loss, abdominal pain (usually post-prandial) and leucocytosis. Once the abdominal pain becomes severe, diarrhoea, systemic hypovolaemia and haemoconcentration occur. By this stage, the patient is ill out of proportion to the physical signs. Treatment is arteriography followed by percutaneous transluminal angioplasty or surgical bypass if the bowel has not already infarcted.

Figure 53.27 Angiogram of an occluded popliteal artery before thrombolysis (left), during successful lysis (middle) and after completion of lysis (right).

Embolic occlusion results in sudden, severe abdominal pain, with bowel emptying (vomiting and diarrhoea) and a source of emboli present (usually cardiac). Angiography and embolectomy, usually of the superior mesenteric artery, or bypass surgery can reduce the otherwise high mortality rate in these patients. A 'second look' laparotomy 24 hours later to check the viability of the bowel is often indicated.

Air embolism

Air may be accidentally injected into the venous circulation or sucked into an open vein. Venous air embolism is a rare complication of neck surgery if a large vein is inadvertently opened and it may be an accessory cause of death following a cut throat. Care should also be taken when infusing intravenous fluids, especially if a pressured system is used for rapid infusion, although a modern drip chamber with a plastic float should stop the injection when the fluid falls to a dangerously low level. If a large volume of air is allowed to reach the right side of the heart it may form an air lock within the pulmonary artery and cause right heart failure.

The treatment of air embolism is to put the patient in a head-down (Trendelenburg) position to encourage the air to enter the veins in the lower part of the body. The patient should also be placed on the left side to help the air to float to the ventricular apex, away from the ostium of the pulmonary artery. In extreme cases air may be aspirated from the heart through a needle introduced below the left costal margin. Oxygen should, of course, be administered.

Air may rarely enter the left side of the heart at open heart surgery or if a pulmonary vein is punctured when inducing a therapeutic pneumothorax. It may also enter via a patent foramen ovale (a common anomaly) as a paradoxical embolism. Air then may reach the coronary and/or the cerebral circulation. Treatment is along similar lines as for right heart air entry. Finally, air embolism may occur after fallopian tube insufflation or illegal abortion. Air may travel to the brain via the paravertebral veins.

Other forms of emboli

These include infective emboli of masses of bacteria or an infected clot, which may cause mycotic aneurysms, pyaemia or infected infarcts. Parasitic emboli, caused by the ova of *Taenia echinococcus* and *Filaria sanguinis hominis*, may occur in some countries; emboli of malignant cells (e.g. hypernephroma and cardiac myxoma) are rare but well recognised. Finally, fat embolism may follow major bony fractures. It is treated by the trauma or orthopaedic surgeon, rather than the vascular surgeon.

Therapeutic embolisation

This is used to arrest haemorrhage from the gastrointestinal, urinary (Fig. 53.28) and respiratory tracts, to treat arteriovenous malformations by blocking their arterial supply and to control the growth of unresectable tumours. Arterial embolisation requires accurate selective catheterisation using the Seldinger technique. A variety of materials may be used, including gelfoam sponge, plastic microspheres, balloons, ethyl alcohol, quick-setting plastics and metal coils.

Figure 53.28 Before (a) and after (b) therapeutic embolisation of the internal iliac artery in a patient with gross haematuria from an ulcerating bladder carcinoma (courtesy of F. Mclvor, FRCR, London, England).

GANGRENE

Gangrene implies death of macroscopic portions of tissue; the term necrosis may be used synonymously. It often affects the distal part of a limb because of arterial obstruction (from thrombosis, embolus or arteritis). This type of gangrene, which affects tissues that were initially sterile, must be distinguished from those forms of gangrene that derive mainly from infection (classically gas gangrene), although both may coexist.

Clinical features

A gangrenous part lacks arterial pulsation, venous return, capillary response to pressure, sensation, warmth and function. The colour of the part changes through a variety of shades according to circumstances (pallor, dusky grey, mottled, purple) until finally taking on the characteristic dark-brown, greenish-black or black appearance, which is caused by the disintegration of haemoglobin and the formation of iron sulphide.

Dry gangrene occurs when the tissues are desiccated by gradual slowing of the bloodstream; it is typically the result of atheromatous occlusion of arteries. The affected part becomes dry and wrinkled, discoloured from disintegration of haemoglobin, and greasy to the touch. Moist gangrene occurs when infection and putrefaction are present; the affected part becomes swollen and discoloured and the epidermis may be raised in blebs. Crepitus may be palpated as a result of infection by gas-forming organisms. This situation is quite common in the feet of diabetics.

Separation of gangrene

A zone of demarcation between the truly viable and the dead or dying tissue will eventually appear. Separation is achieved by the development of a layer of granulation tissue, which forms between the dead and the living parts. In dry gangrene, if the blood supply of the proximal tissues is adequate, the final line of

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock, Bonn and Leipzig, Germany.
Gabrielle Falloppio (Fallopius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy,

demarcation appears in a matter of days and separation occurs neatly and with the minimum of infection (so called separation by aseptic ulceration). If bone is involved, complete separation takes longer than when soft tissues alone are affected, and the stump tends to be conical as the bone has a better blood supply than its coverings.

In moist gangrene there is significant infection and suppuration extends into the neighbouring living tissue, thereby causing the final line of demarcation to be more proximal than in dry gangrene (separation by septic ulceration). This is why dry gangrene must be kept as dry and aseptic as possible, and why every effort should be made to convert moist gangrene into the dry type.

Sometimes in gangrene from atheroma or embolism the line of final demarcation is very slow to form or does not develop. Unless the arterial supply to the living tissues can be improved, the gangrene will spread to adjacent tissues or will suddenly appear as 'skip' areas further up the limb. Skip lesions should always be carefully sought; black patches appear, perhaps on the other side of the foot, on the heel, on the dorsum of the foot or even in the calf. Infection may also cause gangrene to spread proximally into areas of extensive inflammation. To attempt local amputation in the phase of vague demarcation is to court failure, as gangrene reappears in the skin flaps.

Treatment of gangrene

The surgeon is generally concerned with how much of a limb or digit can be salvaged and this depends on the blood supply proximal to the gangrene. Sometimes this can be improved by radiological or surgical intervention. A good blood supply may allow a conservative excision or distal amputation, avoiding a major ablation, but a proximal life-saving amputation is required for rapidly spreading symptomatic gangrene and gas gangrene.

Sometimes, especially with digits, amputation can be avoided. Conservative treatment involves keeping the affected part absolutely dry. Exposure to the air and the use of a fan may assist in the desiccation process and may relieve pain. The limb must not be heated. Local pressure areas, e.g. the skin of the heel or the malleoli, must be protected if fresh patches of gangrene are not to occur in these places. Padded rings, foam blocks and air beds are useful preventative aids. Occasionally, the lifting of a crust or the removal of hard or desiccated skin helps demarcation or releases pus and relieves pain.

Specific varieties of gangrene

Diabetic gangrene

Diabetic gangrene is related to three factors: trophic changes from peripheral neuropathy, ischaemia as a result of atheroma, and low resistance to infection because of excess sugar in the tissues (Fig. 53.29). The neuropathy impairs sensation and thus favours the neglect of minor injuries and infections. Motor involvement is frequently accompanied by loss of reflexes and deformities (neuropathic joints). Thick callosities develop on the sole and amateur chiropody may allow the entry of infection. Whatever the portal, any infection can spread proximally with speed in subfascial planes in diabetic patients. Palpable dorsalis pedis and posterior tibial pulses, and the absence of rest pain and intermittent claudication, may signify that there is no associated major arterial disease. Bacteriological examination is made of any pus and a radiograph may reveal the extent of any osteitis.

Figure 53.29 Diabetic gangrene.

Treatment consists of bringing the diabetes under control by diet and drugs. The gangrene is treated as described above, with a conservative approach if there is no major arterial obstruction. A rapid spread of infection requires drainage by incision and the removal of any obviously dead tissue. This may require quite extensive laying open of infected tissue planes. Good drainage and the control of infection should be followed by rapid healing if the blood supply is adequate.

Bedsore

A bedsore is gangrene caused by local pressure (Fig. 53.30). Bedsore are predisposed to by five factors: pressure, injury, anaemia, malnutrition and moisture. They can appear and extend rapidly in immobile patients and in those with debilitating illness. Prophylactic measures must be taken, including the avoidance of pressure over bony prominences by the use of foam blocks or similar, regular turning, and nursing on specially designed beds that reduce the pressure to the skin. A water bed or a ripple bed is sometimes desirable. Injury from wrinkled sheets and maceration of the skin by sweat, urine or pus must be prevented by skilled nursing and the use of an adhesive film dressing.

A bedsore can be expected if erythema appears that does not

Figure 53.30 Bedsore typically appear over areas exposed to pressure, such as the sacrum and (as in this case) the heel.

change colour on pressure. The affected area must be kept dry and an aerosol silicone spray may be used. Once pressure sores develop, they are difficult to heal. They may be treated by lotions or by exposure to keep them as dry as possible. They should be kept clean and debrided if necessary. Advice from a plastic surgeon should be sought for major lesions; rotation flaps can be effective.

Drug abuse

Inadvertent arterial injection of drugs has become common in many countries with significant numbers of drug addicts. Usually, the femoral artery in the groin is involved and presentation is with pain and mottling distally in the leg. All pulses down to ankle level are generally retained but, if not, imaging and intra-arterial thrombolysis may be considered. If pulses are present, dextran and heparin may be given to help what is a microvascular pathology, but there is no firm evidence of their efficacy in this condition. Fortunately, most cases resolve and progression to gangrene is rare. It should be remembered that many of these patients carry the human immunodeficiency virus and/or various hepatitis viruses.

Frostbite

Frostbite is caused by exposure to cold. It is seen both in climbers at high altitudes and in the elderly or the vagrant during cold, windy spells (Fig. 53.31). Vessel walls are damaged, leading to transudation and oedema. The sufferer experiences a severe burning pain in the affected part, which later assumes a waxy appearance as the pain disappears. Blistering and then gangrene follow. Frostbitten parts must be warmed gradually; any temperature higher than that of the body is detrimental. The part should be wrapped in cotton wool and kept at rest. Friction, e.g. rubbing

with snow, may damage already devitalised tissues. Warm drinks and clothing should be provided and powerful analgesics given to relieve the pain that heralds the return of circulation. Amputations should be conservative.

Ainhum

Ainhum (Fig. 53.32) is a disease of unknown aetiology that usually affects black men (and occasionally women) who have run barefoot in childhood. It is recorded in central Africa, central America and the Orient. A fissure appears at the level of the interphalangeal joint of a toe, usually of the little toe. The fissure is followed by a fibrous band that encircles the digit and causes necrosis. The treatment in the early stage is by Z-plasty and in the later stages by amputation.

Ergot

Ergot is a cause of gangrene in those who eat rye bread infected with *Claviceps purpurea*. Certain groups living on the Mediterranean coast or the Russian steppes are particularly at risk. It may also occur in migraine sufferers who take ergot preparations as prophylaxis over a long period (Fig. 53.33).

Venous gangrene

Although deep vein thrombosis is common, venous gangrene is surprisingly rare. It occurs when the circulation of a limb (usually the leg) is disrupted by overwhelming outflow obstruction and this requires massive deep vein thrombosis at a proximal site. Treatment in those at risk is by full anticoagulation with heparin and effective elevation of the swollen leg, preferably with the head and trunk level or even lowered. It is all too common to see futile

Figure 53.31 (a) Frostbite of the foot. Note the clear demarcation. (b) Frostbite of the middle finger in the same patient. The index finger was lost 2 years before, also from frostbite.

Ainhum is the name given to the condition by the Yoruba people of Nigeria.

Figure 53.32 Ainhum (courtesy of Dennis Morrissey, FRCS, Birmingham).

attempts at treatment with the body in a 'jack-knife' position. This form of management prevents progression to gangrene in most cases. Systemic lytic therapy (e.g. with TPA) has not proved successful for the condition but some would advocate venous thrombectomy in extreme circumstances using a Fogarty catheter.

AMPUTATION

General

Amputation should be considered when part of a limb is dead, deadly or a dead loss. A limb is dead when arterial occlusive disease is severe enough to cause infarction of macroscopic portions of tissue, i.e. gangrene. The occlusion may be in major vessels (atherosclerotic or embolic occlusions) or in small peripheral vessels (diabetes, Buerger's disease, Raynaud's disease, inadvertent intra-arterial injection). If the obstruction cannot be reversed and the symptoms are severe, amputation is required.

A limb is deadly when the putrefaction and infection of moist gangrene spreads to surrounding viable tissues. Cellulitis and severe toxæmia are the result. Amputation is required as a life-

Figure 53.33 Gangrene due to ergot. The patient had taken repeated doses of ergotamine tartrate for 'migraine' while on a transatlantic flight.

Leo Buerger, 1879–1943, Professor of Urologic Surgery, New York Polyclinic Medical School, New York, USA, described thromboangitis obliterans in 1908.
Maurice Raynaud, 1834–1881, Physician, Hospital Lariboisiere, Paris, France, described this condition in 1862.

saving operation. Antibiotic cover should be broad and massive. Other life-threatening situations for which amputation may be required include gas gangrene (as opposed to simple infection), neoplasm (such as osteogenic sarcoma) and arteriovenous fistula.

A limb may be deemed a dead loss in the following circumstances: first, when there is relentless severe rest pain without gangrene – amputation will improve quality of life; second, when a contracture or paralysis makes the limb impossible to use and renders it a hindrance; and third, when there is major unrecoverable traumatic damage (Summary box 53.2).

Summary box 53.2

Indications for amputation

Dead limb

- Gangrene

Deadly limb

- Wet gangrene
- Spreading cellulitis
- Arteriovenous fistula
- Other (e.g. malignancy)

'Dead loss' limb

- Severe rest pain
- Paralysis
- Other (e.g. contracture, trauma)

Distal and transmetatarsal amputation

In patients with small-vessel disease, typically caused by diabetes, gangrene of the toes may occur with relatively good blood supply to the surrounding tissues. In such circumstances local amputation of the digits can result in healing. However, if the metatarsophalangeal joint region is involved, a ray excision is required, taking part of the metatarsal and cutting tendons back. The wound should not be sutured but loosely packed with gauze soaked in an antiseptic solution such as povidone iodine. Early mobility aids drainage provided that cellulitis is not present. For less extensive gangrene, if amputation is taken through a joint, healing is improved by removing the cartilage from the joint surface.

A transmetatarsal amputation can be used in circumstances similar to those meriting distal amputation, when several toes are affected and irreversible ischaemia has extended to the forefoot. A viable long plantar flap is essential for this operation to heal successfully (Fig. 53.34).

Major amputation

Preoperative preparation

The patient should, whenever possible, be given time to come to terms with the inevitability of amputation. Ideally, once the alternatives of a painful useless limb or a painless useful (artificial) one are explained, the patient will make the final decision. In gangrene of the foot, especially with 'skip' areas, this is the time for explanation of, and consent for, above-knee amputation should an attempt at below-knee section prove inadvisable on account of inadequate blood supply to the flaps. If there is time, the nutritional status of the patient should be optimised; certainly any anaemia should be corrected. Antibiotics should be given as required and especially immediately before operation to prevent clostridial infection.

Figure 53.34 Transmetatarsal amputation for diabetic gangrene of the toes.

Choice of operation (Fig. 53.35)

Where good limb-fitting facilities exist, above- or below-knee amputations are preferable because the best cosmetic and functional results can be obtained with the resulting cone-bearing amputation stumps. If limb-fitting facilities are limited, however, an end-bearing amputation may be preferable (Syme's, through-knee, Gritti–Stokes) so that simple prostheses (peg leg or simple boot) can be used. Syme amputations are not suitable for severely ischaemic atheromatous limbs because of the poor healing of the heel flap.

For above- or below-knee amputations with a good stump shape, it is possible to hold a prosthesis in place simply by suction, without any cumbersome and unsightly straps. The stump should be of sufficient length to give the required leverage, i.e. not less than 8 cm below the knee (preferably 10–12 cm) and not less than 20 cm above the knee. There should be room for the artificial joint, i.e. the stump must not be too long; ideally 12 cm proximal to the knee joint above the knee and 8 cm proximal to the ankle joint below the knee are needed for the mechanism. A below-knee amputation is much better than an above-knee amputation in terms of eventual mobility. Every attempt should be made to preserve the knee joint if the extent of ischaemia allows.

James Syme, 1799–1871, Regius Professor of Clinical Surgery, University of Edinburgh, Scotland.

Rocco Gritti, 1828–1920, Surgeon, Milan, Italy, described this operation in 1857.

Sir William Stokes, 1839–1900, Surgeon, Dublin, Ireland, described his modification of Gritti's operation in 1870.

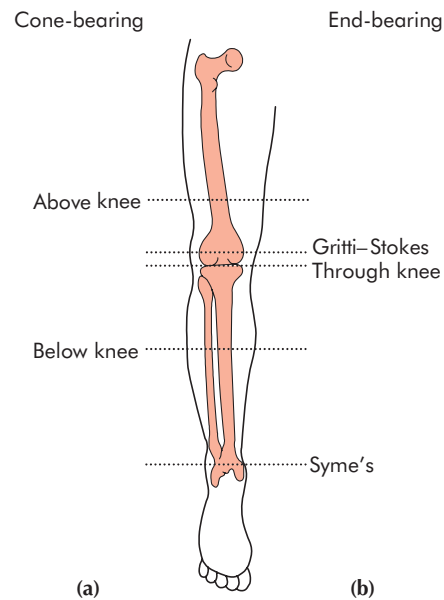

Figure 53.35 Choice of site: (a) cone-bearing and (b) end-bearing amputations.

Below-knee amputations

Two types of skin flap are commonly used: long posterior flap and skew flap. Skew flaps were described by K.P. Robinson. Whichever method is chosen, the total length of flap must be at least one and a half times the diameter of the leg at the point of bone section.

The long posterior flap amputation, although the older method, remains the more popular, probably because of its relative simplicity (Fig. 53.36). Anteriorly, the incision is deepened to bone and the lateral and posterior incisions are fashioned to leave the bulk of the gastrocnemius muscle attached to the flap, muscle and skin being transected together at the same level. If bleeding is inadequate, the amputation is refashioned at a higher level. Blood vessels are identified and ligated. Nerves are not clamped but pulled down gently and transected as high as possible. Vessels in nerves are ligated. The fibula is divided 2 cm proximal to the level of tibial division using bone cutters. The tibia is cleared and transected at the desired level, the anterior aspect of the bone being sawn obliquely before the cross-cut is made. This, with filing, gives a smooth anterior bevel, which prevents pressure necrosis of the flap. The long muscle/skin flap is tapered after removing the bulk of the soleus muscle (much of the gastrocnemius may be left unless it is very bulky). The area is washed with saline to remove bone fragments and the muscle and fascia are sutured with an absorbable material to bring the flap over the bone ends. A suction drain is placed deep to the muscle and brought out through a stab incision in the skin. The skin flap should lie in place with all tension taken by the deep sutures. Interrupted skin sutures are inserted. Gauze, wool and crepe bandages generally make up the stump dressing, although some surgeons prefer a rigid (plaster) dressing system.

The skew flap amputation makes use of anatomical knowledge of the skin blood supply. Equally long flaps are developed; they

Kingsley Peter Robinson, formerly Surgeon, the Westminster Hospital, London, UK.

Figure 53.36 Classic long posterior flap type of below-knee amputation.

join anteriorly 2.5 cm from the tibial crest, overlying the anterior tibial compartment, and posteriorly at the exact opposite point on the circumference of the leg. After division of bone and muscle in a fashion similar to that described above, the gastrocnemius flap is sutured over the cut bone end to the anterior tibial periosteum with absorbable sutures. Finally, drainage and skin sutures are inserted and the limb dressed as for the long posterior flap operation.

Above-knee amputation

The site is chosen as indicated above but may need to be higher if bleeding is poor on incision of the skin. Equal curved anterior and posterior skin flaps are made of sufficient total length. Skin, deep fascia and muscle are transected in the same line. Vessels are ligated. The sciatic nerve is pulled down and transected cleanly as high as possible and the accompanying artery ligated. Muscle and skin are retracted and the bone cleared and sawn at the point chosen. Haemostasis is achieved. The muscle ends are united over the bone by absorbable sutures incorporating the fascia. A suction drain deep to the muscle is brought out through the skin clear of the wound. The fascia and subcutaneous tissues are further brought together so that the skin can be apposed by interrupted sutures. Gauze, wool and crepe bandages form the stump dressing.

Gritti–Stokes, through-knee and Syme’s amputations

These are rarely carried out nowadays. For the femoral level Gritti–Stokes amputation, the section is transcondylar. Through-knee amputation is technically less complex. In Syme’s amputation it is essential to preserve the blood supply to the heel flap by

meticulous clean dissection of the calcaneus. The tibia and fibula are sectioned as low as possible to the top of the mortise joint. This type of procedure is rarely applicable in patients with occlusive vascular disease.

Postoperative care of an amputee

Opiate pain relief should be given regularly. Care of the good limb must not be forgotten as a pressure ulcer on the remaining foot will delay mobilisation, despite satisfactory healing of the stump. Exercise and mobilisation are of the greatest importance. After surgery, flexion deformity can be prevented by the use of a cloth placed over the stump with sand bags on each side to weight it down. Once the drain has been removed, exercises are started to build up muscle power and coordination. Daily stump bandaging in an attempt to mould the shape of the stump is now obsolete. Mobility is progressively increased with walking between bars and the use of an inflatable artificial limb, which allows weight-bearing to be started before a pylon or temporary artificial limb is ready (Fig. 53.37). This whole episode in the patient’s life should be conducted in a positive manner through the various stages towards full independence. Early assessment of the home is part of the programme; it allows time for minor alterations, such as the addition of stair rails, movement of furniture to give support near doors and provision of clearance in confined passages.

Complications

Early complications include haemorrhage, which requires return to the operating room for haemostasis, haematoma, which requires evacuation, and infection, usually in association with a haematoma. Any abscess must be drained and appropriate antibiotics given. Gas gangrene can occur in a mid-thigh stump from faecal contamination. Wound dehiscence and gangrene of the flaps are caused by ischaemia; a higher amputation may well be

Figure 53.37 Inflatable artificial limb.

necessary. Amputees are at risk of deep vein thrombosis and pulmonary embolism in the early postoperative period and prophylaxis with subcutaneous heparin is essential for several weeks after operation.

Later complications include pain resulting from unresolved infection (sinus, osteitis, sequestrum), a bone spur, a scar adherent to bone and an amputation neuroma. Patients frequently remark that they can feel the amputated limb (phantom limb) and sometimes remark that it is painful (phantom pain). The surgeon's attitude should be one of firm reassurance that this sensation will almost certainly disappear with time; amitriptyline or gabapentin may help. Other late complications include ulceration of the stump because of pressure effects of the prosthesis or increased ischaemia.

ANEURYSM

General

Dilatations of localised segments of the arterial system are called aneurysms. They can either be true aneurysms, containing the three layers of the arterial wall (intima, media, adventitia) in the aneurysm sac, or false aneurysms, having a single layer of fibrous tissue as the wall of the sac, e.g. aneurysm following trauma. Aneurysms can also be grouped according to their shape (fusiform, saccular, dissecting) or their aetiology (atheromatous, traumatic, syphilitic, mycotic, etc.). The term mycotic is a misnomer because, although it indicates infection as a causal element in the formation of the aneurysm, this is due to bacteria, not fungi. Aneurysms occur all over the body in major vessels, including the aorta, and the iliac, femoral, popliteal, subclavian, axillary and carotid arteries. They may also occur in cerebral, mesenteric, splenic and renal arteries and their branches. The majority are true fusiform atherosclerotic aneurysms (Summary box 53.3).

Summary box 53.3

Classification of aneurysms

Wall

- True (three layers: intima, media, adventitia)
- False (single layer of fibrous tissue)

Morphology

- Fusiform
- Saccular
- Dissecting

Aetiology

- Atheromatous
- Mycotic (bacterial rather than fungal)
- Collagen disease
- Traumatic

Clinical features

All aneurysms can cause symptoms, as a result of expansion, thrombosis, rupture or the release of emboli. The symptoms relate to the vessel affected and the tissues it supplies. Most aneurysms of clinical significance can be palpated and, typically, an expansile pulsation is felt. Transmitted pulsation through a mass lesion, cyst or abscess lying adjacent to a large artery may be mistaken for aneurysmal pulsation. Before incising a swelling believed to be an

abscess it is essential to make sure that it does not pulsate. Finally, a tortuous (and often ectatic) artery, usually the innominate or carotid, may seem like an aneurysm to the inexperienced clinician.

Abdominal aortic aneurysm

Abdominal aortic aneurysm is by far the commonest type of large vessel aneurysm and is found in 2% of the population at autopsy; 95% have associated atheromatous degeneration and 95% occur below the renal arteries. Symptomatic aneurysms may cause minor symptoms, such as back and abdominal discomfort, before sudden, severe back and/or abdominal pain develops from expansion and rupture. Asymptomatic aneurysms are found incidentally on physical examination, radiography or ultrasound investigation.

Ruptured abdominal aortic aneurysm

Abdominal aortic aneurysms can rupture anteriorly into the peritoneal cavity (20%) or posterolaterally into the retroperitoneal space (80%). Less than 50% of patients with rupture survive to reach hospital. Anterior rupture results in free bleeding into the peritoneal cavity; very few patients reach hospital alive. Posterior rupture on the other hand produces a retroperitoneal haematoma (Fig. 53.38). Often a brief period ensues when a combination of moderate hypotension and the resistance of the retroperitoneal tissues arrests further haemorrhage. The patient may remain conscious but in severe pain. If no operation is performed, death is virtually inevitable. Operation results in a better than 50% survival rate.

To achieve the best results, diagnosis and treatment must be rapid. A tender, pulsatile mass is usually palpable in the abdomen of a hypotensive patient. If there is doubt about the presence of an aneurysm an ultrasonogram may help, but this test is not of use to detect rupture. If there is doubt about rupture a CT scan is of more help, but it is still far from being foolproof. In practice, most diagnoses are reached on clinical grounds alone, without imaging.

Good venous access is needed for infusion of saline or volume-expanding fluids, but the systolic blood pressure should not be raised any more than is necessary to maintain consciousness and permit cardiac perfusion (< 100 mmHg). Elevation into the normotensive range may provoke further uncontrolled haemorrhage. A urinary catheter is passed. If the patient appears stable, surgery may be delayed until cross-matched blood is ready but the patient should still be transferred immediately to the operating room so that the procedure can commence immediately if haemodynamic instability develops. Always remember that the treatment of ruptured aneurysm is operation, not monitoring and resuscitation (Summary box 53.4).

Summary box 53.4

Management of ruptured abdominal aortic aneurysm

- Early diagnosis (abdominal/back pain, pulsatile mass, shock)
- Immediate resuscitation (oxygen, intravenous replacement therapy, central line)
- Maintain systolic pressure, but not > 100 mmHg
- Urinary catheter
- Cross-match six units of blood
- Rapid transfer to the operating room

Figure 53.38 The retroperitoneal haematoma of a ruptured aortic aneurysm. The aortic pulsation is palpated through the haematoma at its upper limit and fingers are insinuated on each side of the aorta. With finger control, the upper clamp is positioned and closed on the aorta. The procedure is then as for a planned case. In this illustration, the clamp is at the proximal end of the aneurysm; the haematoma has spread from the left paracolic gutter to encircle the aneurysm and the aortic bifurcation.

Symptomatic abdominal aortic aneurysm

Patients most commonly present with back and/or abdominal discomfort. Pain may also occur in the thigh and groin because of nerve compression. Gastrointestinal, urinary and venous symptoms can also be caused by pressure from an abdominal aneurysm. About 3% of all aneurysms cause pain as a result of inflammation of the aneurysm itself (Fig. 53.39). Finally, a few cause symptoms from distal embolisation of fragments of their intraluminal thrombus. It is said that without surgery, 80% of those with a symptomatic aneurysm will be dead in a year; with surgery, 80% will be alive. Therefore, an operation is indicated in patients who are otherwise reasonably fit. The risk of operation is particularly increased in the presence of hypertension, chronic airway disease, recent myocardial infarction and impaired renal function. Chronological age is not a bar to surgery but only a few patients are fit enough for this type of procedure once over the age of 80.

Asymptomatic abdominal aortic aneurysm

An aneurysm found incidentally on clinical examination, radiography or ultrasonography (Fig. 53.40) in an otherwise fit patient should be considered for repair if > 55 mm in diameter (measured by ultrasonography). The annual incidence of rupture rises

Figure 53.39 An inflammatory abdominal aortic aneurysm. Note the white 'icing' effect. Such lesions can be technically difficult to manage.

from 1% or less in aneurysms that are < 55 mm in diameter to a significant level, perhaps as high as 20%, in those that are 70 mm in diameter. Assuming elective surgery carries a 5% mortality rate, the balance is in favour of elective operation once the diameter is > 55 mm, provided there is no major comorbidity. Regular ultrasonographic assessment is indicated for asymptomatic aneurysms < 55 mm in diameter (Summary box 53.5).

Summary box 53.5

Abdominal aortic aneurysm: indications for operation

Asymptomatic

- Aneurysm > 55 mm in anteroposterior diameter
- Patient fit for surgery (expected mortality rate < 5%)
- Indications for endoluminal operation are the same as for open operation

Symptomatic

- Aneurysm of any size that is painful or tender
- Aneurysm of any size that is causing distal embolisation
- Indications are wider than for an asymptomatic lesion (expected mortality rate 5–20%)

Figure 53.40 Ultrasonogram of an aortic aneurysm showing the large clot-filled sac with a small central lumen (transverse and longitudinal scans).

Figure 53.41 Computerised tomogram of the abdomen showing an aortic aneurysm. Blood flowing through the thrombus-containing sac is enhanced with contrast agent and appears white.

Investigations

Full blood count, electrolytes, liver function tests, coagulation tests and blood lipid estimation are carried out, with a cross-match if surgery is contemplated within a few days. Electrocardiography and cardiac assessment by echocardiography or isotope ventriculography are useful. Chest radiography and pulmonary function tests should also be carried out.

The morphology of the aneurysm is best assessed by CT scan (Figs 53.41 and 53.42) or magnetic resonance imaging. Although a digital subtraction or magnetic resonance angiogram may be useful in delineating any associated arterial occlusive

Figure 53.42 (a) Spiral computerised tomogram showing an infrarenal abdominal aortic aneurysm; (b) with the bony elements subtracted.

disease (Fig. 53.43), it should be appreciated that this does not permit an assessment of aneurysm diameter because the sac is usually filled with circumferential clot leading to a falsely narrow angiographic appearance (Fig. 53.44).

Open surgical procedure

Under general anaesthesia, with the patient lying supine, a full-length midline or supra-umbilical transverse incision is made. The small bowel is lifted to the patient's right and the aorta identified. The posterior peritoneum overlying the aorta is opened and the upper limit of the aneurysm identified. The aorta immediately above the dilatation is exposed; this is generally just inferior to the left renal vein and renal arteries (Fig. 53.45). The common iliac arteries are then exposed, heparin given and clamps applied above and below the lesion. The aneurysm is opened longitudinally and back-bleeding from lumbar and mesenteric vessels controlled by sutures placed from within the

Figure 53.43 Angiogram of an abdominal aortic aneurysm. The neck of the aneurysm is inferior to the renal arteries.

Figure 53.44 Thrombus removed from an abdominal aortic aneurysm; this thrombus is the reason an angiogram may give a false impression of aneurysm diameter.

Figure 53.45 Operative appearance of a huge, non-ruptured infrarenal abdominal aortic aneurysm.

sac. Upper and lower aortic necks are prepared to which an aortic prosthesis is then sutured end to end inside the sac with a monofilament non-absorbable suture (Fig. 53.46). Clamps are released slowly to prevent sudden hypotension. If haemostasis is satisfactory at this point, the aneurysm sac is closed round the prosthesis (Fig. 53.47) to exclude both it and the suture lines from the bowel to reduce the risk of adherence and potential fistula formation. The abdomen is then closed. Occasionally, when the iliac vessels are also involved with dilatation or severe atheroma, it is necessary to construct an aorto-bi-iliac or aorto-bifemoral bypass, rather than use a simple aorto-aortic tube.

Endoluminal procedure

This has gained in popularity over the last decade and most centres now routinely offer this minimally invasive treatment to elderly patients with suitable aortic morphology, generally on an elective or semi-elective basis. The aorta is accessed via the common femoral arteries, which are exposed surgically. Under radiological control, a delivery system is guided up into the aorta and an endovascular prosthesis (often termed a 'stent graft') placed within the aortic sac. The prosthesis is made from Dacron or PTFE with an integral metallic stent for support and to allow firm attachment to the vessels above and below the sac; most are modular, one part being an aortic body with one iliac attached and the other a separate single iliac stent graft. The larger component

Figure 53.46 (a) Aneurysm sac opened. Note that the posterior wall of the aorta immediately above and below the sac is not divided. A Dacron tube graft is laid in place within the sac ready for suture. (b) Graft sutured in place and vascular clamps removed.

Figure 53.47 Aortic graft. Transverse scan showing the graft in the dilated aortic bed.

is inserted via one groin and the other via the opposite groin. Such modular stent-graft systems must be able to produce a blood-tight seal at the uppermost (infrarenal aortic) level of the graft, at both iliac levels distally and at the junction between the aorto-uni-iliac stent-graft module and its contralateral iliac partner. Although this technique has now been used in many thousands of patients worldwide, concerns remain about prosthetic fragmentation with the passage of time, displacement and leakage (endoleak) at the interface of vessel and stent graft or from patent lumbar arteries. These concerns mean that all patients require lifelong follow-up and regular imaging (Fig. 53.48), and there is a tendency to offer the endoluminal procedure to the older patient whose need for long-term prosthetic integrity is less.

Postoperative complications

The most common complications after open repair are respiratory (lower lobe consolidation, atelectasis and 'shock lung') and cardiac (ischaemia and infarction). A degree of colonic ischaemia because of lack of a collateral blood supply occurs in about 10% of patients but fortunately this usually resolves spontaneously.

Figure 53.48 Spiral computerised tomogram showing an endoluminal aortoiliac 'stent graft'. The metallic stent structure is clearly observed.

Renal failure and infection of the graft are rare events after elective procedures but they may complicate procedures undertaken for rupture. Neurological complications include sexual dysfunction and spinal cord ischaemia. An aortoduodenal fistula is an uncommon but treatable complication of abdominal aortic replacement surgery. It should be suspected whenever haematemesis or melaena occurs in the months or years after operation. Prosthetic infection also occurs uncommonly and may require removal of the graft, limb revascularisation being achieved by simultaneous insertion of an axillo-bifemoral bypass.

Cardiac, respiratory, renal and neurological complications occur less often with the endovascular method but they are not obviated entirely by this minimally invasive technique. In the longer term, fistula and prosthetic infection remain rare but significant problems. Although the immediate mortality and morbidity rates of this method are less than those associated with open surgery, about 20% of patients need a secondary procedure to correct endoleaks or prosthetic migration, thrombosis or rupture.

Peripheral aneurysm

Popliteal aneurysm

Popliteal artery aneurysm accounts for 70% of all peripheral aneurysms; two-thirds are bilateral. Examination of the abdominal aorta is indicated if a popliteal aneurysm is found because one-third are accompanied by aortic dilatation. Popliteal aneurysms present as a swelling behind the knee or with symptoms caused by complications, such as severe ischaemia following thrombosis or distal ischaemic ulceration as a result of emboli. Urgent surgery, possibly with intra-arterial thrombolysis, is indicated in the acute situation. An asymptomatic aneurysm should be considered for elective repair to prevent future complications,

especially if it exceeds 25 mm in diameter. Ultrasonography and CT or magnetic resonance imaging can be helpful in confirming the diagnosis. Treatment is either a bypass with ligation of the aneurysm or an inlay graft.

Femoral aneurysm

True aneurysm of the femoral artery is uncommon. Complications occur in less than 3% so conservative treatment is generally indicated, but it is important to look for aneurysms elsewhere as over half are associated with abdominal or popliteal aneurysms. False aneurysm of the femoral artery occurs in 2% of patients after arterial surgery at this site. Some are infective in origin and rupture is possible; these require surgical correction. Local repair with reanastomosis at the groin under suitable antibiotic cover may be successful, but bypass, clear of the infected area, with subsequent excision of the infected graft is often the only way of preventing further problems.

Iliac aneurysm

This usually occurs in conjunction with aortic aneurysm and only rarely on its own. On its own, it is difficult to diagnose clinically so about half present already ruptured. Operation is indicated, with bypass and exclusion of the aneurysm by ligation above and below the dilatation.

Arteriovenous fistula

Communication between an artery and a vein (or veins) may be either a congenital malformation or the result of trauma. Arteriovenous fistulas for haemodialysis access are also created surgically. All arteriovenous communications have a structural and a physiological effect. The structural effect of arterial blood flow on the veins is characteristic; they become dilated, tortuous and thick walled (arterialised). The physiological effect, if the fistula is big enough, is an increase in cardiac output. In extreme circumstances this can cause left ventricular enlargement and even cardiac failure.

A pulsatile swelling may be present if the lesion is superficial. A thrill is detected on palpation and auscultation reveals a buzzing continuous bruit ('machinery murmur'). Dilated veins may be seen, in which there is a rapid blood flow. Pressure on the artery proximal to the fistula reduces the swelling and the thrill and bruit cease.

Duplex scan and/or angiography confirms the lesion, which is noteworthy for the speed with which venous filling occurs.

Management

Treatment is by embolisation. Excisional surgery can be advocated only rarely, perhaps for severe deformity or recurrent haemorrhage; the assistance of a plastic surgeon is wise. It is important to realise that ligation of a 'feeding' artery on its own is of no lasting value and is actually detrimental as it may preclude treatment by embolisation.

ARTERITIS AND VASOSPASTIC CONDITIONS

Thromboangiitis obliterans (Buerger's disease)

This is characterised by occlusive disease of the small- and medium-sized arteries (plantar, tibial, radial, etc.), thrombophlebitis of the superficial or deep veins, and Raynaud's syndrome; it occurs in

male smokers, usually under the age of 30 years. Often, only one or two of the three manifestations are present. Histologically, there are inflammatory changes in the walls of arteries and veins, leading to thrombosis. Treatment is total abstinence from smoking, which arrests, but does not reverse, the disease. Established arterial occlusions are treated as for atheromatous disease, but amputations may eventually be required.

Other types of arteritis

Arteritis occurs in association with many connective tissue disorders, e.g. rheumatoid arthritis, systemic lupus erythematosus and polyarteritis nodosa. This is usually the province of the specialist physician but the surgeon may be called on to carry out minor amputations. Sympathectomy has previously been used but this is no longer advocated in this context.

Temporal arteritis is a disease in which localised infiltration with inflammatory and giant cells leads to arterial occlusion, ischaemic headache and tender, palpable, pulseless (thrombosed) arteries in the scalp. Irreversible blindness occurs if the ophthalmic artery becomes occluded. The surgeon may be required to perform a temporal artery biopsy, but this should not delay immediate steroid therapy to arrest and reverse the process before the ophthalmic artery is involved.

Takayasu's disease is an arteritis that obstructs major arteries, particularly the large vessels coming off the aorta. It usually pursues a relentless course.

Cystic myxomatous degeneration

This is typified by an accumulation of clear jelly (like a synovial ganglion) in the outer layers of a main artery, especially the popliteal artery. The lesion may narrow the vessel causing claudication. Duplex scan is the investigation of choice. Decompression, by removal of the myxomatous material, is often all that is required, but the 'ganglion' may recur, necessitating excision of part of the artery with interposition vein graft repair.

Raynaud's disease

This idiopathic condition usually occurs in young women and affects the hands more than the feet. There is abnormal sensitivity in the arteriolar response to cold. These vessels constrict and the digits (usually the fingers) turn white and become incapable of fine movements. The capillaries then dilate and fill with slowly flowing deoxygenated blood, resulting in the digits becoming swollen and dusky. As the attack passes off, the arterioles relax, oxygenated blood returns into the dilated capillaries and the digits become red. Thus, the condition is recognised by the characteristic sequence of blanching, dusky cyanosis and red engorgement, often accompanied by pain. Superficial necrosis is very uncommon. This condition must be distinguished from Raynaud's syndrome, which has similar features (see below). Treatment of Raynaud's disease consists of protection from cold and avoidance of pulp and nailbed infection. Calcium antagonists, such as nifedipine, may also have a role to play and electrically heated gloves can be useful in winter. Sympathectomy has been discredited in this condition.

Raynaud's syndrome

Although peripheral vasospasm may be noted in atherosclerosis, thoracic outlet syndrome, carpal tunnel syndrome, etc., the term

Raynaud's syndrome is most often used for a peripheral arterial manifestation of a collagen disease such as systemic lupus erythematosus or rheumatoid arthritis. The clinical features are as for Raynaud's disease but they may be much more aggressive. Raynaud's syndrome may also follow the use of vibrating tools. In this context it is a recognised industrial disease and is known as 'vibration white finger'.

Treatment is directed primarily at the underlying condition, although the conservative measures outlined above are often helpful. The syndrome when secondary to collagen disease leads frequently to necrosis of digits and multiple amputations. Sympathectomy yields disappointing results and should not be used. Nifedipine, steroids and vasospastic antagonists may all have a role in treatment. Patients with vibration white finger should avoid vibrating tools.

Acrocyanosis

Acrocyanosis may be confused with Raynaud's disease but it is painless and not episodic. It tends to affect young women and the mottled cyanosis of the fingers and/or toes may be accompanied by paraesthesia and chilblains.

Cervicodorsal sympathectomy

Open cervicodorsal sympathectomy was previously performed for vasospastic conditions affecting the hands and to treat palmar (sometimes axillary) hyperhidrosis. The operation is now obsolete, having been replaced by endoscopic transthoracic sympathectomy. Furthermore, it has been increasingly recognised that the vasospastic conditions do not respond to this form of treatment, rendering the endoscopic intervention a therapy that is suitable solely for hyperhidrosis.

An endoscope, often a rigid cystoscope, is used. The ipsilateral lung may be deflated by the anaesthetist and a cannula inserted into the chest wall to permit easy access for the scope. The sympathetic chain is visualised and a coagulating electrode used to ablate the ganglia below the stellate. The scope and cannula are then removed, the lung inflated and the small chest would closed.

Lumbar sympathectomy

Lumbar sympathectomy has been used to treat chronic lower limb ischaemia in the past. Lumbar sympathectomy by open operation has, however, been obsolete for several years and even chemical sympathectomy, its minimally invasive equivalent, can now be regarded as outdated. Chemical sympathectomy requires the injection of small quantities of dilute aqueous phenol into the lumbar sympathetic chain under radiographic control.

Venous disorders

LEARNING OBJECTIVES

To understand:

- Venous anatomy and the physiology of venous return
- The pathophysiology of venous disease
- The clinical significance of varicose veins
- Deep venous thrombosis
- Venous insufficiency and venous ulceration

INTRODUCTION

The lower limb is the most common site of venous disorders. More than 5% of the population have varicose veins and 1% have, or have had, venous ulceration. At any one time, up to 200 000 people in the UK have active venous ulceration.

THE ANATOMY OF THE VENOUS SYSTEM OF THE LIMBS

Arterial blood flows through the main axial arteries of the upper and lower limbs before returning via the deep and superficial veins. All of the veins of the upper and lower limbs contain valves, which ensure that blood flows towards the heart.

The superficial venous trunks in the leg are the greater and lesser saphenous veins (Fig. 52.1a and b), which lie above the muscle fascia of the limb. The cephalic and basilic veins are the superficial venous trunks of the arm (Fig. 54.1c and d). The greater saphenous vein joins the femoral vein at a fixed point in the groin 2.5 cm below and lateral to the pubic tubercle, and the lesser saphenous vein terminates at a variable site in the popliteal fossa. Blood passing up the superficial veins enters the deep veins at the saphenopopliteal and saphenofemoral junctions.

In the calf and thigh there are a number of valved perforating (communicating) veins that join the superficial to the deep veins at inconstant sites and which allow blood to flow from the superficial to the deep venous system. The most important of these are the direct perforating veins of the medial and lateral calf and the communicating veins around the knee and in the mid-thigh.

The deep veins of the lower limb arise from three pairs of venae comitantes, which accompany the three crural arteries (anterior and posterior tibial and peroneal arteries). These six veins intercommunicate and join in the popliteal fossa to form the popliteal vein, which also receives the soleal and gastrocnemius veins.

The popliteal vein passes up through the adductor hiatus to enter the subsartorial canal as the femoral vein, which receives the deep (profunda) femoral vein (or veins) in the femoral triangle before passing behind the inguinal ligament to become the

external iliac vein. The internal iliac vein joins with the external iliac vein in the pelvis to form the common iliac vein. The left common iliac vein passes behind the right common iliac artery to join the right common iliac vein on the right side of the abdominal aorta to form the inferior vena cava.

VENOUS PATHOPHYSIOLOGY

Blood enters the limb through the femoral arteries before passing through arterioles into the capillaries, which have a pressure of about 32 mmHg at their arterial ends. This pressure is reduced along the course of the capillaries and is approximately 12 mmHg at the venular end of the capillary.

The pressure continues to fall in the main veins and is as low as -5 mmHg at the upper end of the vena cava where it enters the right atrium.

The venous pressure in a foot vein on standing is equivalent to the height of a column of blood extending from the heart to the foot, e.g. approximately 100 mmHg (Fig. 54.2). To enable blood to be returned against gravity in the standing position an auxiliary pump is required in the lower limb. This is the calf muscle pump, which is augmented to a lesser extent by the thigh and foot pumps. The deep veins of the calf are capacious and are joined by blind-ending sacks called the soleal sinusoids, which force blood into the popliteal and crural veins during calf muscle pump contraction, e.g. walking. The foot pump also ejects blood from the plantar veins during walking. As the calf muscles contract, the veins are compressed and the valves only allow blood to pass in the direction of the heart. The pressure within the calf compartment rises to 200–300 mmHg during muscle contraction. During muscle relaxation the pressure falls and blood from the superficial veins enters the deep veins through the saphenous junctions and the perforating veins. Each time this occurs the pressure falls in the superficial venous compartment until a threshold is reached, when the venous inflow keeps pace with ejection from the deep veins. This is normally around 30 mmHg, a fall of approximately two-thirds of the resting pressure. The reduction in the pressure of the superficial system is dependent on the presence of patent deep veins, perforating

veins and superficial veins, which must contain competent valves. Ambulatory venous hypertension is a consequence of valve failure (reflux) or obstruction in the venous system and may eventually lead to lipodermatosclerosis and ulceration.

VARICOSE VEINS

These are defined as tortuous dilated veins. They affect 5% or more of the adult population of western countries. The gender prevalence was found to be nearly equal in the recent Edinburgh Vein Study. There is often a clear family history of the disorder, with some patients inheriting abnormalities in the *FOXC2* gene. The pathophysiology of varicose vein development is probably related to defective connective tissue and smooth muscle in the vein wall leading to a secondary incompetence of the valves rather than to a primary defect in the valves, which occurs in a small group of patients who have total venous avaluolosis. Varicose veins may develop secondarily in patients with post-thrombotic limbs and in patients with congenital abnormalities such as the Klippel–Trenaunay syndrome or multiple arterio-venous fistulae. Pregnancy and pelvic tumours are also well-recognised predisposing factors. Some of the other factors that may predispose to the development of varicose veins are:

- age;
- sex;
- race;
- weight;
- height;

Clinical features

Varicose veins rarely cause severe symptoms. Aching in the veins at the end of the day, after prolonged standing, is the most common complaint of patients referred to hospital, but many patients with severe varicose veins never consult a doctor. Other symptoms include ankle swelling, itching, bleeding, superficial thrombophlebitis, eczema, lipodermatosclerosis and ulceration. All of these symptoms are rare and it is not known why some patients with primary varicose veins develop the important complications of eczema, lipodermatosclerosis and ulceration.

Tortuous dilated veins in the subcutaneous tissue are indicative of varicose veins (Fig. 54.3). Most develop in the tributaries of the greater and lesser saphenous veins, which are usually dilated but rarely varicose themselves. Varicosities in the thigh are indicative of long saphenous incompetence, whereas varicosities on the back of the leg are suggestive of short saphenous incompetence. Some varicose veins join both systems and it is important to examine both the greater and lesser saphenous veins for the presence of valvular incompetence. Smaller varicosities are called reticular veins and are of dubious significance; the presence of these and thread veins within the skin is not necessarily associated with major varicose veins and is purely cosmetic. The Edinburgh Vein Study failed to show any evidence that the extent of valvular incompetence was related to the presence of symptoms.

Signs of varicose veins

A careful inspection and documentation of the site of the varicosities is extremely important. In addition, the termination of the long and short saphenous veins must be palpated, the latter with the knee slightly bent to relax the popliteal fascia. The

Figure 54.3 Varicose veins of the right leg.

presence of a dilated trunk can usually be detected if fingers are loosely placed over the trunk, which can be 'rolled back and forth'. Percussion over the varices may elicit an impulse tap by the fingers placed over the dilated trunk. A large varicosity in the groin (a saphena varix), often of the anterolateral thigh vein, may be visible (Fig. 54.4) and gentle palpation during coughing may elicit a cough thrill, which is a vibration experienced through the fingers caused by turbulent backflow within the varicosity.

Tourniquet tests have been abandoned by many clinicians. Complete control of all lower limb varicosities by a tourniquet placed around the upper thigh after elevation and emptying of the veins is, however, highly indicative of saphenofemoral incompetence. Release of the tourniquet leading to rapid refilling of varicosities is further confirmation of incompetence of the greater saphenous vein (Fig. 54.5). Greater saphenous incompetence is associated with 80% of all significant varicosities in the lower limbs. Abnormally distributed varices or a suspicion of lesser

Figure 54.4 A saphena varix.

Figure 54.5 A tourniquet test.

saphenous incompetence (e.g. varicosities on the back of the calf with a palpable dilated lesser saphenous trunk and control by a below-knee tourniquet) requires further assessment as the termination of the lesser saphenous vein is very variable.

Investigation

Many now believe that all patients with varicose veins should undergo an assessment by duplex scan. There is some evidence that this policy leads to a more accurate surgical approach and reduces the incidence of recurrence of the varicose veins. Duplex scanning is, however, not always available and clinical acumen combined with tourniquet tests and the use of a standard Doppler probe still suffices in many settings.

Standard Doppler examination

A standard Doppler probe emits a sound when blood flows past the transmitting and receiving crystals. A uniphasic signal indicates flow in one direction. A biphasic signal indicates forward and reverse flow and is indicative of blood refluxing down through incompetent valves. A Doppler probe is placed over the saphenofemoral junction. A calf squeeze is carried out and if a biphasic signal is obtained this confirms the presence of incompetence of the saphenofemoral junction. This diagnosis is further supported if all of the varices are controlled by a thigh tourniquet. The Doppler probe can be placed over distal varices when the tourniquet is released; retrograde flow is indicated by a rumbling noise as the blood refluxes down the long saphenous vein to fill the varices. This is not an accurate method of establishing incompetence of the lesser saphenous vein as its termination is variable and it is difficult to separate lesser saphenous incompetence from popliteal valvular incompetence. In all cases of short saphenous incompetence a further investigation is desirable; this is usually carried out by duplex scanning.

Duplex ultrasound imaging

The probe of a duplex scanner contains multiple emitting and receiving crystals. These allow a grey-scale image to be obtained in which the veins are seen as a black void in the subcutaneous and deep tissues. Directional flow can be shown as a colour image (red or blue) superimposed on the grey-scale image of the vessel (Fig. 54.6). Visible venous flow can only be seen when augmented by a calf squeeze. The B-mode grey-scale image allows the vein to be traced to its termination, while compression and relaxation, or a Valsalva manoeuvre, may demonstrate the presence of retrograde flow (reflux).

Figure 54.6 Duplex scan of the saphenofemoral junction showing antegrade and retrograde flow.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.
Antonio Maria Valsalva, 1666–1723, Professor of Anatomy, Bologna, Italy.

Varicography

In this investigation contrast is injected directly into surface varices. The contrast is non-thrombogenic, as it is non-ionic, and iso-osmolar with blood. This allows detailed mapping of the varices to their termination. This is an extremely useful investigation in patients with recurrent varicose veins or those with complex anatomy (Fig. 54.7).

Venography

In this investigation tourniquets are used to direct contrast injected into the superficial veins of the foot into the deep veins of the calf, thigh and pelvis. It is not used as a standard investigation in patients with varicose veins but is useful if the duplex scan indicates, but cannot confirm, the presence of post-thrombotic change (Fig. 54.8).

Figure 54.8 Venogram showing post-thrombotic venous occlusions with collateral pathways.

Management of patients with varicose veins

Many patients without symptoms or signs of lipodermatosclerosis or ulceration simply require reassurance. Others are concerned about the cosmetic appearance of their limbs and this may explain the female to male preponderance in patients presenting for treatment compared with the natural history studies (3:1 compared with 1:1).

Clear indications for intervention (see below) include recurrent episodes of haemorrhage and the development of skin changes (lipodermatosclerosis or ulceration) associated with an ankle flare indicative of venous hypertension (Fig. 54.9). In such patients a duplex scan and/or venography is essential.

Patients should be treated with elastic compression stockings if the varicose veins are found to be associated with post-thrombotic damage. Stockings can also be used to alleviate symptoms in elderly patients who do not wish to have surgery or other invasive forms of treatment. Most patients are prescribed class II stockings with an ankle pressure of around 30 mmHg decreasing to 10–15 mmHg at knee level. Above-knee stockings should never be prescribed as they are difficult to put on and tend to cut in and roll down. Class I stockings can be used to control simple varicose veins.

Injection sclerotherapy

In this technique a detergent is injected directly into the superficial veins. The most commonly used (and only sclerosant recognised for treatment in the UK) is sodium tetradecyl sulphate, although others are available on a named patient basis. The detergent destroys the lipid membranes of endothelial cells causing them to shed, leading to thrombosis, fibrosis and obliteration (sclerosis). Fegan stressed the importance of continued local compression following sclerosant injections to reduce the incidence and amount of superficial thrombosis and improve the

Figure 54.9 Lipodermatosclerosis of the calf skin associated with an ankle flare.

‘sclerosis’ of the vein. In trials carried out in the 1960s and 1970s injection sclerotherapy was not found to be effective at eradicating varicosities in the presence of major saphenous incompetence. It is, however, useful for dealing with minor varicosities and recurrences, especially in the calf and lower leg.

Ultrasound-guided foam sclerotherapy

This has recently become an alternative to the ‘blind’ sclerotherapy practised in the past and can be used to treat the main saphenous trunks. A needle is inserted into the vein that requires treatment under duplex ultrasound guidance and the sclerosant is made into foam. Foam sclerosants are available commercially or can be easily made by an air-mixing technique using a three-way tap. Ideally, polidocanol, another non-recognised detergent, is used rather than sodium tetradecyl sulphate. The foam is then injected under continued ultrasound monitoring, which can image the foam as it spreads up the vein. The top of the saphenous vein should be compressed by the ultrasound probe, preventing the majority of the foam from entering the deep veins until spasm in the main trunk develops. The leg can also be elevated to reduce spread of the foam into the axial deep veins. Using this technique both the greater and lesser saphenous veins can be obliterated. The distal varicosities can also be directly injected at the same time using the same technique, although many perform this at a separate session to limit the quantity of sclerosant that is administered.

Repeat duplex imaging confirms the presence of occlusion and over 90% of major trunks can be occluded by up to three treatments. As yet, there are no long-term results available for this technique and no controlled trials have been carried comparing this technique with other techniques for saphenous obliteration.

In any form of foam sclerotherapy, extravasation is associated with a risk of cutaneous ulceration and an escape of the sclerosant into the deep veins may cause deep vein thrombosis. More recently, severe headaches have been reported in some patients following foam sclerotherapy, which may be related to air entering the heart and passing through a right-to-left shunt before

entering the brain. Some patients experience transient blindness and one stroke has been reported after a large quantity of foam had been administered. Recurrence rates are at present unknown.

Surgical treatment of varicose veins

Surgical treatment has always been used in the past to treat major long and short saphenous incompetence. The principles are to ligate the point of communication, the saphenofemoral and/or saphenopopliteal junctions, and to remove the major part of the incompetent trunk to prevent connections to the tributaries. The tributaries themselves are then individually removed by making minor cut-downs and teasing them out from under the skin (avulsions). The varicose veins must be carefully marked by tramlines of indelible marker pen to enable the sites of varicosity to be identified when the limbs are elevated. A careful consent is taken, explaining the risks of recurrence and minor nerve damage. The operation can be performed under general anaesthesia or local or regional (spinal/epidural) blockage.

Saphenofemoral junction ligation and greater saphenous stripping

An oblique incision is made in the groin centred 2.5 cm below and lateral to the pubic tubercle. The length of the incision depends on the build of the patient but must be adequate to expose the saphenofemoral junction safely. The greater saphenous vein is found in the superficial fat by blunt dissection and traced upwards to its T-shaped termination with the femoral vein. This must be clearly established before the vein is divided as disasters have befallen surgeons who have divided a femoral vein that has been mistaken for the greater saphenous vein in thin patients. As the vein is traced to its termination four tributaries are normally encountered. These are the superficial inferior epigastric vein, the superficial circumflex iliac vein and the deep and superficial external pudendal veins (see Fig. 54.1, p. 926). A number of anomalies can be present, the most common being a double saphenous vein, which normally receives large anterolateral thigh veins and posteromedial thigh veins. The long saphenous vein is not ligated until the T-junction has been confirmed and the femoral vein has been exposed for a centimetre in either direction. The saphenous trunk is then retrogradely stripped to the knee. Either a variation of Babcock’s intraluminal stripper (Fig. 54.10) or a rigid metal ‘pin’ stripper is used which invaginates the vein and may cause less bruising. Stripping not only avulses the main vein trunk but also pulls out the termination of the tributaries. The posteromedial and anterolateral thigh veins should be separately divided and ligated if at all possible as this reduces bruising in the groin.

Avulsions

The tributaries are then avulsed and many surgeons attempt to do this after application of a tourniquet to reduce blood loss. Although not scientifically proven, the more accurate the avulsion of the tributaries, the better the long-term results. It is therefore very important to mark all of the tributary veins carefully. The avulsion incisions should be placed in Langer’s lines and the

William Wayne Babcock, 1872–1963, Professor of Surgery, Temple University Medical College, Philadelphia, PA, USA.
Karl Ritter von Edenberg Langer, 1819–1887, Professor of Anatomy, Vienna, Austria described these lines in 1862.

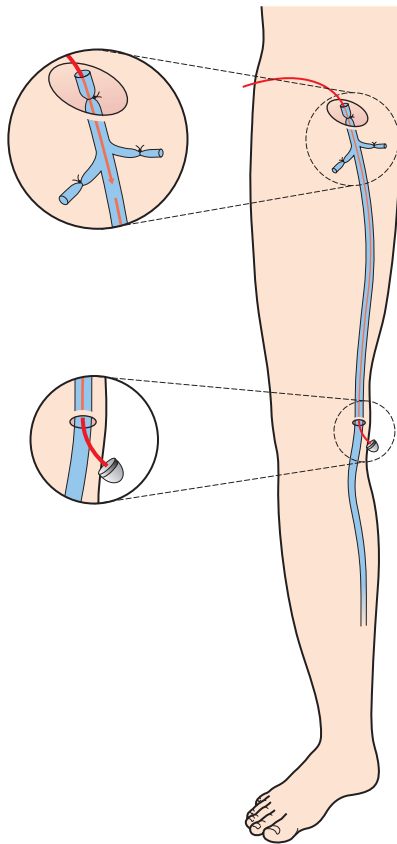

Figure 54.10 Long saphenous vein stripping.

vein must be teased out of the subcutaneous tissue using small hooks or mosquito forceps (Fig. 54.11). Long lengths of varicosity may be successfully teased out by careful surgeons who are not in a rush.

Saphenopopliteal junction ligation and lesser saphenous stripping

Preoperative ultrasound localisation of the junction should ideally be carried out. Approximately one-third of popliteal veins end in the lower part of the popliteal fossa, one-third end in the middle of the popliteal fossa and one-third extend up, often

Figure 54.11 Avulsion of varicose tributaries.

through a vein of Giacomini, to join either the greater saphenous vein or the deep femoral vein in the upper thigh.

A transverse skin incision is made in the popliteal fossa just below the termination of the vein. The deep fascia is divided vertically. The vein is found and traced to the saphenopopliteal junction before it is divided (Fig. 54.12). It is disastrous to divide or damage the popliteal vein. Tributaries may enter the short saphenous vein near its termination. After the vein has been divided, a stripper is passed upwards from the ankle, carefully dissecting off the sural nerve to ensure that the whole of the lesser saphenous vein is removed. This obliterates the junction with the mid-calf perforating vein, which is responsible for many recurrences.

Postoperative care

Postoperatively the legs are elevated, analgesia is given and bandages are applied. Many patients have the surgery under local or spinal block and many can be treated as day cases.

Alternative techniques

A number of newer techniques have been developed to destroy the main saphenous trunks. The first was *radiofrequency ablation* in which a catheter is passed up the saphenous vein from the lower leg and withdrawn under ultrasound control while radiofrequency waves are used to destroy the endothelial lining through a series of metal prongs. Laser is also being used to cause endothelial damage (Fig. 54.13). This technique appears to be effective but is expensive. Long-term follow-up and controlled trials are not available.

Endovenous laser ablation is a more recent development. A laser probe is passed up inside a catheter inserted into the lower

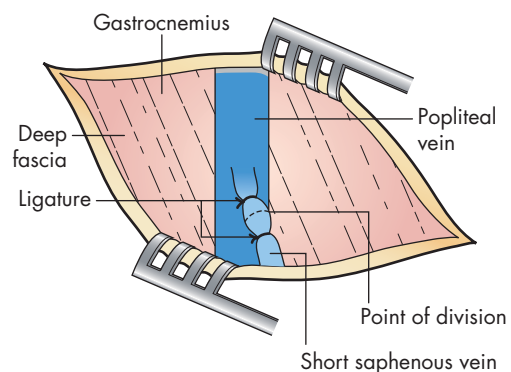

Figure 54.12 Short saphenous ligation.

Figure 54.13 (a) VNUS closure; (b) laser.

part of the saphenous vein under ultrasound guidance (Fig. 54.14). It is very important that large amounts of crystalloid fluid containing local anaesthesia are placed around the vein to separate the skin from the laser probe and avoid cutaneous burns. A duplex ultrasound scan confirms that the laser probe is at the saphenofemoral junction and the laser is then withdrawn, administering a set number of joules to the endothelial lining of the saphenous veins. The laser probes are marginally less expensive than radiofrequency ablation.

Both laser and radiofrequency ablation do not provide 'flush' occlusion of the saphenous vein, often leaving tributaries that would always be divided at surgery. Long-term studies are required to ascertain the recurrence rate of both techniques.

Complications of varicose vein surgery

After surgery bruising and sensory nerve injury are common. The greater saphenous vein should only be stripped to just below the knee to avoid damage to the accompanying saphenous nerve, and the sural nerve must be carefully dissected off the lesser saphenous vein at the ankle. All patients should be warned that numbness and tingling are common but that they will invariably recover. Motor nerve injury should not occur if the anatomy is carefully displayed. Damage to the main veins and accompanying arteries is also avoidable if care is taken to display the anatomy. Deep vein thrombosis is rare unless there is iatrogenic damage to the deep veins. A previous deep vein thrombosis usually contraindicates varicose vein surgery but, if surgery is undertaken, subcutaneous low molecular weight heparin must be given.

The most common complication of varicose vein surgery is recurrence. This is difficult to define and should be divided into recurrence of a previously treated venous system and development of new varicosities arising in a hitherto untreated system. The latter of course cannot be prevented. Careful attention to detail and correct evaluation all reduce the risk of recurrence.

Figure 54.14 Laser probe inside long saphenous vein. (a) Sheath in femoral vein. (b) Sheath pulled back. (c) Laser probe causing heating (sclerosis) of vein.

DEEP VEIN INCOMPETENCE AND OBSTRUCTION

These problems usually follow a deep vein thrombosis, which almost never resolves completely without leaving obliterated segments of vein and damaged valves. Primary deep vein

incompetence does occur but is rare. The exact incidence of primary deep vein incompetence is not known and many cases follow a subclinical thrombosis (see Post-thrombotic leg). Some venous obstruction may follow trauma, which includes iatrogenic injuries.

Post-thrombotic leg

A thrombus normally forms in the calf veins and extends upwards into the main axial veins. When it resolves, segments of vein remain obstructed, valves are destroyed or damaged and collateral veins dilate to bypass obstructed segments. Post-thrombotic damaged veins are often surrounded by fibrotic tissue and can no longer dilate in response to increased flow, which occurs during exercise. The lumen is often criss-crossed with thickened white tissue (synaechae), which is the scarred remains of a thrombosis.

Presentation

All patients who have had a deep vein thrombosis may develop signs of a post-thrombotic limb. These are variable and include leg swelling, discomfort on walking, oedema, varicose veins (which need not be present), the presence of an ankle flare, lipodermatosclerosis and eventually ulceration (Fig. 54.15). Patients should be questioned about previous fractures, childbirth, operations, etc. when a clear history of a deep vein thrombosis is lacking.

Investigations

These include duplex scanning to look for deep vein reflux and venography to demonstrate occluded/obstructed deep venous segments and the presence of collaterals.

Treatment

Treatment is usually by elastic compression hosiery, but bypass surgery and valve reconstruction should be considered in patients with severe symptoms who have clearly obstructed or refluxing veins.

Techniques of venous reconstruction

Venous bypasses may be carried out using the saphenous vein from the opposite limb as a crossover or free bypass (Fig. 54.18). Prosthetic grafts do poorly as venous flow is low and the patients are often highly thrombogenic. Venous valves may be tightened by external compression devices or internally reefed by sutures

Figure 54.15 Post-thrombotic leg.

(Fig. 54.18). Valves may be transplanted from the upper limb and artificial valves may be inserted endovenously. None of these techniques is established apart perhaps from the 'Palma' cross-femoral bypass using the opposite long saphenous vein, which is tunneled suprapubically and anastomosed to the femoral vein below the site of obstruction/occlusion (Fig. 54.16). Many patients continue to have symptoms of swelling and leg discomfort. They must continue to wear stockings to prevent ulceration and unfortunately there is a high incidence of recurrent thrombosis. Patients require lifelong anticoagulants if thromboses recur, especially if they have an associated thrombophilia such as anti-thrombin deficiency (see below).

The condition of patients with narrowed iliac veins (iliac vein compression) can be improved by inserting a metallic stent if the thrombus has been successfully lysed.

LEG ULCERATION

Venous disease is responsible for between 60% and 70% of all ulcers in the lower leg. There are many other causes of leg ulcers and these must be excluded in any patient presenting with ulceration:

- venous disease: superficial incompetence; deep venous damage (post-thrombotic);

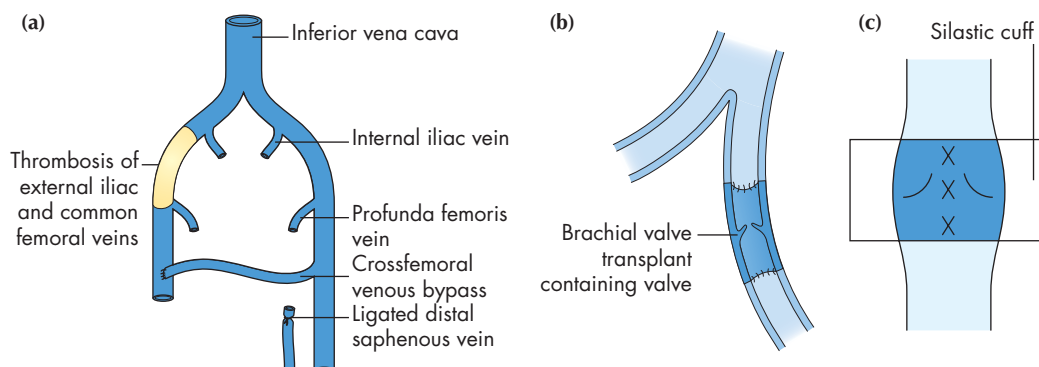

Figure 54.16 Various techniques for bypassing venous obstruction and improving valve competence. (a) Palma; (b) Taheri; (c) Lane.

- arterial ischaemic ulcers;
- rheumatoid ulcers;
- traumatic ulcers;
- neuropathic ulcers (diabetes);
- neoplastic ulcers (squamous cell carcinoma and basal cell carcinoma).

Up to 20% of patients have evidence of arterial disease, which may be the sole cause of ulceration or may be a mixed factor in the development of an ulcer in association with venous disease.

Aetiology of ulceration

The mechanism for ulcer development has not been established. Originally, it was thought that static blood within the superficial veins led to hypoxia, which caused tissue death (stasis ulcers). This was not confirmed by investigation of venous oxygen saturation, which was found to be higher in ulcerated limbs. This led to the concept of arteriovenous fistulae, which were thought to develop in response to the high venous pressure; however, this could not be confirmed. High venous pressure was found to be associated with a pericapillary infiltrate. This includes fibrin and other proteins, which are known to lead to fibrosis. It was hypothesised that these 'cuffs' could act as a diffusion block.

Leucocytes were found to decrease in the venous effluent coming out of dependent limbs. This decrease in leucocyte passage was shown to increase if short-term venous hypertension was induced by application of a tourniquet. This led to the concept of white cell 'trapping', which has not been confirmed by further investigation. Polymorphonuclear leucocytes were not found within the tissues but increased numbers of mast cells, monocytes and lymphocytes have been found in peri-ulcer tissues.

Reactive oxygen species are increased in the ulcer environment and these may generate free radicals, leading to tissue damage. Proteolytic enzymes are also increased in ulcers and the fibroblasts in the ulcer surrounds are also abnormal, being in a 'senescent' state. Growth factors may be inhibited, leading to poor repair, and their absence may also lead to ulceration. It is very difficult to prove whether any of these factors is the cause of or the result of an ulcer.

At present, ambulatory venous hypertension is the only accepted cause of ulceration. It is important to try and define the exact mechanism of ulcer development. The venous hypertension may be the result of primary valve incompetence of the saphenous veins, incompetence of the perforating veins or incompetence or obstruction of the deep veins.

Clinical features

The ulcer must be carefully examined. A venous ulcer has a gently sloping edge and the base contains granulation tissue covered by a variable amount of slough and exudate. Any elevation of the ulcer edge should indicate the need for a biopsy to exclude a carcinoma (squamous cell or basal cell carcinoma).

The venous ulcer of the leg characteristically develops in the skin of the gaiter region, the area between the muscles of the calf and the ankle. This is the region where many of the Cockett perforators join the posterior tibial vein to the surface vein,

A gaiter is a leather or cloth covering for the lower leg and ankle. The name is derived from the French 'guetres' for the same piece of clothing.
Frank Bernard Cockett, formerly Surgeon, St. Thomas's Hospital, London, England.

known as the posterior arch vein. The majority of ulcers develop on the medial side of the calf but ulcers associated with lesser saphenous incompetence often develop on the lateral side of the leg. Ulcers can develop on any part of the calf skin in patients with post-thrombotic legs; however, venous ulcers rarely extend on to the foot or into the upper calf and, if there is ulceration at these sites, other diagnoses should be seriously considered. Ulcers often develop in response to minor trauma; many patients notice some itching, perhaps associated with mast cell degranulation, before the ulcers develop. Almost all venous ulcers have surrounding lipodermatosclerosis (Fig. 54.17). This is thickening, pigmentation, inflammation and induration of the calf skin. The pigmentation comes from haemosiderin and melanin and the haemosiderin itself may be an important factor in the ulcer development. Another cause of ulceration should be considered if there is no evidence of lipodermatosclerosis or an ankle flare.

A full examination of the front and back of the limbs with the patient standing should be carried out to assess the presence of varicosities and truncal incompetence of the saphenous systems (note that venous ulcers are not always accompanied by varicose veins). The presence of an ankle flare suggests venous hypertension.

All patients should have their pulses palpated and, if there is any doubt, their Doppler pressures should be measured. Sensation and proprioception should be assessed to exclude neuropathy, especially in diabetic patients. A careful examination of the hand and other joints may confirm the presence of rheumatoid arthritis or osteoarthritis.

Investigation

Some clinicians will carry out a duplex scan when the patient with an ulcer is first seen to assess the state of the deep and superficial veins. The presence of reflux in these veins does not confirm a venous ulcer but supports the diagnosis in the absence of another cause.

All patients presenting for the first time with a new leg ulcer should have a full blood count, erythrocyte sedimentation rate (C-reactive protein) and sickle cell test if they have an appropriate

Figure 54.17 A venous ulcer.

racial background. Anaemia can both cause ulcers (e.g. sickle cell disease and pernicious anaemia) and result from ulceration (e.g. iron deficiency anaemia and the anaemia of chronic disease). Polycythaemia is a rare cause of ulceration. Any patient found to have evidence of an unexplained peripheral neuropathy or distal ischaemia should have their blood or urinary glucose measured to exclude diabetes. An antibody screen should be obtained if the ulcer appears 'atypical' or there is any suggestion of joint disease (e.g. rheumatoid arthritis). All patients presenting with a new ulcer should have their Doppler pressures measured to document the adequacy of the blood supply to the affected limbs, even when the foot pulses are easily palpable.

Once the ulcer has healed, there is no doubt that a duplex scan assessment (see Fig. 54.6, p. 928) of the veins of both lower limbs is essential to document the major sites of valvular incompetence. Bipodal ascending phlebography will often detect obstruction and post-thrombotic changes missed by the duplex scan (see Fig. 54.8, p. 929). These investigations are invaluable for arriving at a strategy to reduce the risk of re-ulceration.

Management

When the diagnosis of a 'probable venous ulcer' has been made, patients are initially treated by a compression bandaging regimen, which can be applied in a specialised clinic or by a district or practice nurse. Patients with new ulcers should ideally be assessed in a specialised ulcer clinic to confirm the diagnosis and agree the correct treatment regimen.

Many bandaging regimens have been described but three types usually suffice. A multilayered elastic compression bandaging system has been shown to be effective (Charing Cross four-layer bandage), as has a rigid multilayered system (Steripaste three-layer bandage). A low-compression regimen is desirable for mixed venous/arterial ulcers. The alternative to these bandaging regimens is to apply a bland absorbent leak-proof dressing beneath a graduated elastic compression stocking (class II).

These compression regimens are ideally applied by trained staff on a weekly basis until the ulcer is starting to heal and the amount of exudate is reduced. Longer periods between dressing changes can then be instituted. At each attendance ulcer size must be measured to monitor improvement. Measurement of the two maximal diameters is a satisfactory and cheap method of assessment, although other more sophisticated area measurements are often utilised. Antibiotics do not speed ulcer healing and all other specific ulcer-healing drugs are of dubious validity.

Failure to heal an ulcer may indicate that it has another cause (e.g. malignancy, rheumatoid arthritis or arterial ischaemia). Biopsies are indicated if malignancy is suspected and it is important to remember that a Marjolin's type of ulcer (a squamous cell or basal cell carcinoma) can develop in a chronic longstanding venous ulcer (Fig. 54.18).

Once these factors have been excluded, consideration must be given to healing the ulcer by excision and grafting. A number of biological dressings have been developed, including fetal keratinocytes and collagen meshes, which have been shown to improve healing; however, they are not cost-effective for the majority of ulcers and they have been shown to be of value only

Figure 54.18 A Marjolin's ulcer (a squamous cell cancer arising in a chronic venous ulcer; arrow).

in the post hoc analysis of certain sub-groups. Pinch grafts and ulcer excision with mesh grafting have been shown to provide good early healing with moderate long-term results (50% healed at 5 years).

The recent Eschar trial has confirmed that surgery to sites of superficial venous incompetence does not speed ulcer healing and this practice should be abandoned unless new evidence is provided of its efficacy.

Prevention of recurrence

Once an ulcer has healed the patient must be re-evaluated in an attempt to prevent recurrence. Patients with normal deep veins should be offered treatment to obliterate any sites of saphenous or perforator reflux. The Eschar study has confirmed the results of other studies showing that this treatment is effective in reducing the incidence of ulcer recurrence in patients with *normal* deep veins. Some patients will decline treatment and others will be considered unsuitable for major interventions on their veins.

Elastic stockings should be prescribed for all patients with evidence of post-thrombotic deep vein damage and these remain an alternative treatment for patients with superficial venous disease who decline intervention. Further studies are required to determine whether laser ablation and foam sclerotherapy are as satisfactory as surgery in achieving prolonged ulcer-free periods.

Prognosis

All venous ulcers can be healed but, even in those who have successful surgery or wear their stockings religiously, there is a 20–30% incidence of re-ulceration by 5 years. The greatest risk of re-ulceration is in the post-thrombotic leg.

VENOUS THROMBOSIS

A venous thrombus is the formation of a semi-solid coagulum within flowing blood in the venous system. Venous thrombosis of the deep veins of the leg is complicated by the immediate risk of pulmonary embolus and sudden death. Subsequently, patients

Charing Cross. This method of treating venous ulcers was introduced at Charing Cross Hospital, London, England.
Jean-Nicholas Marjolin, 1780–1850, Surgeon, Paris, France, described the development of carcinomatous ulcers in scars in 1828.

are at risk of developing a post-thrombotic limb and venous ulceration.

Aetiology

The three factors described by Virchow over a century ago are still considered important in the development of venous thrombosis. These are:

- changes in the vessel wall (endothelial damage);
- stasis, which is diminished blood flow through the veins;
- coagulability of blood (thrombophilia).

There are many predisposing causes of venous thrombosis. These are listed in Table 54.1. The most important factor is a hospital admission for the treatment of a medical or surgical condition. Injury, especially fractures of the lower limb and pelvis, pregnancy and the oral contraceptive pill are other well-recognised predisposing factors. Endothelial damage is now recognised to be increasingly important. The interaction of the endothelium with inflammatory cells, or previous deep vein damage, may render the endothelial surface hypercoagulable and less fibrinolytic.

Stasis is a predisposing factor seen in many of the conditions described in Table 54.1, especially in the postoperative period, in patients with heart failure and in those with arterial ischaemia.

A number of conditions are associated with increased coagulability of the blood (thrombophilia) (Table 54.2). Deficiencies of anti-thrombin, activated protein C and protein S have all been

Table 54.1 Risk factors for venous thromboembolism

Patient factors	Age Obesity Varicose veins Immobility Pregnancy Puerperium High-dose oestrogen therapy Previous deep vein thrombosis or pulmonary embolism Thrombophilia (see Table 54.2)
Disease or surgical procedure	Trauma or surgery, especially of pelvis, hip and lower limb Malignancy, especially pelvic, and abdominal metastatic Heart failure Recent myocardial infarction Paralysis of lower limb(s) Infection Inflammatory bowel disease Nephrotic syndrome Polycythaemia Paraproteinaemia Paroxysmal nocturnal haemoglobinuria antibody or lupus anticoagulant Behçet's disease Homocystinaemia

Rudolf Ludwig Carl Virchow, 1821–1902, Professor of Pathology, Berlin, Germany.

Table 54.2 Abnormalities of thrombosis and fibrinolysis that lead to an increased risk of venous thrombosis

Congenital	Deficiency of anti-thrombin III, protein C or protein S Antiphospholipid antibody or lupus anticoagulant Factor V Leiden gene defect or activated protein C resistance Dysfibrinogenaeimias
Acquired	Antiphospholipid antibody or lupus anticoagulant

shown to predispose to venous thrombosis in young patients. Activated protein C deficiency is associated with inheritance of the factor V Leiden gene and may account for the higher incidence of venous thrombosis in Caucasian populations (being present in 6–7%). It results in a small increase in the risk of venous thrombosis, although it may act in concert with some of the other predisposing factors. A thrombophilic cause should be sought in any patient presenting with an episode of venous thrombosis who gives a family history of deep vein thrombosis.

Although the development of deep vein thrombosis is probably multifactorial, immobility remains one of the most important factors. Recently the term 'e-thrombosis' has been used to describe blood clots occurring in people sitting at their computers for long periods of time. Deep vein thrombosis has also been recognised as a complication of long-haul flights.

Pathology

A thrombus often develops in the soleal veins of the calf, initially as a platelet aggregate. Subsequently, fibrin and red cells form a mesh until the lumen of the vein wall occludes. The coralline thrombus then extends as a propagated loose red fibrin clot containing many red cells (Fig. 54.19). This is likely to extend up to

Figure 54.19 An organised thrombus. C, clot; T, thrombus.

the next large venous branch and is more likely to break off and embolise to the lung as a pulmonary embolism. In this situation the embolus arising from the lower leg veins becomes detached, passes through the large veins of the limb and vena cava, through the right heart and lodges in the pulmonary arteries. This may totally occlude perfusion to all or part of one or both lungs (pulmonary embolism). Acute right heart obstruction may lead to sudden collapse and death. Lung infarction is rare as the lung has a dual blood supply (bronchial and pulmonary arteries). Moderately sized emboli can cause pyramidal shaped infarcts.

Diagnosis

The most common presentation of a deep vein thrombosis is pain and swelling, especially in the calf of one lower limb. Bilateral deep vein thromboses are common, occurring in up to 30%. When the swelling is bilateral, deep vein thromboses must be differentiated from other causes of systemic oedema, such as hypoproteinaemia, renal failure and heart failure. Many patients have no symptoms of thrombosis and may first present with signs of a pulmonary embolism, e.g. pleuritic chest pain, haemoptysis and shortness of breath. Some patients also develop shortness of breath from chronic pulmonary hypertension. Sometimes the leg appears cellulitic and very occasionally it may be white or cyanosed: phlegmasia alba dolens and phlegmasia cerulea dolens. Patients presenting with venous gangrene (Fig. 54.20) often have an underlying neoplasm.

The physical signs may also be absent or ephemeral. Mild pitting oedema of the ankle, dilated surface veins, a stiff calf and tenderness over the course of the deep veins should be sought. Homans' sign – resistance (not pain) of the calf muscles to forcible dorsiflexion – is not discriminatory and should be abandoned. A low-grade pyrexia may be present, especially in a patient who is having repeated pulmonary emboli. Patients may

Figure 54.20 A foot with venous gangrene. The gangrene is symmetrical involving all of the toes. There is no clear-cut edge and there is marked oedema of the foot.

John Homans, 1877–1954, Professor of Clinical Surgery, The Harvard University Medical School, Boston, MA, USA.

have signs of cyanosis, dyspnoea, raised neck veins, a fixed split second heart sound and a pleural rub if they are having pulmonary emboli causing right heart strain, although these signs may be lacking.

Investigation

The diagnosis of deep vein thrombosis and pulmonary embolism should be established by special investigations as the symptoms and signs are non-specific and may be entirely lacking. In addition, treatment with anticoagulation is not without risk and the diagnosis must be made with certainty.

Patients who present to an accident and emergency department with an idiopathic thrombosis usually have a D-dimer measurement. If this is within the normal range there is no indication for further investigation but, if raised, a duplex ultrasound examination of the deep veins should be performed. The deep veins of the lower limb are located and compressed. Filling defects in flow and a lack of compressibility indicate the presence of a thrombus (Fig. 54.21). Ascending venography, which shows a thrombus as a filling defect, is now rarely required unless other measures are being considered (Fig. 54.22).

Pulmonary embolism is diagnosed by ventilation–perfusion scanning, which shows mismatched defects (Fig. 54.23) by computerised tomographic (CT) scanning of the pulmonary arteries, which can show filling defects in the pulmonary arteries (Fig. 54.24). Pulmonary angiography is rarely required unless treatment is being instigated.

The differential diagnosis of a deep vein thrombosis includes a ruptured Baker's cyst, a calf muscle haematoma, a ruptured plantaris muscle, a thrombosed popliteal aneurysm and arterial

Figure 54.21 A longitudinal (a) and transverse (b) section of a duplex scan of a vein containing a thrombus.

William Marrant Baker, 1839–1896, Surgeon, St. Bartholomew's Hospital, London, England, described these cysts in 1877.

Figure 54.22 An ascending venogram of a deep vein thrombosis seen as filling defects (arrows) with contrast passing around the thrombus.

Figure 54.23 A ventilation–perfusion lung scan showing unmatched filling defects on the perfusion scan that are not present on the ventilation scan. (a) Ventilation, (b) perfusion.

ischaemia. Duplex scanning will detect many of these conditions but often patients present with non-specific pain in the calf that resolves with no firm diagnosis being made. The differential diagnosis of a pulmonary embolism includes myocardial infarction, pleurisy and pneumonia.

Prophylaxis

Patients who are being admitted for surgery can be graded as low, moderate or high risk. Low-risk patients are young, with minor illnesses, who are to undergo operations lasting 30 min or less. Those at moderate risk are patients over the age of 40 or those with a debilitating illness who are to undergo major surgery. High-risk patients are those over the age of 40 who have serious accompanying medical conditions, such as stroke or myocardial infarction, or who are undergoing major surgery with an additional risk factor such as a past history of venous thromboembolism or known malignant disease.

Prophylactic methods can be divided into mechanical and

pharmacological. A variety of mechanical methods have been tried but only the use of graduated elastic compression stockings and external pneumatic compression have stood the test of time. These mechanical measures reduce the incidence of thrombosis. Pharmacological methods are more effective than mechanical methods at reducing the risk of thrombosis, although they carry an increased risk of bleeding. In the past, low-dose unfractionated heparin was used both intravenously and subcutaneously. Most patients now start on low molecular weight heparin given subcutaneously, with the dose based on the patient's weight. This does not require monitoring and has a reduced risk of heparin-induced thrombocytopenia. It can be given once a day and probably has a lower risk of bleeding complications. Unfractionated heparin and warfarin are rarely used in the prophylaxis of deep vein thrombosis. A combination of mechanical and pharmacological treatment with heparin can be used in patients considered at high risk.

Treatment of a deep vein thrombosis

Patients who are confirmed to have a deep vein thrombosis on duplex imaging should be started on subcutaneous low molecular weight heparin and rapidly anticoagulated with warfarin unless there is a specific contraindication. Warfarin is usually started at a dose of 10 mg on day one, 10 mg on day two and 5 mg on day three. A prothrombin time taken on day three guides the maintenance dose of warfarin.

The great majority of patients are treated with heparin and warfarin in this way. Thrombolysis should be considered, however, in patients with an iliac vein thrombosis, especially if they are seen early and the limb is extremely swollen. Very few surgeons still carry out venous thrombectomy, although it may still be attempted in patients with pre-venous gangrene and phlegmasia cerulea dolens. A venous thrombectomy should be accompanied by an arteriovenous fistula to increase venous flow through the vein that has had the thrombus removed.

During thrombolysis the tissue plasminogen activator in most patients is administered directly into the thrombus, either via the popliteal vein or by direct puncture in the groin. New devices are being marketed that physically disrupt the thrombus at the same time as local lysis is carried out. Some thrombi can be compressed

Figure 54.24 A computerised tomography scan showing pulmonary emboli as filling defects (arrow) in the pulmonary artery.

by stent grafting, allowing the venous lumen to be opened, especially in the iliac region. This technique is very good in patients with an anatomical obstruction from an 'iliac vein compression syndrome' (Fig. 54.25).

Treatment of pulmonary embolus

Most pulmonary emboli can be treated by anticoagulation and observation but severe right heart strain and shortness of breath indicates the need for fibrinolytic treatment. Rarely, patients who are on the point of cardiac arrest should undergo surgical pulmonary embolectomy.

Figure 54.25 Venograms. (a) An iliac vein compression with collateral vessels. (b) An iliac vein thrombosis with cross-pubic collaterals.

Prophylaxis against pulmonary embolism

In patients who are considered at high risk of embolism or when anticoagulants are contraindicated, a vena cava filter may be inserted to prevent the onward passage of any emboli. Filters can also be placed in patients who continue to have pulmonary emboli despite adequate anticoagulation. A number of filters are now available, some of which are removable (temporary filters). There are no good randomised trials to determine which filter is best but the Greenfield filter has stood the test of time.

Superficial thrombophlebitis

This is a superficial venous thrombosis. The term 'thrombophlebitis' implies a major inflammatory component; however, this is rarely seen. Common causes include external trauma (especially to varicose veins), venepunctures and infusions of hyperosmolar solutions and drugs. The presence of an intravenous cannula for longer than 24–48 hours often leads to thrombosis. Some systemic diseases such as thromboangiitis obliterans (Buerger's disease) and malignancy, especially of the pancreas, can lead to a flitting thrombophlebitis (thrombophlebitis migrans), affecting different veins at different times. Finally, coagulation disorders such as polycythaemia, thrombocytosis and sickle cell disease are often associated, as is a concomitant thrombosis within the deep veins.

The surface vein feels solid and is tender on palpation. The overlying skin may be attached to the vein and in the early stages may be erythematous before gradually turning brown. A linear segment of vein of variable length can be easily palpated once the inflammation has died down.

A full blood count, coagulation screen and duplex scan of the deep veins should usually be obtained. Any suggestion of an associated malignancy should be investigated using appropriate endoscopy and imaging studies, such as an abdominal CT scan.

Most patients are treated with non-steroidal anti-inflammatory drugs and the condition resolves spontaneously. Rarely, infected thrombi require incision or excision. Ligation to prevent propagation into the deep veins is almost never required. Associated deep vein thrombosis or thrombophilias are treated by anticoagulation.

CONGENITAL VENOUS ANOMALIES

There are four main types of anomaly:

- aplasia;
- hypoplasia;
- duplication;
- persistence of vestigial vessels.

Aplasia is most commonly seen in the inferior vena cava and has a similar presentation to the post-thrombotic limb. Membranous occlusion of the left common iliac vein (May–Thurner–Cockett syndrome) often develops where the vein passes behind the right common iliac artery (iliac vein compression syndrome) (Fig. 54.25). This leads to an iliac vein thrombosis, which most

The Greenfield filter was designed by L. Greenfield a 20th century American Surgeon.

Leo Buerger, 1879–1943, Professor of Urologic Surgery, The New York Polyclinic Medical School, New York, NY, USA, described thromboangiitis obliterans in 1908.

commonly affects the left common and external iliac veins. Membranes may also narrow the hepatic veins, which can become totally occluded, leading to Budd–Chiari syndrome.

Hypoplasia results in a narrow vein.

Duplications are quite common, with double vena cava, femoral and renal veins; they often present as an incidental finding.

Klippel–Trenaunay syndrome

This is a combined anomaly of a cutaneous naevus, persistent vestigial veins with varicose veins, and soft tissue and bone hypertrophy. The condition is a mesodermal abnormality that is not familial (Fig. 54.26).

Segments of the deep veins are often aplastic and there may be an associated obstruction of the lymphatics. The condition must be distinguished from the Parkes Weber syndrome, in which there are multiple arteriovenous fistulae causing venous hypertension, ulceration and high-output cardiac failure.

Most patients with Klippel–Trenaunay syndrome should be treated conservatively with elastic compression hosiery; however, some will benefit from laser ablation of the naevus, stapling of the bones to avoid leg length discrepancy and removal of large veins, provided the deep veins are normal. Low molecular weight heparin should be given to all patients having surgery as this syndrome is associated with an increased risk of deep vein thrombosis.

ENTRAPMENT OF VEINS

The axillary vein and the popliteal vein are the two veins that are most commonly compressed. The former is compressed at the thoracic outlet between the first rib and the clavicle, where it usually presents as an axillary vein thrombosis (see below) (Fig. 54.27a). The latter is compressed by an abnormal insertion of the gastrocnemius muscles. Entrapment may cause discomfort and swelling of the limb during exercise before thrombosis develops. Treatment is by surgical decompression, excising the first rib or dividing the abnormal musculature of the gastrocnemius insertion.

AXILLARY VEIN THROMBOSIS

Thrombosis of the axillary vein may occur following excessive exercise in a patient with an anatomically abnormal thoracic outlet. The vein may be compressed by a cervical rib if this is present (Fig. 54.27b). The arm is swollen and painful and, at an early stage, the thrombus can be removed by treatment with tissue plasminogen activator delivered through one of the arm veins. The vein must then be imaged to see if there is any compression on elevation of the arm. Thoracic outlet decompression can be carried out by resecting the cervical rib or first rib if this is confirmed.

George Budd, 1808–1882, Professor of Medicine, King's College Hospital, London, England, described this syndrome in 1845.

Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany, (Strasbourg was returned to France after the end of World War I, in 1918), gave his account of this condition in 1898.

Frederick Parkes Weber, 1863–1962, Physician, The German Hospital, Dalston, London, England.

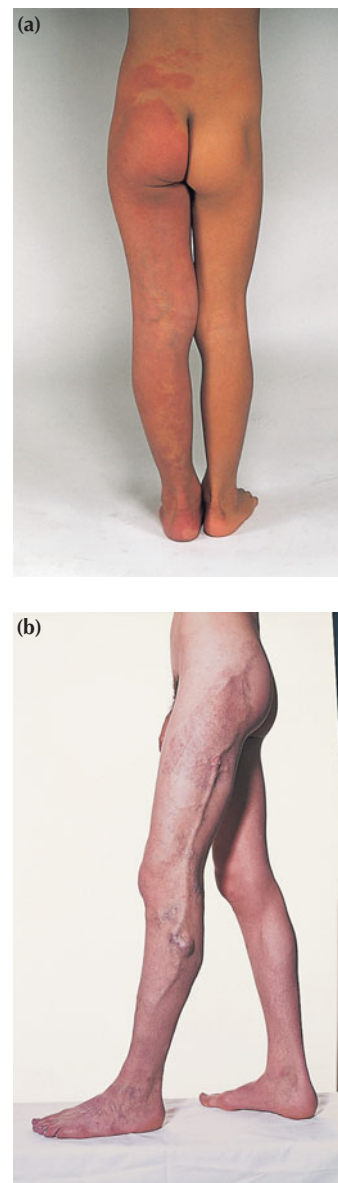

Figure 54.26 Two patients with Klippel–Trenaunay syndrome. (a) This patient has a longer leg and a capillary naevus. (b) This patient has a large lateral anomalous axial vein.

VENOUS INJURY

Blunt or penetrating trauma almost always damages some small- and medium-sized veins, which can be safely ignored or ligated without causing any problems. Larger axial venous channels have in the past been ligated when injured, but it is now recognised that these axial veins should be repaired whenever possible to reduce subsequent morbidity (pain and swelling in the tissues being drained) and limb loss when associated with a concomitant arterial injury. Many venous injuries remain undiagnosed at the time of injury, (e.g. crural vein damage associated with a fractured tibia) and only present many years later when post-thrombotic changes become apparent. Venous injuries occur from both civilian and military trauma but the incidence of venous military injuries has been particularly well documented. In total, 40–50%

Figure 54.27 Thoracic outlet syndrome. (a) Cervical ribs; (b) elevation of the arm causing occlusion of the axillary vein with collateral fillings. The patient has had previous surgery on the left side.

of arterial injuries have concomitant venous injuries, especially in the popliteal fossa.

Classification

Venous injuries may be lacerated, contused or torn apart (stretched) (Fig. 54.28). Iatrogenic injuries result from damage at the time of surgery and from punctures caused by catheter insertion by radiologists and physicians.

Thrombosis, haemorrhage and embolisation are all common complications and arteriovenous fistulae may develop when a penetrating needle transfixes the vein and artery.

Associated injuries to soft tissue, arteries and bones often overshadow the venous injury. Massive haemorrhage from the pelvic bones or the inferior vena cava can rapidly lead to hypovolaemic shock and death if left untreated. Haematomas are common and engorgement, cyanosis and swelling are also indicative of a major venous injury.

Figure 54.28 Types of venous damage. (a) Incision; (b) transection; (c) irregular laceration; (d) avulsion of a tributary.

Investigations are rarely helpful and rapid exploration is usually required. Embolisation and stent grafting can have a limited role, especially if the venous injury is relatively inaccessible or an arteriovenous fistula has developed.

The patient must be adequately resuscitated, have blood cross-matched and have good intravenous access obtained via a central venous pressure line if possible, provided that there are no injuries around the neck or thorax. Gentle wound exploration, under tourniquet control when possible, should assess the extent of the injuries before the vessels are dissected out and clamped. Different types of repair are shown in Fig. 54.29; the type of repair carried out depends on the extent of the venous injury, including how much venous wall has been lost or damaged. Lateral sutures and vein patches are ideal methods of repair and end-to-end anastomosis is satisfactory provided that it is not carried out under tension.

Vein replacement should be by autogenous tissue whenever possible, using vein harvested from another site, e.g. the internal jugular vein or the long saphenous vein from an undamaged limb. Artificial grafts with polytetrafluoroethylene (PTFE) are likely to get infected in contaminated wounds and have given poor results in recent conflicts. The use of anticoagulants and an arteriovenous fistula to reduce the risk of thrombosis in the vein graft are controversial and depend on the associated injuries that are present. In contaminated wounds, tetanus, toxoid and antibiotics should be given. A fasciotomy should always be considered if there is a concomitant arterial and venous injury.

Prognosis

It is now recognised that repair of a major axial vein can be carried out with a 70–80% success rate, reducing the morbidity of a combined arterial and venous injury considerably (especially limb loss). Complex repairs should not, however, be carried out if a patient's life is at risk, when ligation may have to suffice in the short term.

VENOUS TUMOURS

Cystic degeneration of the vein wall is an uncommon cause of venous occlusion. It may be detected by ultrasound. The cyst may be de-roofed or the venous segment excised.

Figure 54.29 Types of venous repair. (a) Lateral suture; (b) patch graft; (c) Carrel triangulation technique of venous anastomosis; (d) panel graft; (e) spiral graft.

Venous malformation cavernous angioma/haemangioma

These malformations are common, often affecting the skin but also extending into the deep tissues, including bones and joints. They usually present with variable swelling and dilated veins beneath the skin. Occasionally, there is no visible mass and the complaint is one of pain. Haemorrhage and thrombophlebitis may exacerbate the pain. A soft compressible mass, which is venous in colour especially if it is under the skin, is usually present (Fig. 54.30a). A dark blue tinge is often apparent even if the malformation is deeply situated. Nodules within the mass usually represent previous episodes of thrombosis. The size and extent of the haemangioma are best visualised by nuclear magnetic resonance with a short tau inversion recovery (STIR) sequence (Fig. 54.30b) or CT scanning with contrast enhancement. Venography rarely shows an abnormality, but direct puncture with contrast injection shows the connections of the malformation.

Treatment options include surgical excision or sclerotherapy. Neither of these is entirely curative because it is difficult to remove all of the angiomatous tissue or sclerose the angioma completely. Sclerosis can be dangerous when the veins connect to the deep system.

Leiomyomas and leiomyosarcomas of the vein wall

These are extremely rare tumours that are usually slow growing. They present with pain and a mass with signs of venous obstruction,

Figure 54.30 (a) Venous angioma of the leg. (b) Magnetic resonance with a short tau inversion recovery sequence showing angioma in white throughout the limb.

e.g. oedema and distended veins. Duplex scanning, CT (Fig. 54.31) and magnetic resonance imaging show a filling defect within the vein wall. Treatment is by resection with replacement by autogenous vein taken from another site. Rarely, a PTFE graft is required. When the tumour affects the vena cava it must be resected and replaced with a prosthetic graft.

Lymphatic disorders

CHAPTER

55

LEARNING OBJECTIVES

To understand:

- The main functions of the lymphatic system
- The development of the lymphatic system
- The various causes of limb swelling
- The aetiology, clinical features, investigations and treatment of lymphoedema

INTRODUCTION

The lymphatic system was first described by Erasistratus in Alexandria more than 2000 years ago. William Hunter, in the late eighteenth century, was the first to describe the function of the lymphatic system. Starling's pioneering work on the hydrostatic and haemodynamic forces controlling the movement of fluid across the capillary provided further insights into the function of the lymphatics. However, there is much about the lymphatic system that is not understood and debate continues over the precise aetiology of the most common abnormality of the system, namely lymphoedema.

ANATOMY AND PHYSIOLOGY OF THE LYMPHATIC SYSTEM

Functions

The principal function of the lymphatics is the return of protein-rich fluid to the circulation through the lymphaticovenous junctions in the jugular area. Thus, water, electrolytes, low-molecular-weight moieties (polypeptides, cytokines, growth factors) and macromolecules (fibrinogen, albumin, globulins, coagulation and fibrinolytic factors) from the interstitial fluid (ISF) return to the circulation via the lymphatics. Intestinal lymph (chyle) transports cholesterol, long-chain fatty acids, triglycerides and the fat-soluble vitamins (A, D, E and K) directly to the circulation, bypassing the liver. Lymphocytes and other immune cells also circulate within the lymphatic system.

Development and macroanatomy

In the human embryo lymph sacs develop at 6–7 weeks' gestation as four cystic spaces, one on either side of the neck and one in each

groin. These cisterns enlarge and develop communications that permit lymph from the lower limbs and abdomen to drain via the cisterna chyli into the thoracic duct, which in turn drains into the left internal jugular vein at its confluence with the left subclavian vein. Lymph from the head and right arm drains via a separate lymphatic trunk, the right lymphatic duct, into the right internal jugular vein. Lymphatics accompany veins everywhere except in the cortical bony skeleton and central nervous system, although the brain and retina possess cerebrospinal fluid and aqueous humour respectively. The lymphatic system comprises lymphatic channels, lymphoid organs (lymph nodes, spleen, Peyer's patches, thymus, tonsils) and circulating elements (lymphocytes and other mononuclear immune cells). Lymphatic endothelial cells are derived from embryonic veins in the jugular and perimesonephric areas from where they migrate to form the primary lymph sacs and plexus. Both transcription (e.g. Prox1) and growth (e.g. VEGF-C) factors are essential for these developmental events.

Microanatomy and physiology

Lymphatic capillaries

Lymphatics originate within the ISF space from specialised endothelialised capillaries (initial lymphatics) or non-endothelialised channels such as the spaces of Disse in the liver. Initial lymphatics are unlike arteriovenous capillaries in that:

- they are blind-ended;
- they are much larger (50 μ m);
- they allow the entry of molecules of up to 1000 kDa in size because the basement membrane is fenestrated, tenuous or even absent and the endothelium itself possesses intra- and intercellular pores;
- they are anchored to interstitial matrix by filaments. In the resting state, initial lymphatics are collapsed. When ISF volume and pressure increases, initial lymphatics and their pores are held open by these filaments to facilitate increased drainage.

Erasistratus of Chios c.300–250 B.C. of the Medical School at Alexandria in Egypt is regarded by many as the first Physiologist.

William Hunter, 1718–1783, Anatomist and Obstetrician who became the first Professor of Anatomy at the Royal Academy of Arts, London, England. He was the elder brother of John Hunter the Anatomist and Surgeon.

Ernest Henry Starling, 1866–1927, Professor of Physiology, University College, London, England.

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine (Peyer's Patches) in 1677.

Josef Disse, 1852–1912, a German Anatomist.

Terminal lymphatics

Initial lymphatics drain into terminal (collecting) lymphatics that possess bicuspid valves and endothelial cells rich in the contractile protein actin. Larger collecting lymphatics are surrounded by smooth muscle. Valves partition the lymphatics into segments (lymphangions) that contract sequentially to propel lymph into the lymph trunks.

Lymph trunks

Terminal lymphatics lead to lymph trunks, which have a structure similar to that of veins, namely a single layer of endothelial cells, lying on a basement membrane overlying a media comprising smooth muscle cells that are innervated with sympathetic, parasympathetic and sensory nerve endings. About 10% of lymph arising from a limb is transported in deep lymphatic trunks that accompany the main neurovascular bundles. The majority, however, is conducted against venous flow from deep to superficial in epifascial lymph trunks. Superficial trunks form lymph bundles of various sizes, which are located within strips of adipose tissue, and tend to follow the course of the major superficial veins.

Starling's forces

The distribution of fluid and protein between the vascular system and ISF depends on the balance of hydrostatic and oncotic pressures between the two compartments (Starling's forces), together with the relative impermeability of the blood capillary membrane to molecules over 70 kDa. In health there is net capillary filtration, which is removed by the lymphatic system.

Transport of particles

Particles enter the initial lymphatics through interendothelial openings and vesicular transport through intraendothelial pores. Large particles are actively phagocytosed by macrophages and transported through the lymphatic system intracellularly.

Mechanisms of lymph transport

Resting ISF is negative (-2 to -6 mmH₂O), whereas lymphatic pressures are positive, indicating that lymph flows against a small pressure gradient. It is believed that prograde lymphatic flow depends upon three mechanisms:

- 1 transient increases in interstitial pressure secondary to muscular contraction and external compression;
- 2 the sequential contraction and relaxation of lymphangions;
- 3 the prevention of reflux because of valves.

Lymphangions are believed to respond to increased lymph flow in much the same way as the heart responds to increased venous return in that they increase their contractility and stroke volume. Contractility is also enhanced by noradrenaline, serotonin, certain prostaglandins and thromboxanes, and endothelin-1. Pressures of up to 30–50 mmHg have been recorded in normal lymph trunks and up to 200 mmHg in severe lymphoedema. Lymphatics may also modulate their own contractility through the production of nitric oxide and other local mediators. Transport in the thoracic and right lymph ducts also depends upon intrathoracic (respiration) and central venous (cardiac cycle) pressures. Therefore, cardiorespiratory disease may have an adverse effect on lymphatic function.

In summary, in the healthy limb, lymph flow is largely due to intrinsic lymphatic contractility, although this is augmented by

exercise, limb movement and external compression. However, in lymphoedema, when the lymphatics are constantly distended with lymph, these external forces assume a much more important functional role.

ACUTE INFLAMMATION OF THE LYMPHATICS

Acute lymphangitis is an infection, often caused by *Streptococcus pyogenes* or *Staphylococcus aureus*, which spreads to the draining lymphatics and lymph nodes (lymphadenitis) where an abscess may form. Eventually this may progress to bacteraemia or septicæmia. The normal signs of infection (rubor, calor, dolor) are present and a red streak is seen in the skin along the line of the inflamed lymphatic (Fig. 55.1). The part should be rested to reduce lymphatic drainage and elevated to reduce swelling, and the patient should be treated with intravenous antibiotics based upon actual or suspected sensitivities. Failure to improve within 48 hours suggests inappropriate antibiotic therapy, the presence of undrained pus or the presence of an underlying systemic disorder (malignancy, immunodeficiency). The lymphatic damage caused by acute lymphangitis may lead to recurrent attacks of infection and lymphoedema; patients with lymphoedema are prone to so-called acute inflammatory episodes (see below).

LYMPHOEDEMA

Definition

Lymphoedema may be defined as abnormal limb swelling caused by the accumulation of increased amounts of high protein ISF secondary to defective lymphatic drainage in the presence of (near) normal net capillary filtration.

The scope of the clinical problem

At birth, 1 in 6000 persons will develop lymphoedema with an overall prevalence of 0.13–2%. The condition is not only associated with significant physical symptoms and complications but is also a frequent cause of emotional and psychological distress, which can lead to difficulties with relationships, education and work (Summary box 55.1).

Figure 55.1 Acute lymphangitis of the arm. Erythematous streaks extend from the site of primary infection on the volar aspect of the forearm to epicondylar nodes at the elbow and from there to enlarged and tender axillary lymph nodes.

Summary box 55.1

Symptoms frequently experienced by patients with lymphoedema

- Constant dull ache, even severe pain
- Burning and bursting sensations
- General tiredness and debility
- Sensitivity to heat
- 'Pins and needles'
- Cramp
- Skin problems including flakiness, weeping, excoriation and breakdown
- Immobility, leading to obesity and muscle wasting
- Backache and joint problems
- Athlete's foot
- Acute infective episodes

Despite this significant impact on quality of life, many sufferers choose not to seek medical advice because of embarrassment and a belief that nothing can be done. Patients who do come forward for help, especially those with non-cancer-related lymphoedema, often find they have limited access to appropriate expertise and treatment. Lymphoedema is often misdiagnosed and mistreated by doctors, who frequently have a poor understanding of the importance of the condition, believing it to be primarily a cosmetic problem in the early stages. However, making an early diagnosis is important because relatively simple measures can be highly effective at this stage and can prevent the development of disabling late disease, which is often very difficult to treat. It is also an opportunity for patients to make contact with patient support groups (Summary box 55.2).

Summary box 55.2

What every patient with lymphoedema should receive

- An explanation of why the limb is swollen and the underlying cause
- Guidance on skin hygiene and care and the avoidance of acute infective episodes
- Anti-fungal prophylactic therapy to prevent athlete's foot
- Rapid access to antibiotic therapy if necessary, hospital admission for acute infective episodes
- Appropriate instructions regarding exercise therapy
- Manual lymphatic drainage (MLD)
- Multilayer lymphoedema bandaging (MLLB)
- Compression garments and, if appropriate, specialised footwear
- Advice on diet
- Access to support services and networks

The severity of unilateral limb lymphoedema can be classified as:

- mild: < 20% excess limb volume;
- moderate: 20–40% excess limb volume;
- severe: > 40% excess limb volume.

Pathophysiology

The ISF compartment (10–12 litres in a 70-kg man) constitutes 50% of the wet weight of the skin and subcutaneous tissues and, in order for oedema to be clinically detectable, its volume has to

double. About 8 litres (protein concentration approximately 20–30 g l⁻¹, similar to ISF) of lymph is produced each day and travels in afferent lymphatics to lymph nodes. There, the volume is halved and the protein concentration doubled, resulting in 4 litres of lymph re-entering the venous circulation each day via efferent lymphatics. In one sense, all oedema is lymphoedema in that it results from an inability of the lymphatic system to clear the ISF compartment. However, in most types of oedema this is because the capillary filtration rate is pathologically high and overwhelms a normal lymphatic system, resulting in the accumulation of low-protein oedema fluid. In contrast, in true lymphoedema, when the primary problem is in the lymphatics, capillary filtration is normal and the oedema fluid is relatively high in protein. Of course, in a significant number of patients with oedema there is both abnormal capillary filtration and abnormal lymphatic drainage, as in chronic venous insufficiency (CVI) for example.

Lymphoedema results from lymphatic aplasia, hypoplasia, dysmotility (reduced contractility with or without valvular insufficiency), obliteration by inflammatory, infective or neoplastic processes, or surgical extirpation. Whatever the primary abnormality, the resultant physical and/or functional obstruction leads to lymphatic hypertension and distension, with further secondary impairment of contractility and valvular competence. Lymphostasis and lymphotension lead to the accumulation in the ISF of fluid, proteins, growth factors and other active peptide moieties, glycosaminoglycans and particulate matter, including bacteria. As a consequence, there is increased collagen production by fibroblasts, an accumulation of inflammatory cells (predominantly macrophages and lymphocytes) and activation of keratinocytes. The end result is protein-rich oedema fluid, increased deposition of ground substance, subdermal fibrosis and dermal thickening and proliferation. Lymphoedema, unlike all other types of oedema, is confined to the epifascial space. Although muscle compartments may be hypertrophied because of the increased work involved in limb movement, they are characteristically free of oedema.

Classification

Two main types of lymphoedema are recognised:

- 1 *primary lymphoedema*, in which the cause is unknown (or at least uncertain and unproven); it is thought to be caused by 'congenital lymphatic dysplasia';
- 2 *secondary or acquired lymphoedema*, in which there is a clear underlying cause.

Primary lymphoedema is usually further subdivided on the basis of the presence of family, age of onset and lymphangiographic findings (Tables 55.1 and 55.2) (see below).

Risk factors for lymphoedema

Although the true risk factor profile for lymphoedema is not currently known, a number of factors are thought to predispose an individual to its development and predict progression, severity and outcome of the condition (Table 55.3).

Symptoms and signs

In most cases, the diagnosis of primary or secondary lymphoedema can be made and the condition can be differentiated from other causes of a swollen limb on the basis of history and examination without recourse to complex investigation (Table 55.4). Unlike other types of oedema, lymphoedema characteristically

Table 55.1 Aetiological classification of lymphoedema

Primary lymphoedema	Congenital (onset < 2 years old): sporadic; familial (Nonne–Milroy’s disease) Praecox (onset 2–35 years old): sporadic; familial (Letessier–Meige’s disease) Tarda (onset after 35 years old)
Secondary lymphoedema	Parasitic infection (filariasis) Fungal infection (tinea pedis) Exposure to foreign body material (silica particles) Primary lymphatic malignancy Metastatic spread to lymph nodes Radiotherapy to lymph nodes Surgical excision of lymph nodes Trauma (particularly degloving injuries) Superficial thrombophlebitis Deep venous thrombosis

involves the foot (Fig. 55.2). The contour of the ankle is lost through infilling of the submalleolar depressions, a ‘buffalo hump’ forms on the dorsum of the foot, the toes appear ‘square’ because of confinement of footwear and the skin on the dorsum of the toes cannot be pinched because of subcutaneous fibrosis (Stemmer’s sign). Lymphoedema usually spreads proximally to knee level and less commonly affects the whole leg (Fig. 55.3). In the early stages, lymphoedema will ‘pit’ and the patient will report that the swelling is down in the morning. This represents a reversible component to the swelling, which can be controlled.

Table 55.3 Risk factors for lymphoedema

Upper limb/trunk lymphoedema	Lower limb lymphoedema
Surgery with axillary lymph node dissection, particularly if extensive breast or lymph node surgery	Surgery with inguinal lymph node dissection
Scar formation, fibrosis and radiodermatitis from postoperative axillary radiotherapy	Postoperative pelvic radiotherapy
Radiotherapy to the breast or to the axillary, internal mammary or subclavicular lymph nodes	Recurrent soft tissue infection at the same site
Drain/wound complications or infection	Obesity
Cording (axillary web syndrome)	Varicose vein stripping and vein harvesting
Seroma formation	Genetic predisposition/family history of chronic oedema
Advanced cancer	Advanced cancer
Obesity	Intrapelvic or intra-abdominal tumours that involve or directly compress lymphatic vessels
Congenital predisposition	Orthopaedic surgery
Trauma in an ‘at-risk’ arm (venepuncture, blood pressure measurement, injection)	Poor nutritional status
Chronic skin disorders and inflammation	Thrombophlebitis and chronic venous insufficiency, particularly post-thrombotic syndrome
Hypertension	Any unresolved asymmetrical oedema
Taxane chemotherapy	Chronic skin disorders and inflammation
Insertion of pacemaker	Concurrent illnesses such as phlebitis, hyperthyroidism, kidney or cardiac disease
Arteriovenous shunt for dialysis	Immobilisation and prolonged limb dependency
Air travel	Air travel
Living in or visiting an area for endemic lymphatic filariasis	Living in or visiting an area for endemic lymphatic filariasis

ab igne is Latin for ‘from fire’.

Table 55.2 Clinical classification of lymphoedema

Grade (Brunner)	Clinical features
Subclinical (latent)	There is excess interstitial fluid and histological abnormalities in lymphatics and lymph nodes, but no clinically apparent lymphoedema
I	Oedema pits on pressure and swelling largely or completely disappears on elevation and bed rest
II	Oedema does not pit and does not significantly reduce upon elevation
III	Oedema is associated with irreversible skin changes, i.e. fibrosis, papillae

Failure to do so allows fibrosis, dermal thickening and hyperkeratosis to occur. In general, primary lymphoedema progresses more slowly than secondary lymphoedema. Chronic eczema, fungal infection of the skin (dermatophytosis) and nails (onychomycosis), fissuring, verrucae and papillae (warts) are frequently seen in advanced disease. Ulceration is unusual, except in the presence of chronic venous insufficiency.

Lymphangiomas are dilated dermal lymphatics that ‘blister’ onto the skin surface. The fluid is usually clear but may be blood-stained. In the long term, lymphangiomas thrombose and fibrose, forming hard nodules that may raise concerns about malignancy. If lymphangiomas are < 5 cm across, they are termed lymphangioma circumscriptum, and if they are more widespread, they are termed lymphangioma diffusum. If they form a reticulate pattern of ridges then it has been termed lymphoedema *ab igne*.

Table 55.4 Differential diagnosis of the swollen limb

Non-vascular or lymphatic	General disease states	Cardiac failure from any cause Liver failure Hypoproteinaemia due to nephrotic syndrome, malabsorption, protein-losing enteropathy Hypothyroidism (myxoedema) Allergic disorders, including angioedema and idiopathic cyclic oedema Prolonged immobility and lower limb dependency	
	Local disease processes	Ruptured Baker's cyst Myositis ossificans Bony or soft-tissue tumours Arthritis Haemarthrosis Calf muscle haematoma Achilles tendon rupture	
	Retroperitoneal fibrosis Gigantism	May lead to arterial, venous and lymphatic abnormalities Rare All tissues are uniformly enlarged	
	Drugs	Corticosteroids, oestrogens, progestagens Monoamine oxidase inhibitors, phenylbutazone, methyl dopa, hydralazine, nifedipine	
	Trauma	Painful swelling due to reflex sympathetic dystrophy	
	Obesity	Lipodystrophy Lipoidosis	
	Venous	Deep venous thrombosis	There may be an obvious predisposing factor, such as recent surgery The classical signs of pain and redness may be absent
		Post-thrombotic syndrome	Swelling, usually of the whole leg, due to iliofemoral venous obstruction Venous skin changes, secondary varicose veins on the leg and collateral veins on the lower abdominal wall Venous claudication may be present
		Varicose veins Klippel–Trenaunay's syndrome and other malformations	Simple primary varicose veins are rarely the cause of significant leg swelling Rare Present at birth or develops in early childhood Comprises an abnormal lateral venous complex, capillary naevus, bony abnormalities, hypo(a)plasia of deep veins and limb lengthening Lymphatic abnormalities often coexist
		External venous compression	Pelvic or abdominal tumour including the gravid uterus Retroperitoneal fibrosis
Ischaemia–reperfusion		Following lower limb revascularisation for chronic and particularly chronic ischaemia	
Arterial	Arteriovenous malformation Aneurysm	May be associated with local or generalised swelling Popliteal Femoral False aneurysm following (iatrogenic) trauma	

Lymphangiomas frequently weep (lymphorrhoea, chyloorrhoea), causing skin maceration, and they act as a portal for infection. Protein-losing diarrhoea, chylous ascites, chylothorax, chyluria and discharge from lymphangiomas suggest lymphangectasia (megalymphatics) and chylous reflux.

Ulceration, non-healing bruises and raised purple-red nodules should lead to suspicion of malignancy. Lymphangiosarcoma was originally described in post-mastectomy oedema (Stewart–Treves'

syndrome) and affects around 0.5% of patients at a mean onset of 10 years. However, lymphangiosarcoma can develop in any long-standing lymphoedema, but usually takes longer to manifest (20 years). It presents as single or multiple bluish/red skin and subcutaneous nodules that spread to form satellite lesions, which may then become confluent. The diagnosis is usually made late and confirmed by skin biopsy. Amputation offers the best chance of survival but, even then, most patients live for less than 3 years. It has been suggested that lymphoedema leads to an impairment of immune surveillance and so predisposes to other malignancies, although the causal association is not as definite as it is for lymphangiosarcoma (Summary box 55.3).

William Marrant Baker, 1839–1896, Surgeon, St. Bartholomew's Hospital, London, England, described these cysts in 1877.

Fred Waldorf Stewart, 1894–1991, an American Physician.

Norman Treves, 1894–1964, an American Surgeon.

Stewart and Treves reported this condition in a joint paper in 1948.

Figure 55.2 The foot of a patient with typical lymphoedema.

Summary box 55.3

Malignancies associated with lymphoedema

- Lymphangiosarcoma (Stewart–Treves' syndrome)
- Kaposi's sarcoma [human immunodeficiency virus (HIV)]
- Squamous cell carcinoma
- Liposarcoma
- Malignant melanoma
- Malignant fibrous histiocytoma
- Basal cell carcinoma
- Lymphoma

PRIMARY LYMPHOEDEMA

Aetiology

It has been proposed that all cases of primary lymphoedema are due to an inherited abnormality of the lymphatic system, sometimes termed 'congenital lymphatic dysplasia'. However, it is possible that many sporadic cases of primary lymphoedema occur in the presence of a (near-)normal lymphatic system and are actually examples of secondary lymphoedema for which the triggering events have gone unrecognised. These might include seemingly trivial (but repeated) bacterial and/or fungal infections, insect bites, barefoot walking (silica), deep venous thrombosis (DVT) or episodes of superficial thrombophlebitis. In animal models, simple excision of lymph nodes and/or trunks leads to acute lymphoedema, which resolves within a few weeks,

Figure 55.3 The lower leg of a patient with typical lymphoedema.

presumably because of the development of collaterals. The human condition can only be mimicked by inducing extensive lymphatic obliteration and fibrosis. Even then, there may be considerable delay between the injury and the onset of oedema. Primary lymphoedema is much more common in the legs than the arms. This may be because of gravity and a bipedal posture, the fact that the lymphatic system of the leg is less well developed, or the increased susceptibility of the leg to trauma and/or infection. Furthermore, loss of the venoarteriolar reflex (VAR), which protects lower limb capillaries from excessive hydrostatic forces in the erect posture, with age and disease (CVI, diabetes), may be important.

Classification

Primary lymphoedema is usually classified on the basis of apparent genetic susceptibility, age of onset or lymphangiographic findings. None of these is ideal and the various classification systems in existence can appear confusing and conflicting as various terms and eponyms are used loosely and interchangeably. This has hampered research and efforts to gain a better understanding of underlying mechanisms, the effectiveness of therapy and prognosis.

Genetic susceptibility

Primary lymphoedema is often subdivided into those cases in which there appears to be a genetic susceptibility or element to the disease, and those in which there is not. The former may be further divided into those cases that are familial (hereditary), when typically the only abnormality is lymphoedema and there is

a family history, and those cases that are syndromic, when the lymphoedema is only one of several congenital abnormalities and is either inherited or sporadic. Syndromic lymphoedema may be sporadic and chromosomal [Turner's (XO karyotype), Klinefelter's (XXY), Down's (trisomy 21) syndrome] or clearly inherited and related to an identified or presumed single-gene defect [lymphoedema–distichiasis (autosomal dominant)], or of uncertain genetic aetiology (yellow-nail and Klippel–Trenaunay–Weber's syndromes). Familial (hereditary) lymphoedema can be difficult to distinguish from non-familial lymphoedema because a reliable family history may be unobtainable, the nature of the genetic predisposition is unknown and the genetic susceptibility may only translate into clinical disease in the presence of certain environmental factors. Although the distinction may not directly affect treatment, the patients are often concerned lest they be 'passing on' the disease to their children.

Two main forms of familial (hereditary) lymphoedema are recognised – Nonne–Milroy (type I) and Letessier–Meige (type II) – although it is likely that both eponymous diseases overlap and represent more than a single disease entity and genetic abnormality. Milroy's disease is estimated to be present in 1:6000 live births and is probably inherited in an autosomal dominant manner with incomplete (about 50%) penetrance. In some families, the condition may be related to abnormalities in the gene coding for a vascular endothelial growth factor (VEGF) on chromosome 5. The disease is characterised by brawny lymphoedema of both legs (and sometimes the genitalia, arms and face), which develops from birth or before puberty. The disease has been associated with a wide range of lymphatic abnormalities on lymphangiography. Meige's disease is similar to Milroy's disease, except that the lymphoedema generally develops between puberty and middle age (50 years). It usually affects one or both legs but may involve the arms. Some, but not all, cases appear to be inherited in an autosomal dominant manner. Lymphangiography generally shows aplasia or hypoplasia.

Age of onset

Lymphoedema congenita (onset at or within 2 years of birth) is more common in males and is more likely to be bilateral and involve the whole leg. Lymphoedema praecox (onset from 2 to 35 years) is three times more common in females, has a peak incidence shortly after menarche, is three times more likely to be unilateral than bilateral and usually only extends to the knee. Lymphoedema tarda develops, by definition, after the age of 35 years and is often associated with obesity, with lymph nodes being

replaced with fibrofatty tissue. The cause is unknown. Lymphoedema developing for the first time after 50 years should prompt a thorough search for underlying (pelvic, genitalia) malignancy. It is worth noting that, in such patients, lymphoedema often commences proximally in the thigh rather than distally (Fig. 55.4).

Lymphangiographic classification

Browse has classified primary lymphoedema on the basis of lymphangiographic findings (Table 55.5 and Figs 55.5 and 55.6). These findings may be related to the clinical presentations described above. Some patients with lymphatic hyperplasia possess megalymphatics in which lymph or chyle refluxes freely under the effects of gravity against the physiological direction of flow. The megalymphatics usually end in thin-walled vesicles on the skin, serous surfaces (chylous ascites, chylothorax), intestine (protein-losing enteropathy), kidney or bladder (chyluria) (Fig. 55.7).

SECONDARY LYMPHOEDEMA

This is the most common form of lymphoedema. There are several well-recognised causes including infection, inflammation, neoplasia and trauma (Table 55.6).

Filariasis

This is the most common cause of lymphoedema worldwide, affecting up to 100 million individuals. It is particularly prevalent in Africa, India and South America where 5–10% of the population may be affected. The viviparous nematode *Wucheria bancrofti*, whose only host is man, is responsible for 90% of cases and is spread by the mosquito. The disease is associated with poor sanitation. The parasite enters lymphatics from the blood and lodges in lymph nodes, where it causes fibrosis and obstruction, due

Figure 55.4 This patient, in her sixth decade, presented with rapid onset of lymphoedema of the right leg. On further investigation she was found to have locally advanced bladder carcinoma. Note that unlike most cases of lymphoedema the swelling is greater proximally than distally.

Henry Hubert Turner, 1892–1970, Professor of Medicine, The University of Oklahoma, OK, USA.
 Harry Fitch Klinefelter, Jr. B. 1912, Associate Professor of Medicine, The Johns Hopkins University Medical School, Baltimore MD, USA, described this syndrome in 1942.
 John Langdon Haydon Down, (sometimes given as Langdon-Down), 1828–1896, Physician, The London Hospital, London, England.
 Maurice Klippel, 1858–1942, Neurologist, La Salpêtrière, Paris, France.
 Paul Trenaunay, B. 1875, a French Neurologist.
 Klippel and Trenaunay described this condition in a joint paper in 1900.
 Frederick Parkes Weber, 1863–1962, Physician, The German Hospital, Dalston, London, England.
 Max Nonne, 1861–1959, a Neurologist of Hamburg, Germany, described this disease in 1891.
 William Forsyth Milroy, 1855–1942, Professor of Clinical Medicine, Columbia University, New York, NY, USA, described the condition in 1892.
 Henri Meige, 1866–1940, Physician, La Salpêtrière, Paris, France, gave his description of the disease in 1899.

Sir Norman Leslie Browse, Formerly Professor of Surgery, The United Medical and Dental Schools of Guy's and St. Thomas's Hospitals, London, England.
 Otto Eduard Heinrich Wucherer, 1820–1873, a German Physician who practised in Brazil, South America.
 Sir Joseph Bancroft, 1836–1894, an English Physician and Epidemiologist who worked in Brisbane, Queensland, Australia.

Table 55.5 Lymphangiographic classification of primary lymphoedema

	Congenital hyperplasia (10%)	Distal obliteration (80%)	Proximal obliteration (10%)
Age of onset	Congenital	Puberty (praecox)	Any age
Sex distribution	Male > female	Female > male	Male = female
Extent	Whole leg	Ankle, calf	Whole leg, thigh only
Laterality	Unilateral = bilateral	Often bilateral	Usually unilateral
Family history	Often positive	Often positive	No
Progression	Progressive	Slow	Rapid
Response to compression therapy	Variable	Good	Poor
Comments	Lymphatics are increased in number; although functionally defective, there is usually an increased number of lymph nodes. May have chylous ascites, chylothorax and protein-losing enteropathy	Absent or reduced distal superficial lymphatics. Also termed aplasia or hypoplasia	There is obstruction at the level of the aortoiliac or inguinal nodes. If associated with distal dilatation, the patient may benefit from lymphatic bypass operation. Other patients have distal obliteration as well

partly to direct physical damage and partly to the immune response of the host. Proximal lymphatics become grossly dilated with adult parasites. The degree of oedema is often massive, in which case it is termed elephantiasis (Fig. 55.8). Immature parasites (microfilariae) enter the blood at night and can be identified on a blood smear, in a centrifuged specimen of urine or in lymph itself. A complement fixation test is also available and is positive in present or past infection. Eosinophilia is usually present. Diethylcarbamazine destroys the parasites but does not reverse the lymphatic changes, although there may be some regression over time. Once the infection has been cleared, treatment is as for primary lymphoedema. Public health measures to reduce mosquito breeding, protective clothing and mosquito netting may be usefully employed to combat the condition (Summary box 55.4).

Figure 55.5 This patient presented with congenital lymphoedema of the right leg. The lymphangiogram shows lymphatic hypoplasia.

Summary box 55.4

Features of filariasis

Acute

- Fever
- Headache
- Malaise
- Inguinal and axillary lymphadenitis
- Lymphangitis
- Cellulitis, abscess formation and ulceration
- Funiculo-epididymo-orchitis

Chronic

- Lymphoedema of legs (arm, breast)
- Hydrocele
- Abdominal lymphatic varices
 - Chyluria
 - Lymphuria

Figure 55.6 This patient presented with lymphoedema of the right leg. A bipodal lymphangiogram demonstrated normal lymphatics in the right leg up to the inguinal nodes, but no progression of contrast above the inguinal ligament – a case of proximal obstruction.

Figure 55.7 Lymphangiogram demonstrating reflux from dilated para-aortic vessels into the left kidney in a patient with filariasis who presented with chyluria.

Endemic elephantiasis (podoconiosis)

This is common in the tropics and affects more than 500 000 people in Africa. The barefoot cultivation of soil composed of alkaline volcanic rocks leads to destruction of the peripheral lymphatics by particles of silica, which can be seen in macrophages in draining lymph nodes. Plantar oedema develops in childhood and rapidly spreads proximally. The condition is prevented and its progression is slowed by the wearing of shoes.

Bacterial infection

Lymphangitis and lymphadenitis can cause lymphatic destruction that predisposes to lymphoedema complicated by further acute inflammatory episodes. Interestingly, in such patients, lymphangiography has revealed abnormalities in the contralateral, unaffected limb, suggesting an underlying, possibly inherited, susceptibility. Lymphatic and lymph node destruction by tuberculosis is also a well-recognised cause of lymphoedema, especially in developing countries.

Malignancy and its treatment

Treatment (surgery, radiotherapy) for breast carcinoma is the most common cause of lymphoedema in developed countries, but is decreasing in incidence as surgery becomes more conservative (see Chapter 50). Lymphoma may present with lymphoedema, as may malignancy of the pelvic organs and external genitalia. Kaposi's

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

Table 55.6 Classification of causes of secondary lymphoedema

Classification	Example(s)
Trauma and tissue damage	Lymph node excision Radiotherapy Burns Varicose vein surgery/harvesting Large/circumferential wounds Scarring
Malignant disease	Lymph node metastases Infiltrative carcinoma Lymphoma Pressure from large tumours
Venous disease	Chronic venous insufficiency Venous ulceration Post-thrombotic syndrome Intravenous drug use
Infection	Cellulitis/erysipelas Lymphadenitis Tuberculosis Filariasis
Inflammation	Rheumatoid arthritis Dermatitis Psoriasis Sarcoidosis Dermatosis with epidermal involvement
Endocrine disease	Pretibial myxoedema
Immobility and dependency	Dependency oedema Paralysis
Factitious	Self harm

sarcoma developing in the course of HIV-related illness may cause lymphatic obstruction and is a growing cause of lymphoedema in certain parts of the world.

Trauma

It is not unusual for patients to develop chronic localised or generalised swelling following trauma. The aetiology is often multifactorial and includes disuse, venous thrombosis and lymphatic injury or destruction. Degloving injuries and burns are particularly likely to disrupt dermal lymphatics. Tenosynovitis can also be associated with localised subcutaneous lymphoedema, which can be a cause of troublesome persistent swelling following ankle and wrist 'sprains' and repetitive strain injury.

Lymphoedema and chronic venous insufficiency

It is important to appreciate the relationship between lymphoedema and CVI as both conditions are relatively common and so often coexist in the same patient, and it can be difficult to unravel which components of the patient's symptom complex are caused by each. There is no doubt that superficial venous thrombophlebitis (SVT) and DVT can both lead to lymphatic destruction and secondary lymphoedema, especially if recurrent. Lymphoedema is an important contributor to the swelling of the

Figure 55.8 Elephantiasis due to filariasis.

post-phlebotic syndrome. It has also been suggested that lymphoedema can predispose to DVT, and possible SVT, through immobility and acute inflammatory episodes. Certainly, tests of venous function (duplex ultrasonography, plethysmography) are frequently abnormal in patients with lymphoedema.

It is not uncommon to see patients (usually women) with lymphoedema in whom a duplex ultrasound scan has revealed superficial reflux (such reflux is present subclinically in up to one-third of the adult population). Although isolated, superficial venous reflux rarely, if ever, leads to limb swelling; such patients are frequently misdiagnosed as having venous disease rather than lymphoedema, and are subjected mistakenly to varicose vein surgery. Not only will such surgery invariably fail to relieve the swelling, it will usually make it worse as saphenofemoral and saphenopopliteal ligation, together with saphenous stripping, will compromise still further drainage through the subcutaneous lymph bundles (which follow the major superficial veins) and draining inguinal and popliteal lymph nodes.

Miscellaneous conditions

Rheumatoid and psoriatic arthritis (chronic inflammation and lymph node fibrosis), contact dermatitis, snake and insect bites, and retroperitoneal fibrosis are all rare but well-documented causes of lymphoedema. Pretibial myxoedema is due to the obliteration of initial lymphatics by mucin.

Conditions mimicking lymphoedema

Factitious lymphoedema

This is caused by application of a tourniquet (a 'rut' and sharp cut-off is seen on examination) or 'hysterical' disuse in patients with psychological and psychiatric problems.

Immobility

Generalised or localised immobility of any cause leads to chronic limb swelling that can be misdiagnosed as lymphoedema, for example the elderly person who spends all day (and sometimes all night) sitting in a chair (armchair legs), the hemiplegic stroke patient and the young patient with multiple sclerosis.

Lipoedema

This presents almost exclusively in women and comprises bilateral, usually symmetrical, enlargement of the legs and, sometimes, the lower half of the body because of the abnormal deposition of fat. It may or may not be associated with generalised obesity. There are a number of features that help to differentiate the condition from lymphoedema but, of course, lipoedema may coexist with other causes of limb swelling. It has been proposed that lipoedema results from, or at least is associated with, fatty obliteration of lymphatics and lymph nodes (Summary box 55.5).

Summary box 55.5

Features of lipoedema that help differentiate it from lymphoedema

- Occurs almost exclusively in women
- Onset nearly always coincides with puberty
- Nearly always bilateral and symmetrical
- Involvement of trunk
- The feet are not involved, leading to an inverse shouldering effect at the malleoli
- No pitting
- No response to elevation or compression
- No skin changes of lymphoedema (negative Stemmer's sign)
- Magnetic resonance imaging shows subcutaneous fat but no fluid accumulation

INVESTIGATION OF LYMPHOEDEMA

Are investigations necessary?

It is usually possible to diagnose and manage lymphoedema purely on the basis of history and examination, especially when the swelling is mild and there are no apparent complicating features. In patients with severe, atypical and multifactorial swelling, investigations may help confirm the diagnosis, inform management and provide prognostic information.

'Routine' tests

These include a full blood count, urea and electrolytes, creatinine, liver function tests, thyroid function tests, plasma total protein and albumin, fasting glucose, urine dipstick including observation for chyluria, blood smear for microfilariae, chest radiograph and ultrasound.

Lymphangiography

Direct lymphangiography involves the injection of contrast medium into a peripheral lymphatic vessel and subsequent radiographic visualisation of the vessels and nodes. It remains the 'gold standard' for showing structural abnormalities of larger lymphatics and nodes (Fig. 55.9). However, it can be technically difficult, it is unpleasant for the patient, it may cause further lymphatic injury and, largely, it has become obsolete as a routine method of investigation. Few centres now perform this technique and those that do generally reserve it for preoperative evaluation of the rare patient with megalymphatics who is being considered for bypass or fistula ligation. Indirect lymphangiography involves the intradermal injection of water-soluble, non-ionic contrast into a web space, from where it is taken up by lymphatics and then followed radiographically. It will show distal lymphatics but not normally proximal lymphatics and nodes.

Isotope lymphoscintigraphy

This has largely replaced lymphangiography as the primary diagnostic technique in cases of clinical uncertainty. Radioactive technetium-labelled protein or colloid particles are injected into an interdigital web space and specifically taken up by lymphatics, and serial radiographs are taken with a gamma camera. The technique provides a qualitative measure of lymphatic function rather than quantitative function or anatomical detail. Quantitative lymphoscintigraphy is performed using a dynamic (exercise) component in addition to the static test and provides information on lymphatic transport.

Computerised tomography

A single, axial computerised tomography (CT) slice through the midcalf has been proposed as a useful diagnostic test for lymphoedema (coarse, non-enhancing, reticular 'honeycomb' pattern in an enlarged subcutaneous compartment), venous oedema (increased volume of the muscular compartment) and

lipoedema (increased subcutaneous fat). CT can also be used to exclude pelvic or abdominal mass lesions.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) can provide clear images of lymphatic channels and lymph nodes, and can be useful in the assessment of patients with lymphatic hyperplasia. MRI can also distinguish venous and lymphatic causes of a swollen limb, and detect tumours that may be causing lymphatic obstruction.

Ultrasound

Ultrasound can provide useful information about venous function including DVT and venous abnormalities.

Pathological examination

In cases in which malignancy is suspected, samples of lymph nodes may be obtained by fine-needle aspiration, needle core biopsy or surgical excision. Skin biopsy will confirm the diagnosis of lymphangiosarcoma.

MANAGEMENT OF LYMPHOEDEMA

Overview

The evaluation of the lymphoedema patient needs to be 'holistic' and their care delivered by a multiprofessional team comprising physical therapists, nurses, orthotists, physicians (dermatologists, oncologists, palliative care specialists), surgeons and social service professionals. Although surgery itself has a very small role, surgeons (especially those with breast and vascular interests) are frequently asked to oversee the management of these patients. Early diagnosis and institution of management are essential because at that stage relatively simple measures can be highly effective and will prevent the development of disabling late-stage disease, which is extremely difficult to treat. There is often a latent period of several years between the precipitating

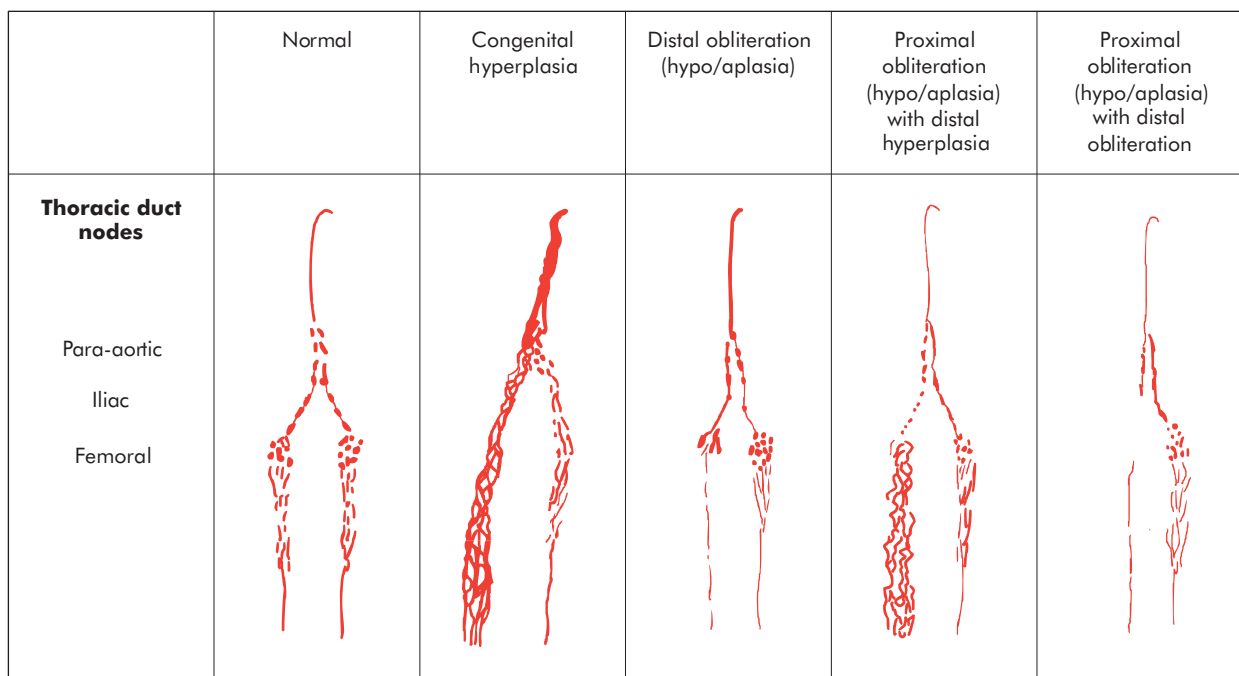

Figure 55.9 Lymphangiographic patterns of primary lymphoedema.

event and the onset of lymphoedema. The identification, education and treatment of such 'at-risk' patients can slow down, even prevent, the onset of disease. In patients with established lymphoedema, the three goals of treatment are to relieve pain, reduce swelling and prevent the development of complications (Summary box 55.6).

Summary box 55.6

Initial evaluation of the patient with lymphoedema

- History (age of onset, location, progression, exacerbating and relieving features)
- Past medical history including cancer history
- Family history
- Obesity (diet, height and weight, body mass index)
- Complications (venous, arterial, skin, joint, neurological, malignant)
- Assessment of physical, emotional and psychosocial symptoms
- Social circumstances (mobility, housing, education, work)
- Special needs (footwear, clothing, compression garments, pneumatic devices, mobility aids)
- Previous and current treatment
- Pain control
- Compliance with therapy and ability to self-care

Relief of pain

On initial presentation, 50% of patients with lymphoedema complain of significant pain. The pain is usually multifactorial and its severity and underlying cause(s) will vary depending on the aetiology of the lymphoedema. For example, following treatment for breast cancer, pain may arise from the swelling itself (radiation and surgery induced); nerve (brachial plexus and intercosto-brachial nerve), bone (secondary deposits, radiation necrosis) and joint (arthritis, bursitis, capsulitis) disease; and recurrent disease. Treatment involves the considered use of non-opioid and opioid analgesics, corticosteroids, tricyclic antidepressants, muscle relaxants, anti-epileptics, nerve blocks, physiotherapy and adjuvant anti-cancer therapies (chemo-, radio- and hormonal therapy), as well as measures to reduce swelling if possible. In patients with non-cancer-related lymphoedema, the best way to reduce pain is to control swelling and prevent the development of complications. Whatever the cause, pain is a somatopsychic experience that is affected by mood and morale. These issues are important in patients with both cancer-related lymphoedema, who are concerned about recurrent disease, and non-cancer-related disease, who often have poor self-esteem and problems with body image and perception.

Control of swelling

Physical therapy for lymphoedema comprising bed rest, elevation, bandaging, compression garments, massage and exercises was first described at the end of the nineteenth century, and through the twentieth century various eponymous schools developed. Although there is little doubt that physical therapy can be highly effective in reducing swelling, its general acceptance and practice has been hampered by a lack of proper research and confusing terminology. The current preferred term is decongestive lymphoedema therapy (DLT), which comprises two phases. The first is a short intensive period of therapist-led care and the second is a

maintenance phase in which the patient uses a self-care regimen with occasional professional intervention. The intensive phase comprises skin care, MLD and MLLB, and exercises. The length of intensive treatment will depend upon the disease severity, the degree of patient compliance and the willingness and ability of the patient to take more responsibility for the maintenance phase. However, weeks rather than months should be the goal.

Skin care

The patient must be carefully educated in the principles and practice of skin care. The patient should inspect the affected skin daily, with special attention paid to skinfolds, where maceration may occur. The limb should be washed daily; the use of bath oil (e.g. Balneum) is recommended as a moisturiser and the limb must be carefully dried afterwards. A hair drier on low heat is more effective and hygienic, and less traumatic, than a towel. If the skin is in good condition daily application of a bland emollient (e.g. aqueous cream) is recommended to keep the skin hydrated. If the skin is dry and flaky then a bland ointment [e.g. 50:50 white soft paraffin/liquid paraffin (WSP/LP)] should be used twice daily and, if there is marked hyperkeratosis, a keratolytic agent, such as 5% salicylic acid, should be added. Many commercially available soaps, creams and lotions contain sensitisers (e.g. lanolin in E45 cream) and are best avoided as patients with lymphoedema are highly susceptible to contact dermatitis (eczema). Apart from causing intense discomfort, eczema acts as an entry point for infection. Management comprises avoidance of the allergen (patch testing may be required) and topical corticosteroids. Fungal infections are common, difficult to eradicate and predispose to acute inflammatory episodes. Chronic application of anti-fungal creams leads to maceration and it is better to use powders in shoes and socks. Ointment containing 3% benzoic acid helps prevent athlete's foot and can be used safely over long periods. Painting at-risk areas with an antiseptic agent such as eosin may be helpful. Lymphorrhoea is uncommon but extremely troublesome. Management comprises emollients, elevation, compression and sometimes cautery under anaesthetic (Summary box 55.7).

Summary box 55.7

Skin care

- Protect hands when washing up or gardening; wear a thimble when sewing
- Never walk barefoot and wear protective footwear outside
- Use an electric razor to depilate
- Never let the skin become macerated
- Treat cuts and grazes promptly (wash, dry, apply antiseptic and a plaster)
- Use insect repellent sprays and treat bites promptly with antiseptics and anti-histamines
- Seek medical attention as soon as the limb becomes hot, painful or more swollen
- Do not allow blood to be taken from, or injections to be given into, an affected arm (and avoid blood pressure measurement)
- Protect the affected skin from sun (shade, high-factor sun block)
- Consider taking antibiotics if going on holiday

Apart from lymphangiosarcoma, acute inflammatory episodes are probably the most serious complications of lymphoedema and

frequently lead to emergency hospital admission. About 25% of primary and 5% of secondary lymphoedema patients are affected. Acute inflammatory episodes start rapidly, often without warning or a precipitating event, with tingling, pain and redness of the limb. Patients feel 'viral' and severe attacks can lead to the rapid onset of fever, rigors, headache, vomiting and delirium. Patients who have suffered previous attacks can usually predict the onset and many learn to carry antibiotics with them and self-medicate at the first hint of trouble. This may stave off a full-blown attack and prevent the further lymphatic injury that each acute inflammatory episode causes. It is rarely possible to isolate a responsible bacterium but the majority are presumed to be streptococcal and/or staphylococcal in origin. The diagnosis is usually obvious but dermatitis, thrombophlebitis and DVT are in the differential diagnosis. Benzyl (intravenous) or phenoxymethyl (oral) penicillin and flucloxacillin (or clindamycin in severe attacks) are the antibiotics of choice and should be given for 2 weeks. Rest will reduce lymphatic drainage and the spread of infection, elevation will reduce the oedema and heparin prophylaxis will reduce the risk of DVT. Co-amoxiclav can be taken by patients who self-medicate. The use of long-term prophylactic antibiotics is not evidence based, but is probably reasonable in patients who suffer frequent attacks. However, the benefits of scrupulous compliance with physical therapy and skin care cannot be underestimated.

Manual lymphatic drainage

Several different techniques of MLD have been described and the details are beyond the scope of this chapter. However, they all aim to evacuate fluid and protein from the ISF space, and stimulate lymphangion contraction. The therapist should perform MLD daily; they should also train the patient (and/or carer) to perform a simpler, modified form of massage termed simple lymphatic drainage (SLD). In the intensive phase, SLD supplements MLD and, once the maintenance phase is entered, SLD will carry on as daily massage.

Multilayer lymphoedema bandaging and compression garments

Elastic bandages provide compression, produce a sustained high resting pressure and 'follow in' as limb swelling reduces. However, the sub-bandage pressure does not alter greatly in response to changes in limb circumference consequent upon muscular activity and posture. By contrast, short-stretch bandages exert support through the production of a semi-rigid casing where the resting pressure is low but changes quite markedly in response to movement and posture.

It is generally believed that non-elastic MLLB is preferable (and arguably safer) in patients with severe swelling during the intensive phase of DLT, whereas compression (hosiery, sleeves) is preferable in milder cases and during the maintenance phase. Whether the aim is to provide support or compression, the pressure exerted must be graduated (100% ankle/foot, 70% knee, 50% mid-thigh, 40% groin) and, of course, the adequacy of the arterial circulation must be assessed. As it is rarely possible to feel pulses in the lymphoedematous limb, non-invasive assessment of the ankle-brachial pressure index (ABPI) using a hand-held Doppler ultrasound device is usually necessary. MLLB is highly skilled and to be effective and safe it needs to be applied by a

specially trained therapist. It is also extremely labour intensive, needing to be changed daily.

Compression garments form the mainstay of management in most clinics. The control of lymphoedema requires higher pressures (30–40 mmHg arm, 40–60 mmHg leg) than are typically used to treat CVI. Confusingly, the British (classes I: 14–17 mmHg; II: 17–24 mmHg; III: 24–35 mmHg) and international (European) (classes I: 20–30 mmHg; II: 30–40 mmHg; III: 40–50 mmHg; IV: 50–60 mmHg) standards are different. The patient should put the stocking on first thing in the morning before rising. It can be difficult to persuade patients to comply. Putting lymphoedema-grade stockings on and off is difficult and many patients find them intolerably uncomfortable, especially in warm climates. Furthermore, although intellectually they understand the benefits, emotionally they may find wearing them presents a greater body image problem than the swelling itself.

Enthusiasm for pneumatic compression devices has waxed and waned. Unless the device being used allows the sequential inflation of multiple chambers up to > 50 mmHg, it will probably be ineffective for lymphoedema. The benefits to the patient are maximised and complications are minimised if these devices are used under the direction of a physical therapist as part of an overall package of care.

Exercise

Lymph formation is directly proportional to arterial inflow and 40% of lymph is formed within skeletal muscle. Vigorous exercise, especially if it is anaerobic and isometric, will tend to exacerbate lymphoedema and patients should be advised to avoid prolonged static activities, for example carrying heavy shopping bags or prolonged standing. In contrast, slow, rhythmic, isotonic movements (e.g. swimming) and massage will increase venous and lymphatic return through the production of movement between skin and underlying tissues (essential to the filling of initial lymphatics) and augmentation of the muscle pumps. Exercise also helps to maintain joint mobility. Patients who are unable to move their limbs benefit from passive exercises. When at rest, the lymphoedematous limb should be positioned with the foot/hand above the level of the heart. A pillow under the mattress or blocks under the bottom of the bed will encourage the swelling to go down overnight.

Drugs

There are considerable, and scientifically inexplicable, differences in the use of specific drugs for venous disease and lymphoedema between different countries. The benzopyrones are a group of several thousand naturally occurring substances, of which the flavonoids have received the most attention. Enthusiasts will argue that a number of clinical trials have shown benefit from these compounds, which are purported to reduce capillary permeability, improve microcirculatory perfusion, stimulate interstitial macrophage proteolysis, reduce erythrocyte and platelet aggregation, scavenge free radicals and exert an anti-inflammatory effect. Detractors will argue that the trials are small and poorly controlled with short follow-up and 'soft' endpoints, and that any benefits observed can be explained by a placebo effect. In the UK, oxerutins (Paroven) are the only such drugs licensed for venous disease and none has a license for lymphoedema. Diuretics are of no value in pure lymphoedema. Their chronic use is associated with side-effects, including electrolyte disturbance, and should be avoided.

Surgery

Only a small minority of patients with lymphoedema benefit from surgery. Operations fall into two categories: bypass procedures and reduction procedures.

Bypass procedures

The rare patient with proximal ilioinguinal lymphatic obstruction and normal distal lymphatic channels might benefit, at least in theory, from lymphatic bypass. A number of methods have been described including the omental pedicle, the skin bridge (Gillies), anastomosing lymph nodes to veins (Neibulowitz) and the ileal mucosal patch (Kinmonth). More recently, direct lymphaticovenular anastomosis has been carried out on vessels of 0.5–0.8 mm diameter using supermicrosurgical techniques, with promising results. The procedures are technically demanding and not without morbidity, and there is no controlled evidence to suggest that these procedures produce a superior outcome to best medical management alone.

Limb reduction procedures

These are indicated when a limb is so swollen that it interferes with mobility and livelihood. These operations are not ‘cosmetic’ in the sense that they do not create a normally shaped leg and are usually associated with significant scarring. Four operations have been described.

Sistrunk

A wedge of skin and subcutaneous tissue is excised and the wound closed primarily. This is most commonly carried out to reduce the girth of the thigh.

Homans

First, skin flaps are elevated, and then subcutaneous tissue is excised from beneath the flaps, which are then trimmed to size to accommodate the reduced girth of the limb and closed primarily. This is the most satisfactory operation for the calf (Fig. 55.10). The main complication is skin flap necrosis. There must be at least 6 months between operations on the medial and lateral sides of the limb and the flaps must not pass the midline. This procedure has also been used on the upper limb, but is contraindicated in the presence of venous obstruction or active malignancy.

Thompson

One denuded skin flap is sutured to the deep fascia and buried beneath the second skin flap (the so called ‘buried dermal flap’) (Fig. 55.11). This procedure has become less popular as pilonidal sinus formation is common. The cosmetic result is no better than that obtained with the Homans’ procedure and there is no evidence that the buried flap establishes any new lymphatic connection with the deep tissues.

Figure 55.10 Homans’ procedure involves raising skin flaps to allow the excision of a wedge of skin and a larger volume of subcutaneous tissue down to the deep fascia. Surgery to the medial and lateral aspects of the leg must be separated by at least 6 months to avoid skin flap necrosis.

Figure 55.11 A cross-sectional representation of Thompson’s reduction operation; the buried dermal flap.

Charles

This operation was initially designed for filariasis and involved excision of all of the skin and subcutaneous tissues down to the deep fascia, with coverage using split-skin grafts (Fig. 55.12). This leaves a very unsatisfactory cosmetic result and graft failure is not

Figure 55.12 The Charles procedure involves circumferential excision of lymphoedematous tissue down to and including the deep fascia followed by split-skin grafting. This procedure gives a very poor cosmetic result but does allow the surgeon to remove very large amounts of tissue and is particularly useful in patients with severe skin changes.

uncommon. However, it does enable the surgeon to reduce greatly the girth of a massively swollen limb.

Chylous ascites and chylothorax

These are associated with megalymphatics. The diagnosis may be obvious if accompanied by lymphoedema and lymphangioma. However, some patients develop chylous ascites and/or chylothorax in isolation, in which case the diagnosis can be confirmed by aspiration and the identification of chylomicrons in the aspirate. Cytology for malignant cells should also be carried out. A CT scan may show enlarged lymph nodes and CT with guided

biopsy, laparoscopy or even laparotomy and biopsy may be necessary to exclude lymphoma or other malignancy. Lymphangiography may indicate the site of a lymphatic fistula that can be surgically ligated. Even if no localised lesion is identified, it may be possible to control leakage at laparotomy or even remove a segment of affected bowel. If the problem is too diffuse to be corrected surgically, a peritoneal venous shunt may be inserted, although occlusion and infection are important complications. Medical treatment comprising the avoidance of fat in the diet and the prescription of medium-chain triglycerides (which are absorbed directly into the blood rather than via the lymphatics) may reduce swelling. Chylothorax is best treated by pleurodesis, but this may lead to death from lymph-logged lungs as the excess lymph has nowhere to drain.

Chyluria

Filariasis is the most common cause, with chyluria occurring in 1–2% of cases 10–20 years after initial infestation. It usually presents as painless passage of milky white urine, particularly after a fatty meal. The chyle may clot, leading to renal colic, and hypoproteinaemia may result. Chyluria may also be caused by ascariasis, malaria, tumour and tuberculosis. Intravenous urography and/or lymphangiography will often demonstrate the lymphourinary fistula. Treatment includes a low-fat and high-protein diet, increased oral fluids to prevent clot colic, and laparotomy and ligation of the dilated lymphatics. Attempts have also been made to sclerose the lymphatics either directly or via instrumentation of the bladder, ureter and renal pelvis.

Abdominal

This page intentionally left blank

History and examination of the abdomen

LEARNING OBJECTIVES

To understand:

- The importance of history-taking and abdominal examination in the overall assessment of the surgical patient
- The significance of a structured format for history-taking
- The mechanisms behind both the symptoms produced by abdominal conditions and the signs elicited from abdominal examination, in order to explain the underlying diagnosis

INTRODUCTION

An accurate history combined with a detailed and full examination is the mainstay of all good clinical assessment in surgery (as in all areas of medicine). In the case of the acute abdomen, this becomes even more important as time for reflection and review is limited and appropriate investigations may need to be organised quickly, along with any management decision for urgent surgery. Furthermore, although advanced imaging techniques, both static and dynamic, are now commonplace, providing very detailed information of diseased organs, a good understanding of the background clinical information is still required for accurate interpretation.

The importance of a good history and examination in the assessment of the acute abdomen was demonstrated in the 1970s by the late Tim de Dombal from Leeds and Tony Gunn from Scotland. Both authors developed and then examined the role of computer-aided diagnosis (CAD) systems in the assessment of acute abdominal pain. A detailed proforma of the patient's history and examination findings needed to be completed by the assessing clinician and entered into a computer, which then produced a list of the most probable diagnoses based on Bayesian reasoning. Repeated studies throughout the UK demonstrated an overall improvement in diagnostic accuracy of around 20% when CAD was used. Further studies subsequently showed that the diagnostic accuracy of medical students (assumed to be the most ignorant in the surgical assessment hierarchy!) using CAD was the same as that of hospital doctors when only the proforma was used (to collect the clinical details), which was not significantly different from clinicians using CAD. In other words,

the improvement in diagnostic accuracy, seen across the board, was related more to using the proforma, or structured data sheets, than to actually using the computer program, emphasising the importance of taking a good history and carrying out a thorough examination.

This chapter will therefore focus on the history-taking and examination requirements for the assessment of patients with both elective and emergency abdominal problems. It will not go into detailed pathological features of the various systems, as these are covered in their respective chapters, but will simply provide the reader with a template on which to base good clinical assessment (Summary box 56.1).

Summary box 56.1

The history

- The single most important factor in obtaining a reliable diagnosis from the history is its comprehensiveness
- History is also important in determining fitness for surgery
- Previous surgery needs careful documentation as it affects the safety of laparoscopic procedures
- If a comprehensive suite of investigations is not available, the history becomes even more important

HISTORY-TAKING

Basic structure

As in all areas of medical history-taking, the basic structure of *presenting complaint*, *history of presenting complaint* and *associated features* is an appropriate start to taking an abdominal surgical history. This is then followed by a review of the *past medical history* and the *systems*. For the former, details of previous operations are important, not just for reaching a diagnosis, but also in the influence these might have on any further operations required and whether a laparoscopic approach might be made

Francis Timothy de Dombal, 1937–1995, Professor of Information Science, The University of Leeds, Leeds, England.

Alexander Anton Gunn, Surgeon, Bangour Village Hospital, Broxburn, West Lothian, Scotland.

Thomas Bayes, 1702–1761, English Presbyterian Minister and Mathematician who published 'Essay towards solving a problem in the doctrine of chances' in 1763.

more difficult or hazardous. When writing up a systems review, it is probably best to put into the *history of present complaint* and *associated features* section the information you have gathered in the system where the problem lies. For example, when taking the *history of the presenting complaint* in a patient complaining of dyspepsia, the questions associated with the *upper gastrointestinal system* should be asked at this point (dysphagia, early satiety, reflux, vomiting, etc). Thereafter, the standard history-taking format (Summary box 56.2) should take place covering all the usual areas of *drug allergies, family and social histories*. The importance of covering all areas of history-taking cannot be overemphasised for the surgeon. It is only by doing this that a complete picture of the patient's overall 'medical condition' can be appreciated and therefore contribute, not only to the differential diagnosis, but also to the assessment of their fitness for any possible surgery (Summary box 56.2).

Summary box 56.2

Format for surgical history-taking

- Presenting complaint
- History of presenting complaint
- Associated features (including systemic review of the relevant system, e.g. gastrointestinal, urological, etc.)
- Past medical and surgical history
- Systems review
- Drug/allergy history
- Family history
- Social history

History-taking in the presence of the acute abdomen, which is almost synonymous with 'acute abdominal pain', takes on an even greater importance. As already mentioned, time may be of the essence and, depending on where the patient is in the world, access to advanced investigative techniques may be limited at best, or completely unavailable at worst.

Abdominal pain

The complaint of abdominal pain is probably one of the more common surgical complaints of patients attending both an outpatient clinic and also as an emergency at hospital. The assessment of abdominal pain will be discussed as for 'acute abdominal pain', but the underlying history-taking and examination should be the same for both the 'elective' and the 'emergency' patient.

All the organs contained in the abdomen, pelvis and retroperitoneum can be the cause of abdominal pain. However, one must not forget that acute abdominal pain can also be caused by some acute medical problems (porphyria, diabetic ketoacidosis, etc.) in addition to both acute cardiac and pulmonary disorders (Summary box 56.3).

Summary box 56.3

Medical causes of abdominal pain

- Diabetic ketoacidosis
- Porphyria
- Pain arising from the heart or lungs

Understanding the mechanism behind the distribution of pain fibres within the abdomen and retroperitoneum helps to explain the clinical symptoms and signs of the acute abdomen. The parietal peritoneum lines the abdominal wall, and the visceral peritoneum invests the viscera. The parietal peritoneum is innervated by the relevant somatic nerves through spinal nerves in the distribution of the overlying dermatomes: the xiphisternum at the level of T4, the umbilicus at T8 and the inguinal ligament at T12. Pain is sharply localised to the point of inflammation of the parietal peritoneum. For example, an acutely inflamed sigmoid colon from diverticulitis causes irritation to the overlying parietal peritoneum, and pain is then localised to the left iliac fossa.

The viscera and visceral peritoneum is innervated by the autonomic nervous system with pain travelling back to the spinal cord along sympathetic fibres. However, the pain is localised or referred to the equivalent somatic distribution of that nerve root (from T1 to L2) (Fig. 56.1). This pain is therefore deep, poorly localised and usually associated with sympathetic symptoms such as sweating and nausea. The gastrointestinal tract is divided embryologically into the foregut, midgut and hindgut, each arising with its own blood and nerve supply. Pain from the foregut is localised to the epigastrium, from the midgut to the peri-umbilical region and from the hindgut to the lower abdomen (Table 56.1). As a result, early inflammation of a mobile part of the viscera, such as the appendix/small bowel, which does not result in parietal peritoneal inflammation, produces referred pain in the peri-umbilical pain region. As the inflammation reaches the parietal peritoneum, the pain localises to that dermatome, as supplied by the somatic nerve supply. In the case of the appendix, this will obviously be the right iliac fossa. Another example of referred pain occurs when the diaphragm is irritated. As the nerve supply comes from the phrenic nerve (C3, 4, 5), the pain is localised to those dermatomes supplied by the equivalent somatic nerves, and pain may be felt in the region of the shoulder (Summary box 56.4).

	Appendix
Hindgut	Left colon
	Sigmoid colon
	Rectum

Summary box 56.4**Origins and presentation of abdominal pain**

Source	Presentation
Parietal peritoneum	Well localised but can radiate forwards and backwards along the dermatome
Visceral peritoneum	Poorly localised; associated with sweating and nausea
Retroperitoneal structures	Pain in the back

The nature of the pain will change as the cause evolves

Pain due to parietal peritoneal inflammation may also radiate back or forwards along the line supplied by the somatic nerve, as is seen in acute cholecystitis, when pain spreads from the right subcostal region around to the back.

Inflammation of the retroperitoneal structures, such as the pancreas and kidney, causes irritation of the somatic spinal nerves, producing back pain. Similarly, an inflamed retrocaecal appendix will irritate the ilio-psoas muscle, producing pain in the right loin at times, especially when the psoas muscle is stretched.

Of course, most causes of abdominal pain will incorporate both visceral and parietal pain, producing a picture that changes as the inflammation increases and spreads. This evolving picture may be picked up within the history-taking process or subsequently by regular and repeated review of the patient. Pain from small bowel obstruction will usually be central and colicky in nature but, as the obstructed loop becomes ischaemic and starts to inflame the overlying peritoneum, the pain will become continuous, more widespread and be associated with signs of 'peritonitis' (see below).

The history of abdominal pain associated with specific disorders

Inflammation and infection

Common intra-abdominal inflammatory conditions include acute appendicitis, acute cholecystitis, acute diverticulitis, acute

**Figure 56.2** Time/intensity graph for the pain of inflammation.

pancreatitis, acute salpingitis (pelvic inflammatory disease) and mesenteric adenitis. The pain is initially often very non-specific, gradually increasing in intensity over a period of several hours or even days (Summary box 56.5; Fig. 56.2).

Summary box 56.5**Sources of pain that evolve over hours or days**

- Acute Appendicitis
- Cholecystitis
- Salpingitis
- Mesenteric adenitis
- Infarction
- Free blood in the peritoneum

Other conditions that cause abdominal pain through this mechanism include infarction (which may initially present as obstruction, see below) and haemorrhage, where the intraperitoneal blood irritates the parietal peritoneum.

Perforation

Perforation of an abdominal viscus usually results in the sudden onset of severe abdominal pain (Fig. 56.3). Identifying the viscus in question may be determined by a history of preceding abdominal symptoms or illness, such as constipation or peptic ulcer disease. In the early stages, the site of maximum tenderness may also indicate the organ that has perforated (upper or lower abdomen), but generalised peritonitis usually follows very quickly as the intra-abdominal structures have not had time to 'wall off' the diseased organ, as often occurs in 'inflammatory' conditions. The most common organs that perforate (excluding the appendix) are the stomach and duodenum (from peptic ulcer disease) and the colon (from diverticular disease or severe constipation).

**Figure 56.3** Time/intensity graph for the pain of perforation.

Of course, the endpoint of many of the conditions that produce visceral inflammation is perforation but, generally, these patients present with symptoms of the underlying disease first, rather than the short severe presentation associated with a sudden perforation (Summary box 56.6).

Summary box 56.6

Causes of sudden onset abdominal pain

■ Perforation	Appendix Stomach Duodenum Colon
---------------	--

Obstruction

Obstruction of any hollow viscus within the abdominal cavity usually causes acute abdominal pain. Obstruction of all viscera except the gall bladder tends to produce colicky pain (Fig. 56.4), while obstruction of the gall bladder (inaccurately termed 'biliary colic') usually presents with a more acute continuous type of pain, often punctuated by acute exacerbations, and is similar to that of inflammation, but may have a slightly quicker onset. Colicky pain classically resolves between short-lived episodes, and it is only when underlying inflammation or infection sets in that a more continuous background element to the pain is introduced. This can of course represent the development of a serious complication (such as ischaemia of the bowel) and, therefore, its recognition by the emergency surgeon is crucial to prompt treatment.

Specific characteristics of 'abdominal pain'

The site, onset, character and duration of the abdominal pain provide important pointers to the diagnosis. Radiation of the pain, progression or alteration of its site or character, factors that aggravate the pain or relieve it and any associated symptoms are also helpful in refining the diagnosis. The site of the abdominal pain is usually related to one of nine areas (Fig. 56.5). These regions are demarcated by the mid-clavicular lines in the vertical axis and by the transpyloric and transtuberular lines in the horizontal axis. Figure 56.5 also indicates some of the common organs and pathological processes that commonly cause pain experienced in these regions.

Obtaining information on aggravating or relieving factors can be particularly helpful to the assessing surgeon. Pain made worse by moving and coughing suggests peritoneal inflammation

Figure 56.4 Time/intensity graph for the pain of obstruction.

'peritonism', whereas pain which makes the patient roll around or double up is typical of 'colic' (Summary box 56.7).

Summary box 56.7

Aggravating features of pain

Aggravating feature	Interpretation
Moving or coughing	Peritoneal inflammation
Patient rolls around with pain	Colic (suggests obstruction of viscus)

Factors that aggravate or relieve pain are also important in making a diagnosis, and information on the influence of movement, injury, position, food, antacids, vomiting, bowel action and micturition on the pain must always be sought. A history of previous trauma, however minor, may also be important. At the same time, it is important to ask about associated symptoms such as vomiting, diarrhoea, dysuria or a missed period that preceded or followed the onset of the pain as these may again provide important diagnostic clues.

As mentioned earlier, true colic is a gripping pain of sudden onset, which rapidly reaches a crescendo before equally swiftly

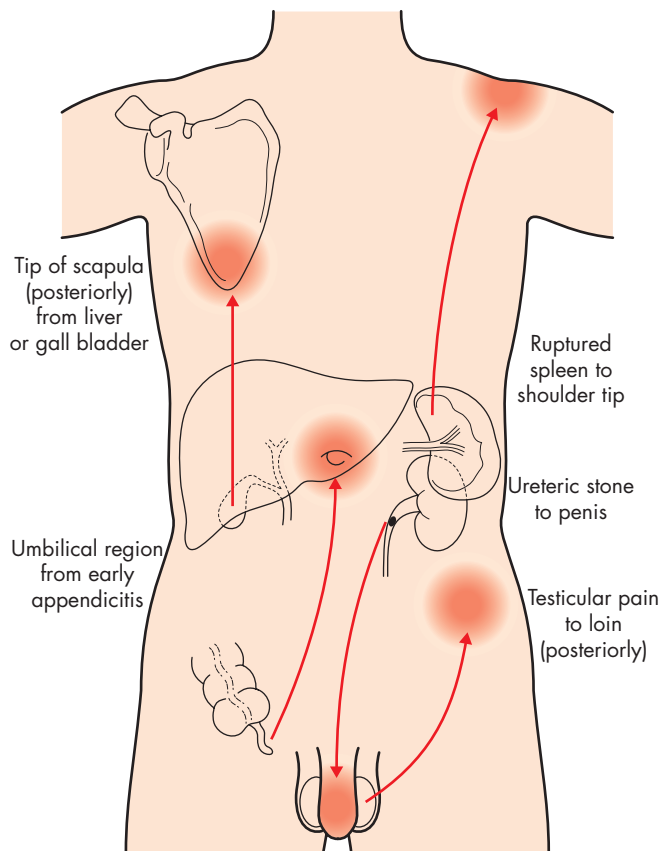

Figure 56.6 Common sites of radiation of abdominal pain.

dying away, usually completely. This description is true of intestinal and renal colic, but biliary colic is a misnomer (see above) as patients tend to complain of a continuous pain with exacerbations of severe pain. As already mentioned, strangulation should be suspected when intestinal colic alters to become a continuous pain.

Other common adjectives for abdominal pains include stabbing, wrenching, boring, burning and crushing, and these should all be taken into account with the other symptoms when trying to reach a diagnosis. Specific areas of radiation are characteristic of certain causes of abdominal pain and help to reach a diagnosis. Some of the classical sites of radiation are shown in Figure 56.6.

Identification of the 'best questions' to ask is obviously important and, in his studies on acute abdominal pain, de Dombal revealed not only how important enquiry into factors aggravating the pain was, but also that this simple question was omitted in half the patients being questioned in a single hospital.

Other surgical symptoms

Although each is important in its own right, the other symptoms that cause a patient to be referred for surgical assessment, in either the elective or the emergency setting, do not present the complex pictures associated with 'abdominal pain' and can therefore be pooled together for the purposes of this chapter. Clearly, the individual chapters in this textbook will focus on the individual symptoms that are important to diseases of that organ. Common symptoms are:

- 1 abdominal distension/bloating;
- 2 nausea/vomiting;

- 3 haematemesis/melaena;
- 4 abdominal lumps/masses (including groin and scrotal lumps);
- 5 jaundice;
- 6 weight loss/cachexia;
- 7 altered bowel habit and bleeding/mucous per rectum.

EXAMINATION

After taking a detailed history, the patient should be carefully examined. An abdominal examination must always be part of a 'general' examination, but must specifically include the general appearance of the patient, including cachexia, anaemia, pallor, cyanosis, jaundice, dehydration, fetor and pyrexia. In the acute setting, a rapid (and/or irregular) pulse and low blood pressure may be important.

The neck and chest should be examined next, looking especially for lymphadenopathy, breast tumours and signs of pulmonary disease, while examination of the cardiovascular system may reveal evidence of cardiac failure, valve disorders or peripheral vascular disease.

The abdominal examination is made easier by the preceding history, which should have alerted the clinician to the possible underlying differential diagnoses. However, the opportunity to identify additional findings, which might either confirm or refute these diagnoses, must not be missed by a less than thorough examination. In the assessment of the patient with acute abdominal pain, several good studies have demonstrated that examination, along with the patient's distress, is facilitated by early administration of adequate analgesia. The old adage that analgesia should be withheld until a patient with acute abdominal pain has been assessed by the surgeon should be banished from every surgical textbook (Summary box 56.8).

Summary box 56.8

Abdominal examination (inspection)

- Analgesia should not be withheld
- Observe the abdomen before palpation
- Make a careful check for scars

Inspection

The swellings caused by enlargements of the liver, spleen, kidneys and bladder or tumours of the bowel or ovary and other intra-abdominal or retroperitoneal structures may all be visible on careful inspection. The expansile pulsation of an abdominal aneurysm may also be seen. All abdominal scars must be noted (and subsequently tested for an incisional hernia). Distension, which is usually caused by ascites, intestinal obstruction or a large intra-abdominal tumour, might also be apparent. A careful inspection may also reveal skin eruptions (such as those caused by herpes zoster), distended veins from portal hypertension (or occlusion of the inferior vena cava) and visible peristalsis. The hernial orifices must be specifically inspected (and then examined) along with the male genitalia, looking especially for tenderness and masses within the scrotum.

Palpation

Palpation of the abdomen should not be carried out until full inspection has been completed. An initial *superficial* examination

might reveal specific sites of a mass or maximum tenderness, which can then be further evaluated by deeper palpation, if appropriate (in the case of pain) (Summary box 56.9).

Summary box 56.9

Abdominal examination (palpation)

- Check for pain first with superficial palpation
- Masses can be localised by checking for mobility (while patient lifts legs)
- Rebound tenderness suggests peritoneal inflammation
- Board-like rigidity suggests generalised peritonitis

Abdominal masses

A mass arising within the anterior abdominal wall will usually be mobile with the patient relaxed. On contracting the abdominal wall muscles (such as by lifting the legs in the straight position), lumps superficial to the abdominal wall muscles will become more obvious, those attached to the deep fascia will become less mobile, whereas those arising within the muscle layer will become fixed and less obvious. Lumps arising deep to the abdominal wall (i.e. within the peritoneal cavity or retroperitoneum) will usually become impalpable on tensing the anterior abdominal wall muscles. Intraperitoneal lumps will usually have some degree of mobility, even if only movement on respiration (i.e. liver and spleen), depending on which organs are involved. Retroperitoneal masses are usually fixed, although an enlarged kidney may be 'ballotable'.

Guarding and rebound tenderness

In the presence of abdominal pain, the degree of abdominal wall rigidity and involuntary guarding should be assessed. *Guarding* represents contraction of the abdominal wall muscles over the area of pain. This might occur 'voluntarily' when the patient wishes to avoid the pain from examination, or 'involuntarily' when the muscles go into spasm as the inflamed viscus touches the parietal peritoneum, resulting in a reflex spasm contracting the overlying abdominal wall muscles. The presence of *rebound* tenderness indicates underlying peritoneal inflammation and is best examined using percussion, although pain on coughing is also indicative of rebound tenderness. When the underlying peritoneal inflammation becomes generalised, the abdomen becomes 'board-like' to palpation, and selective tenderness can no longer be elicited. This sign represents widespread *involuntary guarding*. Specific pain due to *abdominal wall tenderness* is apparent as an increase in pain at the point of maximal abdominal tenderness when the abdominal muscles are contracted.

Ascites

The presence of fluid within the peritoneal cavity may be suspected from clinical examination, but will usually require confirmation by either ultrasonography or computerised tomography (CT). Percussion of the abdomen in a patient with significant ascites will reveal dull flanks and a resonant central area, where the bowels 'float' on the underlying fluid. If the patient is asked to turn onto their side, the area of dullness will move downwards over their abdominal wall, while the area of resonance will 'float' to the flank of the side facing upwards (Summary box 56.10).

Summary box 56.10

Ascites

- Produces distension and dullness to percussion in the flanks
- The dullness 'shifts' as the patient is rolled onto their side

Pelvic examination

In the assessment of a patient with any gastrointestinal symptoms, a rectal examination is required and, if there is suspicion of underlying anorectal disease, this should be followed by a proctoscopy and sigmoidoscopy. A stool sample for occult blood should also be obtained where possible. However, the role of the rectal examination in assessment of the acute abdomen has changed over the last decade following a large study from Edinburgh, which demonstrated that, in patients with right iliac fossa pain (i.e. suspected appendicitis), no further additional information was obtained if rebound tenderness had already been demonstrated. However, when a gynaecological diagnosis is suspected, or needs to be excluded, a gentle pelvic examination should be carried out (Summary box 56.11).

Summary box 56.11

Pelvic examination

- Palpation for tenderness
- Rectal examination for tenderness and blood
- Proctoscopy for haemorrhoids, fissure and anal tumour
- Sigmoidoscopy for rectal tumours, inflammation and ulceration

Auscultation

Listening to the noises emanating from within the abdominal cavity requires experience, and interpretation is highly subjective. However, additional useful information can be obtained in relation to the characteristic bowel sounds produced by intestinal obstruction (gurgling and high pitched) and the total absence of bowel sounds found in patients with a severe generalised peritonitis or a postoperative paralytic ileus. Abdominal bruits associated with underlying vascular disease may also be detected (Summary box 56.12).

Summary box 56.12

Source of change in bowel sounds

- Gurgling and high pitched = Obstruction
- Absent = Peritonitis or ileus
- Bruits = Vascular

Specific signs

There are a number of specific 'named' signs that are still used to describe specific abdominal conditions, and these are described in Table 56.2.

OBSERVATION AND REVIEW

In the case of acute abdominal pain, there is a group of patients in whom, after full clinical assessment, the admitting surgeon

Table 56.2 Specific signs in abdominal examination

Sign	Description	Pathology
Courvoisier	Palpable gall bladder and jaundice	Carcinoma of the head of the pancreas
Cullen	Peri-umbilical bruising	Haemorrhagic pancreatitis or ectopic pregnancy
Grey Turner	Bruising of flank	Haemorrhagic pancreatitis
Rovsing	Pain on extension of the hip joint (due to psoas irritation)	Retrocaecal appendicitis
Murphy	Right upper quadrant tenderness exacerbated by inspiration	Acute cholecystitis
Virchow	Palpable left supraclavicular fossa lymph node	Oesophagogastric carcinoma

considers that the need for an urgent operation is uncertain. This is probably the most difficult group to deal with compared with those in whom an urgent operation is either clearly required, or clearly not required, and undoubtedly the one in which the majority of errors occur. Further expeditious investigations are obviously essential in this group and are discussed in some detail elsewhere in this book. However, while these are taking place, a

period of observation with regular review is essential, and the benefits have been clearly reported on several occasions by surgeons from Aberdeen. This has now become an integral part of the early management of patients with acute abdominal pain and has been further highlighted by a recent prospective trial of CT in the investigation of abdominal pain. In this study, the presumed diagnosis was recorded on admission and at 24 hours, with a further review at 6 months. Only 50% of diagnoses on admission were correct at 6-month follow-up, but 76% of the diagnoses at 24 hours were correct. This included patients in the CT arm and the standard treatment arm.

Hernias, umbilicus and abdominal wall

CHAPTER 57

LEARNING OBJECTIVES

To know and understand:

- That hernias can strangulate and then become surgical emergencies
- That femoral hernias are especially susceptible to strangulation
- The anatomy of the common hernias
- The common surgical approaches to hernias

HERNIA

No disease of the human body, belonging to the province of the surgeon, requires in its treatment a better combination of accurate anatomical knowledge with surgical skill than Hernia in all its varieties.

Sir Astley Paston Cooper (1804)

A hernia is a protrusion of a viscus or part of a viscus through an abnormal opening in the walls of its containing cavity. The external abdominal hernia is the most common form, the most frequent varieties being the inguinal, femoral and umbilical, accounting for 75% of cases (Fig. 57.1). The rarer forms constitute 1.5%, excluding incisional hernias.

General features common to all hernias

Aetiology

Any condition that raises intra-abdominal pressure, such as a powerful muscular effort, may produce a hernia. Whooping

cough is a predisposing cause in childhood, whereas a chronic cough, straining on micturition or straining on defaecation may precipitate a hernia in an adult. Hernias are more common in smokers, which may be the result of an acquired collagen deficiency increasing an individual's susceptibility to the development of hernias. It should be remembered that the appearance of a hernia in an adult can be a sign of intra-abdominal malignancy. Stretching of the abdominal musculature because of an increase in contents, as in obesity, can be another factor. Fat acts to separate muscle bundles and layers, weakens aponeuroses and favours the appearance of paraumbilical, direct inguinal and hiatus hernias. A femoral hernia is rare in men and nulliparous women but more common in multiparous women due to stretching of the pelvic ligaments. An indirect hernia may occur in a congenital preformed sac – the remains of the processus vaginalis.

Peritoneal dialysis can cause the development of a hernia from a previously occult weakness or enlargement of a patent processus vaginalis (Summary box 57.1).

Figure 57.1 External hernias. Red = common; white = not unusual; black = rare.

Sir Astley Paston Cooper, 1768–1841, Surgeon, Guy's Hospital, London, England.

Summary box 57.1

Causes of hernias

- Coughing
- Straining
- Obesity
- Intra-abdominal malignancy

Composition of a hernia

As a rule, a hernia consists of three parts – the sac, the coverings of the sac and the contents of the sac.

The sac

The sac is a diverticulum of peritoneum, consisting of mouth, neck, body and fundus. The neck is usually well defined but in some direct inguinal hernias and in many incisional hernias there is no actual neck. The diameter of the neck is important because strangulation of bowel is a likely complication when the neck is narrow, as in femoral and paraumbilical hernias.

The body of the sac varies greatly in size and is not necessarily occupied. In cases occurring in infancy and childhood, the sac is gossamer thin. In longstanding cases the wall of the sac may be comparatively thick.

The covering

Coverings are derived from the layers of the abdominal wall through which the sac passes. In longstanding cases they become atrophied from stretching and so amalgamated that they are indistinguishable from each other.

Contents

These can be:

- omentum = omentocele (synonym: epiplocele);
- intestine = enterocele; more commonly small bowel but may be large intestine or appendix;
- a portion of the circumference of the intestine = Richter's hernia;
- a portion of the bladder (or a diverticulum) may constitute part of or be the sole content of a direct inguinal, a sliding inguinal or a femoral hernia;
- ovary with or without the corresponding fallopian tube;
- a Meckel's diverticulum = a Littre's hernia;
- fluid, as part of ascites or as a residuum thereof.

Classification

Irrespective of site, a hernia can be classified into five different types (Summary box 57.2).

August Gottlieb Richter, 1742–1812, Lecturer in Surgery, Göttingen, Germany described this form of hernia in 1777.
 Gabriele Falloppio, (Fallopius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy.
 Johann Friedrich Meckel, (The Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.
 Alexis Littre, 1658–1726, Surgeon and Lecturer in Anatomy, Paris, France, described 'Meckel's Diverticulum' in a hernial sac in 1700, 81 years before Meckel was born.

Summary box 57.2

Types of hernia

- Reducible – contents can be returned to abdomen
- Irreducible – contents cannot be returned but there are no other complications
- Obstructed – bowel in the hernia has good blood supply but bowel is obstructed
- Strangulated – blood supply of bowel is obstructed
- Inflamed – contents of sac have become inflamed

Reducible hernias

The hernia either reduces itself when the patient lies down or can be reduced by the patient or the surgeon. The intestine usually gurgles on reduction and the first portion is more difficult to reduce than the last. Omentum, in contrast, is described as doughy and the last portion is more difficult to reduce than the first. A reducible hernia imparts an expansile impulse on coughing.

Irreducible hernia

In this case the contents cannot be returned to the abdomen but there is no evidence of other complications. It is usually due to adhesions between the sac and its contents or overcrowding within the sac. Irreducibility without other symptoms is almost diagnostic of an omentocele, especially in femoral and umbilical hernias. Note that any degree of irreducibility predisposes to strangulation.

Obstructed hernia

This is an irreducible hernia containing intestine that is obstructed from without or within, but there is no interference to the blood supply to the bowel. The symptoms (colicky abdominal pain and tenderness over the hernia site) are less severe and the onset more gradual than in strangulated hernias, but more often than not the obstruction culminates in strangulation. Usually there is no clear distinction clinically between obstruction and strangulation and the safe course is to assume that strangulation is imminent and treat accordingly.

Incarcerated hernia

The term 'incarceration' is often used loosely as an alternative to obstruction or strangulation but is correctly employed only when it is considered that the lumen of that portion of the colon occupying a hernial sac is blocked with faeces. In this case, the scybalous contents of the bowel should be capable of being indented with the finger, like putty.

Strangulated hernia

A hernia becomes strangulated when the blood supply of its contents is seriously impaired, rendering the contents ischaemic. Gangrene may occur as early as 5–6 hours after the onset of the first symptoms. Although inguinal hernia may be 10 times more common than femoral hernia, a femoral hernia is more likely to strangulate because of the narrowness of the neck and its rigid surrounds (Summary box 57.3).

Summary box 57.3

Natural history of hernias

- Irreducible hernias – there is a risk of strangulation at any time
- Obstructed hernias – usually go on to strangulation
- Strangulated hernias – gangrene can occur within 6 hours

Pathology

The intestine is obstructed and its blood supply impaired. Initially, only the venous return is impeded; the wall of the intestine becomes congested and bright red with the transudation of serous fluid into the sac. As congestion increases the wall of the intestine becomes purple in colour. The intestinal pressure increases, distending the intestinal loop and impairing venous return further. As venous stasis increases, the arterial supply becomes more and more impaired. Blood is extravasated under the serosa and is effused into the lumen. The fluid in the sac becomes blood-stained and the shining serosa dull because of a fibrinous, sticky exudate. At this stage the walls of the intestine have lost their tone and become friable. Bacterial transudation occurs secondary to the lowered intestinal viability and the sac fluid becomes infected. Gangrene appears at the rings of constriction (Fig. 57.2), which become deeply indented and grey in colour. The gangrene then develops in the anti-mesenteric border, the colour varying from black to green depending on the decomposition of blood in the subserosa. The mesentery involved by the strangulation also becomes gangrenous. If the strangulation is unrelieved, perforation of the wall of the intestine occurs, either at the convexity of the loop or at the seat of constriction. Peritonitis spreads from the sac to the peritoneal cavity.

Clinical features

Sudden pain, at first situated over the hernia, is followed by generalised abdominal pain, colicky in character and often located mainly at the umbilicus. Nausea and subsequently vomiting ensue. The patient may complain of an increase in hernia size. On examination the hernia is tense, extremely tender and irreducible, and there is no expansile cough impulse.

Unless the strangulation is relieved by operation, the spasms of pain continue until peristaltic contractions cease with the onset of ischaemia, when paralytic ileus (often the result of peritonitis) and septicaemia develop. Spontaneous cessation of pain must be viewed with caution, as this may be a sign of perforation (Summary box 57.4).

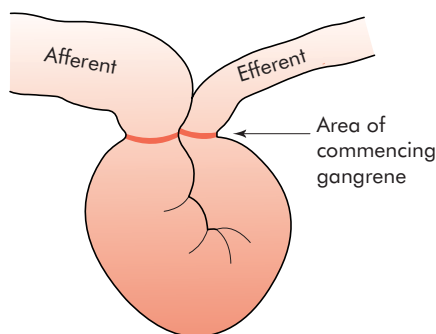

Figure 57.2 Gangrene commences at the areas of constriction and then at the anti-mesenteric border.

Summary box 57.4

Strangulated hernias

- Present with local then general abdominal pain and vomiting
- A normal hernia can strangulate at any time
- Most common in hernias with narrow necks such as femoral hernias
- Require urgent surgery

Richter's hernia

Richter's hernia is a hernia in which the sac contains only a portion of the circumference of the intestine (usually small intestine). It usually complicates femoral and, rarely, obturator hernias.

Strangulated Richter's hernia

Strangulated Richter's hernia (Fig. 57.3) is particularly noteworthy as operation is frequently delayed because the clinical features mimic gastroenteritis. The local signs of strangulation are often not obvious, the patient may not vomit and, although colicky pain is present, the bowels are often opened normally or there may be diarrhoea; absolute constipation is delayed until paralytic ileus supervenes. For these reasons, gangrene of the knuckle of bowel and perforation have often occurred before operation is undertaken.

Strangulated omentocele

The initial symptoms are in general similar to those of strangulated bowel. Vomiting and constipation may be absent as omentum, unlike intestine, can exist on a very meagre blood supply. The onset of gangrene is therefore delayed, occurring first in the centre of the fatty mass. Unrelieved, a bacterial invasion of the ischaemic contents of the sac will occur and an abscess eventually develops. In an inguinal hernia, infection usually terminates as a scrotal abscess, but extension from the sac to the general peritoneal cavity is always a possibility.

Inflamed hernia

Inflammation can occur from inflammation of the contents of the sac, e.g. acute appendicitis or salpingitis, or from external causes, e.g. the trophic ulcers that develop in the dependent areas of large umbilical or incisional hernias. The hernia is usually tender but not tense and the overlying skin red and oedematous. Treatment is based on treatment of the underlying cause.

Figure 57.3 Diagrammatic representation of gangrenous Richter's hernia from a case of strangulated femoral hernia.

Inguinal hernia

Surgical anatomy

The *superficial inguinal ring* is a triangular aperture in the aponeurosis of the external oblique muscle and lies 1.25 cm above the pubic tubercle. The ring is bounded by a superomedial and an inferolateral crus joined by the criss-crossed intercrural fibres. Normally the ring will not admit the tip of the little finger.

The *deep inguinal ring* is a U-shaped condensation of the transversalis fascia and it lies 1.25 cm above the inguinal (Poupart's) ligament, midway between the symphysis pubis and the anterior superior iliac spine. The transversalis fascia is the fascial envelope of the abdomen and the competency of the deep inguinal ring depends on the integrity of this fascia.

The inguinal canal

In infants, the superficial and deep inguinal rings are almost superimposed and the obliquity of the canal is slight. In adults, the inguinal canal, which is about 3.75 cm long, is directed downwards and medially from the deep to the superficial inguinal ring. In the male, the inguinal canal transmits the spermatic cord, the ilioinguinal nerve and the genital branch of the genitofemoral nerve. In the female, the round ligament replaces the spermatic cord.

Figure 57.4 illustrates the canal, viewing the structures from superficial to deep as is seen at operation. The anterior boundary comprises mainly the external oblique aponeurosis with the conjoined muscle laterally. The posterior boundary is formed by the fascia transversalis and the conjoined tendon (internal oblique and transversus abdominus medially). The inferior epigastric vessels lie posteriorly and medially to the deep inguinal ring. The superior boundary is formed by the conjoined muscles (internal oblique and transversus) and the inferior boundary is the inguinal ligament.

An indirect hernia travels down the canal on the outer (lateral and anterior) side of the spermatic cord. A direct hernia comes out directly forwards through the posterior wall of the inguinal canal. Whereas the neck of the indirect hernia is lateral to the inferior epigastric vessels, the direct hernia usually emerges medial to this except in the saddle-bag or pantaloon type, which has both a lateral and a medial component. An inguinal hernia can be differentiated from a femoral hernia by ascertaining the relation of the neck of the sac to the medial end of the inguinal ligament and the pubic tubercle; i.e. in the case of an inguinal hernia the neck is above and medial, whereas that of a femoral hernia is below and lateral (Fig. 57.4). Digital control of the internal ring may help in distinguishing between an indirect and a direct inguinal hernia, although some reports have found that the preoperative diagnosis is incorrect as often as it is correct.

Indirect (synonym: oblique) inguinal hernia

This is the most common form of hernia (see Aetiology p. 968). Indirect hernias are most common in the young, whereas direct hernias are most common in the old. In the first decade of life, inguinal hernia is more common on the right side in the male. This is no doubt associated with the later descent of the right testis and a higher incidence of failure of closure of the processus vaginalis. In adult males, 65% of inguinal hernias are indirect and 55% are right-sided. The hernia is bilateral in 12% of cases. If both sides are explored in an infant presenting with one hernia,

Figure 57.4 The relationships of an indirect inguinal and a femoral hernia to the pubic tubercle; the inguinal hernia emerges above and medial to the tubercle whereas the femoral hernia lies below and lateral to it.

the incidence of a patent processus vaginalis on the other side is 60% (Summary box 57.5).

Summary box 57.5

Natural history of inguinal hernias

- Inguinal hernias in babies are the result of a persistent processus vaginalis
- Indirect inguinal hernia is the most common hernia of all, especially in the young
- Direct inguinal hernia becomes more common in the elderly

Three types of indirect inguinal hernia occur (Fig. 57.5):

- 1 *Bubonocoele*. The hernia is limited to the inguinal canal.
- 2 *Funicular*. The processus vaginalis is closed just above the epididymis. The contents of the sac can be felt separately from the testis, which lies below the hernia.
- 3 *Complete (synonym: scrotal)*. A complete inguinal hernia is rarely present at birth but is commonly encountered in infancy. It also occurs in adolescence or in adulthood. The testis appears to lie within the lower part of the hernia.

Clinical features

Notes on examination The clinician examines the patient from the front with the patient standing with legs apart. The patient is instructed to look at the ceiling and cough. If the hernia will

Figure 57.5 Types of oblique inguinal hernia. *Bubon* (Greek) = groin; *funiculus* (Latin) = a small cord.

come down, it usually does. The examiner looks and feels for the impulse and then addresses the following questions:

- Is the hernia right, left or bilateral?
- Is it an inguinal or femoral hernia?
- Is it a direct or an indirect hernia?
- Is it reducible or irreducible (the patient may have to lie down for this to be ascertained)?
- Is the inguinal hernia incomplete or complete?
- What are the contents?

Looking at all ages, males are 20 times more commonly affected than females. The patient complains of pain in the groin or pain referred to the testicle when performing heavy work or taking strenuous exercise. When asked to cough, a small transient bulging may be seen and felt together with an expansile impulse. When the sac is still limited to the inguinal canal, the bulge may be better seen by observing the inguinal region from the side or even looking down the abdominal wall while standing behind the relevant shoulder of the patient.

As an indirect inguinal hernia increases in size it becomes apparent when the patient coughs, and persists until reduced (Fig. 57.6). As time goes on, the hernia comes down as soon as the patient stands up. In large hernias there is a sensation of weight and dragging on the mesentery. This may produce epigastric pain. If the contents of the sac are reducible, the inguinal canal will be found to be commodious.

In infants the swelling appears when the child cries. It can be translucent in infancy and early childhood but never in an adult. In girls an ovary may prolapse into the sac.

Differential diagnosis in the male

In males the differential diagnosis includes the following:

- vaginal hydrocele (Fig. 57.7);
- encysted hydrocele of the cord;
- spermatocele;
- femoral hernia;
- incompletely descended testis in the inguinal canal – an inguinal hernia is often associated with this condition;
- lipoma of the cord – this is often a difficult but unimportant diagnosis and it is usually not settled until the parts are displayed by operation.

Figure 57.6 Oblique left inguinal hernia that became apparent when the patient coughed and persisted until it was reduced when he lay down.

Figure 57.7 Large transilluminant cystic swelling present in the lower abdomen, extending down the inguinal canal in the scrotum. (a) Lesion being removed. (b) Excised specimen. It is not possible to distinguish between a complex scrotal hernia, a hydrocele of the cord and a vaginal hydrocele in such cases before exposing the anatomy; in this case the lesion was an abdominoscrotal hydrocele (courtesy of Drs D. Pratep and R. Sahai, Jhabsi, India).

Note that examination using finger and thumb across the neck of the scrotum will help to distinguish between a swelling of inguinal origin and one that is entirely intrascrotal.

Differential diagnosis in the female

In females the differential diagnosis includes the following:

- hydrocele of the canal of Nuck – this is the most common differential diagnostic problem;
- femoral hernia.

Treatment

Operation is the treatment of choice. It must be remembered that patients who have a bad cough from chronic bronchitis should not be denied an operation, for these are the very people who are in danger of developing a strangulated hernia. In adults, local, epidural or spinal, as well as general anaesthesia, can be used (Summary box 57.6).

Anton Nuck, 1650–1692, Professor of Anatomy and Medicine, Leiden, The Netherlands.

Summary box 57.6

Treatment of hernias

- Surgery is the treatment of choice
- Surgery is either open or laparoscopic
- Any hernia can strangulate

The basic operation is inguinal herniotomy, which entails dissecting out and opening the hernial sac, reducing any contents and then transfixing the neck of the sac and removing the remainder. It is employed either by itself or as the first step in a repair procedure (herniorrhaphy). By itself it is sufficient for the treatment of hernia in infants, adolescents and young adults. Any attempts at repair in such cases may, in fact, do more harm than good.

In infants it is not necessary to open the canal, as the internal and external rings are superimposed. Excellent results are obtained. The operation is usually now performed as a day case unless there are additional medical or social problems.

Herniotomy and repair (herniorrhaphy) consists of: (1) excision of the hernial sac; plus (2) repair of the stretched internal inguinal ring and the transversalis fascia; and (3) further reinforcement of the posterior wall of the inguinal canal. (2) and (3) must be achieved without tension resulting in the wound and various techniques exist to achieve this, e.g. Shouldice operation, fascial flaps or mesh implants.

Excision of the hernial sac (adult herniotomy) An incision¹ is made in the skin and subcutaneous tissue 1.25 cm above and parallel to the medial two-thirds of the inguinal ligament. In large, irreducible hernias the incision may be extended laterally or into the upper part of the scrotum. After dividing the superficial fascia and securing haemostasis, the external oblique aponeurosis and the superficial inguinal ring are identified. The external oblique aponeurosis is incised in the line of its fibres and the structures beneath carefully separated from its deep surface before completing the incision through the superficial inguinal ring. In this way, the ilioinguinal nerve is safeguarded. With the inguinal canal thus opened, the upper leaf of the external oblique muscle is separated from the internal oblique muscle by blunt dissection. In the same way, the lower leaf is separated from the contents of the inguinal canal until the inner aspect of the inguinal ligament is seen. The cremasteric muscle fibres may be divided longitudinally to display the spermatic cord, but this is by no means essential.

- **Excision of the sac.** The indirect sac may be distinguished as a pearly white structure lying on the outer side of the cord and, when the internal spermatic fascia has been incised longitudinally, it can usually be dissected out and then opened between artery forceps.
- **Variations in dissection.** If the sac is small it can be freed *in toto*. If it is of the long, funicular or scrotal type, or is extremely thickened and adherent, the fundus must not be sought because in doing so the blood supply to the testis may be compromised. The sac is freed within the inguinal canal and divided circumferentially such that the fundus remains in the

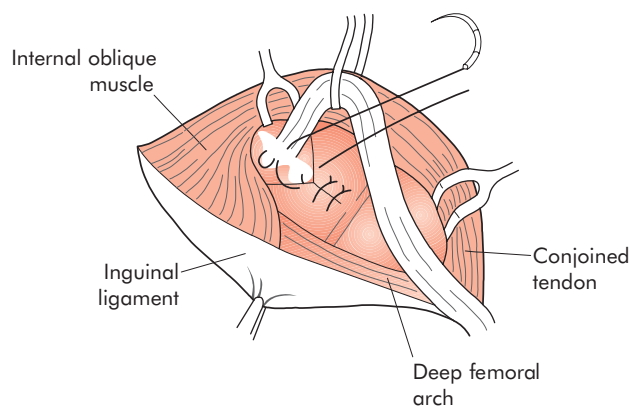

Figure 57.8 The Lytle method of repair of the stretched internal inguinal ring, which should be narrowed to admit the tip of the little finger. Lateral displacement of the cord is often advantageous (after F.S.A. Doran, FRCS, Bromsgrove, UK).

scrotum. Care must be taken to avoid damage to the vas and spermatic artery when freeing the sac posteriorly.

- An *adherent sac* can be separated from the cord by first injecting saline under the posterior wall from within (hydrodissection). A similar tactic is employed when dissecting the gossamer sac of infants and children.
- **Reduction of contents.** Intestine or omentum is returned to the peritoneal cavity. Omentum is often adherent to the neck or fundus of the sac: if adherent to the neck it is freed and if adherent to the fundus of a large sac it may be transfixed, ligated and cut across at a suitable point. The distal part of the omentum, like the distal part of a large scrotal sac, can be left *in situ* (the fundus should, however, not be ligated).
- **Isolation and ligation of the neck of the sac.** Whatever type of sac is encountered, it is necessary to free the neck by blunt dissection until the parietal peritoneum can be seen on all sides. The dissection is considered complete only when the extraperitoneal fat has been encountered and the inferior epigastric vessels have been seen on the medial side. It used to be considered essential to open the sac to ensure that no bowel or omentum was adherent to the neck. If the sac is obviously empty, it is sufficient to simply reduce it, close the internal ring and perform a herniorrhaphy if required. If the sac is opened, all contents should be reduced and the neck transfixed as high as possible before excising the sac.

Repair of the transversalis fascia and the internal ring When the internal ring is weak and stretched and the transversalis is bulging, the repair should include a technique of narrowing the deep ring, e.g. the Lytle method of narrowing the ring with lateral displacement of the cord (Fig. 57.8), or the Shouldice method, whereby the ring and fascia are incised and carefully separated from the deep inferior epigastric vessels and extraperitoneal fat before an overlapping repair ('double breasting') of the lower flap behind the upper flap is performed (Fig. 57.9). In the classic Shouldice operation, a third and fourth layer of tension-free suturing, using monofilament materials, polypropylene, polyamide or wire, are placed between the internal oblique aponeurosis arch and the inguinal ligament.

¹ Prior to the skin incision in large inguinoscrotal hernias, the usual antiseptic preparation of the skin should not be extended to the perineal aspect of the scrotum because, by doing so, severe bacterial contamination of the operation is likely.

William James Lytle, 1896–1986, Surgeon, The Royal Infirmary, Sheffield, England.

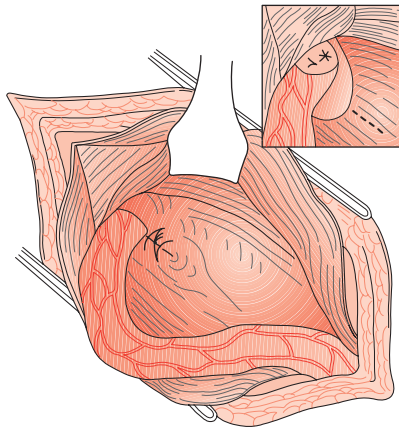

Figure 57.9 After the neck of the sac has been divided at the deep inguinal ring, the fascia transversalis of the deep opening is identified and assessed. If the ring is of normal size, the stump of the sac is reduced and no more need be done. If the ring is marginally dilated (stretched), it should be carefully dissected and possibly divided slightly (inset), and then sutured tightly around the medial side of the cord with polypropylene to reconstitute a competent deep inguinal ring.

Reinforcement of the posterior inguinal wall This is achieved by suturing without tension the tendinous aponeurotic arch of the internal oblique to the undersurface of the inguinal ligament and to the pubic tubercle (as described above in the Shouldice operation) or by reinforcing the posterior wall of the canal with a prosthetic mesh. Care is taken when suturing not to pick up the same tendinous bundle for each suture. Suturing of muscle bundles is of no value. The suturing method can include a rectus-relaxing incision (Halsted–Tanner). The Lichtenstein tension-free hernioplasty involves placement of an approximately 16 × 8 cm (tailored to the individual patient's requirements) mesh as an extra lamina, anterior to the posterior wall and overlapping it generously in all directions, including medially over the pubic tubercle (Fig. 57.10).

Figure 57.10 Lichtenstein repair. The 'tails' of the mesh are overlapped and crossed and a single suture is placed to create a new 'internal' ring.

William Stewart Halsted, 1852–1922, Professor of Surgery, Johns Hopkins Hospital Medical School, Baltimore, MD, USA.
Norman Cecil Tanner, 1906–1982, Surgeon, Charing Cross Hospital, London, England.

Other historical techniques, which should now be abandoned because of poor results, include overlapping the external oblique behind the cord (making it lie subcutaneously). Special care is needed to avoid excessive narrowing of the new external ring, which could jeopardise the vascular supply to and the venous return from the testis.

Completion of operation If desired, the cremasteric muscle can be reconstituted: the external oblique is directly sutured or overlapped, leaving a new external ring that should accommodate the tip of a finger.

A truss A truss may be used when operation is contraindicated or when operation is refused. Its use should be mainly historical, as there are very few contraindications to surgery with today's variety of anaesthetic techniques. If a truss is to be worn, the hernia must be reducible. A rat-tailed spring truss with a perineal band to prevent the truss slipping will, with due care and attention, control a small or moderately sized inguinal hernia. A truss must be worn continuously during waking hours, kept clean and in proper repair and renewed when it shows signs of wear. It must be applied before the patient gets up and while the hernia is reduced. A properly fitting truss must control the hernia when the patient stands with legs apart, stoops and coughs violently. If it does not it is a menace because it increases the risk of strangulation.

There is no place for trusses in the management of infant hernias. If an infant hernia becomes suddenly irreducible, urgent operative repair is indicated. Otherwise, the infant hernia can be left alone until the child is over 3 months old, when routine day-case repair can be performed.

Direct inguinal hernia

In adult males, 35% of inguinal hernias are direct. At presentation, 12% of patients will have a contralateral hernia in addition, and there is a fourfold increased risk of future development of a contralateral hernia if one is not present at the original presentation.

A direct inguinal hernia is always acquired. The sac passes through a weakness or defect of the transversalis fascia in the posterior wall of the inguinal canal. In some cases the defect is small and is represented by a discrete defect in the transversalis fascia, whereas in others there is a generalised bulge. Often the patient has poor lower abdominal musculature, as shown by the presence of elongated bulgings (Malgaigne's bulges). Women practically never develop a direct inguinal hernia (Brown). Predisposing factors are smoking and occupations that involve straining and heavy lifting. Damage to the ilioinguinal nerve (previous appendicectomy) is another cause, because of the resulting weakness of the conjoint tendon.

Direct hernias do not often attain a large size or descend into the scrotum (Fig 57.11). In contrast to an indirect inguinal hernia, a direct inguinal hernia lies behind the spermatic cord. The sac is often smaller than the hernial mass would indicate, the protruding mass mainly consisting of extraperitoneal fat. As the neck of the sac is wide, direct inguinal hernias do not often strangulate (Summary box 57.7).

Francis Robert Brown, 1889–1967, Surgeon, The Royal Infirmary, Dundee, Scotland.
Joseph Francois Malgaigne, 1806–1865, Professor of Surgery, Paris, France.

Figure 57.11 A huge inguinal hernia (direct) that has descended into the scrotum. The overlying skin has become gangrenous and sloughed away (courtesy of Dr Anupam Rai, Jabalpur, India).

Summary box 57.7

Direct inguinal hernias

- All are acquired
- They are most common in older men
- They rarely strangulate

Funicular direct inguinal hernia (synonym: prevesical hernia)

This is a narrow-necked hernia with prevesical fat and a portion of the bladder that occurs through a small oval defect in the medial part of the conjoint tendon just above the pubic tubercle. It occurs principally in elderly men and occasionally becomes strangulated. Unless there are definite contraindications, operation should always be advised.

Dual (synonym: saddle-bag, pantaloon) hernia

This type of hernia consists of two sacs that straddle the inferior epigastric artery, one sac being medial and the other lateral to this vessel. The condition is not rare and is a cause of recurrence, one of the sacs having been overlooked at the time of operation.

Operation for direct hernia

The principles of repair of direct hernias are the same as those of an indirect hernia, with the exception that the hernia sac can usually be simply inverted after it has been dissected free and the transversalis fascia reconstructed in front of it. This reconstruction of the posterior wall of the inguinal canal should be undertaken by the Shouldice repair or by using a mesh implant according to the Lichtenstein technique (see Figs 57.9 and 57.10). The ‘Bassini’ darn operation is no longer acceptable because of its high recurrence rate and slow rehabilitation.

Edoardo Bassini, 1844–1924, Professor of Surgery, Padua, Italy, described this method of herniorrhaphy in 1889.

Laparoscopic herniorrhaphy (see Chapter 19) Over the last 10 years, minimally invasive techniques have been developed for the treatment of inguinal hernias. Two techniques are described, a transabdominal approach (TAPP) and a preperitoneal approach (TEP). The TAPP approach establishes a pneumoperitoneum and places a synthetic mesh preperitoneally by dissecting the peritoneum off the hernial orifices and positioning the mesh beneath the peritoneum before closing the peritoneum over the mesh. The TEP approach is completely preperitoneal. The preperitoneal plane is opened by either balloon dissection or direct dissection via a paraumbilical incision. The hernial orifices can be identified bilaterally and any hernia sac reduced. Placing a large mesh over the hernial orifices in the preperitoneal plane completes the repair (Fig. 57.12). There is some discussion about the requirement for mesh fixation, and various techniques are available to fix the mesh in place. In the UK, there has been a general trend away from TAPP repairs as the incidence of complications is higher than with the TEP repair. However, the TEP repair is technically more difficult to perform and is associated with a longer learning curve. In experienced hands, the recurrence rate for TEP repairs is less than 1%.

Laparoscopic repairs can be applied to primary, bilateral and recurrent inguinal hernias as well as to femoral hernias. The National Institute for Clinical Excellence (NICE) in the UK has produced guidelines on the use of laparoscopic surgery for inguinal hernias and has recommended the consideration of the TEP laparoscopic technique for any inguinal hernia, unilateral, recurrent or bilateral, but only in laparoscopic centres where there are surgeons experienced in the technique.

Strangulated inguinal hernia

The pathological and clinical features of strangulated inguinal hernias have been described earlier in this chapter. Strangulation of an inguinal hernia occurs at any time during life and in both sexes. Indirect inguinal hernias strangulate more commonly, the direct variety not so often because of the wide neck of the sac. Sometimes a hernia strangulates on the first occasion that it descends; more often strangulation occurs in patients who have

Figure 57.12 TEP repair. Laparoscopically placed preperitoneal mesh covering the myopectineal orifice. Extraperitoneal dissection has proceeded to reveal loose areolar tissue in the space of Retzius.

Robert Edward Gross, B. 1905, Ladd Professor of Children’s Surgery, Harvard University Medical School, Boston, MA, USA.

worn a truss for a long time and in those with a partially reducible or an irreducible hernia.

In order of frequency, the constricting agent is: (1) the neck of the sac; (2) the external inguinal ring in children; and (3) adhesions within the sac (rarely).

Contents

Usually the small intestine is involved in the strangulation, with the next most frequent being the omentum; sometimes both are involved. It is rare for the large intestine to become strangulated in an inguinal hernia, even when the hernia is of the sliding variety.

Strangulation during infancy

The incidence of strangulation in infancy is 4% (Gross) and the ratio of girls to boys is 5:1. More frequently, the hernia is irreducible but not strangulated. In most cases of strangulated inguinal hernia occurring in female infants, the content of the sac is an ovary or an ovary plus its fallopian tube.

Treatment of strangulated inguinal hernia

The treatment of strangulated hernia is by emergency operation. Vigorous resuscitation with intravenous fluids, nasogastric aspiration and antibiotics is essential, although operation should not be unduly delayed in moribund patients. It is also advisable to empty the bladder, if necessary by catheterisation (Summary box 57.8).

Summary box 57.8

Preoperative treatment of strangulated inguinal hernias

- Resuscitate with adequate fluids
- Empty stomach with nasogastric tube
- Give antibiotics to contain infection
- Catheterise to monitor haemodynamic state

Inguinal herniotomy for strangulation An incision is made over the most prominent part of the swelling. The external oblique aponeurosis is exposed and the sac, with its coverings, is seen issuing from the superficial ring. In all but very large hernias it is possible to deliver the body and fundus of the sac together with its coverings and (in the male) the testis on to the surface (it is not necessary to deliver the testis if the fundus of the sac can be adequately exposed). Each layer covering the anterior surface of the body of the sac near the fundus is incised and, if possible, stripped off the sac. The sac is then incised and any fluid, which may be highly infective, drained effectively. The external oblique aponeurosis and the superficial inguinal ring are divided. A finger is then passed into the opening in the sac and, employing the finger as a guide, the sac is slit along its length. If the constriction lies at the superficial inguinal ring or within the canal, it is readily divided by this procedure. When the constriction is at the deep ring, by applying artery forceps to the cut edge of the neck of the sac and drawing them downwards, and at the same time retracting the internal oblique upwards, it may be possible to continue slitting the sac over the finger towards the point of constriction. When the constriction is too tight to admit a finger, a grooved dissector is inserted and the neck of the sac is divided with a knife in an upward and inward direction, i.e. parallel to the inferior epigastric vessels, under vision. Once the constriction has

been divided, the strangulated contents can be drawn down. Devitalised omentum is excised after being securely ligated. Viable intestine is returned to the peritoneal cavity. Doubtfully viable and gangrenous intestine is excised by localised resection. If the hernial sac is of moderate size and can be separated easily from its coverings, it is excised and closed by a purse-string suture. When the sac is large and adherent, much time is saved by cutting across the sac circumferentially, as described earlier. Having tied or sutured the neck of the sac, a repair can be made if the condition of the patient permits. If the incision has been soiled or gangrenous bowel resected, the use of prosthetic mesh may be questionable, although some authorities have successfully utilised polypropylene mesh with antibiotic cover. Biosynthetic meshes made from collagen or dermis are also available and, because they are totally absorbed, are more suited to use in a contaminated environment.

Conservative measures These are indicated only in infants. The child is given analgesics and placed in gallow's traction (the judgement of Solomon position). In 75% of cases reduction is effected and there appears to be no danger of gangrenous intestine being reduced (Irvine Smith).

Note that vigorous manipulation (taxis) has no place in modern surgery and is mentioned only to be condemned. Its dangers include:

- contusion or rupture of the intestinal wall;
- reduction-en-masse: 'The sac together with its contents is pushed forcibly back into the abdomen; as the bowel will still be strangulated by the neck of the sac, the symptoms are in no way relieved' (Treves);
- reduction into the a loculus of the sac;
- the sac may rupture at its neck and the contents are reduced, not into the peritoneal cavity but extraperitoneally (Summary box 57.9).

Summary box 57.9

Non-operative treatment of hernias

- Only indicated in children
- Forcible reduction must never be attempted

Maydl's hernia (synonym: hernia-in-W) Maydl's hernia is rare. The strangulated loop of the W lies within the abdomen, so local tenderness over the hernia is not marked. At operation, two comparatively normal-looking loops of intestine are present in the sac. After the obstruction has been relieved, the strangulated loop will become apparent if traction is exerted on the middle of the loops occupying the sac.

Results of operations for inguinal hernia

Recurrence

Reported recurrence rates vary between 0.2% and 15% depending on the technique employed. Only by using a meticulous

Irvine Battinson Smith, Formerly Surgeon, Burton-on-Trent General Hospital, Burton-on-Trent, Staffordshire, England.

en masse is French for 'in a body'.

Sir Frederick Treves, 1853–1923, Surgeon, The London Hospital, London, England.

Karl Maydl, 1853–1903, Professor of Surgery, Prague, The Czech Republic.

technique, principally concentrating on reinforcement of the posterior wall of the inguinal canal using the Shouldice technique or mesh hernioplasty, can a recurrence rate of less than 2% be achieved. Only 50% of recurrences will become apparent within 2 years. In a few cases 'false' recurrences occur, i.e. another type of hernia occurs – direct after indirect, femoral after inguinal. However, to the patient it is a recurrence! (Summary box 57.10.)

Summary box 57.10

Recurrence of hernias

- The recurrence rate after surgery should be less than 2%
- Some recurrences will be new hernias

The spermatic cord as a barrier to effective closure of the inguinal canal

Even in the elderly patient, removal of the testis and cord is very rarely required for effective repair, even in cases of recurrent inguinal hernia. In operations for multiple recurrences or when previous surgery has been associated with infections or excessive scarring, the operation should be approached through virgin territory, i.e. the preperitoneal route, by an experienced surgeon.

Sliding hernia (synonym: hernia-en-glissade) (Fig. 57.13)

As a result of slipping of the posterior parietal peritoneum on the underlying retroperitoneal structures, the posterior wall of the sac is not formed of peritoneum alone, but by the sigmoid colon and its mesentery on the left, the caecum on the right and, sometimes, on either side by a portion of the bladder. It should be clearly understood that the caecum, appendix or a portion of the colon wholly within a hernial sac does not constitute a sliding hernia. A small bowel sliding hernia occurs approximately once in 2000 cases, a sacless hernia once in 8000 cases.

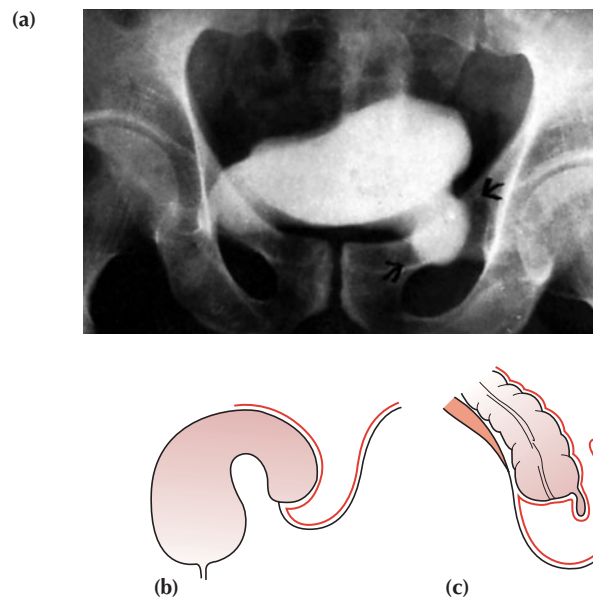

Figure 57.13 Sliding hernia. (a) Cystogram showing a left inguinal hernia involving a bladder. (b) Diagram of the same. (c) Caecum and appendix in a right sliding hernia.

Clinical features

A sliding hernia occurs almost exclusively in men. Five out of six sliding hernias are situated on the left side; bilateral sliding hernias are rare. The patient is nearly always over 40 years of age, the incidence rising with age. There are no clinical findings that are pathognomonic of a sliding hernia, but it should be suspected in a very large globular inguinal hernia descending well into the scrotum.

Occasionally, large intestine is strangulated in a sliding hernia; more often, non-strangulated large intestine is present behind the sac containing strangulated small intestine.

Treatment

A sliding hernia is impossible to control with a truss and, as a rule, the hernia is a cause of considerable discomfort. Consequently, operation is indicated and the results are very good.

Operation

It is unnecessary to remove any of the sliding hernial sac provided it is freed completely from the cord and the abdominal wall and that it is replaced deep to the repaired fascia transversalis. In some circumstances it is desirable to perform an orchidectomy to effect a secure repair. No attempt should be made to dissect the caecum or colon free from the peritoneum under the impression that these are adhesions. If this is attempted, peritonitis or a faecal fistula may result from necrosis of a devascularised portion of the bowel. This is especially liable to occur on the left side, as vessels in the mesocolon may be injured.

Femoral hernia

Femoral hernia is the third most common type of primary hernia. It accounts for about 20% of hernias in women and 5% in men. The over-riding importance of femoral hernia lies in the facts that it cannot be controlled by a truss and that of all hernias it is the most liable to become strangulated, mainly because of the narrowness of the neck of the sac and the rigidity of the femoral ring. Strangulation is the initial presentation of 40% of femoral hernias (Summary box 57.11).

Summary box 57.11

Femoral hernias

- More common in women
- Cannot be controlled with a truss
- Have a high incidence of strangulation
- Should be operated on as soon as possible

Surgical anatomy

The femoral canal occupies the most medial compartment of the femoral sheath and extends from the femoral ring above to the saphenous opening below. It is 1.25 cm long and 1.25 cm wide at its base, which is directed upwards. The femoral canal contains fat, lymphatic vessels and the lymph node of Cloquet. It is closed above by the septum crurale, a condensation of extraperitoneal tissue pierced by lymphatic vessels, and below by the cribriform fascia.

Jules Germain Cloquet, 1790–1883, Professor of Anatomy and Surgery, Paris, France.

The femoral ring is bounded:

- anteriorly by the inguinal ligament;
- posteriorly by Astley Cooper's (iliopectineal) ligament, the pubic bone and the fascia over the pectineus muscle;
- medially by the concave knife-like edge of Gimbernat's (lacunar) ligament, which is also prolonged along the iliopectineal line, as Astley Cooper's ligament;
- laterally by a thin septum separating it from the femoral vein.

Sex incidence

The female to male ratio is about 2:1, but it is interesting that, whereas female patients are frequently elderly, male patients are usually between 30 and 45 years of age. The condition is more prevalent in women who have borne children than in nulliparae.

Pathology

A hernia passing down the femoral canal descends vertically as far as the saphenous opening. While it is confined to the inelastic walls of the femoral canal the hernia is necessarily narrow but, once it escapes through the saphenous opening into the loose areolar tissue of the groin, it expands, sometimes considerably. A fully distended femoral hernia assumes the shape of a retort and its bulbous extremity may be above the inguinal ligament. By the time the contents have pursued so tortuous a path, they are usually irreducible and apt to strangulate.

Clinical features

Femoral hernia is rare before puberty. Between 20 and 40 years of age the prevalence rises and this continues to old age. The right side (Fig. 57.14) is affected twice as often as the left and in 20% of cases the condition is bilateral. The symptoms to which a femoral hernia gives rise are less pronounced than those of an inguinal hernia; indeed, a small femoral hernia may be unnoticed by the patient or disregarded for years, perhaps until the day it strangulates. Adherence of the greater omentum sometimes causes a dragging pain. Rarely, a large sac is present.

Figure 57.14 The patient has a left inguinal and a right femoral hernia (see Fig. 57.15).

Manoel Louise Antonio don Gimbernat, 1734–1816, Professor of Anatomy, Barcelona, Spain, and later Director of the Royal College of Surgeons in Spain.

Differential diagnosis

A femoral hernia has to be distinguished from:

- *An inguinal hernia.* The neck of the sac lies above and medial to the medial end of the inguinal ligament at its attachment to the pubic tubercle. The neck of the sac of a femoral hernia lies below this (Fig. 57.15). The fundus of an inguinal or femoral hernia may follow the line of least resistance and occupy a variety of places; for instance, occasionally, the fundus of a femoral hernia sac overlies the inguinal ligament.
- *A saphena varix.* A saccular enlargement of the termination of the long saphenous vein, usually accompanied by other signs of varicose veins. The swelling disappears completely when the patient lies flat whereas a femoral hernia sac is usually still palpable. In both, there is an impulse on coughing. A saphena varix will, however, impart a fluid thrill to the examining fingers when the patient coughs or when the saphenous vein below the varix is tapped with the fingers of the other hand. Sometimes a venous hum can be heard when a stethoscope is applied over a saphena varix.
- *An enlarged femoral lymph node.* There may be other enlarged lymph nodes to aid the diagnosis. If Cloquet's lymph node alone is affected it may be impossible to distinguish from a femoral hernia sac unless there are other clues, such as an infected wound or abrasion on the corresponding limb or on the perineum.
- *Lipoma.*
- *A femoral aneurysm.* See Chapter 53.
- *A psoas abscess.* There is often a fluctuating swelling – an iliac abscess – which communicates with the swelling in question. If suspected, an examination of the spine and a radiograph will confirm the diagnosis.
- *A distended psoas bursa.* The swelling diminishes when the hip is flexed and osteoarthritis of the hip is present.
- *Rupture of the adductor longus with haematoma formation.* Suspected on clinical history.

Hydrocele of a femoral hernial sac

The neck of the sac becomes plugged with omentum or by adhesions and a hydrocele of the sac results.

Laugier's femoral hernia

This is a hernia through a gap in the lacunar (Gimbernat's) ligament. The diagnosis is based on the unusual medial position of a small femoral hernia sac. The hernia has nearly always strangulated.

Figure 57.15 The essentials of the differential diagnosis between a femoral and an inguinal hernia (as in Fig. 57.14).

Stanislaus Laugier, 1799–1872, Surgeon, Hôtel Dieu, Paris, France.

Narath's femoral hernia

This occurs only in patients with congenital dislocation of the hip and is the result of lateral displacement of the psoas muscle. The hernia lies hidden behind the femoral vessels.

Cloquet's hernia

Cloquet's hernia is one in which the sac lies under the fascia covering the pectineus muscle. Strangulation is likely. The sac may coexist with the usual type of femoral hernia sac.

Strangulated femoral hernia

A femoral hernia strangulates frequently and gangrene rapidly develops. This is explained by the narrow, unyielding femoral ring. In 40% of cases the obstructing agent is not the lacunar ligament but the neck of the femoral sac itself. A Richter's hernia is a frequent occurrence (see above).

Treatment of a femoral hernia

The constant risk of strangulation is sufficient reason to recommend operation, which should be carried out soon after the diagnosis has been made. A truss is contraindicated because of this risk.

Operative treatment

Several approaches to the femoral hernia have been advocated including the low operation (Lockwood), the high operation (McEvedy) and the inguinal operation (Lotheissen). In all cases the bladder must be emptied by catheterisation immediately before commencing surgery. To these well-described techniques may be added the laparoscopic approach – the TEP repair visualising the femoral canal and the iliac vessels from a preperitoneal approach, enabling safe reduction of the hernia sac while monitoring the iliac vessels under direct vision. It should be noted that throughout operations for the repair of a femoral hernia on the lateral side, the external iliac/femoral vein must be protected; on the medial side, great care must be taken not to injure the bladder, particularly as a portion of the bladder may form part of the wall of the sac (a sliding femoral hernia).

The low operation (Lockwood) The sac is dissected out below the inguinal ligament via a groin crease incision. It is essential to peel off the anatomical layers that cover the sac. These are often thick and fatty. After dealing with the contents (e.g. freeing adherent omentum), the neck of the sac is pulled down, ligated as high as possible and allowed to retract through the femoral canal. The canal may be closed by suturing the inguinal ligament to the iliopectineal line using three non-absorbable sutures. An alternative method of closure is to roll a sheet of polypropylene mesh into a cylinder and anchor the cylinder in the canal with non-absorbable sutures placed medially, superiorly and inferiorly.

The high (McEvedy) operation Classically, a vertical incision is made over the femoral canal and continued upwards above the inguinal ligament. An acceptable alternative that heals well and

with less pain is to use a 'unilateral' Pfannenstiel incision, which can be extended to form a complete Pfannenstiel incision if formal laparotomy is required. This incision provides good access to the preperitoneal space. Through the lower part of the incision, the sac is dissected out. The upper part of the incision exposes the inguinal ligament and the rectus sheath. The superficial inguinal ring is identified and an incision 2.5 cm above the ring and parallel to the outer border of the rectus muscle is deepened until the extraperitoneal space is identified. By gauze dissection in this space, the hernial sac entering the femoral canal can easily be identified. If the sac is empty and small it may be drawn upwards; if it is large, the fundus is opened below and its contents, if any, dealt with appropriately before delivering the sac upwards from its canal. The sac is then freed from the extraperitoneal tissue and its neck ligated. An excellent view of the iliopectineal ligament is obtained and the conjoined tendon is sutured to it with non-absorbable sutures. An alternative repair, particularly suitable for recurrent femoral hernias, is to suture a sheet of polypropylene mesh over the femoral canal orifice, anchoring the mesh inferiorly to the iliopectineal ligament and medially to the rectus sheath.

An advantage of this approach is that, if resection of intestine is required, ample room can be obtained by opening the peritoneum. The disadvantage of this approach is that, if infection occurs, an incisional hernia may develop.

Lotheissen's operation The inguinal canal is opened as for inguinal herniorrhaphy. The transversalis fascia is incised to the medial side of the epigastric vessels and the opening is enlarged. The peritoneum is now in view; one must be certain that it is the peritoneum and not the bladder or a diverticulum thereof. The peritoneum is picked up with dissecting forceps and incised. It is now possible to ascertain if any intraperitoneal structure is entering the femoral sac. If the sac is empty, artery forceps are placed upon the edges of the opening into the peritoneum and, by gauze dissection, the sac is withdrawn from the femoral canal. An empty sac can be delivered easily. If strangulation is suspected, as soon as the external oblique has been exposed, the inferior margin of the wound is retracted, thereby displaying the swelling. The coverings of the sac are incised and peeled off, until the sac, dark from contained blood-stained fluid, is apparent. The sac is incised and the fluid that escapes is mopped up with care. The retractor is removed and the operation is continued above the inguinal ligament as described above. Once the peritoneum has been opened above the inguinal ligament, one can see exactly what is entering the sac. Should the obstruction lie in a narrow neck of the sac, the neck of the sac may be gently stretched by insertion of artery forceps.² The contents of the sac are delivered and dealt with appropriately. Sometimes, to facilitate reduction of the hernial contents, it is necessary to divide or digitally dilate part of the lacunar (Gimbernat's) ligament.

The Lotheissen repair is effected by suturing the conjoined tendon to the iliopectineal line to form a shutter. While protecting

² An abnormal obturator artery is present on the medial or the lateral side of the neck of the sac in 28% of cases.

Albert Narath, 1864–1924, Professor of Surgery, Heidelberg, Germany.
Charles Barrett Lockwood, 1856–1914, Surgeon, St. Bartholomew's Hospital, London, England.
Peter George McEvedy, 1890–1951, Surgeon, Ancoats Hospital, Manchester, England.

Hermann Johann Pfannenstiel, 1862–1909, Gynaecologist, Breslau, Germany, (now Wrocław, Poland), described this incision in 1900.
George Lotheissen, 1868–1941, Surgeon, The Kaiser Franz Joseph Hospital, Vienna, Austria, described this operation in 1898.

the external iliac/femoral vein with the forefinger, non-absorbable sutures are passed through the periosteum and Cooper's ligament overlying the iliopectineal line. The retractor is removed and the long ends of the sutures are passed outwards from within, through the conjoined tendon and tied, thus approximating the conjoined tendon to the iliopectineal line. If there is any tension, a Tanner's slide will facilitate this step. The incised external oblique is sutured.

An alternative repair is to buttress the femoral canal with a sheet of polypropylene mesh. Once the sac has been dealt with, a sheet of mesh is inserted into the preperitoneal space and anchored inferiorly to the iliopectineal line, inferomedially to Cooper's ligament and superomedially to the rectus sheath. The transversalis fascia may then be approximated in front of the mesh and the incised external oblique repaired. It should be noted that the peritoneum must be closed before placement of the mesh.

Umbilical hernia

Exomphalos (synonym: omphalocele) occurs once in every 6000 births; it is due to failure of all or part of the midgut to return to the coelom during early fetal life. There is some debate as to whether gastroschisis represents a separate entity or is simply an exomphalos with ruptured membranes, but the debate has little practical importance because the principles of treatment are similar. When the sac remains unruptured it is semitranslucent (Fig. 57.16) and, although very thin, it consists of two layers – an outer layer of amniotic membrane and an inner layer of peritoneum. Omphaloceles may be divided into those with a fascial defect less than 4 cm and those with a defect greater than 4 cm. The former are termed herniation of the umbilical cord. In smaller defects a single loop of intestine may not be obvious and ligation of what was thought to be a normal umbilical cord will result in transection of the intestine, leaving the embarrassing problem of an umbilico-enteric fistula.

In large defects, the liver, spleen, stomach, pancreas, colon or bladder may be seen through the membrane. The intestine lies freely mobile within the intact sac without evidence of adhesions or inflammation. In contrast, the liver has dense adhesions to the sac, a fact that must be remembered during surgical repair.

Treatment

Small defects may be closed primarily soon after birth as there is usually no difficulty with disproportion between the size of the abdominal cavity and the volume of the sac contents.

Figure 57.16 Exomphalos. The delicate sac ruptured soon afterwards.

Large defects present a more substantial problem and four techniques have been described: non-operative therapy, skin flap closure, staged closure and primary closure.

Non-operative therapy

This is appropriate for premature infants with a gigantic intact sac or those in whom associated anomalies make survival of a major operation unlikely. The intact sac is painted daily with a desiccating antiseptic solution and, if successful, an eschar forms over the sac. Eventually, granulation tissue grows in from the periphery and the subsequent ventral hernia can be repaired later.

Skin flap closure

The sac is gently trimmed away enabling inspection of the abdominal contents. The skin is freed from the fascial edges and undermined laterally. The umbilical vessels are ligated or one artery is cannulated for monitoring. The skin flaps are approximated in the midline with simple sutures and the ventral hernia is then closed at a later date (months to years later).

Staged closure

The sac is gently trimmed away from the skin edge and the skin further freed from the fascial attachments. The prosthetic material [polypropylene mesh or expanded polytetrafluoroethylene (PTFE)] is sutured with interrupted non-absorbable sutures circumferentially to the full thickness of the musculofascial abdominal wall to form a silo. The top of the silo is gathered and tied with umbilical tape. At daily intervals the silo is opened under strict aseptic conditions and the contents examined for infection or dehiscence. The viscera are pushed gently back in to the abdominal cavity and the infant observed for signs of raised intra-abdominal pressure. The silo is then tied at a reduced level and the cycle repeated until the sac is flush with the abdominal wall. At this stage the fascia may be closed with interrupted sutures and skin closed over the top.

Primary closure

The sac is gently dissected away from the skin edge and the underlying fascia. The intestine is then evacuated completely of meconium and fluid, distally and proximally, through a nasogastric tube. The abdominal wall is stretched gradually and repeatedly in quadrants, usually achieving a doubling of volume. The viscera are then replaced and the fascial layer closed primarily, usually under moderate tension. Intra-gastric pressure monitoring is helpful to prevent undue vena caval compression (Summary box 57.12).

Summary box 57.12

Exomphalos

- Small defects may result in the sac being tied off with cord
- Large defects need a staged approach

Congenital umbilical hernia

Rarely, a fully developed umbilical hernia is present at birth, presumably due to intrauterine epithelialisation of a small exomphalos.

Umbilical hernia of infants and children

This is a hernia through a weak umbilicus, which may result partly from failure of the round ligament (obliterated umbilical

Figure 57.17 Infantile umbilical hernia.

vein) to cross the umbilical ring and partly from absence of the Richet fascia. Both sexes seem to be equally affected although there are significant racial differences; the incidence in black infants is reported to be up to eight times higher than that in white infants. The hernia is often symptomless but increases in size on crying and assumes a classical conical shape (Fig. 57.17). Obstruction or strangulation below the age of 3 years is extremely uncommon.

Treatment

Conservative treatment is indicated under the age of 2 years; when the hernia is symptomless, reassurance of the parents is all that is necessary, as 95% of hernias will disappear spontaneously. If the hernia persists at 2 years of age or older it is unlikely to resolve and herniorrhaphy is indicated.

Operation A small curved incision is made immediately below the umbilicus. The skin cicatrix is dissected upwards and the neck of the sac isolated. After ensuring that the sac is empty of contents, it is either inverted into the abdomen or ligated by transfixion and excised. The defect in the linea alba is closed with interrupted absorbable sutures (Summary box 57.13).

Summary box 57.13

Umbilical hernias in infants and children

- Rarely strangulate
- Most resolve spontaneously

Paraumbilical hernia (synonyms: supraumbilical hernia, infraumbilical hernia)

In adults the hernia does not occur through the umbilical scar but is a protrusion through the linea alba, just above or sometimes just below the umbilicus (Fig. 57.18). As it enlarges it becomes rounded or oval in shape, with a tendency to sag downwards.

Louis Alfred Richet, 1816–1891, Professor of Clinical Surgery, The Faculty of Medicine, Paris, France.

Figure 57.18 A large paraumbilical hernia.

Paraumbilical hernias can become very large. The neck of the sac is often remarkably narrow compared with the size of the sac and the volume of its contents, which usually consist of greater omentum often accompanied by small intestine and, alternatively or in addition, a portion of transverse colon. In long-standing cases the sac sometimes becomes loculated because of adherence of omentum to its fundus.

Clinical features

Women are affected five times more frequently than men. The patient is usually overweight and between the ages of 35 and 50. Increasing obesity, with flabbiness of the abdominal muscles, and repeated pregnancy are important aetiological factors. These hernias may become irreducible because of the formation of omental adhesions within the sac. Symptomatically, a large umbilical hernia causes a dragging pain because of its weight. Gastrointestinal symptoms are common and are probably due to traction on the stomach or transverse colon. Often there are transient attacks of intestinal colic because of partial intestinal obstruction. In long-standing cases, intertrigo of the adjacent surfaces of skin and trophic ulcers of the fundus are troublesome complications.

Treatment

If the hernia is untreated it increases in size and more and more of its contents become irreducible. Eventually, strangulation may occur. Thus, operation should be advised in nearly all cases. If the patient is obese and the hernia is symptomless, operation can be postponed until the patient has lost weight.

Umbilical herniorrhaphy If the defect is small, a primary herniorrhaphy can be performed. If the defect is large, the repair is best performed with prosthetic buttressing of the abdominal wall. The classic primary repair is that described by Mayo. A transverse elliptical incision is made around the umbilicus and the subcutaneous tissues are dissected off the rectus sheath to expose the neck of the sac. The neck is incised to expose the contents. Intestine is returned to the abdomen and any adherent omentum

William James Mayo, 1861–1939, Surgeon, The Mayo Clinic, Rochester, MN, USA, described this operation in 1901.

freed. Excess adherent omentum can be removed with the sac if necessary. The sac is then removed and the peritoneum closed with an absorbable suture. The aponeurosis on both sides of the umbilical ring is mobilised from underlying tissue sufficiently to allow an overlap of 5 or 7.5 cm. Interrupted mattress sutures are then inserted into the aponeurosis as shown in Fig. 57.19. When this row of mattress sutures has been tied, the overlapping upper margin is stitched to the sheath of the rectus abdominis and the midline aponeurosis. A suction drain should be placed in the wound in fat patients, who ooze blood and liquid fat. The subcutaneous fat and skin are then approximated with deep sutures.

Paraumbilical hernioplasty In the case of very large primary umbilical hernias (fascial defects >4 cm) or for recurrent paraumbilical hernias, the use of prosthetic material (polypropylene mesh) is recommended.

Additional lipectomy In patients with a paraumbilical hernia associated with a large, pendulous, fat-laden abdominal wall, the operation can, with great advantage, be combined with panniculectomy by fashioning the incisions to embrace a larger area of the fat-laden superficial layers of the abdominal wall.

Strangulation

Strangulation is a frequent complication of a large paraumbilical hernia in adults. Because of the narrow neck and the fibrous edge of the linea alba, gangrene is liable to supervene unless early operation is carried out. It should also be remembered that in large hernias the presence of loculi may result in a strangulated knuckle of the bowel in one part of an otherwise soft and non-tender hernia.

Operation In early cases the operation does not differ from that for non-strangulated cases. Gangrenous contents are dealt with as in other situations. If a portion of the transverse colon is gangrenous it should be exteriorised by the Paul–Mikulicz method and the gangrenous portion excised. If the ring is large enough to transmit the colon unhampered it is left alone; otherwise, it is enlarged. It is important that the small intestine is thoroughly scrutinised as a small loop may have been trapped and slipped back when the constriction was relieved. If non-viable gut is overlooked, peritonitis quickly supervenes and the symptoms are

Figure 57.19 Mayo's operation for umbilical hernia. Interrupted sutures to provide an overlap are first inserted. Inset: the overlap has been made and completed with a continuous suture. It is important to denude the area of fat before stitching the flap into position.

Johann von Mikulicz-Radecki, 1850–1905, Professor of Surgery, Breslau, Germany, (now Wrocław, Poland).

ascribed to postoperative discomfort. The condition of the patient steadily deteriorates until he or she succumbs after a few days (Summary box 57.14).

Summary box 57.14

Paraumbilical hernias

- Usually occur in obese women
- Will increase in size and may get very large indeed
- May strangulate so need surgery

Epigastric hernia (synonym: fatty hernia of the linea alba)

An epigastric hernia occurs through the linea alba anywhere between the xiphoid process and the umbilicus, usually midway between these structures. Such a hernia commences as a protrusion of extraperitoneal fat through the linea alba, and it was hypothesised that this protrusion occurred at the site where small blood vessels pierced the linea alba. However, only a minority of epigastric hernias are accompanied by blood vessels, and it is more likely that the defect occurs as a result of a weakened linea alba due to abnormal decussation of the fibres of the aponeurosis. More than one hernia may be present, and the most common cause of 'recurrence' is failure to identify a second defect at the time of original repair.

A swelling the size of a pea consists of a protrusion of extraperitoneal fat only (fatty hernia of the linea alba). If the protrusion enlarges, it drags a pouch of peritoneum after it and so becomes a true epigastric hernia. The mouth of the hernia is rarely large enough to permit a portion of hollow viscus to enter it; consequently, either the sac is empty or it contains a small portion of greater omentum.

It is likely that an epigastric hernia is the direct result of a sudden strain tearing the interlacing fibres of the linea alba. The patients are often manual workers between 30 and 45 years of age.

Clinical features

Symptomless

A small fatty hernia of the linea alba can be felt more easily than it can be seen and may be symptomless, discovered only in the course of routine abdominal palpation.

Painful

Sometimes such a hernia gives rise to attacks of local pain, worse on physical exertion, and tenderness to touch and light clothing. This may be because the fatty contents become nipped sufficiently to produce partial strangulation.

Referred pain

It is not uncommon to find that the patient, who may not have noticed the hernia, complains of pain suggestive of a peptic ulcer. However, as the majority of these hernias are asymptomatic, symptoms should not be ascribed to the hernia until any gastrointestinal pathology has been excluded.

Treatment

If the hernia is giving rise to symptoms, operation should be undertaken.

Operation An adequate vertical or transverse incision is made over the swelling, exposing the linea alba. The protruding extraperitoneal fat is cleared from the hernial orifice by gauze dissection. If the pedicle passing through the linea alba is slender, it is separated on all sides of the opening by blunt dissection. After ligating the pedicle, the small opening in the linea alba is closed with non-absorbable sutures in adults and with absorbable sutures in children. When a hernial sac is present, it is opened and any contents reduced, after which the sac neck is transfixed and the sac excised before repairing the linea alba. If smaller protrusions of fat are found above or below the hernia, these should also be dealt with. If the hernia is large (defect greater than 4 cm diameter), the repair should be reinforced with polypropylene mesh positioned in the retromuscular plane (Summary box 57.15).

Summary box 57.15

Epigastric hernias

- Too small to contain bowel
- Only need surgery if painful

Rare external hernias

Interparietal hernia (synonym: interstitial hernia)

An interparietal hernia has a hernial sac that passes between the layers of the anterior abdominal wall. The sac may be associated with, or communicate with, the sac of a concomitant inguinal or femoral hernia. Lack of knowledge of this condition is the cause of misdiagnosis and mismanagement.

Other varieties

- 1 *Preperitoneal* (20%). Usually the sac takes the form of a diverticulum from a femoral or inguinal hernia.
- 2 *Intermuscular* (60%). The sac passes between the muscular layers of the anterior abdominal wall, usually between the external oblique and internal oblique muscles. The sac is nearly always bilocular and is associated with an inguinal hernia.
- 3 *Inguino-superficial* (20%). The sac expands beneath the superficial fascia of the abdominal wall or the thigh. This type is commonly associated with an incompletely descended testis.

Clinical features

The patients (mostly male) present with intestinal obstruction caused by obstruction or strangulation of the hernia. In the preperitoneal variety swelling is unlikely to be apparent and delays in diagnosis occur; consequently the mortality rate is high.

Treatment

Operation is imperative because of intestinal obstruction.

Spigelian hernia

This is a variety of interparietal hernia occurring at the level of the arcuate line. It is very rare, with only 1000 cases reported in the literature. The fundus of the sac, clothed by extraperitoneal fat, may lie beneath the internal oblique muscle, where it is virtually impalpable. More often, it advances through that muscle and spreads out like a mushroom between the internal and external

oblique muscles and gives rise to a more evident swelling. The patient is often corpulent and usually over 50 years of age, men and women being equally affected. Typically, a soft, reducible mass will be encountered lateral to the rectus muscle and below the umbilicus. Diagnosis is confirmed by computerised tomography or ultrasound scanning. The latter has the advantage that it can be performed in the upright patient if no defect is visible in the reclining position. Because of the rigid fascia surrounding the neck, strangulation may occur.

Treatment

If a defect is palpable, a muscle-splitting approach is used. After isolating the sac, dealing with any contents, and ligating and excising it, the transversus and internal oblique and external oblique muscles are repaired by direct apposition. If no sac is palpable, a paramedian approach is used and the sac sought in the extraperitoneal space. The repair then proceeds as described above. A transabdominal laparoscopic approach may also be employed.

Lumbar hernia

Most primary lumbar hernia occur through the inferior lumbar triangle of Petit (Fig. 57.20), bounded below by the crest of the ilium, laterally by the external oblique muscle and medially by the latissimus dorsi. Less commonly, the sac comes through the superior lumbar triangle, which is bounded by the 12th rib above, medially by the sacrospinalis and laterally by the posterior border of the internal oblique muscle. Primary lumbar hernias are very rare, with only 300 cases reported. More commonly, lumbar hernias are secondary to renal operations, when extensive incisional sacs may be present.

Figure 57.20 Inferior lumbar hernia, which contained caecum, appendix and small bowel. Note the filarial skin rash on the buttocks (courtesy of V.J. Hartfield, formerly of S.E. Nigeria).

Adrien Van der Spieghel, (Spigelius), 1578–1625, Professor of Anatomy, Padua, Italy.

Jean Louis Petit, 1674–1750, Director of the Academie de Chirurgie, Paris, France.

Differential diagnosis

A lumbar hernia must be distinguished from:

- a lipoma;
- a cold (tuberculous) abscess pointing to this position;
- phantom hernia due to local muscular paralysis – lumbar phantom hernia can result from any interference with the nerve supply of the affected muscles (e.g. poliomyelitis).

Treatment

Being small, a primary lumbar hernia is easily repaired. As the natural history is for these hernias to increase in size with time, any primary lumbar hernia should be repaired at presentation. Incisional lumbar hernias may be large and the defect is impossible to repair unless fascial flaps are used. The repair can be reinforced with a sheet of polypropylene mesh.

Perineal hernia

This type of hernia is very rare and includes:

- postoperative hernia through a perineal scar, which may occur after excision of the rectum;
- median sliding perineal hernia, which is a complete prolapse of the rectum (Chapter 68);
- anterolateral perineal hernia, which occurs in women and presents as a swelling of the labium majus;
- posterolateral perineal hernia, which passes through the levator ani to enter the ischiorectal fossa.

Treatment

A combined operation is generally the most satisfactory for the last two types of hernia. The hernia is exposed by an incision directly over it. The sac is opened and its contents are reduced. The sac is cleared from surrounding structures and the wound closed. With the patient in semi-Trendelenburg position, the abdomen is opened and the mouth of the sac is exposed. The sac is inverted, ligated and excised and the pelvic floor repaired by muscle apposition and, if indicated, buttressing of the repair with prosthetic mesh.

Obturator hernia

Obturator hernia, which passes through the obturator canal, occurs six times more frequently in women than in men. Most patients are over 60 years of age. The swelling is liable to be overlooked because it is covered by the pectineus. It seldom causes a definite swelling in Scarpa's triangle, but if the limb is flexed, abducted and rotated outwards, the hernia sometimes becomes more apparent. The leg is usually kept in a semi-flexed position and movement increases the pain. In more than 50% of cases of strangulated obturator hernia, pain is referred along the obturator nerve by its geniculate branch to the knee. On vaginal or rectal examination the hernia can sometimes be felt as a tender swelling in the region of the obturator foramen.

Cases of obturator hernia that present themselves have usually undergone strangulation, which is frequently of the Richter type.

Friedrich Trendelenburg, 1844–1924, Professor of Surgery, Rostock (1875–1882), Bonn (1882–1895), and Leipzig (1895–1911), Germany.
Antonio Scarpa, 1747–1832, Professor of Anatomy, Pavia, Italy.

Treatment

Operation is indicated. A lower laparotomy should be performed (on the side of the lesion, if known). The diagnosis is confirmed and a full Trendelenburg position adopted. The constricting agent is the obturator fascia. Taking every precaution to avoid spilling infected fluid from the hernial sac into the peritoneal cavity, this fascia can be stretched to allow reduction by inserting suitable forceps through the gap in the fascia and opening the blades with care. If incision of the fascia is required, it is made parallel to the obturator vessels and nerve. The contents of the sac are dealt with. The defect is repaired by stitching the broad ligament over the opening to prevent recurrence.

Gluteal and sciatic hernias

A gluteal hernia passes through the greater sciatic foramen, either above or below the piriformis. A sciatic hernia passes through the lesser sciatic foramen. Differential diagnosis must be made between these conditions and:

- a lipoma or fibrosarcoma beneath the gluteus maximus;
- a tuberculous abscess;
- a gluteal aneurysm.

All doubtful swellings in this situation should be explored by operation.

UMBILICUS**Inflammation of the umbilicus****Infection of the umbilical cord**

In over 50% of babies born in maternity hospitals the stump of the umbilical cord is found to be carrying staphylococci by the third or fourth day post delivery. Less commonly the stump of the cord harbours streptococci, and epidemics of puerperal sepsis in maternity hospitals have been traced to the umbilical cord of one infant in the nursery thus infected. *Escherichia coli* and *Clostridium tetani* (causing neonatal tetanus) are other possible invaders. The chief prophylaxis is strict asepsis during severance of the cord and the use of 0.1% chlorhexidine locally for a few days (Summary box 57.16).

Summary box 57.16**Infection of umbilical cord**

- Most become infected
- Staff must wash hands between patients to prevent cross-infection

Omphalitis

The incidence of an infected umbilicus is much higher in communities that do not practise aseptic severance of the umbilical cord. When the stump of the umbilical cord becomes inflamed, antibiotic therapy usually localises the inflammation. By employing warm, moist dressings, the crusts separate, giving exit to pus. Exuberant granulation tissue requires a touch of silver nitrate. In more serious cases infection is liable to spread along the defunct hypogastric arteries or umbilical vein when, in all probability, one or other of the following complications will supervene:

- *Abscess of the abdominal wall.* If gentle pressure is exerted above or below the navel and a bead of pus exudes at the navel, a deep abscess associated with one of the defunct umbilical vessels is present. This must be opened. A probe is passed into the sinus to determine its direction and this is followed by a grooved director on to which the skin and overlying tissues are incised in the midline.
- *Extensive ulceration of the abdominal wall.* Extensive ulceration of the abdominal wall due to synergistic infection is treated in the same way as postoperative subcutaneous gangrene (see below).
- *Septicaemia* can occur from organisms entering the bloodstream via the umbilical vein. Jaundice is often the first sign. An abscess in the abdominal wall above the umbilicus should be sought. In other respects, the treatment of this grave complication follows the usual lines.
- *Jaundice in the newborn.* Infection reaching the liver via the umbilical vein may cause a stenosing intrahepatic cholangiolitis, appearing some 3–6 weeks after birth.
- *Portal vein thrombosis and subsequent portal hypertension.*
- *Peritonitis* carries a bad prognosis.
- *Umbilical hernia.*

Umbilical granuloma

Chronic infection of the umbilical cicatrix that continues for weeks causes granulation tissue to pout at the umbilicus. There is no certain means of distinguishing this condition from an adenoma. Usually, an umbilical granuloma can be treated by one application of silver nitrate followed by dry dressings, but an adenoma soon recurs in spite of these measures.

Dermatitis of and around the umbilicus

This is common at all times of life. Fungus and parasitic infections are more difficult to eradicate from the umbilicus than from the skin of the abdomen. Sometimes the dermatitis is consequent upon a discharge from the umbilicus, as is the case when an umbilical fistula or a sinus is present. In overweight women, intertrigo occurs.

A deep, tender swelling in the midline below the umbilicus signifies that an abscess is present in the extraperitoneal fat; this is usually due to an infected urachal remnant. Exploration and proper drainage is necessary.

Pilonidal sinus

Pilonidal sinus (a sinus containing a sheath of hairs) is sometimes encountered. It should be excised.

Umbilical calculus (umbolith)

This is often black in colour and is composed of desquamated epithelium, which becomes inspissated and collects in the deep recess of the umbilicus. The treatment is to dilate the orifice and extract the calculus but, to prevent recurrence, it may be necessary to excise the umbilicus.

Umbilical fistulae

As the umbilicus is a central abdominal scar it is understandable that a slow leak from any viscus is liable to track to the surface at this point. Added to this, very occasionally, the vitellointestinal duct or the urachus remains patent; consequently, it has been aptly remarked that the umbilicus is a creek into which many fistulous streams may open.

For instance, an enlarged, inflamed gall bladder perforating at its fundus may discharge gallstones through the umbilicus. An unremitting flow of pus from a fistula at the umbilicus of a middle-aged woman led to the discovery of a length of gauze overlooked during a hysterectomy 5 years previously.

The vitellointestinal duct

The vitellointestinal duct occasionally persists and gives rise to one of the following conditions:

- It remains patent (Fig. 57.21a). The resulting umbilical fistula discharges mucus and, rarely, faeces. Often, a small portion only of the duct near the umbilicus remains unobliterated. This gives rise to a sinus that discharges mucus. The epithelial lining of the sinus often becomes everted to form an ‘adenoma’.
- Sometimes both the umbilical and the intestinal ends of the duct close but the mucous membrane of the intervening portion remains and an intra-abdominal cyst develops (Fig. 57.21b).
- With its lumen obliterated or unobliterated the vitellointestinal duct provides an intraperitoneal band (Fig. 57.21c); this is a potential danger because intestinal obstruction is liable to occur. The obstruction results from a coil of small intestine passing under or over or becoming twisted around the band.
- Such a band may contract and pull a Meckel’s diverticulum into a congenital umbilical hernia (Fig. 57.21d).
- A vitellointestinal cord connected to a Meckel’s diverticulum, but not attached to the umbilicus, becomes adherent to or knotted around another loop of small intestine and so causes intestinal obstruction.
- Sometimes a band extending from the umbilicus is attached to the mesentery near its junction with a distal part of the ileum. In this case the band is probably an obliterated vitelline artery and is not necessarily associated with a Meckel’s diverticulum.

Treatment

A patent vitellointestinal duct should be excised, together with a Meckel’s diverticulum if present, preferably when the child is about 6 months old. When a vitellointestinal band gives rise to acute intestinal obstruction, after removing the obstruction by dividing the band it is expedient, when possible, to excise the band and bury the cut ends.

Figure 57.21 Anomalies connected with the vitellointestinal duct. (a) Umbilical fistula; (b) intra-abdominal cyst; (c) intraperitoneal band; (d) Meckel’s diverticulum with a band adherent to the sac of a congenital umbilical hernia.

Patent urachus

A patent urachus seldom reveals itself until maturity or even old age. This is because the contractions of the bladder commence at the apex of the organ and pass towards the base. Because it opens into the apex of the bladder a patent urachus is closed temporarily during micturition and so the potential urinary stream from the bladder is cut off. Thus, the fistula remains unobtrusive until a time when the organ is overfull, usually due to some form of obstruction.

Treatment

Treatment is directed to removing the obstruction in the lower urinary tract. If, after this has been remedied, the leak continues or a cyst develops in connection with the urachus, umbilectomy and excision of the urachus down to its insertion into the apex of the bladder, with closure of the latter, is indicated.

Neoplasms of the umbilicus**Benign****Umbilical adenoma or raspberry tumour**

This is commonly seen in infants (Fig. 57.22) but only occasionally later in life. It is due to a partially (occasionally a completely) unobliterated vitellointestinal duct. Mucosa prolapsing through the umbilicus gives rise to a raspberry-like tumour, which is moist and tends to bleed.

Treatment If the tumour is pedunculated, a ligature is tied around it and, in a few days, the polypus drops off. Should the tumour reappear after this procedure, umbilectomy is indicated. Sometimes a patent vitellointestinal duct, or more often a vitellointestinal band, will be found associated with a Meckel's diverticulum. The Meckel's diverticulum and the attached cord or duct should be excised at the same time as the umbilicus. Histologically, the tumour at the umbilicus consists of columnar epithelium rich in goblet cells.

Endometrioma

Endometrioma occurs in women between the ages of 20 and 45 years. On histological examination it is found to consist of endometrial glands occupying the same plane in the dermis as the sudoriferous glands and opening onto the surface in the same

Figure 57.22 Adenoma (raspberry tumour) of the umbilicus.

Figure 57.23 Secondary nodule at the umbilicus in a case of carcinoma of the stomach.

way. The umbilicus becomes painful and bleeds at each menstruation, when the small fleshy tumour between the folds of the umbilicus becomes more apparent. Occasionally, an umbilical endometrioma is accompanied by endometriomas in the uterus or ovary. When the tumour is solitary, as is usually the case, umbilectomy will cure the condition.

Malignant**Secondary carcinoma**

Secondary carcinoma at the umbilicus (or Sister Joseph's nodule³) (Fig. 57.23) is quite common but is always a late manifestation of the disease. The primary neoplasm is often situated in the stomach, colon or ovary, but a metastasis from the breast, probably transmitted along the lymphatics of the round ligament of the liver, is sometimes located here.

THE ABDOMINAL WALL**Burst abdomen and incisional hernia**

In 1–2% of cases, mostly between the sixth and eighth day after operation, an abdominal wound bursts open and viscera are extruded. The disruption of the wound tends to occur a few days beforehand when the sutures apposing the deep layers (peritoneum, posterior rectus sheath) tear through or even become untied. An incisional hernia usually starts as a symptomless partial disruption of the deeper layers during the immediate or early postoperative period, the event passing unnoticed if the skin wound remains intact after the skin sutures have been removed.

³ The neoplastic nodule sited at the umbilicus is known as Sister Joseph's nodule. Sister Joseph of the Mayo Clinic imparted this clinical observation to the late Dr William Mayo.

Sister Mary Joseph (nee Julia Dempsey), Nursing Superintendent, St. Mary's Hospital, which became the Mayo Clinic, Rochester, MN, USA. The Mayo Clinic in Rochester, MN, USA, was founded in 1889 as the St. Mary's Hospital by William Worrall Mayo and his two sons, William James Mayo and Charles Horace Mayo, both of whom became surgeons to the hospital.

Factors relating to the incidence of burst abdomen and incisional hernia

Technique of wound closure

Choice of suture material Catgut leads to a higher incidence of 'bursts' than the use of non-absorbable monofilament polypropylene, polyamide or wire, and should never be used.

Method of closure Interrupted suturing has a low incidence of bursts. Through and through suturing is good for the obstructed case. The incidence of burst hernia following one-layer closure is low but it is higher than that following a two-layered closure. Interrupted 'far and near' sutures are a recommended technique for single-layer mass closures. When continuous suturing of layers (one or two) is performed, a particular fault is the use of a short length of material pulled tightly; in an anaesthetised relaxed patient the incision is thus shortened and made taut so that when the patient is conscious and coughing the material will act as if it is a cheese-wire cutter. The golden rule is to insert a length of suture that is at least four times but less than five times the length of the incision. This ensures that the layers are gently apposed.

Drainage Drainage directly through a wound leads to a higher incidence of bursts than employing drainage through a separate (stab) incision.

Factors relating to incisions

Midline and vertical incisions have a greater tendency to burst than those that are transverse. Since the widespread use of non-absorbable suture materials, even midline vertical incisions are associated with a very low incidence of disruption.

Reasons for initial operation

Deep wound infection is notorious for causing burst abdomen and/or late incisional hernia. Operations on the pancreas, with leakage of enzymes, and on obstructed cases are other reasons for disruption.

Coughing, vomiting and distension

At the completion of an operation, any violent coughing set off by the removal of an endotracheal tube and suction of the laryngopharynx strains the sutures; likewise cough, vomiting and distension (e.g. due to ileus) in the early postoperative period. Overvigorous postoperative ventilation in sedated patients can lead to wound disruption.

General condition of the patient

Obesity, jaundice, malignant disease, hypoproteinaemia and anaemia are all factors conducive to disruption of a laparotomy wound. Abdominal wounds in pregnancy are notorious for a high risk of disruption; steroids delay healing (Summary box 57.17).

Summary box 57.17

Causes of burst abdomen

- Poor closure technique
- Deep wound infection
- Coughing or vomiting
- Poor metabolic state of patient

Burst abdomen (synonym: abdominal dehiscence)

Clinical features

A serosanguinous (pink) discharge from the wound is a forerunner of disruption in 50% of cases. It is the most pathognomonic sign of impending wound disruption and it signifies that intraperitoneal contents are lying extraperitoneally. Patients often volunteer the information that they 'felt something give way'. If skin sutures have been removed, omentum or coils of intestine may be forced through the wound and will be found lying on the skin. Pain and shock are often absent. It is important to note that there may be symptoms and signs of intestinal obstruction.

Treatment

An emergency operation is required to replace the bowel, relieve any obstruction and resuture the wound. While awaiting operation, reassure the patient and cover the wound with a sterile towel and, if necessary, administer appropriate analgesics. The stomach is emptied by a nasogastric tube and intravenous fluid therapy commenced.

Operation

Each protruding coil of intestine is washed gently with saline solution and returned to the abdominal cavity. The protruding greater omentum is treated similarly and spread over the intestine. Having cleansed the abdominal wall, all layers are approximated by through and through sutures of monofilament nylon, which may be passed through a soft rubber or plastic tube collar. The abdominal wall may be supported by strips of adhesive plaster encircling the anterior two-thirds of the circumference of the trunk. Antibiotic therapy is started.

Contrary to what might be thought, peritonitis rarely supervenes and, although the skin wound may become infected, healing is satisfactory. A second dehiscence rarely occurs. There is biochemical evidence that healing after disruption produces a stronger wound. This is because of the improvement in collagen metabolism in these circumstances. An incisional hernia is often a late sequel (see below).

Incisional hernia (synonym: postoperative hernia)

Aetiology

Incisional hernia occurs most often in obese individuals, and a persistent postoperative cough and postoperative abdominal distension are its precursors. There is a high incidence of incisional hernia following operations for peritonitis because, as a rule, the wound becomes infected. The placing of a drainage tube through a separate stab incision as opposed to bringing such a tube through the laparotomy wound reduces the frequency (see also General features common to all hernias, p. 968).

An incisional hernia usually starts as a symptomless partial disruption of the deeper layers of a laparotomy wound during the immediate or very early postoperative period. Often the event passes unnoticed if the skin wound remains intact after the stitches have been removed (or because subcuticular stitches have been used, which remain in place). A serosanguinous discharge is often the signal of dehiscence and resuture of the deeper layers of the incision obviates the more difficult repair of an established and much larger hernia later on.

Clinical features

There are great variations in the degree of herniation. The hernia may occur through a small portion of the scar, often the lower end. More frequently there is a diffuse bulging of the whole length of the incision. A postoperative hernia, especially one through a lower abdominal scar, usually increases steadily in size and more and more of its contents become irreducible. Sometimes the skin overlying it is so thin and atrophic that normal peristalsis can be seen in the underlying intestine. Attacks of partial intestinal obstruction are common and strangulation is liable to occur at the neck of a small sac or in a loculus of a large one. Nevertheless, most cases of incisional hernia are asymptomatic and broad-necked and do not need treatment (Summary box 57.18).

Summary box 57.18

Incisional hernias

- Rarely strangulate
- Large ones may be dangerous to reduce

Treatment

Palliative

An abdominal belt is sometimes satisfactory, especially in cases of a hernia through an upper abdominal incision.

Operation

Many procedures have been advocated, which is testimony to the fact that the repairs may be difficult to accomplish, but it is now clear that one technique is superior to all the others.

To obtain a lasting repair, very special preparation is required. If the patient is obese, weight reduction by dieting should precede the operation. To attempt to return the contents of a very large hernia to the main abdominal cavity if they have not been there for several years is to court danger, particularly if weight reduction has not been effected. In these circumstances there is not only a risk of failure of the hernioplasty but also a greatly increased risk of paralytic ileus from visceral compression and of pulmonary complications from elevation of the diaphragm. The repair of these large hernias is highly specialised surgery and should be performed only in centres with considerable experience in dealing with them. For example, one technique employed to enlarge the abdominal cavity is that of prolonged pneumoperitoneum, in which the intra-abdominal pressure is raised to 15–18 cmH₂O for up to several weeks preoperatively. The technique requires careful monitoring and patient counselling to be effective but, if employed correctly, can enable a primary repair to be successful.

Three techniques have been described: simple and complex apposition and plastic fibre mesh or net closures.

Simple apposition The hernial sac is dissected. It is then formally, if not already inadvertently, opened and the contents are reduced. Adherent omentum and bowel have to be freed by dissection before the mouth of the sac can be defined. The layers are repaired, usually with non-absorbable sutures: first the peritoneum and then the fascial (aponeurotic) layers. The lateral edges of the fascia are freed from the overlying muscles for some distance, and this fascial layer is approximated with interrupted

sutures at the upper and lower ends of the wound. The muscles and the remaining fascial layer are approximated. Tension-relaxing incisions may be required and should be placed well laterally.

Complex apposition This consists of various types of layered closures (Mayo, 'Keel', da Silva) and should be considered obsolete and of historical interest only.

Plastic fibre mesh or net closures These techniques are now the method of choice for all but the smallest defects (< 4 cm). The sac is dealt with as above. The layers of the fascia are dissected out and, if above the umbilicus, the posterior rectus sheath edges apposed. A sheet of polypropylene mesh is then inserted between the posterior rectus sheath and the muscle fibres and anchored in place. If below the umbilicus, the mesh is placed in the preperitoneal space. The anterior rectus sheath is then apposed as above. If the defect is too large to close by simple apposition of the rectus sheath, advanced techniques involving muscle-relaxing incisions are employed, such as the Ramirez component separation technique, which enable either the anterior or posterior component of the rectus sheath to be closed and reinforced with an onlay prosthetic mesh.

Incisional and primary ventral hernias are also increasingly being repaired by the laparoscopic placement of mesh. A laparoscopy and division of adhesions is initially performed and the hernia defect defined intraperitoneally. One of a variety of meshes specifically designed for intraperitoneal use is introduced through a port and fixed to the abdominal wall by tacks or trans-fascial sutures (Fig. 57.24). The critical steps of the laparoscopic approach are ensuring a sufficient circumferential overlap of the fascial defect (> 4 cm) and adequate fixation of the mesh to the anterior abdominal wall. Prospective trials are currently taking place to define the method and degree of optimum fixation.

Careful haemostasis and meticulous asepsis are essential during these operations. Postoperative collections of serum can be removed by drainage using plastic tubing that leads, via skin punctures lateral to the wound, into closed suction drainage bottles (e.g. RediVac).

Postoperative care

Gastric decompression and intravenous fluids are employed and nothing by mouth allowed until the bowels have functioned.

Figure 57.24 Laparoscopic repair of an incisional hernia. The position of the intraperitoneal mesh covering a fascial defect. After the contents of the sac have been reduced the hernial defect can be defined.

Early ambulation and gentle physical exercise is to be encouraged. The patient should not resume strenuous exercise for several weeks.

Results of treatment

Most series report recurrence of the hernia in 30–50% of patients, except where mesh inlay techniques have been employed in specialist centres, in which case recurrence rates may be as low as 10%.

Divarication of the rectus abdominis

Divarication of the rectus abdominis is seen principally in elderly multiparous patients. When the patient strains, a gap can be seen between the rectus abdominis, through which the abdominal contents bulge. When the abdomen is relaxed, the fingers can be introduced between the rectus.

Treatment

An abdominal belt is all that is required. There is no risk of strangulated intestinal contents. A similar condition is seen in babies, except that the divarication exists above the umbilicus. No treatment is necessary; as the child grows a spontaneous cure results.

Tearing of the inferior epigastric artery

Tearing of the inferior epigastric artery occurs in three dissimilar types of individual: elderly women, often thin and feeble; athletic, muscular men, usually below middle age; and pregnant women, mainly multiparae late in pregnancy. The site of the haematoma is usually at the level of the arcuate line, where the posterior sheath of the rectus abdominis is lacking.

Clinical features

The possibility of tearing of the epigastric vessels should always be considered when, following a bout of coughing or a sudden blow to the abdominal wall, an exquisitely tender lump appears in relation to the rectus abdominis. Occasionally a haematoma occurs within the muscles lateral to the rectus sheath. Unless there is bruising of the overlying skin, the diagnosis may be difficult.

Differential diagnosis

The conditions for which the haematoma is frequently mistaken are a twisted ovarian cyst in women and, when the lump is on the right side, an appendix abscess in both sexes. The sign most likely to be of value in differentiating a haematoma of the abdominal wall from these conditions, namely tensing of the abdominal musculature, is often unsatisfactory because of the pain it causes. The differential diagnosis between the haematoma and a strangulated Spigelian hernia may be difficult. The absence of vomiting suggests a haematoma and the presence of resonance over the swelling favours a Spigelian hernia; a plain radiograph of the abdomen sometimes gives positive evidence of the latter.

As a complication of pregnancy

Rupture of the inferior epigastric artery occurs occasionally during pregnancy. Surprisingly, haemorrhage into this closed space from this comparatively small artery has proved fatal.

Treatment

With rest, a comparatively small haematoma may resolve, but sometimes renewed haemorrhage causes the haematoma to

rupture into the peritoneal cavity. Thus, it is safer to operate early, evacuate the clot and ligate the artery (Summary box 57.19).

Summary box 57.19

Tear of epigastric artery

- Follows a bout of coughing
- May mimic intra-abdominal sepsis

Infections

Cellulitis can occur in any of the planes of the abdominal wall.

Superficial cellulitis is usually discovered when an abdominal wound is inspected following pyrexia. The earliest sign is when the stitches become embedded in the oedematous skin. Later there is a blush extending for a variable distance from the incision or the stitch holes. On palpation with the gloved hand, one area is usually found to be more indurated and tender than the remainder. A stitch should be removed from the immediate vicinity and if pus or seropus escapes it should be sent for bacteriological examination; treatment should then be commenced with a broad-spectrum antibiotic.

Deep cellulitis is characterised by brawny oedema towards one or both flanks, and not infrequently of the scrotum or vulva as well. Antibiotic therapy is the mainstay of treatment. When tenderness persists, an anatomical incision dividing the muscles carefully, layer by layer until pus or purulent fluid is encountered, is often advisable.

Progressive postoperative bacterial synergistic gangrene

Fortunately, this is a rare complication after laparotomy, usually for a perforated viscus (notably perforated appendicitis). It has also occurred after gall bladder operations, after colectomy for ulcerative colitis and even after drainage of an empyema thoracis. The condition is due to the synergistic action of microaerophilic non-haemolytic streptococci and, usually, a *Staphylococcus*. The skin in the immediate vicinity of the wound exhibits signs of cellulitis. Within a few hours, a central purplish zone with an outer brilliant red zone can be distinguished and the whole region is extremely tender. The condition advances with various degrees of rapidity (Fig. 57.25). The gangrenous skin liquefies, exposing underlying granulation tissue. If the condition persists, overwhelming septicaemia and associated multi-organ failure supervene.

Figure 57.25 Bacterial synergistic gangrene of the chest and abdominal wall. The area has become gangrenous and looks like suede leather. Beware of amoebiasis cutis.

Treatment

Identification of the organisms and a report on their sensitivity to antibiotics is essential. Metronidazole should be given together with a powerful broad-spectrum antibiotic. Without vigorous and effective treatment, the gangrene spreads to the flanks and the patient may die of toxæmia. If the infection has become established, surgical debridement of all the necrotic and infected tissue should be performed. Hyperbaric oxygen, if available, can be life-saving. Cellulitis due to bacteroids may give no bacterial growth by conventional techniques and may be missed.

Amoebic cutis

The possibility of this potentially lethal complication of amoebic colitis, liver abscess or empyema should always be considered. Confirmation may be difficult and an immunofluorescence test necessary.

Subcutaneous gas-forming infection

This is described in Chapter 4 (under Gas gangrene).

Neoplasms of the abdominal wall**Desmoid tumour**

A desmoid tumour is a tumour arising in the musculoaponeurotic structures of the abdominal wall, especially below the level of the umbilicus. It is a completely unencapsulated fibroma and is so hard that it creaks when it is cut. Some cases recur repeatedly in spite of apparently adequate excision.

Aetiology

About 80% of cases occur in women, many of whom have borne children, and the neoplasm occurs occasionally in scars of old hernial or other abdominal operation wounds. Consequently, trauma, for example the stretching of the muscle fibres during pregnancy or possibly a small haematoma of the abdominal wall, appears to be an aetiological factor. They can occur in cases of familial adenomatous polyposis (FAP).

Pathology

The tumour is composed of fibrous tissue containing multinucleated plasmodial masses resembling foreign body giant cells. Usually of very slow growth, it tends to infiltrate muscle in the immediate area. Eventually it undergoes a myxomatous change and it then increases in size more rapidly. Metastasis does not occur. Unlike fibroma elsewhere, no sarcomatous change occurs.

Treatment

Unless the tumour is excised widely, with a surrounding margin of at least 2.5 cm of healthy tissue, recurrence commonly takes place. After removal of a large tumour, repair of the defect in the abdominal wall by nylon mesh is required. These tumours are moderately radiosensitive. (Intraperitoneal desmoids are best left alone when possible.)

Fibrosarcoma of the abdominal wall

Fibrosarcoma of the abdominal wall is rare. It is resistant to radiotherapy and only in some cases can a wide excision with nylon mesh repair offer hope of a cure.

Adenocarcinoma

Adenocarcinoma of the colon or of other viscera may invade the abdominal wall. In such cases, the resection of this extension, along with the primary growth, may require special repair of the resulting defect.

Secondary implantation in the wound may follow any abdominal operation for carcinoma; bladder cancer is notorious for this propensity.

The peritoneum, omentum, mesentery and retroperitoneal space

CHAPTER 58

LEARNING OBJECTIVES

To recognise and understand:

- The clinical features of localised and generalised peritonitis
- The common causes and complications of peritonitis
- The principles of surgical management in patients with peritonitis
- The clinical presentations and treatment of abdominal/pelvic abscesses
- The clinical presentations of tuberculous peritonitis
- The causes and pathophysiology of ascites
- The spectrum of mesenteric and retroperitoneal conditions

THE PERITONEUM

The peritoneal membrane is conveniently divided into two parts – the visceral peritoneum surrounding the viscera and the parietal peritoneum lining the other surfaces of the cavity. The peritoneum has a number of functions (Summary box 58.1).

Summary box 58.1

Functions of the peritoneum

- Pain perception (parietal peritoneum)
- Visceral lubrication
- Fluid and particulate absorption
- Inflammatory and immune responses
- Fibrinolytic activity

The parietal portion is richly supplied with nerves and, when irritated, causes severe pain accurately localised to the affected area. The visceral peritoneum, in contrast, is poorly supplied with nerves and its irritation causes vague pain that is usually located to the midline.

The peritoneal cavity is the largest cavity in the body, the surface area of its lining membrane (2 m² in an adult) being nearly equal to that of the skin. The peritoneal membrane is composed of flattened polyhedral cells (mesothelium), one layer thick, resting upon a thin layer of fibroelastic tissue. Beneath the peritoneum, supported by a small amount of areolar tissue, lies a network of lymphatic vessels and rich plexuses of capillary blood vessels from which all absorption and exudation must occur. In health, only a few millilitres of peritoneal fluid is found in the peritoneal cavity. The fluid is pale yellow, somewhat viscid and contains lymphocytes and other leucocytes; it lubricates the viscera, allowing easy movement and peristalsis.

In the peritoneal space, mobile gas-filled structures float

upwards, as does free air ('gas'). In the erect position, when free fluid is present in the peritoneal cavity, pressure is reduced in the upper abdomen compared with the lower abdomen. When air is introduced, it rises, allowing all of the abdominal contents to sink.

During expiration, intra-abdominal pressure is reduced and peritoneal fluid, aided by capillary attraction, travels in an upward direction towards the diaphragm. Experimental evidence shows that particulate matter and bacteria are absorbed within a few minutes into the lymphatic network through a number of 'pores' within the diaphragmatic peritoneum. This upward movement of peritoneal fluids is responsible for the occurrence of many subphrenic abscesses.

The peritoneum has the capacity to absorb large volumes of fluid: this ability is used during peritoneal dialysis in the treatment of renal failure. But the peritoneum can also produce an inflammatory exudate when injured (Summary box 58.2).

Summary box 58.2

Causes of a peritoneal inflammatory exudate

- Bacterial infection, e.g. appendicitis, tuberculosis
- Chemical injury, e.g. bile peritonitis
- Ischaemic injury, e.g. strangulated bowel, vascular occlusion
- Direct trauma, e.g. operation
- Allergic reaction, e.g. starch peritonitis

When a visceral perforation occurs, the free fluid that spills into the peritoneal cavity runs downwards, largely directed by the normal peritoneal attachments. For example, spillage from a perforated duodenal ulcer may run down the right paracolic gutter.

When parietal peritoneal defects are created, healing occurs not from the edges but by the development of new mesothelial

cells throughout the surface of the defect. In this way, large defects heal as rapidly as small defects.

ACUTE PERITONITIS

Most cases of peritonitis are caused by an invasion of the peritoneal cavity by bacteria, so that when the term 'peritonitis' is used without qualification, bacterial peritonitis is implied. Bacterial peritonitis is usually polymicrobial, both aerobic and anaerobic organisms being present. The exception is primary peritonitis ('spontaneous' peritonitis), in which a pure infection with streptococcal, pneumococcal or *Haemophilus* bacteria occurs.

Bacteriology

Bacteria from the gastrointestinal tract

The number of bacteria within the lumen of the gastrointestinal tract is normally low until the distal small bowel is reached, whereas high concentrations are found in the colon. However, disease (e.g. obstruction, achlorhydria, diverticula) may increase proximal colonisation. The biliary and pancreatic tracts are normally free from bacteria, although they may be infected in disease, e.g. gallstones. Peritoneal infection is usually caused by two or more bacterial strains. Gram-negative bacteria contain endotoxins (lipopolysaccharides) in their cell walls that have multiple toxic effects on the host, primarily by causing the release of tumour necrosis factor (TNF) from host leucocytes. Systemic absorption of endotoxin may produce endotoxic shock with hypotension and impaired tissue perfusion. Other bacteria such as *Clostridium welchii* produce harmful exotoxins.

Bacteroides are commonly found in peritonitis. These Gram-negative, non-sporing organisms, although predominant in the lower intestine, often escape detection because they are strictly anaerobic and slow to grow on culture media unless there is an adequate carbon dioxide tension in the anaerobic apparatus (Gillespie). In many laboratories, the culture is discarded if there is no growth in 48 hours. These organisms are resistant to penicillin and streptomycin but sensitive to metronidazole, clindamycin, lincomycin and cephalosporin compounds. Since the widespread use of metronidazole (Flagyl), *Bacteroides* infections have greatly diminished.

Non-gastrointestinal causes of peritonitis

Pelvic infection via the fallopian tubes is responsible for a high proportion of 'non-gastrointestinal' infections.

Immunodeficient patients, for example those with human immunodeficiency virus (HIV) infection or those on immunosuppressive treatment, may present with opportunistic peritoneal infection, e.g. *Mycobacterium avium-intracellulare* (MAI) (Summary box 58.3).

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900), and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

William Henry Welch, 1850–1934, Professor of Pathology, Johns Hopkins University, Baltimore, MD, USA, discovered the causative organism of gas gangrene in 1892.

William Alexander Gillespie, Formerly Professor of Clinical Bacteriology, The University of Bristol, Bristol, England.

Gabriele Falloppio, (Fallopius), 1523–1563, Professor of Anatomy, Surgery, and Botany, Padua, Italy.

Summary box 58.3

Bacteria in peritonitis

Gastrointestinal source

- *Escherichia coli*
- Streptococci (aerobic and anaerobic)
- *Bacteroides*
- *Clostridium*
- *Klebsiella pneumoniae*
- *Staphylococcus*

Other sources

- *Chlamydia*
- Gonococcus
- β -Haemolytic streptococci
- Pneumococcus
- *Mycobacterium tuberculosis*

Route of infection

Infecting organisms may reach the peritoneal cavity via a number of routes (Summary box 58.4).

Summary box 58.4

Paths to peritoneal infection

- Gastrointestinal perforation, e.g. perforated ulcer, diverticular perforation
- Exogenous contamination, e.g. drains, open surgery, trauma
- Transmural bacterial translocation (no perforation), e.g. inflammatory bowel disease, appendicitis, ischaemic bowel
- Female genital tract infection, e.g. pelvic inflammatory disease
- Haematogenous spread (rare), e.g. septicaemia

Even in patients with non-bacterial peritonitis (e.g. acute pancreatitis, intraperitoneal rupture of the bladder or haemoperitoneum), the peritoneum often becomes infected by transmural spread of organisms from the bowel, and it is not long (often a matter of hours) before a bacterial peritonitis develops. Most duodenal perforations are initially sterile for up to several hours, and many gastric perforations are also sterile at first; intestinal perforations are usually infected from the beginning. The proportion of anaerobic to aerobic organisms increases with the passage of time. Mortality reflects:

- the degree and duration of peritoneal contamination;
- the age of the patient;
- the general health of the patient;
- the nature of the underlying cause.

Localised peritonitis

Anatomical, pathological and surgical factors may favour the localisation of peritonitis.

Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the Bacterium Coli Commune in 1886.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, in the Czech Republic; Zurich, Switzerland, and The Rush Medical College, Chicago, IL, USA.

Anatomical

The greater sac of the peritoneum is divided into (1) the subphrenic spaces, (2) the pelvis and (3) the peritoneal cavity proper. The last is divided into a supracolic and an infracolic compartment by the transverse colon and transverse mesocolon, which deters the spread of infection from one to the other. When the supracolic compartment overflows, as is often the case when a peptic ulcer perforates, it does so over the colon into the infracolic compartment or by way of the right paracolic gutter to the right iliac fossa and hence to the pelvis.

Pathological

The clinical course is determined in part by the manner in which adhesions form around the affected organ. Inflamed peritoneum loses its glistening appearance and becomes reddened and velvety. Flakes of fibrin appear and cause loops of intestine to become adherent to one another and to the parietes. There is an outpouring of serous inflammatory exudate rich in leucocytes and plasma proteins that soon becomes turbid; if localisation occurs, the turbid fluid becomes frank pus. Peristalsis is retarded in affected bowel and this helps to prevent distribution of the infection. The greater omentum, by enveloping and becoming adherent to inflamed structures, often forms a substantial barrier to the spread of infection.

Surgical

Drains are frequently placed during operation to assist localisation (and exit) of intra-abdominal collections: their value is disputed. They may act as conduits for exogenous infection.

Diffuse peritonitis

A number of factors may favour the development of diffuse peritonitis:

- *Speed of peritoneal contamination* is a prime factor. If an inflamed appendix (Fig. 58.1) or other hollow viscus perforates before localisation has taken place, there is a gush of contents into the peritoneal cavity, which may spread over a large area almost instantaneously. Perforation proximal to an obstruction or from sudden anastomotic separation is associated with severe generalised peritonitis and a high mortality rate.

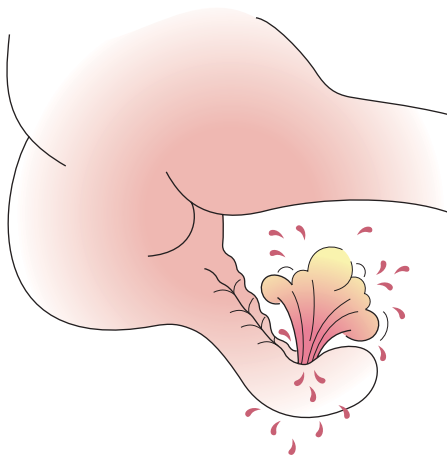

Figure 58.1 Sudden perforation, especially if engendered by purgation, often results in an immediate, widespread bacterial peritonitis.

- *Stimulation of peristalsis* by the ingestion of food or even water hinders localisation. Violent peristalsis occasioned by the administration of a purgative or an enema may cause the widespread distribution of an infection that would otherwise have remained localised.
- The *virulence of the infecting organism* may be so great as to render the localisation of infection difficult or impossible.
- *Young children* have a small omentum, which is less effective in localising infection.
- *Disruption of localised collections* may occur with injudicious handling, e.g. appendix mass or pericolic abscess.
- *Deficient natural resistance* ('immune deficiency') may result from use of drugs (e.g. steroids), disease [e.g. acquired immune deficiency syndrome (AIDS)] or old age.

Clinical features

Localised peritonitis

Localised peritonitis is bound up intimately with the causative condition, and the initial symptoms and signs are those of that condition. When the peritoneum becomes inflamed, the temperature, and especially the pulse rate, rise. Abdominal pain increases and usually there is associated vomiting. The most important sign is guarding and rigidity of the abdominal wall over the area of the abdomen that is involved, with a positive 'release' sign (rebound tenderness). If inflammation arises under the diaphragm, shoulder tip ('phrenic') pain may be felt. In cases of pelvic peritonitis arising from an inflamed appendix in the pelvic position or from salpingitis, the abdominal signs are often slight; there may be deep tenderness of one or both lower quadrants alone, but a rectal or vaginal examination reveals marked tenderness of the pelvic peritoneum. With appropriate treatment, localised peritonitis usually resolves; in about 20% of cases, an abscess follows. Infrequently, localised peritonitis becomes diffuse. Conversely, in favourable circumstances, diffuse peritonitis can become localised, most frequently in the pelvis or at multiple sites within the abdominal cavity.

Diffuse (generalised) peritonitis

Diffuse (generalised) peritonitis may present in differing ways dependent on the duration of infection.

Early

Abdominal pain is severe and made worse by moving or breathing. It is first experienced at the site of the original lesion and spreads outwards from this point. Vomiting may occur. The patient usually lies still. Tenderness and rigidity on palpation are found typically when the peritonitis affects the anterior abdominal wall. Abdominal tenderness and rigidity are diminished or absent if the anterior wall is unaffected, as in pelvic peritonitis or, rarely, peritonitis in the lesser sac. Patients with pelvic peritonitis may complain of urinary symptoms; they are tender on rectal or vaginal examination. Infrequent bowel sounds may still be heard for a few hours but they cease with the onset of paralytic ileus. The pulse rises progressively but, if the peritoneum is deluged with irritant fluid, there is a sudden rise. The temperature changes are variable and *can be subnormal*.

Late

If resolution or localisation of generalised peritonitis does not occur, the abdomen remains silent and increasingly distends.

Circulatory failure ensues, with cold, clammy extremities, sunken eyes, dry tongue, thready (irregular) pulse and drawn and anxious face (Hippocratic facies; Fig. 58.2). The patient finally lapses into unconsciousness. With early diagnosis and adequate treatment, this condition is rarely seen in modern surgical practice (Summary box 58.5).

Summary box 58.5

Clinical features in peritonitis

- Abdominal pain, worse on movement
- Guarding/rigidity of abdominal wall
- Pain/tenderness on rectal/vaginal examination (pelvic peritonitis)
- Pyrexia (may be absent)
- Raised pulse rate
- Absent or reduced bowel sounds
- 'Septic shock' [systemic inflammatory response syndrome (SIRS)] in later stages

Diagnostic aids

Investigations may elucidate a doubtful diagnosis, but the importance of a careful history and repeated examination must not be forgotten.

- A radiograph of the abdomen may confirm the presence of dilated gas-filled loops of bowel (consistent with a paralytic ileus) or show free gas, although the latter is best shown on an erect chest radiograph (Fig. 58.3). If the patient is too ill for an 'erect' film to demonstrate free air under the diaphragm, a lateral decubitus film is just as useful, showing gas beneath the abdominal wall.
- Serum amylase estimation may establish the diagnosis of acute pancreatitis provided that it is remembered that moderately raised values are frequently found following other

Figure 58.2 The Hippocratic facies in terminal diffuse peritonitis.

Hippocrates of Cos, a Greek Physician and Surgeon, and by common consent 'The Father of Medicine', was born on the island of Cos, off Turkey, about 460 bc and probably died in 375 bc.

Figure 58.3 Gas under the diaphragm in a patient with free perforation and peritonitis (courtesy of Dr S. Padley, Chelsea and Westminster Hospital, London, UK).

abdominal catastrophes and operations, e.g. perforated duodenal ulcer.

- Ultrasound and computerised tomography (CT) scanning are increasingly used to identify the cause of peritonitis (Fig. 58.4). Such knowledge may influence management decisions.
- Peritoneal diagnostic aspiration may be helpful but is usually unnecessary. Bile-stained fluid indicates a perforated peptic ulcer or gall bladder; the presence of pus indicates bacterial peritonitis. Blood is aspirated in a high proportion of patients with intraperitoneal bleeding (Summary box 58.6).

Figure 58.4 Acute pancreatitis seen on computerised tomography scanning with swelling of the gland and surrounding inflammatory changes (courtesy of Dr J. Healy, Chelsea and Westminster Hospital, London, UK).

Summary box 58.6**Investigations in peritonitis**

- Raised white cell count and C-reactive protein are usual
- Serum amylase > 4× normal indicates acute pancreatitis
- Abdominal radiographs are occasionally helpful
- Erect chest radiographs may show free peritoneal gas (perforated viscus)
- Ultrasound/CT scanning often diagnostic
- Peritoneal fluid aspiration (with or without ultrasound guidance) may be helpful

Treatment

In case of doubt, early surgical intervention is to be preferred to a 'wait and see' policy. This rule is particularly true for previously healthy patients and those with postoperative peritonitis. Caution is required in patients at high operative risk because of comorbidity or advanced age.

Treatment consists of:

- general care of the patient;
- specific treatment of the cause;
- peritoneal lavage when appropriate.

General care of the patient

The care of critically ill surgical patients is described in detail in Chapters 13, 16 and 20. Nutritional support is covered in Chapter 17 and anaesthesia and pain relief in Chapter 14.

Correction of circulating volume and electrolyte imbalance

Patients are frequently hypovolaemic with electrolyte disturbances. The plasma volume must be restored and electrolyte concentrations corrected. Central venous catheterisation and pressure monitoring may be helpful, particularly in patients with concurrent disease. Plasma protein depletion may also need correction as the inflamed peritoneum leaks large amounts of protein. If the patient's recovery is delayed for more than 7–10 days, intravenous nutrition is required.

Gastrointestinal decompression

A nasogastric tube is passed into the stomach and aspirated. Intermittent aspiration is maintained until the paralytic ileus has resolved. Measured volumes of water are allowed by mouth when only small amounts are being aspirated. If the abdomen is soft and not tender, and bowel sounds return, oral feeding may be progressively introduced. It is important not to prolong the ileus by missing this stage.

Antibiotic therapy

Administration of antibiotics prevents the multiplication of bacteria and the release of endotoxins. As the infection is usually a mixed one, initial treatment with parenteral broad-spectrum antibiotics active against aerobic and anaerobic bacteria should be given.

Correction of fluid loss

A fluid balance chart must be started so that daily output by gastric aspiration and urine is known. Additional losses from the lungs, skin and in faeces are estimated, so that the intake requirements can be calculated and seen to have been administered.

Throughout recovery, the haematocrit and serum electrolytes and urea must be checked regularly.

Analgesia

The patient should be nursed in the sitting-up position and must be relieved of pain before and after operation. If appropriate expertise is available, epidural infusion may provide excellent analgesia. Freedom from pain allows early mobilisation and adequate physiotherapy in the postoperative period, which help to prevent basal pulmonary collapse, deep vein thrombosis and pulmonary embolism.

Vital system support

Special measures may be needed for cardiac, pulmonary and renal support, especially if septic shock is present (see Chapter 2).

Specific treatment of the cause

If the cause of peritonitis is amenable to surgery, operation must be carried out as soon as the patient is fit for anaesthesia. This is usually within a few hours. In peritonitis caused by pancreatitis or salpingitis, or in cases of primary peritonitis of streptococcal or pneumococcal origin, non-operative treatment is preferred provided the diagnosis can be made with confidence.

Peritoneal lavage

In operations for general peritonitis it is essential that, after the cause has been dealt with, the whole peritoneal cavity is explored with the sucker and, if necessary, mopped dry until all seropurulent exudate is removed. The use of a large volume of saline (1–2 litres) containing dissolved antibiotic (e.g. tetracycline) has been shown to be effective (Matheson) (Summary box 58.7).

Summary box 58.7**Management of peritonitis**

General care of patient:

- Correction of fluid and electrolyte imbalance
- Insertion of nasogastric drainage tube
- Broad-spectrum antibiotic therapy
- Analgesia
- Vital system support

Operative treatment of cause when appropriate with peritoneal debridement/lavage

Prognosis and complications

With modern treatment, diffuse peritonitis carries a mortality rate of about 10%. The systemic and local complications are shown in Summary boxes 58.8 and 58.9.

Summary box 58.8**Systemic complications of peritonitis**

- Bacteraemic/endotoxic shock
- Bronchopneumonia/respiratory failure
- Renal failure
- Bone marrow suppression
- Multisystem failure

Summary box 58.9

Abdominal complications of peritonitis

- Adhesional small bowel obstruction
- Paralytic ileus
- Residual or recurrent abscess
- Portal pyaemia/liver abscess

Acute intestinal obstruction due to peritoneal adhesions

This usually gives central colicky abdominal pain with evidence of small bowel gas and fluid levels sometimes confined to the proximal intestine on radiography. Bowel sounds are increased. It is more common with localised peritonitis. It is essential to distinguish this from paralytic ileus.

Paralytic ileus

There is usually little pain, and gas-filled loops with fluid levels are seen distributed throughout the small and large intestines on abdominal imaging. In paralytic ileus, bowel sounds are reduced or absent.

Abdominal and pelvic abscesses

Abscess formation following local or diffuse peritonitis usually occupies one of the situations shown in Fig. 58.5. The symptoms and signs of a purulent collection may be vague and consist of nothing more than lassitude, anorexia and malaise; pyrexia (often low-grade), tachycardia, leucocytosis, raised C-reactive protein and localised tenderness are also common (Summary box 58.10).

Summary box 58.10

Clinical features of an abdominal/pelvic abscess

- Malaise
- Sweats with or without rigors
- Abdominal/pelvic (with or without shoulder tip) pain
- Anorexia and weight loss
- Symptoms from local irritation, e.g. hiccoughs (subphrenic), diarrhoea and mucus (pelvic)
- Swinging pyrexia
- Localised abdominal tenderness/mass

Figure 58.5 Common situations for residual abscesses: (1) subphrenic; (2) paracolic; (3) right iliac fossa; (4) pelvic.

Later, a palpable mass may develop that should be monitored by marking out its limits on the abdominal wall and meticulous daily examination. More commonly, its course is monitored by repeat ultrasound or CT scanning. In most cases, with the aid of antibiotic treatment, the abscess or mass gradually reduces in size until, finally, it is undetectable. In others, the abscess fails to resolve or becomes larger, in which event it must be drained. In many situations, by waiting for a few days the abscess becomes adherent to the abdominal wall, so that it can be drained without opening the general peritoneal cavity. If facilities are available, ultrasound- or CT-guided drainage may avoid further operation. Open drainage of an intraperitoneal collection should be carried out by cautious blunt finger exploration to minimise the risk of an intestinal fistula.

Pelvic abscess

The pelvis is the commonest site of an intraperitoneal abscess because the vermiform appendix is often pelvic in position and the fallopian tubes are frequent sites of infection. A pelvic abscess can also occur as a sequel to any case of diffuse peritonitis and is common after anastomotic leakage following colorectal surgery. The most characteristic symptoms are diarrhoea and the passage of mucus in the stools. Rectal examination reveals a bulging of the anterior rectal wall, which, when the abscess is ripe, becomes softly cystic. Left to nature, a proportion of these abscesses burst into the rectum, after which the patient nearly always recovers rapidly. If this does not occur, the abscess should be drained deliberately. In women, vaginal drainage through the posterior fornix is often chosen. In other cases, when the abscess is definitely pointing into the rectum, rectal drainage (Fig. 58.6) is employed. If any uncertainty exists, the presence of pus should be confirmed by ultrasound or CT scanning with needle aspiration if indicated. Laparotomy is almost never necessary. Rectal drainage of a pelvic abscess is far preferable to suprapubic drainage, which risks exposing the general peritoneal cavity to infection. Drainage tubes can also be inserted percutaneously or via the vagina or rectum under ultrasound or CT guidance (Fig. 58.7).

Intraperitoneal abscess**Anatomy**

The complicated arrangement of the peritoneum results in the formation of four intraperitoneal spaces in which pus may collect (Figs 58.8 and 58.9).

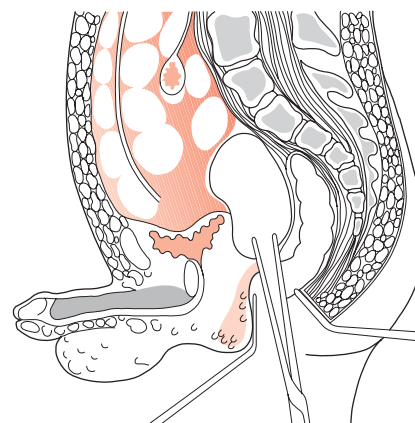

Figure 58.6 Opening a pelvic abscess into the rectum.

Figure 58.7 A pelvic abscess seen on computerised tomography scanning (courtesy of Dr J. Healy, Chelsea and Westminster Hospital, London, UK).

Figure 58.8 Intraperitoneal abscesses on transverse section. (1) The left subphrenic space; (2) left subhepatic space/lesser sac; (3) right subphrenic space; (4) right subhepatic space.

Figure 58.9 Intraperitoneal abscesses on sagittal section. (1) Left subphrenic; (2) left subhepatic/lesser sac; (3) right subphrenic; (4) right subhepatic.

Left subphrenic space

This is bounded above by the diaphragm and behind by the left triangular ligament and the left lobe of the liver, the gastrohepatic omentum and the anterior surface of the stomach. To the right is the falciform ligament and to the left the spleen, gastrosplenic omentum and diaphragm. The common cause of an

abscess here is an operation on the stomach, the tail of the pancreas, the spleen or the splenic flexure of the colon.

Left subhepatic space/lesser sac

The commonest cause of infection here is complicated acute pancreatitis. In practice, a perforated gastric ulcer rarely causes a collection here because the potential space is obliterated by adhesions.

Right subphrenic space

This space lies between the right lobe of the liver and the diaphragm. It is limited posteriorly by the anterior layer of the coronary and the right triangular ligaments and to the left by the falciform ligament. Common causes of abscess here are perforating cholecystitis, a perforated duodenal ulcer, a duodenal cap 'blow-out' following gastrectomy and appendicitis.

Right subhepatic space

This lies transversely beneath the right lobe of the liver in Rutherford Morison's pouch. It is bounded on the right by the right lobe of the liver and the diaphragm. To the left is situated the foramen of Winslow and below this lies the duodenum. In front are the liver and the gall bladder and behind are the upper part of the right kidney and the diaphragm. The space is bounded above by the liver and below by the transverse colon and hepatic flexure. It is the deepest space of the four and the commonest site of a subphrenic abscess, which usually arises from appendicitis, cholecystitis, a perforated duodenal ulcer or following upper abdominal surgery.

Clinical features

The symptoms and signs of subphrenic infection are frequently non-specific and it is well to remember the aphorism, 'pus somewhere, pus nowhere else, pus under the diaphragm'.

Symptoms

A common history is that, when some infective focus in the abdominal cavity has been dealt with, the condition of the patient improves temporarily but, after an interval of a few days or weeks, symptoms of toxæmia reappear. The condition of the patient steadily, and often rapidly, deteriorates. Sweating, wasting and anorexia are present. There is sometimes epigastric fullness and pain, or pain in the shoulder on the affected side, because of irritation of sensory fibres in the phrenic nerve, referred along the descending branches of the cervical plexus. Persistent hiccoughs may be a presenting symptom.

Signs

A swinging pyrexia is usually present. If the abscess is anterior, abdominal examination will reveal some tenderness, rigidity or even a palpable swelling. Sometimes the liver is displaced downwards but more often it is fixed by adhesions. Examination of the chest is important and, in the majority of cases, collapse of the lung or evidence of basal effusion or even an empyema is found.

James Rutherford Morison, 1853–1939, Professor of Surgery, The University of Durham, Durham, England.
Jacob Benignus Winslow, 1669–1760, Professor of Anatomy, Physic and Surgery, Paris, France.

Investigations

A number of the following investigations may be helpful:

- *Blood tests* usually show a leucocytosis and raised C-reactive protein.
- A *plain radiograph* sometimes demonstrates the presence of gas or a pleural effusion. On screening, the diaphragm is often seen to be elevated (so called 'tented' diaphragm) and its movements impaired.
- *Ultrasound* or *CT scanning* is the investigation of choice and permits early detection of subphrenic collections (Fig. 58.10).
- *Radiolabelled white cell scanning* may occasionally prove helpful when other imaging techniques have failed.

Differential diagnosis

Pyelonophritis, amoebic abscess, pulmonary collapse and pleural empyema may give rise to diagnostic difficulty.

Treatment

The clinical course of suspected cases is monitored, and blood tests and imaging investigations are carried out at suitable intervals. If suppuration seems probable, intervention is indicated. If skilled help is available it is usually possible to insert a percutaneous drainage tube under ultrasound or CT control. The same tube can be used to instil antibiotic solutions or irrigate the abscess cavity. To pass an aspirating needle at the bedside through the pleura and diaphragm invites potentially catastrophic spread of the infection into the pleural cavity.

If an operative approach is necessary and a swelling can be detected in the subcostal region or in the loin, an incision is made over the site of maximum tenderness or over any area where oedema or redness is discovered. The parietes usually form part of the abscess wall so that contamination of the general peritoneal cavity is unlikely.

If no swelling is apparent, the subphrenic spaces should be explored by either an anterior subcostal approach or from behind after removal of the outer part of the 12th rib according to the position of the abscess on imaging. With the posterior approach, the pleura must not be opened and, after the fibres of the diaphragm have been separated, a finger is inserted beneath the diaphragm so as to explore the adjacent area. The aim with all techniques of drainage is to avoid dissemination of pus into the peritoneal or pleural cavities.

Figure 58.10 A subphrenic abscess drained under computerised tomography guidance (courtesy of Dr J. Healy, Chelsea and Westminster Hospital, London, UK).

When the cavity is reached, all of the fibrinous loculi must be broken down with the finger and one or two drainage tubes must be fully inserted. These drains are withdrawn gradually during the next 10 days and the closure of the cavity is checked by sinograms or scanning. Appropriate antibiotics are also given.

SPECIAL FORMS OF PERITONITIS

Postoperative

The patient is ill with raised pulse and peripheral circulatory failure. Following an anastomotic dehiscence, the general condition of a patient is usually more serious than if the patient had suffered leakage from a perforated peptic ulcer with no preceding operation. Local symptoms and signs are less definite. Abdominal pain may not be prominent and is often difficult to assess because of normal wound pain and postoperative analgesia. The patient's deterioration may be attributed wrongly to cardiopulmonary collapse, which is usually concomitant.

Peritonitis follows abdominal operations more frequently than is realised. The principles of treatment do not differ from those of peritonitis of other origin. Antibiotic therapy alone is inadequate; no antibiotic can stay the onslaught of bacterial peritonitis caused by leakage from a suture line, which must be dealt with by operation.

In patients on treatment with steroids

Pain is frequently slight or absent. Physical signs are similarly vague and misleading.

In children

The diagnosis can be more difficult, particularly in the preschool child (see Chapter 6). Physical signs should be elicited by a gentle, patient and sympathetic approach.

In patients with dementia

Such patients can be fractious and unable to give a reliable history. Abdominal tenderness is usually well localised, but guarding and rigidity are less marked because the abdominal muscles are often thin and weak.

Bile peritonitis

Unless there is reason to suspect that the biliary tract was damaged during operation, it is improbable that bile as a cause of peritonitis will be thought of until the abdomen has been opened. The common causes of bile peritonitis are shown in Summary box 58.11.

Summary box 58.11

Causes of bile peritonitis

- Perforated cholecystitis
- Post cholecystectomy:
 - Cystic duct stump leakage
 - Leakage from an accessory duct in the gall bladder bed
 - Bile duct injury
 - T-tube drain dislodgement (or tract rupture on removal)
- Following other operations/procedures:
 - Leaking duodenal stump post gastrectomy
 - Leaking biliary-enteric anastomosis
 - Leakage around percutaneous placed biliary drains
- Following liver trauma

Unless the bile has extravasated slowly and the collection becomes shut off from the general peritoneal cavity, there are signs of diffuse peritonitis. After a few hours a tinge of jaundice is not unusual. Laparotomy (or laparoscopy) should be undertaken with evacuation of the bile and peritoneal lavage. The source of bile leakage should be identified. A leaking gall bladder is excised or a cystic duct ligated. An injury to the bile duct may simply be drained or alternatively intubated; later, reconstructive operation is often required. Infected bile is more lethal than sterile bile. A 'blown' duodenal stump should be drained as it is too oedematous to repair, but sometimes it can be covered by a jejunal patch. The patient is often jaundiced from absorption of peritoneal bile, but the surgeon must ensure that the abdomen is not closed until any obstruction to a major bile duct has been either excluded or relieved. Bile leaks after cholecystectomy or liver trauma may be dealt with by percutaneous (ultrasound-guided) drainage and endoscopic biliary stenting to reduce bile duct pressure. The drain is removed when dry and the stent at 4–6 weeks.

Meconium peritonitis (see Chapter 6)

Pneumococcal peritonitis

Primary pneumococcal peritonitis may complicate nephrotic syndrome or cirrhosis in children. Otherwise healthy children, particularly girls between 3 and 9 years of age, may also be affected, and it is likely that the route of infection is sometimes via the vagina and fallopian tubes. At other times, and always in males, the infection is blood-borne and secondary to respiratory tract or middle ear disease. The prevalence of pneumococcal peritonitis has declined greatly and the condition is now rare.

Clinical features

The onset is sudden and the earliest symptom is pain localised to the lower half of the abdomen. The temperature is raised to 39°C or more and there is usually frequent vomiting. After 24–48 hours, profuse diarrhoea is characteristic. There is usually increased frequency of micturition. The last two symptoms are caused by severe pelvic peritonitis. On examination, abdominal rigidity is usually bilateral but is less than in most cases of acute appendicitis with peritonitis.

Differential diagnosis

A leucocytosis of 30 000 μl^{-1} ($30 \times 10^9 \text{ l}^{-1}$) or more with approximately 90% polymorphs suggests pneumococcal peritonitis rather than appendicitis. Even so, it is often impossible to exclude perforated appendicitis. The other condition that can be difficult to differentiate from primary pneumococcal peritonitis in its early stage is basal pneumonia. An unduly high respiratory rate and the absence of abdominal rigidity are the most important signs supporting the diagnosis of pneumonia, which is usually confirmed by a chest radiograph.

Treatment

After starting antibiotic therapy and correcting dehydration and electrolyte imbalance, early surgery is required unless spontaneous infection of pre-existing ascites is strongly suspected, in which case a diagnostic peritoneal tap is useful. Laparotomy or laparoscopy may be used. Should the exudate be odourless and

sticky, the diagnosis of pneumococcal peritonitis is practically certain, but it is essential to perform a careful exploration to exclude other pathology. Assuming that no other cause for the peritonitis is discovered, some of the exudate is aspirated and sent to the laboratory for microscopy, culture and sensitivity tests. Thorough peritoneal lavage is carried out and the incision closed. Antibiotic and fluid replacement therapy are continued. Nasogastric suction drainage is essential. Recovery is usual.

Other organisms are now known to cause some cases of primary pneumococcal peritonitis in children, including *Haemophilus*, other streptococci and a few Gram-negative bacteria. Underlying pathology (including an intravaginal foreign body in girls) must always be excluded before primary peritonitis can be diagnosed with certainty.

Idiopathic streptococcal and staphylococcal peritonitis in adults

Idiopathic streptococcal and staphylococcal peritonitis in adults is fortunately rare. In streptococcal peritonitis, the peritoneal exudate is odourless and thin, contains some flecks of fibrin and may be blood-stained. In these circumstances pus is removed by suction, the abdomen closed with drainage and non-operative treatment of peritonitis performed. The use of intravaginal tampons has led to an increased incidence of *Staphylococcus aureus* infections: these can be associated with 'toxic shock syndrome' and disseminated intravascular coagulopathy.

Familial Mediterranean fever (periodic peritonitis)

Familial Mediterranean fever (periodic peritonitis) is characterised by abdominal pain and tenderness, mild pyrexia, polymorphonuclear leucocytosis and, occasionally, pain in the thorax and joints. The duration of an attack is 24–72 hours, when it is followed by complete remission, but exacerbations recur at regular intervals. Most of the patients have undergone appendectomy in childhood. This disease, often familial, is limited principally to Arab, Armenian and Jewish populations; other races are occasionally affected. Mutations in the *MEFV* (Mediterranean fever) gene appear to cause the disease. This gene produces a protein called pyrin, which is expressed mostly in neutrophils but whose exact function is not known.

Usually, children are affected but it is not rare for the disease to make its first appearance in early adult life, with cases in women outnumbering those in men by two to one. Exceptionally, the disease becomes manifest in patients over 40 years of age. At operation, which may be necessary to exclude other causes but should be avoided if possible, the peritoneum – particularly in the vicinity of the spleen and the gall bladder – is inflamed. There is no evidence that the interior of these organs is abnormal. Colchicine therapy is used during attacks and to prevent recurrent attacks.

Starch peritonitis

Like talc, starch powder has found disfavour as a surgical glove lubricant. In a few starch-sensitive patients, it causes a painful ascites, fortunately of limited duration. Should laparotomy be performed, any small granulomas in, say, the omentum will be found to contain birefringent starch particles. Starch-free surgical gloves are now widely available.

TUBERCULOUS PERITONITIS

Acute tuberculous peritonitis

Tuberculous peritonitis sometimes has an onset that so closely resembles acute peritonitis that the abdomen is opened. Straw-coloured fluid escapes and tubercles are seen scattered over the peritoneum and greater omentum. Early tubercles are greyish and translucent. They soon undergo caseation and appear white or yellow and are then less difficult to distinguish from carcinoma. Occasionally, they appear like patchy fat necrosis. On opening the abdomen and finding tuberculous peritonitis, the fluid is evacuated, some being retained for bacteriological studies. A portion of the diseased omentum is removed for histological confirmation of the diagnosis and the wound closed without drainage.

Chronic tuberculous peritonitis

The condition presents with abdominal pain (90% of cases), fever (60%), loss of weight (60%), ascites (60%), night sweats (37%) and abdominal mass (26%) (Summary box 58.12).

Summary box 58.12

Tuberculous peritonitis

- Acute and chronic forms
- Abdominal pain, sweats, malaise and weight loss are frequent
- Caseating peritoneal nodules are common – distinguish from metastatic carcinoma and fat necrosis of pancreatitis
- Ascites common, may be loculated
- Intestinal obstruction may respond to anti-tuberculous treatment without surgery

Origin of the infection

Infection originates from:

- tuberculous mesenteric lymph nodes;
- tuberculosis of the ileocaecal region;
- a tuberculous pyosalpinx;
- blood-borne infection from pulmonary tuberculosis, usually the 'miliary' but occasionally the 'cavitating' form.

Varieties of tuberculous peritonitis

There are four varieties of tuberculous peritonitis: ascitic, encysted, fibrous and purulent.

Ascitic form

The peritoneum is studded with tubercles and the peritoneal cavity becomes filled with pale, straw-coloured fluid. The onset is insidious. There is loss of energy, facial pallor and some loss of weight. The patient is usually brought for advice because of distension of the abdomen. Pain is often absent; in other cases there is considerable abdominal discomfort, which may be associated with constipation or diarrhoea. On inspection, dilated veins may be seen coursing beneath the skin of the abdominal wall. Signs of ascites can be elicited readily (see below). In boys, congenital hydroceles sometimes appear, resulting from the patent processus vaginales becoming filled with ascitic fluid. Because of the increased intra-abdominal pressure, an umbilical hernia commonly occurs. On abdominal palpation, a transverse solid mass

can often be detected. This is rolled-up greater omentum infiltrated with tubercles.

Diagnosis is seldom difficult except when it occurs in an acute form or when it first appears in an adult, in which case it has to be differentiated from other forms of ascites, especially malignancy. Laparoscopy is useful by allowing inspection of the peritoneal cavity, where the appearance is often diagnostic. The 'open' (Hasson) technique of trocar insertion should be used because of the risk of adhesions to the abdominal wall. Areas of caseation can be biopsied for histology and microbiological studies. The ascitic fluid is pale yellow, usually clear and rich in lymphocytes. The specific gravity is comparatively high, often 1.020 or more. Even after centrifugation, *Mycobacterium tuberculosis* can rarely be found, but its presence can be demonstrated by culture.

Once the diagnosis of tuberculous peritonitis has been made, it is always important to look for tuberculous disease elsewhere. The possibility of tuberculous salpingitis in females should be remembered. A chest radiograph should always be taken before laparoscopy or laparotomy is performed. If the general condition is good, the patient can return home and, if an adult, carry out light work before the course of anti-tuberculous therapy has been completed.

Encysted form

The encysted (loculated) form is similar to the ascitic form except that one part of the abdominal cavity alone is involved. Thus, a localised intra-abdominal swelling is produced, which may give rise to difficulty in diagnosis. In a woman above the age of puberty, when the swelling is in the pelvis, an ovarian cyst will probably be diagnosed. In the case of a child it is sometimes difficult to distinguish the swelling from a mesenteric cyst. For these reasons, operation is often performed and, if an encapsulated collection of fluid is found, it is evacuated and sent for microscopy and culture. Late intestinal obstruction is a possible complication.

Fibrous form

The fibrous (synonym: plastic) form is characterised by the production of widespread adhesions, which cause coils of intestine, especially the ileum, to become matted together and distended. These distended coils act as a 'blind loop' and give rise to steatorrhoea, wasting and attacks of abdominal pain. On examination, the adherent intestine with omentum attached, together with the thickened mesentery, may give rise to a palpable swelling or swellings. The first intimation of the disease may be subacute or acute intestinal obstruction. Sometimes the cause of the obstruction can be remedied easily by the division of bands. Small bowel bypass should be avoided to prevent development of a 'blind loop' syndrome. If the adhesions are accompanied by fibrous strictures of the ileum as well, it is best to excise the affected bowel, provided that not too much of the small intestine needs to be sacrificed. Anti-tuberculous therapy will often rapidly cure the condition without the need for surgery.

Purulent form

The purulent form is rare. When it occurs, usually it is secondary to tuberculous salpingitis. Amidst a mass of adherent intestine and omentum, tuberculous pus is present. Sizeable cold abscesses often form and point on the surface, commonly near

Harith Hasson, Professor of Gynaecology, Chicago, USA.

the umbilicus, or burst into the bowel. In addition to prolonged general treatment, operative treatment may be necessary for the evacuation of cold abscesses and possibly for intestinal obstruction. If a faecal fistula forms, it usually persists because of distal intestinal obstruction. Closure of the fistula must therefore be combined with some form of anastomosis between the segment of intestine above the fistula and an unobstructed area below. The prognosis of this variety of tuberculous peritonitis is relatively poor.

ASCITES

Ascites, an excess of serous fluid within the peritoneal cavity, can be recognised clinically only when the amount of fluid present exceeds 150 ml; in the obese a greater quantity than this is necessary before there is clear evidence. Ultrasound and CT scanning can detect much smaller volumes of ascitic fluid (Fig. 58.11).

Mechanism of ascites

The balanced effects of plasma and peritoneal colloid osmotic and hydrostatic pressures determine the exchange of fluid between the capillaries and the peritoneal fluid. Protein-rich fluid enters the peritoneal cavity when capillary permeability is increased, as in peritonitis and carcinomatosis peritonei. Capillary pressure may be increased because of generalised water retention, cardiac failure, constrictive pericarditis or vena cava obstruction. Capillary pressure is raised selectively in the portal venous system in the Budd–Chiari syndrome, cirrhosis of the liver or extrahepatic portal venous obstruction. Plasma colloid osmotic pressure may be lowered in patients with reduced nutritional intake, diminished intestinal absorption, abnormal protein losses or defective protein synthesis such as occurs in cirrhosis. Peritoneal lymphatic drainage may be impaired, resulting in the accumulation of protein-rich fluid.

Clinical features

The abdomen is distended evenly with fullness of the flanks, which are dull to percussion. Usually, shifting dullness is present

Figure 58.11 Computerised tomography scan showing gross ascites.

George Budd, 1808–1882, Professor of Medicine, King’s College Hospital, London, England, described this syndrome in 1845.

Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany, (Strasbourg was returned to France in 1918 at the end of the First World War). He gave his account of this condition in 1898.

but when there is a very large accumulation of fluid this sign is absent. In such cases, on flicking the abdominal wall, a characteristic fluid thrill is transmitted from one side to the other. In women, ascites must be differentiated from an enormous ovarian cyst.

Congestive heart failure, the commonest cause of ascites, results in increased venous pressure in the vena cava and consequent obstruction to the venous outflow from the liver. This increased pressure can be seen as engorgement of the veins of the neck – a striking sign in this condition. The ascitic fluid is light yellow and of low specific gravity, about 1.010, with a low protein concentration ($< 25 \text{ g l}^{-1}$). Patients with constrictive pericarditis (Pick’s disease) have both peritoneal and pleural effusions because of engorgement of the venae cavae consequent upon the diminished capacity of the right side of the heart.

In cirrhosis, there is obstruction to the portal venous system, which is caused by obliterative fibrosis of the intrahepatic venous bed. Lymph flow may be increased. In the Budd–Chiari syndrome (see Chapter 61), thrombosis or obstruction of the hepatic veins is responsible for obstruction to venous outflow from the liver.

The ascites seen in patients with peritoneal metastases is caused by excessive exudation of fluid and lymphatic blockage. The fluid is dark yellow and frequently blood-stained. The specific gravity, 1.020 or over, and the protein content ($> 25 \text{ g l}^{-1}$) are high. Microscopic examination often reveals cancer cells, especially if large quantities of fluid are ‘spun down’ to produce a concentrated deposit for sampling.

Ascites occurs with low plasma albumin concentrations, for example in patients with albuminuria or starvation. The ascites in this instance is caused by alterations in the osmotic pressure of the capillary blood and has a low specific gravity.

Rarely, ascites and pleural effusion are associated with solid fibroma of the ovary (Meigs’ syndrome). The effusions disappear when the tumour is excised (Summary box 58.13).

Summary box 58.13

Causes of ascites

Transudates (protein $< 25 \text{ g l}^{-1}$)

- Low plasma protein concentrations:
 - Malnutrition
 - Nephrotic syndrome
 - Protein-losing enteropathy
- High central venous pressure:
 - Congestive cardiac failure
- Portal hypertension:
 - Portal vein thrombosis
 - Cirrhosis

Exudates (protein $> 25 \text{ g l}^{-1}$)

- Tuberculous peritonitis
- Peritoneal malignancy
- Budd–Chiari syndrome (hepatic vein occlusion or thrombosis)
- Pancreatic ascites
- Chylous ascites
- Meigs’ syndrome

Friedel Pick, 1867–1926, Physician, Prague, The Czech Republic, described this disease in 1896.

Joe Vincent Meigs, 1892–1963, Professor of Gynaecology, Harvard University Medical School, Boston, MA, USA.

Treatment

Treatment of the specific cause is undertaken whenever possible; for example, if portal venous pressure is raised, it may be possible to lower it by treatment of the primary condition. Dietary sodium restriction to 200 mg day⁻¹ may be helpful, but diuretics are usually required.

Paracentesis abdominis

The bladder having been emptied, puncture of the peritoneum is carried out under local anaesthetic using a moderately sized trocar and cannula at one of the points shown in Fig. 58.12. Alternatively, a peritoneal drain may be inserted under ultrasound guidance to minimise the risk of visceral injury. In cases where the effusion is caused by cardiac failure, the fluid must be evacuated slowly. Fluid is sent for microscopy, culture, including mycobacteria, and analysis of protein content and amylase. Unless other measures are taken the fluid soon reaccumulates, and repeated tapings remove valuable protein.

Permanent drainage of ascitic fluid

In rare cases in which ascites accumulates rapidly after paracentesis and the patient is otherwise fit, permanent drainage of the ascitic fluid via a peritoneovenous shunt (e.g. LeVein, Denver) may render the patient more comfortable. Similar in concept to shunts for hydrocephalus (see Chapter 40), a catheter (e.g. of silicone) is constructed with a valve so as to allow one-way flow from the peritoneum to a central vein (e.g. internal jugular). A chamber placed subcutaneously over the chest wall may be included for manual compression. Insertion is relatively simple. The complications include overloading the venous system, cardiac failure and disseminated intravascular coagulopathy. The frequency of these complications may be reduced by evacuating ascitic fluid and partially replacing it with normal saline at the time of shunt insertion. The procedure may also be used for patients with terminal malignant ascites, giving improved quality of life despite the risk of further dissemination of malignant cells.

Figure 58.12 Usual points of puncture for tapping ascites. The bladder must be emptied by a catheter before the puncture is made. Note the relationship of the sites of the puncture to the inferior epigastric artery (red) (courtesy of Drs V.C. and V.V. Shah, Jamnagar, India).

Chylous ascites

In some patients the ascitic fluid appears milky because of an excess of chylomicrons (triglycerides). Most cases are associated with malignancy, usually lymphomas; other causes are cirrhosis, tuberculosis, filariasis, nephrotic syndrome, abdominal trauma (including surgery), constrictive pericarditis, sarcoidosis and congenital lymphatic abnormality. The prognosis is poor unless the underlying condition can be cured. In addition to other measures used to treat ascites, patients should be placed on a fat-free diet with medium-chain triglyceride supplements.

PERITONEAL LOOSE BODIES (PERITONEAL MICE)

Peritoneal loose bodies almost never cause symptoms. One or more may be found in a hernial sac or in the pouch of Douglas. The loose body may come from an appendix epiploica that has undergone axial rotation followed by necrosis of its pedicle and detachment but they are also found in those who suffer from subacute attacks of pancreatitis. These hyaline bodies attain the size of a pea or bean and contain saponified fat surrounded by fibrin.

NEOPLASMS OF THE PERITONEUM

Carcinoma peritonei

This is a common terminal event in many cases of carcinoma of the stomach, colon, ovary or other abdominal organs and also of the breast and bronchus. The peritoneum, both parietal and visceral, is studded with secondary growths and the peritoneal cavity becomes filled with clear, straw-coloured or blood-stained ascitic fluid.

The main forms of peritoneal metastases are:

- discrete *nodules* – by far the most common variety;
- *plaques* varying in size and colour;
- diffuse *adhesions* – this form occurs at a late stage of the disease and gives rise, sometimes, to a ‘frozen pelvis’.

Gravity probably determines the distribution of free malignant cells within the peritoneal cavity. Cells not caught in peritoneal folds gravitate into the pelvic pouches or into a hernial sac, the enlargement of which is occasionally the first indication of the condition. Implantation occurs also on the greater omentum, the appendices epiploicae and the inferior surface of the diaphragm.

Differential diagnosis

Early discrete tubercles common in tuberculous peritonitis are greyish and translucent and closely resemble the discrete nodules of peritoneal carcinomatosis. Fat necrosis can usually be distinguished from a carcinomatous nodule by its opacity. Peritoneal hydatids can also simulate malignant disease after rupture of a hydatid cyst, with seeding of daughter cysts.

Treatment

Ascites caused by carcinomatosis of the peritoneum may respond to systemic or intraperitoneal chemotherapy or to endocrine therapy in the case of hormone receptor-positive tumours.

Pseudomyxoma peritonei

This rare condition occurs more frequently in women. The abdomen is filled with a yellow jelly, large quantities of which are often encysted. The condition is associated with mucinous cystic tumours of the ovary and appendix. Recent studies suggest that most cases arise from a primary appendiceal tumour with secondary implantation on to one or both ovaries. It is often painless and there is frequently no impairment of general health. Pseudomyxoma peritonei does not give rise to extraperitoneal metastases. Although an abdomen distended with what seems to be fluid that cannot be made to shift should raise the possibility, the diagnosis is more often suggested by ultrasound and CT scanning or made at operation. At laparotomy, masses of jelly are scooped out. The appendix, if present, should be excised together with any ovarian tumour. Unfortunately, recurrence is inevitable, but patients may gain symptomatic benefit from repeated 'debulking' surgery. Occasionally, the condition responds to radioactive isotopes or intraperitoneal chemotherapy. The role of early radical peritoneal excision is uncertain.

Mesothelioma

As in the pleural cavity, this is a highly malignant tumour. Asbestos is a recognised cause. It has a predilection for the pelvic peritoneum. Chemocytotoxic agents are the mainstay of treatment.

Desmoid

This is considered under familial adenomatous polyposis (see Chapter 65).

LAPAROSCOPY (PERITONEOSCOPY)

Laparoscopic surgery has developed rapidly over recent years. The principles of the technique are discussed in Chapter 19 and numerous examples of its application for common procedures are given throughout the book.

THE OMENTUM

Rutherford Morison called the greater omentum 'the abdominal policeman'. The greater omentum attempts, often successfully, to limit intraperitoneal infective and other noxious processes (Fig. 58.13). For instance, an acutely inflamed appendix is often found wrapped in omentum, and this saves many patients from developing diffuse peritonitis. Some sufferers of herniae are also greatly indebted to this structure, for it often plugs the neck of a hernial sac and prevents a coil of intestine from entering and becoming strangulated.

The omentum is usually involved in tuberculous peritonitis and carcinomatosis of the peritoneum.

Torsion of the omentum

Torsion of the omentum is a rare emergency and consequently is seldom diagnosed correctly. It is usually mistaken for appendicitis with somewhat abnormal signs. It may be primary or secondary to an adhesion of the omentum, to an old focus of infection or to a hernia.

The patient is most frequently a middle-aged, obese man. A tender lump may be present in the abdomen. The blood supply having been jeopardised, the twisted mass sometimes becomes gangrenous, in which case bacterial peritonitis may follow.

Figure 58.13 The greater omentum. (a) Normal; (b) in appendicitis; (c) in a (comparatively small) laceration of the spleen.

Treatment is surgical; the pedicle above the twist is ligated securely and the mass removed.

THE MESENTERY

Mesenteric injury

A wound of the mesentery can follow severe abdominal contusion and is a cause of haemoperitoneum.

Seatbelt syndrome

If a car accident occurs when a seatbelt is worn, sudden deceleration can result in a torn mesentery. This possibility should be borne in mind, particularly as multiple injuries may distract attention from this injury. If there is any bruising of the abdominal wall, or even marks of clothing impressed into the skin, laparotomy may be indicated.

Diagnostic peritoneal lavage

Diagnostic peritoneal lavage may be helpful in this situation. Under local anaesthesia, a subumbilical incision is made down to the peritoneum in a similar way to that used for 'open' laparoscopy. A purse-string suture is placed in the peritoneum, which is then incised. Free fluid, e.g. blood or intestinal contents, may be found but, if not, a peritoneal dialysis catheter is inserted and the purse-string suture tied. A litre of normal saline is run into the peritoneum and then drained off by placing the bag and tubing below the patient's abdomen. The presence of blood (>100 000 red blood cells per μl), bile or intestinal contents is an indication for laparotomy.

In about 60% of cases, the mesenteric laceration is associated with a rupture of the intestine. If the tear is a large one, and especially if it is transverse (Fig. 58.14a), the blood supply to the neighbouring intestine is cut off and a limited resection of gut is

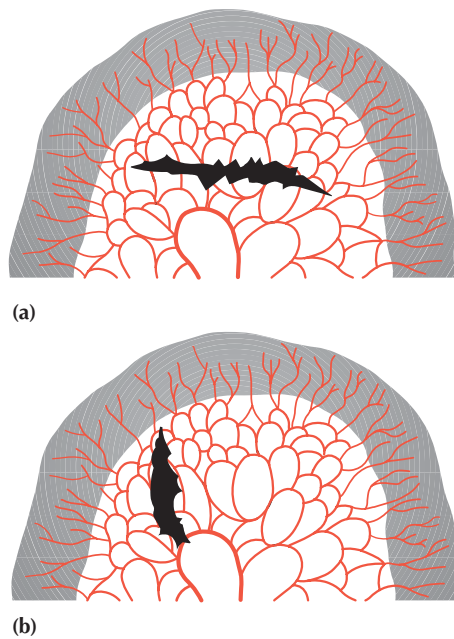

Figure 58.14 Laceration of the mesentery, a common injury in driving accidents. (a) A transverse tear often imperils the blood supply of a segment of intestine, making resection necessary; (b) a longitudinal tear can be closed by suture.

imperative. Small wounds and wounds in the long axis (Fig. 58.14b) should be sutured.

Torsion of the mesentery

See midgut volvulus and volvulus of the small intestine (see Chapter 66).

Embolism and thrombosis of mesenteric vessels

See Chapter 66.

Acute non-specific ileocaecal mesenteric adenitis

Aetiology

Non-specific mesenteric adenitis was so named to distinguish it from specific (tuberculous) mesenteric adenitis. It is now much more common than the tuberculous variety. The aetiology often remains unknown, although some cases are associated with *Yersinia* infection of the ileum. In other cases, an unidentified virus is blamed. In about 25% of cases, a respiratory infection precedes an attack of non-specific mesenteric adenitis. This self-limiting disease is never fatal but may be recurrent.

Pathology

There is a small increase in the amount of peritoneal fluid. The ileocaecal mesenteric lymph nodes are enlarged and can be seen and felt between the leaves of the mesentery. In very acute cases they are distinctly red, and many of them are the size of a walnut. The nodes nearest the attachment of the mesentery are the largest. They are not adherent to their peritoneal coats and, if a

small incision is made through the overlying peritoneum, a node is extruded easily.

Clinical features

During childhood, acute non-specific mesenteric adenitis is a common condition. The typical history is one of short attacks of central abdominal pain lasting from 10 to 30 min, and associated with circumoral pallor. Vomiting is common but there is no alteration of bowel habit. If vomiting is absent, it is more likely to be a case of mesenteric adenitis than appendicitis.

Examination

There are spasms of general abdominal colic, usually referred to the umbilicus, with intervals of complete freedom. The patient seldom looks ill. In more than half of the cases the temperature is elevated. Abdominal tenderness is poorly localised. When present, shifting tenderness is a valuable sign for differentiating the condition from appendicitis. The neck, axillae and groins should be palpated for enlarged lymph nodes.

Leucocyte count

There is often a leucocytosis of $10\,000\text{--}12\,000\ \mu\text{l}^{-1}$ ($10\text{--}12 \times 10^9\ \text{l}^{-1}$) or more on the first day of the attack, but this falls on the second day.

Treatment

When the diagnosis can be made with assurance, bed rest and simple analgesia is the only treatment necessary. If at a second examination a few hours later, acute appendicitis cannot be excluded, it is safer to perform either appendicectomy or diagnostic laparoscopy.

Tuberculosis of the mesenteric lymph nodes

Tuberculous mesenteric lymphadenitis is considerably less common than acute non-specific lymphadenitis. Tubercle bacilli, usually, but not necessarily, bovine, are ingested and enter the mesenteric lymph nodes by way of Peyer's patches. Sometimes only one lymph node is infected; usually there are several; occasionally massive involvement occurs.

Presentation

Demonstrated radiologically

The shadows cast by one or more calcified tuberculous lymph nodes are seen in a plain radiograph of the abdomen. They must be distinguished from other calcified lesions, e.g. renal or ureteric stones.

As a cause of general symptoms

The patient, usually a child under 10 years of age, loses their appetite, looks pale and there is some loss of weight; sometimes evening pyrexia occurs.

As a cause of abdominal pain

Sometimes abdominal pain is the cause of the patient being brought for advice; usually this pain is central, not severe but rather a discomfort, and is often constant. On examination the abdomen is somewhat protuberant and there is tenderness on

Alexandre Emile Jean Yersin, 1863–1943, Bacteriologist, The Institute Pasteur, Paris, France.

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

deep pressure to the right of the umbilicus. In these circumstances, the condition resembles acute non-specific mesenteric lymphadenitis. A normal leucocyte count favours tuberculosis and, in a child, a positive Mantoux test is confirmatory evidence of tuberculosis.

Symptoms indistinguishable from those of appendicitis

On occasions, the abdominal pain is acute and may be accompanied by vomiting. This, combined with tenderness and some rigidity in the right iliac fossa, makes the diagnosis from appendicitis almost impossible. When, as is sometimes the case, the tuberculous infection of the mesenteric lymph nodes becomes reactivated in adolescence or adulthood, the diagnostic difficulties are even greater. A radiograph may show calcified lymph nodes but, as such a condition can coexist with appendicitis, in some cases laparoscopy or laparotomy is necessary. If the mesentery is found to be in an inflamed state with caseation of some of the lymph nodes, the diagnosis of active tuberculosis is confirmed.

As a cause of intestinal obstruction

Remote, rather than recent, tuberculous mesenteric adenitis can be the cause of intestinal obstruction. For instance, a coil of small intestine becomes adherent to a caseating node and is thereby angulated or a free coil may become imprisoned in the tunnel beneath the site of adherence and the mesentery.

As a cause of pseudomesenteric cyst

When tuberculous mesenteric lymph nodes break down, the tuberculous pus may remain confined between the leaves of the mesentery and a cystic swelling having the characteristics of a mesenteric cyst is found. When such a condition is confirmed at operation, the tuberculous pus should be aspirated without soiling the peritoneal cavity, the wound closed, the sensitivity of the organism should be sought and medical treatment continued until the infection has been overcome.

As ileocaecal lymph nodes

At laparotomy, hard, enlarged lymph nodes may be found limited to the ileocaecal mesentery as a result of previous tuberculous infection.

Treatment

Therapy is similar to that of other tuberculous infections. Most cases subside but from time to time a local abscess forms, usually in the right iliac fossa, in which case the tuberculous pus should be evacuated and the abdomen closed without drainage.

Mesenteric cysts

Mesenteric cysts are classified as:

- chylolymphatic;
- simple (mesothelial)
- enterogenous;
- urogenital remnant;
- dermoid (teratomatous cyst).

Chylolymphatic cyst, the commonest variety, probably arises in congenitally misplaced lymphatic tissue that has no efferent

communication with the lymphatic system; it arises most frequently in the mesentery of the ileum. The thin wall of the cyst, which is composed of connective tissue lined by flat endothelium, is filled with clear lymph or, less frequently, with chyle varying in consistency from watered milk to cream. Occasionally, the cyst attains a great size. More often unilocular than multilocular, a chylolymphatic cyst is almost invariably solitary, although there is an extremely rare variety in which myriads of cysts are found in the various mesenteries of the abdomen. A chylolymphatic cyst has a blood supply that is independent from that of the adjacent intestine and, thus, enucleation is possible without the need for resection of gut.

Enterogenous cysts are believed to be derived either from a diverticulum of the mesenteric border of the intestine that has become sequestered from the intestinal canal during embryonic life or from a duplication of the intestine (see Chapter 6). An enterogenous cyst has a thicker wall than a chylolymphatic cyst and it is lined by mucous membrane, sometimes ciliated. The content is mucinous and is either colourless or yellowish brown as a result of past haemorrhage. The muscle in the wall of an enteric duplication cyst and the bowel with which it is in contact have a common blood supply; consequently, removal of the cyst always entails resection of the related portion of intestine.

Clinical features of a mesenteric cyst

A mesenteric cyst is encountered most frequently in the second decade of life, less often between the ages of 1 and 10 years and, exceptionally, in infants under 1 year.

The patient presents on account of:

- *A painless abdominal swelling.* A cyst of the mesentery presents characteristic physical signs:
 - there is a fluctuant swelling near the umbilicus (Fig. 58.15a);
 - the swelling moves freely in a plane at right angles to the attachment of the mesentery (Fig. 58.15b);
 - there is a zone of resonance around the cyst.
- *Recurrent attacks of abdominal pain* with or without vomiting. The pain results from recurring temporary impaction of a food bolus in a segment of bowel narrowed by the cyst or possibly from torsion of the mesentery.
- *An acute abdominal catastrophe*, which arises as a result of:
 - torsion of that portion of the mesentery containing the cyst;
 - rupture of the cyst, often as a result of a comparatively trivial accident;
 - haemorrhage into the cyst;
 - infection.

Radiography

Ultrasound and CT scanning will demonstrate the lesion and may allow diagnosis of cyst type. A barium meal and follow-through may show displacement of the hollow viscera around the cyst and, not infrequently, some portion of the lumen of the small intestine will be narrowed.

Treatment

Many chylolymphatic cysts can be enucleated *in toto*.

When, after aspiration of about half the contents of the cyst, the major portion of the cyst has been dissected free, but one portion abutting on the intestine or a major blood vessel seems too dangerous to remove, this portion can be left attached and its lining destroyed by careful diathermy.

Charles Mantoux, 1877–1947, Physician, Le Cannet, Alpes Maritimes, France, described the intra-dermal tuberculin test in 1908.

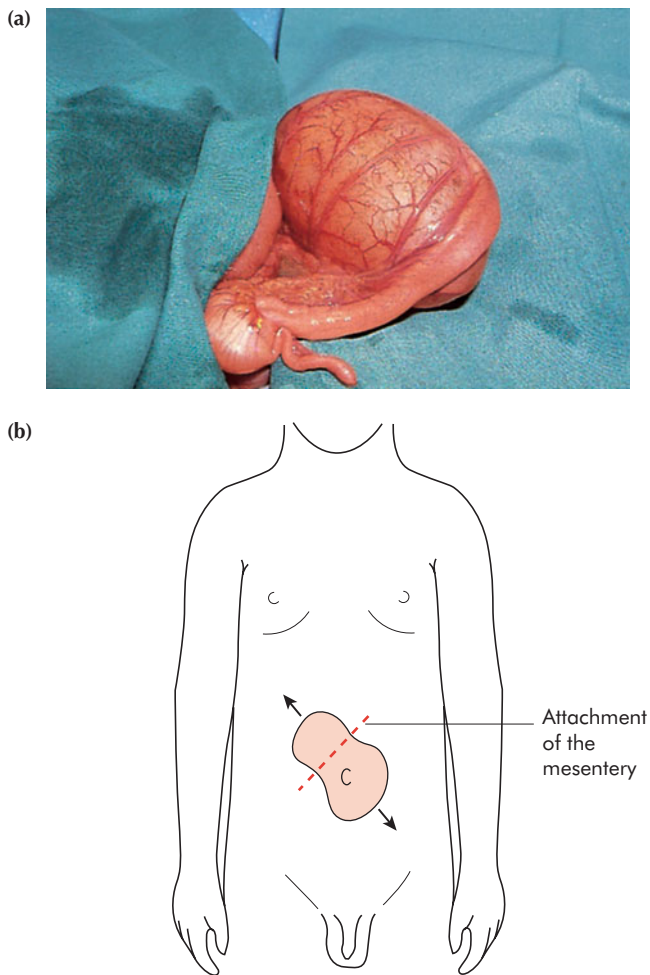

Figure 58.15 A mesenteric cyst (a) moves freely in the direction of the arrows, i.e. at right angles to the attachment of the mesentery (b).

In the case of an enterogenous cyst, enucleation must not be attempted. If a comparatively short segment of the intestine is involved, resection of the cyst with the adherent portion of the intestine, followed by intestinal anastomosis, is the correct course.

The older treatment of marsupialisation of a mesenteric cyst has little to recommend it; a fistula or recurrence results.

Omental cysts

Omental cysts occur nearly as frequently as mesenteric cysts. Preoperative differentiation is possible because a lateral radiograph, ultrasound or CT scan shows the cyst in front of the intestines. Treatment is omentectomy.

Cyst of the mesocolon

Cyst of the mesocolon is uncommon and is differentiated from a mesenteric cyst only at operation. The treatment is similar.

Cysts arising from a urogenital remnant

Cysts arising from a urogenital (wolffian or müllerian) remnant are essentially retroperitoneal but they are included in the

Kaspar Friedrich Wolff, 1733–1794, Professor of Anatomy and Physiology, St. Petersburg, Russia, described the mesonephric duct and body in 1759.
Johannes Peter Müller, 1801–1858, Professor of Anatomy and Physiology, Berlin, Germany, described the para-mesonephric duct in 1825.

classification because it is possible for such a cyst to project forward into the mesentery.

Other cysts

The following, although not being mesenteric cysts in the true meaning of the term, give rise to the same physical signs:

- *serosanguinous cyst*, probably traumatic in origin although a history of an accident is seldom obtained;
- *tuberculous abscess of the mesentery*;
- *hydatid cyst of the mesentery*.

Neoplasms of the mesentery

Mesenteric tumours are classified as:

- benign:
 - lipoma;
 - fibroma;
 - fibromyxoma;
- malignant:
 - lymphoma;
 - secondary carcinoma.

Tumours situated in the mesentery give rise to physical signs that are similar to those of a mesenteric cyst, the sole exception being that they sometimes feel solid.

If indicated, a benign tumour of the mesentery is excised in the same way as an enterogenous mesenteric cyst, i.e. with resection of the adjacent intestine. A malignant tumour of the mesentery usually requires biopsy confirmation and non-surgical treatment, e.g. chemotherapy for lymphoma (Summary box 58.14).

Summary box 58.14

Conditions of the mesentery

- Traumatic tears
- Torsion
- Embolism/thrombosis
- Acute non-specific adenitis
- Tuberculous adenitis
- Cysts
- Neoplasms – benign and malignant

THE RETROPERITONEAL SPACE

Pus or blood in the retroperitoneal space tends to track to the corresponding iliac fossa. If a retroperitoneal abscess develops, it should be evacuated by the nearest route through the abdominal wall, avoiding opening the peritoneum. Should the retroperitoneal collection be found at laparotomy, it must be drained by a counterincision in the flank. Pus may develop from a renal or spinal source and is sometimes tuberculous ('cold abscess'); tracking can develop alongside the psoas muscle and appear in the groin, where it must be distinguished from other swellings (e.g. hernia; see Chapter 57). Retroperitoneal haematoma may be caused by a fractured spine or pelvis, a leaking abdominal aneurysm, acute pancreatitis or a ruptured kidney.

Retroperitoneal cyst

A cyst developing in the retroperitoneal space often attains very large dimensions and has first to be distinguished from a

hydronephrosis. Even after the latter condition has been eliminated by scanning or urography, a retroperitoneal cyst can seldom be distinguished with certainty from a retroperitoneal tumour until displayed at operation. The cyst may be unilocular or multilocular. Many of these cysts are believed to be derived from a remnant of the wolffian duct, in which case they are filled with clear fluid. Others are either teratomatous and filled with sebaceous material or multicystic lymphangiomas.

Excision of these and other retroperitoneal swellings is best performed through a transperitoneal incision.

Idiopathic retroperitoneal fibrosis

This is one of a group of fibromatoses (others being Dupuytren's contracture and Peyronie's disease). Most cases are idiopathic but in other patients the cause is known (Summary box 58.15).

Summary box 58.15

Causes of retroperitoneal fibrosis

Benign

- Idiopathic (Ormond's disease)
- Chronic inflammation
- Extravasation of urine
- Retroperitoneal irritation by leakage of blood or intestinal content
- Aortic aneurysm ('inflammatory type')
- Trauma
- Drugs:
 - Chemotherapeutic agents
 - Methysergide
 - β-Adrenoceptor antagonists

Malignant

- Lymphoma
- Carcinoid tumours
- Secondary deposits (especially from carcinoma of stomach, colon, breast and prostate)

Familial cases are known, involving mediastinal fibrosis, sclerosing cholangitis, Riedel's thyroiditis and orbital pseudotumour. Extensive collagen deposition surrounds the ureters, mostly at the level of the pelvic brim or below. Most patients present with ureteric obstruction, often with renal failure (see Chapter 71). Ureteric stenting and steroid therapy are often effective. Cases resulting from malignancy are treated appropriately according to the cause.

Primary retroperitoneal neoplasms arising from connective tissues

Retroperitoneal lipoma

The patient may seek advice on account of a swelling or because of indefinite abdominal pain. Women are more often

affected. These swellings sometimes reach an immense size. Diagnosis is usually by ultrasound and CT scanning. A retroperitoneal lipoma sometimes undergoes myxomatous degeneration, a complication that does not occur in a lipoma in any other part of the body. Moreover, a retroperitoneal lipoma is often malignant (liposarcoma) (Fig. 58.16) and may increase rapidly in size.

Retroperitoneal sarcoma

Retroperitoneal sarcoma presents signs that are similar to those of a retroperitoneal lipoma. Occasionally, the tumour, by pressure on the colon, causes symptoms of subacute intestinal obstruction. On examination, a smooth fixed mass, which is not tender, is palpated. The most likely original diagnosis is that of a neoplasm of the kidney. This is ruled out by scanning. The ureter, however, is liable to become displaced by the tumour. Exploratory laparotomy should be performed and, when possible, the tumour is removed. Often, it is found to be widely disseminated in the retroperitoneal space, rendering complete removal impossible, in which case a portion is excised for histology. Even when excised at a comparatively early stage, recurrence always takes place, and these tumours must be looked upon as being necessarily fatal. Radiotherapy sometimes keeps recurrence in abeyance for a time.

Removal of a retroperitoneal cyst or neoplasm

After the anterior abdominal wall has been opened and the diagnosis of a retroperitoneal tumour has been confirmed, the incision is extended as necessary. The small intestine is packed away in the upper abdomen or exteriorised and the caecum and the sigmoid colon are relegated to their respective fossae. The posterior peritoneum is then incised throughout its length over the area to be exposed, the incision being parallel to the left border of the aorta. The peritoneum is dissected from the tumour, which is removed as completely as possible.

Retroperitoneal tumours arising from specific organs

These may arise from:

- lymph nodes (Fig. 58.17) (see Chapter 55);
- adrenal gland (see Chapter 49);
- kidney and ureter (see Chapter 71);
- nervous tissue.

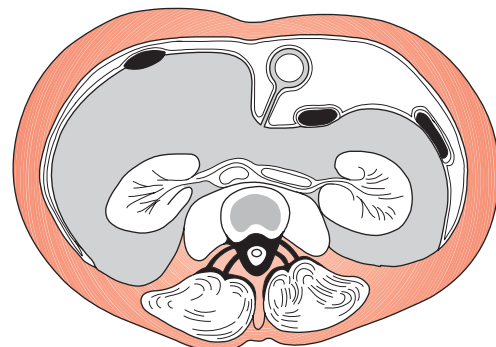

Figure 58.16 Rapidly growing retroperitoneal liposarcoma.

Baron Guillaume Dupuytren, 1777–1835, Surgeon in Chief, Hôtel Dieu, Paris, France, described this condition in 1831.

François de la Peyronie, 1678–1747, Surgeon to King Louis XIV of France, and Founder of the Royal Academy of Surgery, Paris, France.

J.K. Ormond, An American Urologist.

Bernard Moritz Carl Ludwig Riedel, 1864–1916, Professor of Surgery, Jena, Germany, described this form of Thyroiditis in 1896.

Figure 58.17 Computerised tomography scan showing enlarged necrotic retroperitoneal nodes in a patient with lymphoma. The nodes caused obstructive jaundice by compressing the bile duct; a plastic biliary stent has been inserted at endoscopic retrograde cholangiopancreatography to relieve jaundice.

The oesophagus

LEARNING OBJECTIVES

To understand:

- The anatomy and physiology of the oesophagus and their relationship to disease
- The clinical features, investigations and treatment of benign and malignant disease with particular reference to the common adult disorders

BACKGROUND

Surgical anatomy

The oesophagus is a muscular tube, approximately 25 cm long, mainly occupying the posterior mediastinum and extending from the upper oesophageal sphincter (the cricopharyngeus muscle) in the neck to the junction with the cardia of the stomach. The musculature of the upper oesophagus, including the upper sphincter, is striated. This is followed by a transitional zone of both striated and smooth muscle with the proportion of the latter progressively increasing so that, in the lower half of the oesophagus, there is only smooth muscle. It is lined throughout with squamous epithelium. The parasympathetic nerve supply is mediated by branches of the vagus nerve that has synaptic connections to the myenteric (Auerbach's) plexus. Meissner's submucosal plexus is sparse in the oesophagus.

The upper sphincter consists of powerful striated muscle. The lower sphincter is more subtle, and is created by the asymmetrical arrangement of muscle fibres in the distal oesophageal wall just above the oesophagogastric junction. It is helpful to remember the distances 15, 25 and 40 cm for anatomical location during endoscopy (Fig. 59.1).

Physiology

The main function of the oesophagus is to transfer food from the mouth to the stomach in a coordinated fashion. The initial movement from the mouth is voluntary. The pharyngeal phase of swallowing involves sequential contraction of the oropharyngeal musculature, closure of the nasal and respiratory passages, cessation of breathing and opening of the upper oesophageal sphincter. Beyond this level, swallowing is involuntary. The body of the oesophagus propels the bolus through a relaxed lower oesophageal sphincter (LOS) into the stomach, taking air with it (Fig. 59.2). This coordinated oesophageal wave that follows a

conscious swallow is called primary peristalsis. It is under vagal control, although there are specific neurotransmitters that control the LOS.

The upper oesophageal sphincter is normally closed at rest and serves as a protective mechanism against regurgitation of oesophageal contents into the respiratory passages. It also serves to stop air entering the oesophagus other than the small amount that enters during swallowing.

The LOS is a zone of relatively high pressure that prevents gastric contents from refluxing into the lower oesophagus (Fig. 59.3). In addition to opening in response to a primary peristaltic wave, the sphincter also relaxes to allow air to escape from the stomach and at the time of vomiting. A variety of factors influence sphincter tone, notably food, gastric distension, gastrointestinal hormones, drugs and smoking. The arrangement of muscle fibres, their differential responses to specific neurotransmitters and the

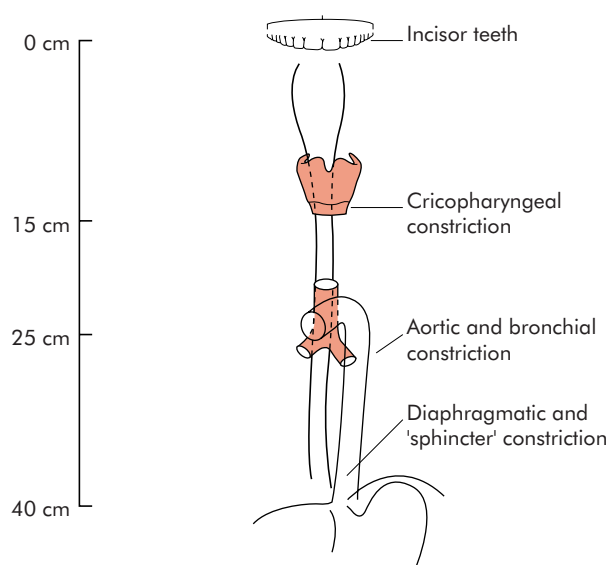

Figure 59.1 Endoscopic landmarks. Distances are given from the incisor teeth. They vary slightly with the build of the individual.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany, (now Wrocław, Poland), described the myenteric plexus in 1862.

Georg Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany, described the submucosal plexus in 1852.

Figure 59.2 A bolus of barium or food usually takes air with it into the stomach.

relationship to diaphragmatic contraction all contribute to the action of the LOS. The presence of the physiological sphincter was first demonstrated by Code using manometry with small balloons. Nowadays, LOS pressure is measured by perfused tubes or micro-transducers. The normal LOS is 3–4 cm long and has a pressure of 10–25 mmHg. Accurate measurement of sphincter relaxation is achieved using a device (Dent sleeve) that straddles the high-pressure zone.

Manometry is also used to assess the speed and amplitude of oesophageal body contractions and ensure that peristalsis is propagated down the entire length of the oesophagus (Fig. 59.4). Secondary peristalsis is the normal reflex response to a stubborn food bolus or refluxed material designed to clear the oesophagus by a contraction that is not preceded by a conscious swallow. It is worth remembering that the majority of clearance swallows to neutralise refluxed gastric acid are, however, achieved by primary peristalsis, which carries saliva with its high bicarbonate content down to the lower oesophagus. Tertiary contractions are non-peristaltic waves that are infrequent (< 10%) during laboratory-based manometry, although readily detected if manometry is undertaken while the patient eats a meal (Fig. 59.5).

Symptoms (Summary box 59.1)

Summary box 59.1

Symptoms of oesophageal disease

- Difficulty in swallowing described as food or fluid sticking (oesophageal dysphagia)
Must rule out malignancy
- Pain on swallowing (odynophagia)
Suggests inflammation and ulceration
- Regurgitation or reflux (heartburn)
Common in gastro-oesophageal reflux disease
- Chest pain
Difficult to distinguish from cardiac pain

Figure 59.3 Correlation between the radiological appearances of a barium column and the lower oesophageal sphincter open and closed. The three curves on the right, set up vertically, show the pH gradient, the mucosal potential difference (PD) marking the junction of squamous and columnar epithelium and the high-pressure zone of the sphincter.

Figure 59.4 Triple water-perfused tube study of normal lower oesophagus and lower oesophageal sphincter. Note that the swallowing contractions (S) in the body of the oesophagus are sequential, i.e. peristaltic

Dysphagia

Dysphagia is used to describe difficulty with swallowing. When there is a problem with swallowing in the voluntary (oral or pharyngeal) phases, patients will usually say that they cannot swallow properly, but they do not characteristically describe 'food sticking'. Instead, when they try to initiate a conscious swallow, food fails to enter the oesophagus, stays in the mouth or enters the airway causing coughing or spluttering. Virtually all causes of this type of dysphagia are chronic neurological or muscular diseases. Oesophageal dysphagia occurs in the involuntary phase and is characterised by a sensation of food sticking. The nature of this type of dysphagia is often informative regarding a likely diagnosis. Dysphagia may occur acutely or in a chronic fashion, can affect solids and/or fluids and be intermittent or progressive. While many patients point to a site of impaction, this is unreliable.

Odynophagia

Odynophagia refers to pain on swallowing. Patients with reflux oesophagitis often feel retrosternal discomfort within a few

seconds of swallowing hot beverages, citrus drinks or alcohol. Odynophagia is also a feature of infective oesophagitis and may be particularly severe in chemical injury.

Regurgitation and reflux

Regurgitation and reflux are often used synonymously. It is helpful to differentiate between them, although it is not always possible. Regurgitation should strictly refer to the return of oesophageal contents from above a functional or mechanical obstruction. Reflux is the passive return of gastrooduodenal contents to the mouth as part of the symptomatology of gastro-oesophageal reflux disease (GORD). Loss of weight, anaemia, cachexia, change of voice due to refluxed material irritating the vocal cords and cough or dyspnoea due to tracheal aspiration may all accompany regurgitation and/or reflux.

Chest pain

Chest pain similar in character to angina pectoris may arise from an oesophageal cause, especially gastro-oesophageal reflux and motility disorders. Exercise-induced chest pain can be due to reflux.

Investigations

Radiography

Contrast radiography has been somewhat overshadowed by endoscopy but remains a useful investigation for demonstrating narrowing, space-occupying lesions, anatomical distortion or abnormal motility. An adequate barium swallow should be tailored to the problem under investigation. It may be helpful to give a solid bolus (bread or marshmallow) if a motility disorder is suspected. Video recording is useful to allow subsequent replay and detailed analysis. Barium radiology is, however, inaccurate in the diagnosis of gastro-oesophageal reflux, unless reflux is gross, and should not be used for this purpose. Plain radiographs will show some foreign bodies.

Cross-sectional imaging by computerised tomography (CT) scanning is now an essential investigation in the assessment of neoplasms of the oesophagus and can be used in place of a contrast swallow to demonstrate perforation. The role of CT and other cancer-specific tests is described later.

Figure 59.5 Manometric recording from the body of a normal oesophagus. Peristalsis is seen in the first and last panels, but other waves are simultaneous. Non-peristaltic simultaneous contractions are called 'tertiary contractions'.

Endoscopy

Endoscopy is necessary for the investigation of most oesophageal conditions. It is required to view the inside of the oesophagus and the oesophagogastric junction, to obtain a biopsy or cytology specimen, for the removal of foreign bodies and to dilate strictures. Traditionally, there are two types of instrument available, the rigid oesophagoscope and the flexible video endoscope, but the rigid instrument is now virtually obsolete.

For flexible video gastroduodenoscopy, general anaesthesia is not required; most examinations can be done on an out-patient basis, and the quality of the magnified image is superb. The technology associated with video endoscopy continues to improve.

As a matter of routine, the stomach and duodenum are examined as well as the oesophagus. If a stricture is encountered, it may be helpful to dilate it to allow a complete inspection of the upper gastrointestinal tract, but this decision should be dictated by clinical circumstances and an appreciation of the perforation risk.

Endosonography

Endoscopic ultrasonography relies on a high-frequency (5–30 MHz) transducer located at the tip of the endoscope to provide highly detailed images of the layers of the oesophageal wall and mediastinal structures close to the oesophagus. Radial echoendoscopes have a rotating transducer that creates a circular image with the endoscope in the centre, and this type of scanner is widely used to create diagnostic transverse sectional images at right angles to the long axis of the oesophagus (Fig. 59.6). Linear echoendoscopes produce a sectoral image in the line of the endoscope and are used to biopsy submucosal oesophageal lesions or mediastinal masses such as lymph nodes (Fig. 59.7). Radial scanners without optical components are available for passage through narrow strictures over a guidewire, and there are even catheter probes that can be passed down the endoscope biopsy channel.

Oesophageal manometry

Manometry is now widely used to diagnose oesophageal motility disorders. Recordings are usually made by passing a multilumen catheter with three to eight recording orifices at different levels down the oesophagus and into the stomach. Electronic microtransducers that are not influenced by changes in patient position during the test have gradually supplanted perfusion systems. With either system, the catheter is withdrawn progressively up the oesophagus, and recordings are taken at intervals of 0.5–1.0 cm to measure the length and pressure of the LOS and assess motility in the body of the oesophagus during swallowing.

24-hour pH recording

Prolonged measurement of pH is now accepted as the most accurate method for the diagnosis of gastro-oesophageal reflux. It is particularly useful in patients with atypical reflux symptoms, those without endoscopic oesophagitis and when patients respond poorly to intensive medical therapy. A small pH probe is passed into the distal oesophagus and positioned 5 cm above the upper margin of the LOS, as defined by manometry. The probe is connected to a miniature digital recorder that is worn on a belt and allows most normal activities. Patients mark symptomatic events such as heartburn. A 24-hour recording period is usual, and the pH record is analysed by an automated computer

Figure 59.6 Radial endosonography indicating wall layers as alternating hyper- and hypoechoic bands.

program. An oesophageal pH < 4 at the level of the pH electrode is conventionally considered the cut-off value and, in most oesophageal laboratories, the total time when pH is < 4 in a 24-hour period does not exceed 4% in a healthy adult. Patterns of reflux and the correlation between symptoms and oesophageal pH < 4 can be calculated. Most laboratories use a scoring system (Johnson–DeMeester) to create a numerical value, above which reflux is considered pathological. Radiotelemetry pH probes are also available that can be fixed to the oesophageal wall endoscopically without the need for a transnasal catheter.

Tom R. DeMeester, Professor of Surgery, Los Angeles, CA, USA.

Therapeutic procedures

Dilatation of strictures

Stricture dilatation is essentially undertaken for benign conditions and should be used with caution in the context of malignant disease. The risks associated with dilatation for malignant disease are discussed later. The advent of guidewire-directed dilatation of the oesophagus in the 1970s was a major advance over earlier blind dilatation systems. Their use is now considered standard practice. There are many different designs, but essentially they are solid dilators of increasing diameter. To restore normal swallowing, a stricture should be dilated to at least 16 mm in diameter. A guidewire is passed down the biopsy channel of an endoscope and through the stricture under vision. If the stricture is long or tortuous, this should be undertaken under radiological guidance to ensure that the guidewire passes easily into the stomach. The endoscope is withdrawn, leaving the guidewire in place, and graduated dilators are passed over the guidewire, sometimes with radiographic screening for safety purposes. The dilatation of reflux-induced strictures is usually straightforward. These strictures are nearly always short and at the oesophagogastric junction, so that the stomach is visible through the narrowed segment. Radiological control is rarely needed. Conversely, distal oesophageal adenocarcinomas extending into the stomach are often soft, friable and tortuous to negotiate.

Balloons with inflation diameters of 25–40 mm may also be used for dilatation. Pneumatic dilatation is widely used to disrupt the non-relaxing LOS in achalasia.

Thermal recanalisation

Various types of laser (mainly Nd-YAG), bipolar diathermy, injection of absolute alcohol or argon-beam plasma coagulation have all been used successfully to ablate tissue in order to recanalise the oesophagus.

CONGENITAL ABNORMALITIES

See Chapter 6.

FOREIGN BODIES IN THE OESOPHAGUS

All manner of foreign bodies have become arrested in the oesophagus (Fig. 59.8). Button batteries may be a troublesome problem in children. The most common impacted material is food, and this usually occurs above a significant pathological lesion (Fig. 59.9). Plain radiographs are often useful for foreign bodies, but modern denture materials are not always radiopaque. A contrast examination is not usually required and only makes endoscopy more difficult (Summary box 59.2).

Figure 59.8 False teeth impacted in the oesophagus. (Note: modern dentures are usually radiolucent.)

Figure 59.9 An impacted meat bolus at the lower end of the oesophagus. This may be the first presentation of a benign stricture or a malignant tumour.

Summary box 59.2

Foreign bodies

- The most common is a food bolus, which usually signifies underlying disease
- It is usually possible to remove foreign bodies by flexible endoscopy
- Beware of button batteries in the oesophagus

Foreign bodies that have become stuck in the oesophagus should be removed by flexible endoscopy using suitable grasping forceps, a snare or a basket. If the object may injure the oesophagus on withdrawal, an overtube can be used, and the endoscope and object can be withdrawn into the overtube before removal. Button batteries can be a particular worry as they are difficult to grasp, and it is tempting to push them on into the stomach. However, an exhausted battery may rapidly corrode in the gastrointestinal tract and is best extracted. A multiwire basket of the type used for gallstone retrieval nearly always works. An impacted food bolus will often break up and pass on if the patient is given fizzy drinks and confined to fluids for a short time. The cause of the impaction must then be investigated. If symptoms are severe or the bolus does not pass, it can be extracted or broken up at endoscopy.

PERFORATION

Perforation of the oesophagus is usually iatrogenic (at therapeutic endoscopy) or due to 'barotrauma' (spontaneous perforation). Many instrumental perforations can be managed conservatively, but spontaneous perforation is often a life-threatening condition that regularly requires surgical intervention (Summary box 59.3).

Summary box 59.3

Perforation of the oesophagus

- Potentially lethal complication due to mediastinitis and septic shock
- Numerous causes, but may be iatrogenic
- Surgical emphysema is virtually pathognomonic
- Treatment is urgent; it may be conservative or surgical, but requires specialised care

Barotrauma (spontaneous perforation, Boerhaave syndrome)

This occurs classically when a person vomits against a closed glottis. The pressure in the oesophagus increases rapidly, and the oesophagus bursts at its weakest point in the lower third, sending a stream of material into the mediastinum and often the pleural cavity as well. The condition was first reported by Boerhaave, who reported the case of a grand admiral of the Dutch fleet who was a glutton and practised autoemesis. Boerhaave syndrome is the most serious type of perforation

Hermann Boerhaave, 1668–1738, Professor of Medicine and Botany, The University of Leiden, The Netherlands. He was the creator of the modern method of clinical teaching.

because of the large volume of material that is released under pressure. This causes rapid chemical irritation in the mediastinum and pleura followed by infection if untreated. Barotrauma has also been described in relation to other pressure events when the patient strains against a closed glottis (e.g. defaecation, labour, weight-lifting).

Diagnosis of spontaneous perforation

The clinical history is usually of severe pain in the chest or upper abdomen following a meal or a bout of drinking. Associated shortness of breath is common. Many cases are misdiagnosed as myocardial infarction, perforated peptic ulcer or pancreatitis if the pain is confined to the upper abdomen. There may be a surprising amount of rigidity on examination of the upper abdomen, even in the absence of any peritoneal contamination.

The diagnosis can usually be suspected from the history and associated clinical features. A chest X-ray is often confirmatory with air in the mediastinum, pleura or peritoneum. Pleural effusion occurs rapidly either as a result of free communication with the pleural space or as a reaction to adjacent inflammation in the mediastinum. A contrast swallow or CT is nearly always required to guide management (Fig. 59.10).

Pathological perforation

Free perforation of ulcers or tumours of the oesophagus into the pleural space is rare. Erosion into an adjacent structure with fistula formation is more common. Aerodigestive fistula is most common and usually encountered in primary malignant disease of the oesophagus or bronchus. Coughing on eating and signs of aspiration pneumonitis may allow the problem to be recognised at a time when intervention may be appropriate and feasible. Covering the communication with a self-expanding metal stent is the usual solution. Erosion into a major vascular structure is invariably fatal.

Penetrating injury

Perforation by knives and bullets is uncommon, even in war, as the oesophagus is a relatively small target surrounded by other vital organs.

Figure 59.10 Computerised tomography scan showing the site of perforation in the lower oesophagus.

Foreign bodies

The oesophagus may be perforated during removal of a foreign body but, occasionally, an object that has been left in the oesophagus for several days will erode through the wall.

Instrumental perforation

Instrumentation is by far the most common cause of perforation. Modern instrumentation is remarkably safe, but perforation remains a risk that should never be forgotten (Summary box 59.4).

Summary box 59.4

Instrumental perforation

- Prevention of perforation is better than cure

Perforation related to diagnostic upper gastrointestinal endoscopy is unusual with an estimated frequency of about 1:4000 examinations. Perforation can occur in the pharynx or oesophagus, usually at sites of pathology or when the endoscope is passed blindly. A number of patient-related factors are associated with increased risk, including large anterior cervical osteophytes, the presence of a pharyngeal pouch and mechanical causes of obstruction. Perforation may follow biopsy of a malignant tumour.

Patients undergoing therapeutic endoscopy have a perforation risk that is at least 10 times greater than those undergoing diagnostic endoscopy. The oesophagus may be perforated by guidewires, graduated dilators or balloons, or during the placement of self-expanding stents. The risk is considerably higher in patients with malignancy.

Diagnosis of instrumental perforation

In most cases, a combination of technical difficulties and an interventional procedure should lead to a high index of suspicion. History and physical signs may be useful pointers to the site of perforation.

Cervical perforation may result in pain localised to the neck, hoarseness, painful neck movements and subcutaneous emphysema. Intrathoracic and intra-abdominal perforations, which are more common, can give rise to immediate symptoms and signs either during or at the end of the procedure, including chest pain, haemodynamic instability, oxygen desaturation or visual evidence of perforation. Within the first 24 hours, patients may additionally complain of abdominal pain or respiratory difficulties. There may be evidence of subcutaneous emphysema, pneumothorax or hydropneumothorax. In some patients, the diagnosis may be missed and recognised only at a late stage beyond 24 hours, as unexplained pyrexia, systemic sepsis or the development of a clinical fistula.

Prompt and thorough investigation is the key to management. Careful endoscopic assessment at the end of any procedure combined with a chest X-ray will identify many cases of perforation immediately. If not recognised immediately, then early and late suspected perforations should be assessed by a water-soluble contrast swallow. If this is negative, a dilute barium swallow should be considered. A CT scan can be used to replace a contrast swallow or as an adjunct to accurately delineate specific fluid collections.

Treatment of oesophageal perforations

Perforation of the oesophagus usually leads to mediastinitis. The loose areolar tissues of the posterior mediastinum allow a rapid spread of gastrointestinal contents. The aim of treatment is to limit mediastinal contamination and prevent or deal with infection. Operative repair deals with the injury directly, but imposes risks of its own; non-operative treatment aims to limit the effects of mediastinitis and provide an environment in which healing can take place.

The decision between operative and non-operative management rests on four factors. These are:

- 1 the site of the perforation (cervical vs. thoracoabdominal oesophagus);
- 2 the event causing the perforation (spontaneous vs. instrumental);
- 3 underlying pathology (benign or malignant);
- 4 the status of the oesophagus before the perforation (fasted and empty vs. obstructed with a stagnant residue).

It follows that most perforations that can be managed non-operatively occur in the context of small instrumental perforations of a clean oesophagus without obstruction, where leakage is likely to be confined to the nearby mediastinum at worst (Table 59.1).

Instrumental perforations in the cervical oesophagus are usually small and can nearly always be managed conservatively. The development of a local abscess is an indication for cervical drainage preventing the extension of sepsis into the mediastinum.

The conservative management of an instrumental perforation in the thoracoabdominal parts of the oesophagus can be undertaken when the perforation is detected early and prior to oral alimentation. General guidelines for non-operative management include:

- pain that is readily controlled with opiates;
- absence of crepitus, diffuse mediastinal gas, hydropneumothorax or pneumoperitoneum;
- mediastinal containment of the perforation with no evidence of widespread extravasation of contrast material;
- no evidence of on-going luminal obstruction or a retained foreign body.

In addition, conservative management might be appropriate in patients who have remained clinically stable despite diagnostic delay. The principles of non-interventional management involve hyperalimentation, preferably by an enteral route, nasogastric suction and broad-spectrum intravenous antibiotics.

Surgical management is required whenever patients:

- are unstable with sepsis or shock;
- have evidence of a heavily contaminated mediastinum, pleural space or peritoneum;

Table 59.1 Management options in perforation of the oesophagus

Factors that favour non-operative management	Factors that favour operative repair
Small septic load	Large septic load
Minimal cardiovascular upset	Septic shock
Perforation confined to mediastinum	Pleura breached
Perforation by flexible endoscope	Boerhaave's syndrome
Perforation of cervical oesophagus	Perforation of abdominal oesophagus

- have widespread intrapleural or intraperitoneal extravasation of contrast material.

On-going luminal obstruction (often related to malignancy) in a frail patient considered unfit for major surgery can be dealt with by placement of a covered self-expanding stent. Expanding metal stents should be used with caution in patients with benign disease as they cause significant tissue reaction and some designs are impossible to remove at a later date. Biodegradable and removable stents are being developed and may be used alone or as a bridge to later definitive treatment where perforation accompanies obstruction.

For patients requiring surgery, the choice rests between direct repair, the deliberate creation of an external fistula or, rarely, oesophageal resection with a view to delayed reconstruction. Direct repair is preferred by many surgeons if the perforation is recognised early (within the first 4–6 hours) and the extent of mediastinal and pleural contamination is small. After 12 hours, the tissues become swollen and friable and less suitable for direct suture. The hole in the mucosa is always bigger than the hole in the muscle, and the muscle should be incised to see the mucosal edges clearly. It is essential that there should be no obstruction distal to the repair. A variety of local tissues (gastric fundus, pericardium, intercostal muscle) have been used to buttress such repairs.

Primary repair is inadvisable with late presentation and in the presence of widespread mediastinal and pleural contamination. These patients tend to be more ill as a result of the delay, and the aim of treatment should be to achieve wide drainage with the creation of a controlled fistula and distal enteral feeding. This can usually be achieved by placing a T-tube into the oesophagus along with appropriately located drains and a feeding jejunostomy. In unusual circumstances, for instance with extensive necrosis following corrosive ingestion, emergency oesophagectomy may be necessary. Oesophagostomy and gastrostomy should be performed with a view to delayed reconstruction.

MALLORY-WEISS SYNDROME

Forceful vomiting may produce a mucosal tear at the cardia rather than a full perforation. The mechanism of injury is different. In Boerhaave's syndrome, vomiting occurs against a closed glottis, and pressure builds up in the oesophagus. In Mallory–Weiss syndrome, vigorous vomiting produces a vertical split in the gastric mucosa, immediately below the squamocolumnar junction at the cardia in 90% of cases. In only 10% is the tear in the oesophagus (Fig. 59.11). The condition presents with haematemesis. Usually, the bleeding is not severe, but endoscopic injection therapy may be required for the occasional, severe case. Surgery is rarely required. There are two other injuries to the oesophagus that lie within the spectrum of the mucosal tear of Mallory–Weiss and the full-thickness tear of Boerhaave. Intramural rupture produces a dissection within the oesophageal wall that causes severe chest pain, often with odynophagia. It is best diagnosed by contrast radiology. Intramural haematoma is seen most often in elderly patients on

Figure 59.11 The endoscopic appearance of a mucosal tear at the cardia (Mallory–Weiss).

anticoagulants or patients with coagulation disorders, and usually follows an episode of vomiting. Large haematomas causing dysphagia can occur extending from the cardia up to the carina. The diagnosis is readily made on endoscopy. Both intramural rupture and intramural haematoma can be managed conservatively. Symptoms usually resolve in 7–14 days, and oral intake can be reinstated as soon as symptoms allow.

CORROSIVE INJURY

Corrosives such as sodium hydroxide (lye, caustic soda) or sulphuric acid may be taken in attempted suicide. Accidental ingestion occurs in children and when corrosives are stored in bottles labelled as beverages. All can cause severe damage to the mouth, pharynx, larynx, oesophagus and stomach. The type of agent, its concentration and the volume ingested largely determine the extent of damage. In general, alkalis are relatively odourless and tasteless, making them more likely to be ingested in large volume. Alkalis cause liquefaction, saponification of fats, dehydration and thrombosis of blood vessels that usually leads to fibrous scarring. Acids cause coagulative necrosis with eschar formation, and this coagulant may limit penetration to deeper layers of the oesophageal wall. Acids also cause more gastric damage than alkalis because of the induction of intense pylorospasm with pooling in the antrum.

Symptoms and signs are notoriously unreliable in predicting the severity of injury. The key to management is early endoscopy by an experienced endoscopist to inspect the whole of the oesophagus and stomach (Fig. 59.12). Deep ulcers and the recognition of a grey or black eschar signify the most severe lesions with the greatest risk of perforation. Minor injuries with only oedema

Figure 59.12 Acute caustic burn in the haemorrhagic phase.

Soma Weiss, 1898–1942, Professor of Medicine, Harvard University Medical School, Boston, MA, USA.

of the mucosa resolve rapidly with no late sequelae. These patients can safely be fed. With more severe injuries, a feeding jejunostomy may be appropriate until the patient can swallow saliva satisfactorily. The widespread use of broad-spectrum antibiotics and steroids is not supported by evidence.

Regular endoscopic examinations are the best way to assess stricture development (Fig. 59.13). Significant stricture formation occurs in about 50% of patients with extensive mucosal damage (Fig. 59.14). The role and timing of repeat endoscopies with or without dilatation in such patients remains controversial. Other than the need for emergency surgery for bleeding or

Figure 59.13 The late result of a caustic alkali burn with a high oesophageal stricture.

Figure 59.14 Caustic or lye stricture with marked stenosis high in the body of the oesophagus. The strictures are frequently multiple and difficult to dilate unless treated energetically at an early stage.

perforation, elective oesophageal resection should be deferred for at least 3 months until the fibrotic phase is established. Oesophageal replacement is usually required for very long or multiple strictures. Resection can be difficult because of peri-oesophageal inflammation in these patients. Because of associated gastric damage, colon may have to be used as the replacement conduit.

There is also controversy regarding the risk of developing carcinoma in the damaged oesophagus and stomach and how this might influence management. The lifetime risk is certainly less than 5%. Some surgeons advocate resection and replacement, while others believe that oesophageal bypass and endoscopic surveillance is preferable, as removal of the badly damaged oesophagus from a scarred mediastinum can be hazardous (Summary box 59.5).

Summary box 59.5

Corrosive injury

- Skilled early endoscopy is mandatory

DRUG-INDUCED INJURY

Many medications, such as antibiotics and potassium preparations, are potentially damaging to the oesophagus, as tablets may remain for a long time, especially if taken without an adequate drink. Acute injury presents with dysphagia and odynophagia, which may be severe. The inflammation usually resolves within 2–3 weeks, and no specific treatment is required apart from appropriate nutritional support. A stricture may follow.

GASTRO-OESOPHAGEAL REFLUX DISEASE

Aetiology

Normal competence of the gastro-oesophageal junction is maintained by the LOS. This is influenced by both its physiological function and its anatomical location relative to the diaphragm and the oesophageal hiatus. In normal circumstances, the LOS transiently relaxes as a coordinated part of swallowing, as a means of allowing vomiting to occur and in response to stretching of the gastric fundus, particularly after a meal to allow swallowed air to be vented. Most episodes of physiological reflux occur during postprandial transient lower oesophageal sphincter relaxations (TLOSRS). In the early stages of GORD, most pathological reflux occurs as a result of an increased number of TLOSRS rather than a persistent fall in overall sphincter pressure. In more severe GORD, LOS pressure tends to be generally low, and this loss of sphincter function seems to be made worse if there is loss of an adequate length of intra-abdominal oesophagus.

The absence of an intra-abdominal length of oesophagus results in a sliding hiatus hernia. The normal condensation of peritoneal fascia over the lower oesophagus (the phreno-oesophageal ligament) is weak, and the crural opening widens allowing the upper stomach to slide up through the hiatus. The loss of the normal anatomical configuration exacerbates reflux, although sliding hiatus hernia alone should not be viewed as the cause of reflux. Sliding hiatus hernia is associated with GORD and may make it worse but, as long as the LOS remains competent, pathological GORD does not occur. Many GORD sufferers do not have a hernia, and many of those with a hernia do not

have GORD. It should be noted that rolling or paraoesophageal hiatus hernia is a quite different and potentially dangerous condition (see below). A proportion of patients have a rolling hernia and symptomatic GORD or a mixed hernia with both sliding and rolling components. Reflux oesophagitis that is visible endoscopically is a complication of GORD and occurs in a minority of sufferers overall, but in around 40% of patients referred to hospital.

In western societies, GORD is the most common condition affecting the upper gastrointestinal tract. This is partly due to the declining incidence of peptic ulcer as the incidence of infection with *Helicobacter pylori* has reduced as a result of improved socio-economic conditions along with a rising incidence of GORD in the last 20–30 years. The cause of the increase is unclear, but may be due in part to increasing obesity. The strong association between GORD, obesity and the parallel rise in the incidence of adenocarcinoma of the oesophagus represents a major health challenge for most western countries.

Clinical features

The classical triad of symptoms is retrosternal burning pain (heartburn), epigastric pain (sometimes radiating through to the back) and regurgitation. Most patients do not experience all three. Symptoms are often provoked by food, particularly those that delay gastric emptying (e.g. fats, spicy foods). As the condition becomes more severe, gastric juice may reflux to the mouth and produce an unpleasant taste often described as ‘acid’ or ‘bitter’. Heartburn and regurgitation can be brought on by stooping or exercise. A proportion of patients have odynophagia with hot beverages, citrus drinks or alcohol. Patients with nocturnal reflux and those who reflux food to the mouth nearly always have severe GORD. Some patients present with less typical symptoms such as angina-like chest pain, pulmonary or laryngeal symptoms. Dysphagia is usually a sign that a stricture has occurred, but may be caused by an associated motility disorder.

Because GORD is such a common disorder, it should always be the first thought when a patient presents with oesophageal symptoms that are unusual or that defy diagnosis after a series of investigations.

Diagnosis

In most cases, the diagnosis is assumed rather than proven, and treatment is empirical. Investigation is only required when the diagnosis is in doubt, when the patient does not respond to a proton pump inhibitor (PPI) or if dysphagia is present. The most appropriate examination is endoscopy with biopsy. If the typical appearance of reflux oesophagitis, peptic stricture or Barrett’s oesophagus is seen, the diagnosis is clinched, but visible oesophagitis is not always present, even in patients selected as above. This is compounded in clinical practice by the widespread use of PPIs, which cause rapid healing of early mucosal lesions. Many patients will have received such treatment before referral. The endoscopic appearances of the normal oesophagus, hiatus hernia, oesophagitis and stricture are shown in Figures 59.15–59.21. It is worth remembering that the correlation between symptoms and endoscopic appearances is poor. On the other hand, there is a strong correlation between worsening endoscopic appearances and the duration of oesophageal acidification on pH testing.

Norman Rupert Barrett, 1903–1979, Surgeon, St. Thomas’s Hospital, London, England.

Figure 59.15 The endoscopic appearance of the normal squamous mucosa in the body of the oesophagus.

Figure 59.16 The normal lower oesophageal sphincter: (a) open; (b) closed.

In patients with atypical or persistent symptoms despite therapy, oesophageal manometry and 24-hour oesophageal pH recording may be justified to establish the diagnosis and guide management (Summary box 59.6).

Summary Box 59.6

Diagnostic measurement in GORD

- 24-hour pH recording is the 'gold standard' for diagnosis of GORD
- TLOSRS are the most important manometric findings in GORD
- The length and pressure of the LOS are also important

As a matter of routine, PPIs are stopped 1 week before oesophageal pH recording, but acid secretion is sometimes reduced for 2 weeks or more, and this can necessitate repeat examination after a prolonged interval without a PPI. Manometry and pH recording are also essential in patients being considered for anti-reflux surgery. While the main purpose of the test is objectively to quantify the extent of reflux disease, it is also used to rule out a diagnosis of achalasia. In the early stages of achalasia, chest pain can dominate the clinical picture and, when associated with intermittent swallowing problems and non-specific symptoms, it is easy to see how a clinical diagnosis of GORD might be made. Patients with achalasia can also have an abnormal pH study as a result of fermentation of food residue in a dilated oesophagus. Usually, the form of the pH trace is different from that of GORD, with slow undulations of pH rather than rapid bursts of reflux, but the complete absence of peristalsis on manometry is pathognomonic of achalasia.

Barium swallow and meal examination gives the best appreciation of gastro-oesophageal anatomy (Fig. 59.22). This may be important in the context of surgery for rolling or mixed hiatus hernias, but it is unimportant in most patients with GORD.

Management of uncomplicated GORD

Medical management

Most sufferers from GORD do not consult a doctor and do not need to do so. They self-medicate with over-the-counter medicines such as simple antacids, antacid-alginate preparations and H_2 -receptor antagonists. Consultation is more likely when symptoms are severe, prolonged and unresponsive to the above treatments. Simple measures that are often neglected include advice about weight loss, smoking, excessive consumption of alcohol, tea or coffee, the avoidance of large meals late at night and a modest degree of head-up tilt of the bed. Tilting the bed has been shown to have an effect that is similar to taking an H_2 -receptor antagonist. The common practice of using additional pillows has no significant effect.

Figure 59.22 (a) Sliding hiatus hernia with a sphincter and diaphragmatic crural narrowing clearly shown. (b) Another sliding hernia in which the sphincter is lax, and the diaphragm is wide open. The patient is in the Trendelenburg position to demonstrate barium in the fundus. This unphysiological position may stimulate 'reflux' in those who do not have gastro-oesophageal reflux disease (GORD).

PPIs are the most effective drug treatment for GORD. Indeed, they are so effective that, once started, patients are very reluctant to stop taking them. Given an adequate dose for 8 weeks, most

patients have a rapid improvement in symptoms (within a few days), and more than 90% can expect full mucosal healing at the end of this time. For this reason, a policy of 'step-down' medical treatment is advocated based on the general advice outlined above and a standard dose of a PPI given for 8 weeks. At the end of that time, the dose of PPI is reduced to that which keeps the patient free of symptoms, and this might even mean the cessation of PPI treatment. Because most patients do not make major lifestyle changes and because PPIs are so effective, many remain on long-term treatment. For the minority who do not respond adequately to a standard dose, a trial at an increased dose or the addition of an H_2 -receptor antagonist is recommended. If unsuccessful, these patients should be formally investigated.

PPI therapy is also important in patients with reflux-induced strictures, resulting in significant prolongation of the intervals between endoscopic dilatation. As yet, fears that chronic acid suppression might have serious long-term side-effects including the risk of gastric cancer seem unwarranted.

Surgery

Strictly speaking, the need for surgery should have been reduced as medication has improved so much. Paradoxically, the number of anti-reflux operations has remained relatively constant and may even be increasing. This is probably due partly to increased patient expectations and partly to the advent of minimal access surgery, which has improved the acceptability of procedures.

Endoscopic treatments

A number of endoscopic treatments have been tried in the last 10 years that attempt to augment a failing LOS. These involve endoscopic suturing devices that plicate gastric mucosa just below the cardia to accentuate the angle of His, radiofrequency ablation applied to the level of the sphincter and the injection of submucosal polymers into the lower oesophagus. The procedures have generally been applied to patients with only small hiatus hernias or none at all, so only a small proportion of patients who present to hospitals are suitable. While all methods produce some temporary improvement in symptoms and objective assessments of reflux, failure rates at 1 year are over 50%, and there are no large case series that have reported long-term outcomes.

Surgical treatments

The indication for surgery in uncomplicated GORD is essentially patient choice. The risks and possible benefits need to be discussed in detail. Risks include a small mortality rate (0.1–0.5%, depending on patient selection), failed operation (5–10%) and side-effects such as dysphagia, gas bloat or abdominal discomfort (10%). With current operative techniques, 85–90% of patients should be satisfied with the result of an anti-reflux operation. Patients who are asymptomatic on a PPI need a careful discussion of the risk side of the equation. Those who are symptomatic on a PPI need a careful clinical review to make sure that they will benefit from an operation. Reasons for failure on a PPI include 'volume' reflux (a good indication for surgery), a 'hermit' lifestyle in which the least deviation from lifestyle rules leads to symptoms (a good indication), psychological distress with intolerance of minor symptoms (a poor indication; these patients are likely to be dissatisfied with surgery), poor compliance (a good indication if the reason for poor compliance is the side-effects of treatment, otherwise a bad indication) and misdiagnosis of GORD.

Friedrich Trendelenburg, 1844–1924, successively Professor of Surgery at Rostock (1875–1882), Bonn (1882–1895), and Leipzig, Germany (1895–1911).

Which operation?

There are many operations for GORD, but they are virtually all based on the creation of an intra-abdominal segment of oesophagus, crural repair and some form of wrap of the upper stomach (fundoplication) around the intra-abdominal oesophagus. The contribution of each component to operative success is widely debated, but it is clear that operations that fail to address all three components have inferior success rates. The major types of anti-reflux operation were all developed in the 1950s (Fig. 59.23). When performed correctly, these are all effective operations. Randomised clinical trials do not show a clear advantage for any one operation over the others.

Total fundoplication (Nissen) tends to be associated with slightly more short-term dysphagia but is the most durable repair in terms of long-term reflux control. Partial fundoplication, whether performed posteriorly (Toupet) or anteriorly (Dor, Watson), has fewer short-term side-effects at the expense of a slightly higher long-term failure rate. One disadvantage of total fundoplication is the creation of an overcompetent cardia, resulting in the 'gas bloat' syndrome in which belching is impossible. The stomach fills with air, the patient feels very full after small meals and passes excessive flatus. This does not seem to occur with partial fundoplication. The problem has been largely overcome by the 'floppy' Nissen technique in which the fundoplication is loose around the oesophagus and is kept short in length. While the other short-term side-effects of fundoplication usually resolve within 3 months of surgery, this is rarely the case for gas bloat. The problem is best remedied by conversion to a partial fundoplication.

As with primary surgery, a variety of revisional procedures

Figure 59.23 Various operations for the surgical correction of gastro-oesophageal reflux disease. (a) The original Allison repair of hiatus hernia (this is ineffective and is no longer done); (b) Nissen fundoplication; (c) Hill procedure; (d) Belsey mark IV operation.

have been described. For most patients, recurrent reflux relates to anatomical failure, so the solution is a revisional fundoplication. A very small proportion of patients may undergo more than two operations to correct recurrent reflux or unacceptable side-effects. Revisional surgery carries a lower chance of success and, in some patients, local revision is technically impossible. The final resort is partial gastrectomy with a Roux-en-Y reconstruction. This reduces gastric acid secretion and diverts bile and pancreatic secretions away from the stomach. Thus, the volume of potential refluxate in the stomach is reduced and, because of its changed composition, it is less damaging to the oesophagus.

For many years, the relative merits of thoracic and abdominal approaches were hotly debated. The introduction of minimal access surgery has made this debate practically obsolete, and most anti-reflux operations are now done with a laparoscopic approach.

Laparoscopic fundoplication

Five cannulae are inserted in the upper abdomen (Fig. 59.24). The cardia and lower oesophagus are separated from the diaphragmatic hiatus. An appropriate length of oesophagus is mobilised in the mediastinum. The fundus may be mobilised by dividing the short gastric vessels that tether the fundus to the spleen. The hiatus is narrowed by sutures placed behind the oesophagus. In total (Nissen) fundoplication, the fundus is drawn behind the oesophagus and then sutured to itself in front of the oesophagus (Fig. 59.25a). In partial fundoplication, the fundus is drawn either behind or in front of the oesophagus and sutured to it on each side, leaving a strip of exposed oesophagus either at the front (Fig. 59.25b) or at the back.

Figure 59.25 (a) Total (Nissen) fundoplication; (b) partial fundoplication (Toupet).

Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.

Complications of gastro-oesophageal reflux disease

Stricture

Reflux-induced strictures (see Fig. 59.21, p. 1019) occur mainly in the late middle-aged and the elderly, but they may present in children. It is important to distinguish a benign reflux-induced stricture from a carcinoma. This is not usually difficult on the basis of location (immediately above the oesophagogastric junction), length (only about 1–2 cm) and smooth mucosa, but sometimes a cancer spreads under the oesophageal mucosa at its upper margin, producing a benign-looking stricture.

Peptic strictures generally respond well to dilatation and long-term treatment with a PPI. As most patients are elderly, anti-reflux surgery is not usually considered. However, it is an alternative to long-term PPI treatment, just as in uncomplicated GORD in younger and fitter patients. Most patients do not require anything other than a standard operation (Summary box 59.8).

Summary box 59.8

Peptic stricture

- Day-case dilatation and PPI for peptic stricture

Oesophageal shortening

The issue of oesophageal shortening continues to provoke debate. There can be no doubt that, in the presence of a large sliding hiatus hernia, the oesophagus is short, but this does not necessarily mean that, with mobilisation from the mediastinum, it cannot easily be restored to its normal length. The extent to which severe inflammation in the wall of the oesophagus causes fibrosis and real shortening is less clear. If a good segment of intra-abdominal oesophagus cannot be restored without tension, a Collis gastroplasty should be performed (Fig. 59.26). This produces a neo-oesophagus around which a fundoplication can be done (Collis–Nissen operation) (Summary box 59.8).

Figure 59.26 Collis gastroplasty to produce a neo-oesophagus around which a Nissen fundoplication is done. The operation may be performed by a laparoscopic as well as an open approach using circular and linear staplers.

John Leigh Collis, 1911–2003, Professor of Thoracic Surgery, The University of Birmingham, Birmingham, England.

Summary box 59.8

GORD

- Is due to loss of competence of the LOS and is extremely common
- May be associated with a hiatus hernia, which may be sliding or, less commonly, rolling (paraoesophageal)
- The most common symptoms are heartburn, epigastric discomfort and regurgitation, often made worse by stooping and lying

Achalasia and GORD are diagnostically easily confused

- Dysphagia may occur, but a neoplasm must be excluded
- Diagnosis and treatment can be instituted on clinical grounds

Endoscopy may be required and 24-hour pH is the 'gold standard'

- Management is primarily medical (PPIs being the most effective), but surgery may be required; laparoscopic fundoplication is the most popular technique
- Stricture may develop in time

Barrett's oesophagus (columnar-lined lower oesophagus)

Barrett's oesophagus is a metaplastic change in the lining mucosa of the oesophagus in response to chronic gastro-oesophageal reflux (Fig. 59.27). Many of these patients do not have particularly severe symptoms, although they do have the most abnormal pH profiles. This adaptive response involves a mosaic of cell types, probably beginning as a simple columnar epithelium that becomes 'specialised' with time. The hallmark of 'specialised' Barrett's epithelium is the presence of mucus-secreting goblet cells (intestinal metaplasia). One of the great mysteries of GORD

Figure 59.27 Barrett's oesophagus with proximal migration of the squamocolumnar junction (a) and with a view of the distal oesophagus (b).

is why some people develop oesophagitis and others develop Barrett's oesophagus, often without significant oesophagitis. In Barrett's oesophagus, the junction between squamous oesophageal mucosa and gastric mucosa moves proximally. It may be difficult to distinguish a Barrett's oesophagus from a tubular, sliding hiatus hernia during endoscopy, as the two often coexist (Fig. 59.28) or where the visible Barrett's segment is very short. The key is where the gastric mucosal folds end. The mucosa in the body of the stomach has longitudinal folds; the columnar lining of Barrett's oesophagus is smooth. Strictures can occur in Barrett's oesophagus and nearly always appear at the new squamocolumnar junction (Fig. 59.29). Rarely, a stricture may occur in the columnar segment after healing of a Barrett's ulcer (Fig. 59.30). When intestinal metaplasia occurs, there is an increased risk of adenocarcinoma of the oesophagus (Summary box 59.9), which is about 25 times that of the general population (Figs 59.30–32).

Summary box 59.9

Barrett's oesophagus

- Intestinal metaplasia is an important risk factor for the development of adenocarcinoma
- Do not confuse Barrett's ulcer with oesophagitis

Patients who are found to have Barrett's oesophagus may be submitted to regular surveillance endoscopy with multiple biopsies in the hope of finding dysplasia or *in situ* cancer rather than allowing invasive cancer to develop and cause symptoms. There is as yet no general agreement about the benefits of surveillance endoscopy, nor about its ideal frequency. Annual endoscopy has been widely practised, but 2-year intervals are probably adequate, provided no dysplasia has been detected. A significant problem is that the incidence of Barrett's oesophagus in the community is estimated to be at least 10 times the incidence discovered in dyspeptic patients referred for endoscopy. Thus, adenocarcinoma in Barrett's oesophagus often presents with invasive cancer without any preceding reflux symptoms.

Figure 59.30 Barrett's ulcer in the columnar cell-lined oesophagus.

Figure 59.31 The macroscopic appearances of an adenocarcinoma in Barrett's oesophagus.

Figure 59.32 Endoscopic view of carcinoma in Barrett's oesophagus.

Until recently, Barrett's oesophagus was not diagnosed until there was at least 3 cm of columnar epithelium in the distal oesophagus. With the better appreciation of the importance of intestinal metaplasia, Barrett's oesophagus may be diagnosed if there is any intestinal metaplasia in the oesophagus. The relative risk of cancer probably increases with increasing length of abnormal mucosa. The following terms are widely used:

- *classic Barrett's* (3 cm or more columnar epithelium);
- *short-segment Barrett's* (less than 3 cm of columnar epithelium);
- *cardia metaplasia* (intestinal metaplasia at the oesophagogastric junction without any macroscopic change at endoscopy).

When Barrett's oesophagus is discovered, the treatment is that of the underlying GORD. There has been considerable interest in recent years in endoscopic methods of ablating Barrett's mucosa in the hope of eliminating the risk of cancer development. Laser, photodynamic therapy, argon-beam plasma coagulation and endoscopic mucosal resection (EMR) have all been used. In conjunction with high-dose PPI treatment or an anti-reflux operation, these endoscopic methods can result in a neosquamous lining. There is no evidence yet that any of these methods is reliable in eliminating cancer risk. Residual islands of Barrett's epithelium can persist, glands may be buried beneath the new lining, and damage to the oesophageal wall may cause stricturing.

PARAOESOPHAGEAL ('ROLLING') HIATUS HERNIA

True paraoesophageal hernias in which the cardia remains in its normal anatomical position are rare. The vast majority of rolling hernias are mixed hernias in which the cardia is displaced into the chest and the greater curve of the stomach rolls into the mediastinum (Fig. 59.33). Sometimes, the whole of the stomach lies in the chest (Fig. 59.34). Colon or small intestine may sometimes lie in the hernia sac. The hernia is most common in the elderly, but may occur in young fit people. As the stomach rolls up into the chest, there is always an element of rotation (volvulus) (Summary box 59.10).

Summary box 59.10

'Rolling' hiatus hernia

- Potentially dangerous, because of volvulus

The symptoms of rolling hernia are mostly due to twisting and distortion of the oesophagus and stomach. Dysphagia is common. Chest pain may occur from distension of an obstructed stomach. Classically, the pain is relieved by a loud belch. Symptoms of GORD are variable. Strangulation, gastric perforation and gangrene can occur. Emergency presentation with any of these complications carries high mortality on account of a combination of late diagnosis, generally elderly patients with comorbid diseases and the complexity of surgery involved.

The hernia may be visible on a plain radiograph of the chest as a gas bubble, often with a fluid level behind the heart (Fig. 59.35). A barium meal is the best method of diagnosis. The endoscopic appearances may be confusing, especially in large hernias when it is easy to become disorientated.

Figure 59.33 A paraoesophageal hernia showing the gastro-oesophageal junction just above the diaphragm and the fundus alongside the oesophagus, compressing the lumen.

Figure 59.34 A huge paraoesophageal hernia with an upside-down stomach and the pylorus just below the hiatus.

Symptomatic rolling hernias nearly always require surgical repair as they are potentially dangerous. The risk of an asymptomatic patient developing a significant problem when a rolling hiatus hernia is discovered incidentally has probably been overestimated in the past. The annual risk is probably no more than 1%. Patients who present as an emergency with acute chest pain may be treated initially by nasogastric tube to relieve the distension that

Figure 59.35 A gas bubble seen on a plain chest radiograph, showing the fundus of the stomach in the chest. Courtesy of Dr Stephen Ellis, Barts and the London NHS Trust.

causes the pain, followed by operative repair. If the pain is not relieved or perforation is suspected, immediate operation is mandatory.

Emergency surgery needs to be tailored to the problem encountered and the fitness of the patient. Elective surgery involves reduction of the hernia, excision of the sac, reducing the crural defect and some form of retention of the stomach in the abdomen. Some surgeons perform a fundoplication, arguing that this is a very effective means of maintaining reduction and that it deals with the associated GORD. Others argue that fundoplication should only be done if reflux can be conclusively demonstrated beforehand. Surprisingly, both philosophies achieve good results. Laparoscopic repair has recently become popular. Full anatomical repair of a large rolling hernia can be difficult by this approach and requires considerable expertise. Secure closure of the hiatal defect can be a problem, and some surgeons advocate mesh to reinforce the repair.

NEOPLASMS OF THE OESOPHAGUS

Benign tumours

Benign tumours of the oesophagus are relatively rare. True papillomas, adenomas and hyperplastic polyps do occur, but the majority of 'benign' tumours are not epithelial in origin and arise from other layers of the oesophageal wall [gastrointestinal stromal tumour (GIST), lipoma, granular cell tumour]. Most benign oesophageal tumours are small and asymptomatic, and even a large benign tumour may cause only mild symptoms (Fig. 59.36). The most important point in their management is usually to carry out an adequate number of biopsies to prove beyond reasonable doubt that the lesion is not malignant (Fig. 59.37).

Malignant tumours

Non-epithelial primary malignancies are also rare, as is malignant melanoma. Secondary malignancies rarely involve the oesophagus with the exception of bronchogenic carcinoma by direct invasion of either the primary and/or contiguous lymph nodes.

Figure 59.36 Classic appearance of a large oesophageal gastrointestinal stromal tumour on barium swallow.

Figure 59.37 An intraluminal polyp that proved to be a leiomyosarcoma.

Carcinoma of the oesophagus

Cancer of the oesophagus is the sixth most common cancer in the world. In general, it is a disease of mid to late adulthood, with a poor survival rate. Only 5–10% of those diagnosed will survive for 5 years (Summary box 59.11).

Summary box 59.11

Carcinoma of the oesophagus

- Squamous cell usually affects the upper two-thirds; adenocarcinoma usually affects the lower third
- Common aetiological factors are tobacco and alcohol (squamous cell) and GORD (adenocarcinoma)
- The incidence of adenocarcinoma is increasing
- Lymph node involvement is a bad prognostic factor
- Dysphagia is the most common presenting symptom, but is a late feature
- Accurate pretreatment staging is essential in patients thought to be fit to undergo 'curative' treatment

Pathology and aetiology

Squamous cell cancer (Figs 59.38 and 59.39) and adenocarcinoma (Figs 59.40 and 59.41) are the most common types. Squamous cell carcinoma generally affects the upper two-thirds of the oesophagus and adenocarcinoma the lower one-third. Worldwide, squamous cell cancer is most common, but adenocarcinoma predominates in the west and is increasing in incidence.

Geographical variation in oesophageal cancer

The incidence of oesophageal cancer varies more than that of any other cancer. Squamous cell cancer is endemic in the Transkei region of South Africa and in the Asian 'cancer belt' that extends across the middle of Asia from the shores of the Caspian Sea (in northern Iran) to China. The highest incidence in the world is in Linxian in Henan province in China, where it is the most common single cause of death, with more than 100 cases per 100 000 population per annum. The cause of the disease in the endemic areas is not known, but it is probably due to a combination of fungal contamination of food and nutritional deficiencies. In Linxian, supplementation of the diet with beta-carotene, vitamin E and selenium has been shown to reduce the incidence.

Away from the endemic areas, tobacco and alcohol are major factors in the occurrence of squamous cancer. Incidence rates vary from less than 5:100 000 in white people in the USA to 26.5:100 000 in some regions of France.

In many western countries, the incidence of squamous cell cancer has fallen or remained static, but the incidence of adenocarcinoma of the oesophagus has increased dramatically since the mid-1970s at a rate of 5–10% per annum. The change is greater than that of any other neoplasm in this time. Adenocarcinoma now accounts for 60–75% of all oesophageal cancers in several countries. The reason for this change is not understood. A similar rate of increase in GORD over the same period, which mirrors an increase in obesity in the west, is likely to be an important factor, particularly through the link to Barrett's oesophagus.

Figure 59.38 The classic appearances of a mid-oesophageal proliferative squamous cell carcinoma.

There has been a similar increase in the incidence of carcinoma of the cardia of the stomach, which suggests that cancer of the cardia and adenocarcinoma of the oesophagus may share common aetiological factors. With a falling incidence of cancer in the rest of the stomach, more than 60% of all upper gastrointestinal cancers in the west involve the cardia or distal oesophagus.

Both adenocarcinomas and squamous cell carcinomas tend to disseminate early. Sadly, the classical presenting symptoms of dysphagia, regurgitation and weight loss are often absent until the primary tumour has become advanced, and so the tumour is often well established before the diagnosis is made. Tumours can spread in three ways: invasion directly through the oesophageal wall, via lymphatics or in the bloodstream. Direct spread occurs both laterally, through the component layers of the oesophageal wall, and longitudinally within the oesophageal wall. Longitudinal spread is mainly via the submucosal lymphatic channels of the oesophagus. The pattern of lymphatic drainage is therefore not segmental, as in other parts of the gastrointestinal tract. Consequently, the length of oesophagus involved by tumour is frequently much longer than the macroscopic length of the malignancy at the epithelial surface. Lymph node spread occurs commonly. Although the direction of spread to regional lymphatics is predominantly caudal, the involvement of lymph nodes is potentially widespread and can also occur in a cranial direction. Any regional lymph node from the superior mediastinum to the coeliac axis and lesser curve of the stomach may be involved regardless of the location of the primary lesion within the oesophagus. Haematogenous spread may involve a variety of different organs including the liver, lungs, brain and bones. Tumours arising from

Figure 59.39 Squamous cell carcinoma of the oesophagus producing an irregular stricture with shouldered margins.

the intra-abdominal portion of the oesophagus may also disseminate transperitoneally.

Clinical features

Most oesophageal neoplasms present with mechanical symptoms, principally dysphagia, but sometimes also regurgitation, vomiting, odynophagia and weight loss. Clinical findings suggestive of advanced malignancy include recurrent laryngeal nerve palsy, Horner's syndrome, chronic spinal pain and diaphragmatic paralysis. Other factors making surgical cure unlikely include weight loss of more than 20% and loss of appetite. Cutaneous tumour metastases or enlarged supraclavicular lymph nodes may be seen on clinical examination and indicate disseminated disease. Hoarseness due to recurrent laryngeal nerve palsy is a sign of advanced and incurable disease. Palpable lymphadenopathy in the neck is likewise a sign of advanced disease.

Patients with early disease may have non-specific dyspeptic symptoms or a vague feeling of 'something that is not quite right' during swallowing. Some are diagnosed during endoscopic surveillance of patients with Barrett's oesophagus and, while this does identify patients with the earliest stages of disease, such

Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.

Figure 59.40 Adenocarcinoma of the lower oesophagus, spreading upwards from the cardia.

Figure 59.41 Computerised tomography scan showing a primary tumour of the lower oesophagus.

programmes have little overall impact, as most patients with Barrett's oesophagus are unknown to the medical profession and make their first presentation with a symptomatic and therefore usually locally advanced oesophageal cancer. The widespread use of endoscopy as a diagnostic tool does nevertheless provide an opportunity for early diagnosis (Fig. 59.42). Biopsies should be

Figure 59.42 Carcinoma *in situ* showing the varied presentations: (a) occult form; (b) erythroplakia; (c) leucoplakia. The right-hand pictures in (a) and (b) demonstrate the use of vital staining with methylene blue.

taken of all lesions in the oesophagus (Figs 59.43 and 59.44), no matter how trivial they appear and irrespective of the indication for the examination.

Investigation

Endoscopy is the first-line investigation for most patients. It provides an unrivalled direct view of the oesophageal mucosa and any lesion allowing its site and size to be documented. Cytology and/or histology specimens taken via the endoscope are crucial for accurate diagnosis. The combination of histology and cytology increases the diagnostic accuracy to more than 95%. The chief limitation of conventional endoscopy is that only the mucosal surface can be studied and biopsied. Other investigations are therefore usually required to define the extent of local or distant spread. The improved image resolution of modern endoscopes and novel techniques involving magnification and the use of dyes to enhance surface detail may lead to more early lesions being recognised (see Fig 59.42).

General assessment and staging

Once the initial diagnosis of a malignant oesophageal neoplasm has been made, patients should be assessed first in terms of their general health and fitness for potential therapies. Their preferences should also be considered. Most potentially curative therapies

Figure 59.43 Endoscopic appearances of a mid-oesophageal squamous cell carcinoma.

Figure 59.44 Beware the differential diagnosis of infection, for what appears to be a tumour. This mid-oesophageal mass was actually tuberculosis.

include radical surgery, although chemoradiotherapy is an alternative in squamous cell carcinoma. Patients who are unfit for, or who do not wish to contemplate, radical treatments should not be investigated further, but should be diverted to appropriate palliative therapies, depending on symptoms and current quality of life. Only those patients suitable for potentially curative therapies should proceed to staging investigations to rule out haematogenous spread

and then to assess locoregional stage [endoscopic ultrasound (EUS) \pm laparoscopy]. This will distinguish between early (T1/T2, N0) and advanced lesions (T3/T4, N1) and indicate whether surgery alone or multimodal therapy is most appropriate. Where attempted cure is deemed possible, the aim should be to provide the best chance of cure while minimising perioperative risks. In general, surgery alone should be reserved for patients with early disease, and multimodal therapy should be used in patients with locally advanced disease, in whom the chance of cure by surgery alone is small (generally less than 20%).

The most widely used pathological staging system is the World Health Organization (tumour–nodes–metastasis TNM) classification.

Table 59.2 shows the TNM system for oesophageal cancer in its most updated form. Like all pathological systems, it is reliant on the nature and extent of the surgery performed. For example, performing more extensive radical surgical lymphadenectomy provides a more accurate assessment of the ‘N’ stage. There is evidence that many patients described as N0 in the past were probably N1, a phenomenon described as stage migration.

Staging information may be gathered before the commencement of therapy, during therapy (e.g. at open operation) or following treatment (histology or post-mortem). The techniques commonly used to provide preoperative staging data are described in Figure 59.45, along with a suggested algorithm.

Blood tests

These are of limited value. Blood tests reveal nothing about local invasion or regional lymph node spread and, to date, no reliable tumour marker for oesophageal cancer has been isolated from peripheral blood. The presence of abnormal liver function tests (LFTs) may suggest the presence of liver metastases, but this is generally too insensitive to be diagnostic. Many patients with known liver metastases have normal LFTs. At best, abnormal LFTs only reinforce the clinical suspicion of spread to the liver, and further imaging is usually required to confirm the diagnosis.

Transcutaneous ultrasound

It is difficult to visualise mediastinal structures with transcutaneous ultrasound. With the relatively low-frequency sound waves

Table 59.2 TNM staging scheme for oesophageal cancer

Tis	High-grade dysplasia
T1	Tumour invading lamina propria or submucosa
T2	Tumour invading muscularis propria
T3	Tumour invading beyond muscularis propria
T4	Tumour invading adjacent structures
Tx	Primary tumour cannot be assessed
N0	No regional lymph node metastases
N1	Regional lymph node metastases
Nx	Lymph nodes cannot be assessed
M0	No distant metastases
M1(a)	Coeliac node involved (for distal oesophageal tumours) Supraclavicular node involved (for proximal tumours)
M1(b)	Coeliac or supraclavicular node involved if not remote from tumour site (i.e. not 1a) All other distant metastases
Mx	Distant metastases cannot be assessed

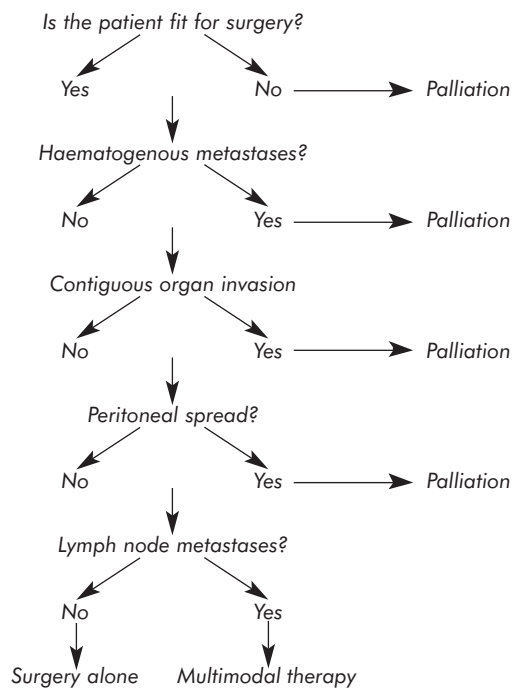

Figure 59.45 Algorithm for the management of oesophageal cancer.

used, good depth of tissue penetration is achieved at the expense of poor image resolution. In addition, the mediastinal organs are surrounded by bone and air, which renders them largely inaccessible to external ultrasound. The technique is therefore used mainly to assess spread to the liver, the whole of which can be clearly visualised by standard transcutaneous ultrasound. Haematogenous spread can be more fully assessed by combining ultrasound with chest radiography, although this combination is less accurate than CT scanning.

Bronchoscopy

Many middle- and upper-third oesophageal carcinomas (and therefore usually squamous carcinomas) are sufficiently advanced at the time of diagnosis that the trachea or bronchi are already involved (Fig. 59.46). Bronchoscopy may reveal either impingement or

Figure 59.46 Invasion into the posterior wall of the trachea from an oesophageal carcinoma.

invasion of the main airways in over 30% of new patients with cancers in the upper third of the oesophagus. In some cases, therefore, bronchoscopy alone can confirm that the tumour is locally unresectable.

Laparoscopy

This is a useful technique for the diagnosis of intra-abdominal and hepatic metastases. It has the advantage of enabling tissue samples or peritoneal cytology to be obtained and is the only modality reliably able to detect peritoneal tumour seedlings (Fig. 59.47). This is particularly important for tumours arising from the intra-abdominal portion of the oesophagus, cardia and where there is a potential communication between a full-thickness tumour and the peritoneal cavity, for instance where there is a hiatus hernia.

Computerised tomography

CT scanning is the modality most used to identify haematogenous metastases (Fig. 59.48). Distant organs are easily seen and metastases within them visualised with high accuracy (94–100%). The normal thoracic oesophagus is easily demonstrated by CT scanning. The mediastinal fat planes are usually clearly imaged in healthy individuals, and any blurring or distortion of these images is a fairly reliable indicator of abnormality. In cachectic patients with dysphagia and malnutrition, the mediastinal fat plane may be virtually absent, making local invasion difficult to assess. Spiral and thin-slice CT permit structures such as lymph nodes to be adequately imaged, down to a minimum diameter of about 5 mm. Smaller nodes cannot be reliably visualised, and it is not possible to distinguish between enlarged lymph nodes that have reactive changes only and metastatic nodes. Similarly, micrometastases within normal-sized nodes cannot be detected.

Magnetic resonance imaging scanning

Magnetic resonance imaging (MRI) does not expose the patient to ionising radiation and needs no intravascular contrast medium, although intraoesophageal air or contrast media may help to assess wall thickness. Distant metastases to organs such as the

Figure 59.47 Adenocarcinoma of the cardia. Transcoelomic spread may occur with this type of lesion.

Figure 59.48 Computerised tomography scan demonstrating liver metastases.

liver are usually reliably identified by MRI but, at the moment, there do not seem to be additional benefits over CT.

Endoscopic ultrasound

After haematogenous spread, the two principal prognostic factors for oesophageal cancer are the depth of tumour penetration through the oesophageal wall and regional lymph node spread. Although CT will detect distant metastasis, its limited axial resolution precludes a reliable assessment of both the depth of wall penetration and lymph node involvement. EUS can determine the depth of spread of a malignant tumour through the oesophageal wall (T1–3), the invasion of adjacent organs (T4) and metastasis to lymph nodes (N0 or N1) (Figs 59.49–59.51). It can also detect contiguous spread downward into the cardia and more distant metastases to the left lobe of the liver.

EUS visualises the oesophageal wall as a multilayered structure. The layers represent ultrasound interfaces rather than true anatomical layers, but there is close enough correlation to allow

Figure 59.49 Endosonography demonstrating an 'early' tumour. Note the preservation of the outer dark wall layer that represents the muscle coat.

Figure 59.50 Endosonography demonstrating an 'advanced' local tumour. Note the breach of the outer white line that represents the interface between the oesophageal wall and the mediastinum.

Figure 59.51 Endosonography demonstrating malignant nodes. These are usually large, hypoechoic and round compared with normal nodes.

accurate assessment of the depth of invasion through the oesophageal wall. Structures smaller than 5 mm can be clearly seen enabling very small nodes to be imaged. The EUS image morphology of such structures provides an additional means of distinguishing malignant from reactive or benign lymph nodes. For submucosal lesions, EUS can demonstrate the wall layer of origin of a lesion, suggesting the likely histological type.

Narrow EUS instruments are available for insertion over a guidewire to minimise the risk of technical failure, and linear array echoendoscopes can be used to biopsy lesions that might signify incurability outside the wall of the gastrointestinal tract (e.g. coeliac lymph nodes).

Positron emission tomography/computerised tomography scanning

Positron emission tomography (PET) in the context of cancer staging relies on the generally high metabolic activity (particularly in the glycolytic pathway) of tumours compared with normal tissues. The patient is given a small dose of the radiopharmaceutical

agent ^{18}F -fluorodeoxyglucose (FDG). This enters cells and is phosphorylated. FDG-6-phosphate cannot be metabolised further and, because it is a highly polar molecule, it cannot easily diffuse back out of the cell. After intravenous injection of FDG, it continuously accumulates in metabolically active cells. Primary oesophageal cancers are usually sufficiently active to be easily visible, and spatial resolution of positive PET areas occurs down to about 5–8 mm. When used in isolation, there are problems with the anatomical location of these areas. This has been significantly improved by combining PET with CT (Fig. 59.52). Although there are wide variations between centres, a change in stage is frequently reported in around 15% of patients. It has also been suggested that a reduction in PET activity following chemotherapy might be a way of predicting ‘responders’ to this approach.

Treatment of malignant tumours

Principles

At the time of diagnosis, around two-thirds of all patients with oesophageal cancer will already have incurable disease. The aim of palliative treatment is to overcome debilitating or distressing symptoms while maintaining the best quality of life possible for the patient. Some patients do not require specific therapeutic interventions, but do need supportive care and appropriate liaison with community nursing and hospice care services.

As dysphagia is the predominant symptom in advanced oesophageal cancer, the principal aim of palliation is to restore adequate swallowing. A variety of methods are available and, given the short life expectancy of most patients, it is important that the choice of treatment should be tailored to each individual. Tumour location and endoscopic appearance are important in this regard, as is the general condition of the patient.

Once oesophageal neoplasms reach the submucosal layer of the oesophagus, the tumour has access to the lymphatic system, meaning that, even at this early local stage, there is an incidence of nodal positivity for both squamous cell carcinoma and adenocarcinomas of between 10% and 50%. The principle of oesophagectomy is to deal adequately with the local tumour in order to minimise the risk of local recurrence and achieve an adequate lymphadenectomy to reduce the risk of staging error. Although studies in Japan would indicate that more extensive lymphadenectomy is associated with better survival, this may simply reflect more accurate staging. A number of studies support the view that the proximal extent of resection should ideally be 10 cm above the macroscopic tumour and 5 cm distal. When such a margin cannot be achieved proximally, particularly with

squamous cell carcinoma, there is evidence that postoperative radiotherapy can minimise local recurrence, although not improve survival.

Adenocarcinoma commonly involves the gastric cardia and may therefore extend into the fundus or down the lesser curve. Some degree of gastric excision is essential in order to achieve adequate local clearance and accomplish an appropriate lymphadenectomy. Excision of contiguous structures, such as crura, diaphragm and mediastinal pleura, needs to be considered as a method of creating negative resection margins.

The rarity of intramucosal cancer in symptomatic patients means that there are no randomised studies to compare different approaches to this type of very early disease. Even in Barrett’s oesophagus, where high-grade dysplasia and early cancer coexist, most centres favour oesophagectomy in fit patients. Photodynamic therapy (PDT) is an alternative approach that has largely been used in patients who were either unfit or unwilling to undergo surgery. This endoscopic technique relies on the administration of a photosensitiser that is taken up preferentially by dysplastic and malignant cells followed by exposure of an appropriate segment of the oesophagus to laser light. The main drawback is skin photosensitisation, so patients must avoid sunlight exposure in the short term. PDT is also associated with a risk of stricture formation although, as the technique and photosensitising agents improve, these problems are reducing.

Surgery alone is best suited to patients with disease confined to the oesophagus (T1, T2) without nodal metastasis (N0). As a result of careful preoperative investigation, most of these patients are now identifiable and can be offered surgery alone, with a prospect of cure in between 50% and 80%. Patients with more advanced stages of disease require either multimodal approaches or entry into appropriate trials.

It is essential that oesophagectomy should be performed with a low hospital mortality and complication rate. Case selection, volume and experience of the surgical team are all important. Preoperative risk analysis has shown that this can play a major part in reducing hospital mortality. There are really no circumstances in the western world in which surgery should be undertaken if it is not part of an overall treatment plan aimed at cure (Summary box 59.12).

Summary box 59.12

Treatment of carcinoma of the oesophagus

- Radical oesophagectomy is the most important aspect of curative treatment
- Neoadjuvant treatments before surgery may improve survival in a proportion of patients
- Chemoradiotherapy alone may cure selected patients, particularly those with squamous cell cancers
- Useful palliation may be achieved by chemo/radiotherapy or endoscopic treatments

Treatments with curative intent

Surgery

Histological tumour type, location and the extent of the proposed lymphadenectomy all influence the operative approach. This is largely an issue of surgical preference, although it should be recognised that a left thoracoabdominal approach is limited proximally by the aortic arch and should be avoided when the primary

Figure 59.52 Positron emission tomography/computerised tomography demonstrating a primary tumour and a distant metastatic node.

tumour is at or above this level. Similarly, transhiatal oesophagectomy is unsuitable for most patients with squamous cell carcinoma because a complete mediastinal lymphadenectomy is not easily achieved by this approach. The most widely practised approach in the west is the two-phase Ivor Lewis (sometimes called Lewis–Tanner) operation (Fig. 59.53), with an initial laparotomy and construction of a gastric tube, followed by a right thoracotomy to excise the tumour and create an oesophago-gastric anastomosis. The closer this is placed to the apex of the thoracic cavity, the fewer problems there are with reflux disease. Three-phase oesophagectomy (McKeown) may be more appropriate for more proximal tumours in order to achieve better longitudinal clearance, although the additional distance gained is less than many surgeons believe. A third cervical incision also permits lymphadenectomy in this region.

The extent of lymphadenectomy is highly controversial. For squamous cell carcinoma, because a higher proportion of patients will have middle- and upper-third tumours in the thoracic oesophagus, the rationale behind a three-phase operation with three-field lymphadenectomy is more understandable, even though this approach has not been widely adopted in the west. For adenocarcinoma, the incidence of metastases in the neck is relatively low in the context of patients who would otherwise be curable. For this reason, two-phase operations with two-field lymphadenectomy seem the most logical operations. While two-field lymphadenectomy does not substantially increase operative morbidity or mortality, the same cannot be said for more extended operations.

The introduction of minimal access techniques has been

Figure 59.53 The two usual approaches for surgery of the oesophagus are the thoracoabdominal (a), which opens the abdominal and thoracic cavities together, and the two-stage Ivor Lewis approach (b), in which the abdomen is opened first, closed and then the thoracotomy is performed. In the McKeown operation, a third incision in the neck is made to complete the cervical anastomosis.

Ivor Lewis, 1895–1982, Surgeon, The North Middlesex Hospital, London, England, and later at Rhyl, North Wales.

Norman Cecil Tanner, 1906–1982, Surgeon, Charing Cross Hospital, London, England.

Kenneth Charles McKeown, 1912–1995, Surgeon, Darlington Memorial Hospital, Darlington, County Durham, England.

pioneered in Australia by Gotley and Smithers and in North America by Luketich. In experienced hands, the open operation can be reproduced without significant compromise. As yet, benefits seem to be confined to reduced wound pain and the absence of specific complications associated with long incisions.

While many centres have reduced hospital mortality to single figures following oesophagectomy, the complication rate remains high. At least one-third of all patients will develop some significant complication after surgery. The most common of these is respiratory, followed by anastomotic leakage, chylothorax and injury to the recurrent laryngeal nerves. The most common late problem is benign anastomotic stricture, which seems to be higher with cervical rather than with intrathoracic anastomoses, although the problem is usually easily dealt with by endoscopic dilatation.

Lesions of the cardia that do not involve the oesophagus to any significant extent may be dealt with by extended total gastrectomy to include the distal oesophagus, or by proximal gastrectomy and distal oesophagectomy (Summary box 59.13).

Summary box 59.13

Oesophago-gastric surgery

- Beware of satellite nodules proximal to the primary lesion
- Carefully preserve the blood supply of the stomach, both venous and arterial
- Right thoracic approach gives easy access to the oesophagus

Two-phase oesophagectomy (abdomen and right chest, Ivor Lewis)

Mobilisation of the stomach must be done with care as it is essential to have a tension-free, well-vascularised stomach for transposition. The left gastric, short gastric and left gastroepiploic arteries are all divided. The viability of the transposed stomach mainly depends on the right gastroepiploic and, to a lesser extent, the right gastric vessels. It should be noted that venous drainage is as important as arterial supply, and it is essential to perform an accurate anatomical dissection that preserves the right gastroepiploic vein as well as the artery. The stomach is divided to remove the cardia and the upper part of the lesser curve, including the whole of the left gastric artery and its associated lymph nodes.

The approach to the oesophagus through the right chest is straightforward. A thoracotomy with entry above the fifth rib gives excellent access to the mediastinum and the thoracic inlet. The azygos vein is divided, and the whole of the intrathoracic oesophagus can be mobilised along with the thoracic duct (which is ligated by most surgeons) and the mediastinal lymph nodes. The oesophagus is divided just below the thoracic inlet. As most lesions are in the lower or middle thirds, this usually gives adequate proximal clearance of at least 5 cm. Carcinomas of the upper thoracic oesophagus are almost always incurable at the time of diagnosis, and invasion of the trachea is common. If one of these lesions is resectable, it is essential to use an incision in the neck (McKeown or three-phase operation) and to resect more of the oesophagus than is customary in the operation of subtotal oesophagectomy.

Oesophago-gastric anastomosis may be performed equally well by hand or by stapler. Both methods require attention to detail. In experienced hands, clinical anastomotic leakage should be less than 5%. Most surgeons still prefer to keep the patient

nil-by-mouth for 5–7 days. Most centres have abandoned the use of routine contrast swallows in patients who are clinically well. Conversely, aggressive investigation of a suspected leak is mandatory for any unexplained fever or clinical event. This may involve contrast radiology, CT scan or endoscopy to resolve the situation adequately.

Postoperative nutritional support remains controversial. There is general agreement that parenteral feeding is associated with more nosocomial infection, including pneumonia, than enteral feeding. It is also expensive. If nutritional support is given, a feeding jejunostomy is probably the best method.

Transhiatal oesophagectomy (without thoracotomy)

This approach was popularised for cancer by Orringer, adapting a technique developed in Brazil by Pinotti for the removal of Chagasic megaesophagus (see the section on Achalasia, p. 1036). The stomach is mobilised through a midline abdominal incision, and the cervical oesophagus is mobilised through an incision in the neck. The diaphragm is then opened from the abdomen, and the posterior mediastinum is entered. The lower oesophagus and the tumour are mobilised under direct vision, and the upper oesophagus is mobilised by blunt dissection. This approach can provide an adequate removal of the tumour and lymph nodes in the lower mediastinum, but it is not possible to remove the nodes in the middle or upper mediastinum. It may be a useful procedure for lesions of the lower oesophagus, but is hazardous for a middle third lesion that may be adherent to the bronchus or to the azygos vein.

Neoadjuvant treatments with surgery

Apart from the earliest stages of disease, surgery alone produces relatively few cures in either squamous cell carcinoma or adenocarcinoma patients. This led to a number of trials throughout the 1980s and 1990s to investigate the value of chemotherapy and surgery or chemoradiotherapy and surgery compared with surgery alone. Some studies relate only to squamous cell cancer, and many are open to criticism on the grounds of trial design or patient numbers. Nevertheless, positive results in favour of neoadjuvant therapy for adenocarcinoma in two studies as well as a limited meta-analysis indicate that it is no longer appropriate to consider surgery alone as the 'gold standard' treatment for most patients who are surgical candidates with adenocarcinoma. The exact role of surgery in a multimodal approach to squamous cell carcinoma is an unresolved issue.

Gastro-oesophageal reflux following oesophagogastric resection

Gastro-oesophageal reflux may be a major problem following any operation that involves resecting the cardia. Reflux may present with the typical symptoms of GORD or with a peptic stricture at the site of the anastomosis. However, the presentation may be different with a miserable patient who fails to thrive following the operation and who is then suspected of having recurrent cancer. This atypical presentation is particularly common following total gastrectomy with an inadequate reconstruction that allows bile reflux (Summary box 59.14).

Carlos Justiniano Ribeiro Chagas, 1879–1934, Director the Oswaldo Cruz Institute, and Professor of Tropical Medicine, The University of Rio de Janeiro, Brazil.

Summary box 59.14

Post oesophagectomy

- Reflux may be a problem following resection
- Symptoms may be atypical
- Reflux may be limited or avoided by subtotal oesophagectomy and gastric transposition high in the chest

Non-surgical treatments

Radiotherapy alone was widely used as a single-modality treatment for squamous cell carcinoma of the oesophagus until the late 1970s. The 5-year survival overall was 6%. As a result, multimodal approaches were adopted throughout the 1980s, initial trials indicating that similar long-term survival rates could be obtained with surgery. Subsequent randomised studies essentially confined to patients with squamous cell carcinoma have indicated significant survival advantages with chemoradiotherapy over radiotherapy alone. While it is clear that chemoradiotherapy does offer a prospect of cure for patients who may not be fit for surgery, particularly in squamous cell carcinoma, the high rate of locoregional failure has meant that surgery remains the mainstay of attempted curative treatments for both adenocarcinoma and squamous cell carcinoma in patients who have potentially resectable disease and are fit for oesophagectomy. In most western series, this represents about one-third of patients with adenocarcinoma and a slightly lower percentage of patients with squamous cell carcinoma. There has been no formal comparison of the results of radiotherapy and surgical resection, and it is therefore impossible to make dogmatic statements about the relative merits of each form of treatment (Summary box 59.15).

Summary box 59.15

Alternative therapeutic approaches

- Chemoradiotherapy may be a useful alternative to surgery, especially in unfit patients

Palliative treatment

Surgical resection and external beam radiotherapy may be used for palliation, but are not suitable when the expected survival is short, as most of the remainder of life will be spent recovering from the 'treatment'. Surgical bypass is likewise too major a procedure for use in a patient with limited life expectancy. A variety of relatively simple methods of palliation are now available that will produce worthwhile relief of dysphagia with minimal disturbance to the patient (Summary box 59.16).

Summary box 59.16

Palliation should be simple and effective

Intubation has been used for many years following the invention of the Souttar tube, which was made of coiled silver wire. A variety

Sir Henry Sessions Souttar, 1875–1964, Surgeon, The London Hospital, London, England.

of rigid plastic or rubber tubes were developed for placement under endoscopic and/or radiological control. The technology of intubation has now moved on with the development of various types of expanding metal stent (Fig. 59.54). These are also inserted under radiographic or endoscopic control. The stent is collapsed during insertion and released when it is in the correct position. Expanding stents produce a wider lumen for swallowing than rigid tubes. More importantly, it is not necessary to dilate the oesophagus to beyond 8 mm to insert the unexpanded stent through the tumour, so there is a lower risk of injury to the oesophagus.

Endoscopic laser treatment may be used to core a channel through the tumour. It is based on thermal tumour destruction. It produces a worthwhile improvement in swallowing, but has the disadvantage that it has to be repeated every few weeks. Lasers may also be used to unblock a stent that has become occluded by tumour overgrowth. *Other endoscopic methods* include bipolar diathermy, argon-beam plasma coagulation and alcohol injection.

Brachytherapy is a method of delivering intraluminal radiation with a short penetration distance (hence the term brachy) to a tumour. An introduction system is inserted through the tumour, and the treatment is then delivered in a single session lasting approximately 20 min. The equipment is expensive to purchase, but running costs are low.

While the above methods are suitable for patients with very advanced disease, the elderly and those with significant comorbidities that would make more aggressive strategies inappropriate, an increasing proportion of patients (particularly with adenocarcinoma) are being treated by platinum-based chemotherapy. In general, this leads to only a modest prolongation of survival but a better quality of life than in those receiving an endoscopic treatment alone.

Malignant tracheo-oesophageal fistula

Malignant tracheo-oesophageal fistula is a sign of incurable disease. Some have advocated surgical bypass and oesophageal exclusion, but this is a major procedure. An expanding metal stent is probably the best treatment.

Post-cricoid carcinoma

Post-cricoid carcinoma is considered in Chapter 45 in neoplasms of the pharynx.

MOTILITY DISORDERS AND DIVERTICULA

Oesophageal motility disorders

A motility disorder can be readily understood when a patient has dysphagia in the absence of a stricture, and a barium-impregnated

Figure 59.54 Expanding metal stents, covered and uncovered.

food bolus is seen to stick in the oesophagus. If this can be correlated with a specific abnormality on oesophageal manometry, accepting that this is the cause of the patient's symptoms may be straightforward. Unfortunately, this is often not the case. Pain, with or without a swallowing problem, is frequently the dominant symptom, and patients often undergo extensive hospital investigation before the oesophagus is considered as a source of symptoms. Symptoms are often intermittent, and the correlation between symptoms and test 'abnormalities' is poor. Much harm may be done by inappropriate enthusiastic surgery for ill-defined conditions. It should also be remembered that oesophageal dysmotility may be only a feature of a general disturbance in gastrointestinal function (Summary box 59.17).

Summary box 59.17

Oesophageal motility disorders

- May be part of a more diffuse gastrointestinal motility problem
- May be associated with GORD

It is convenient to classify oesophageal motility disorders as in Table 59.3.

Functional pain and the oesophagus

Pain that is assumed to arise from dysfunction of the gastrointestinal tract may reflect abnormal motor activity, abnormal perception or a combination of the two. There is evidence that all three exist. Very high-pressure uncoordinated contractions ('spasm') have been shown to correlate with pain. Distension of a balloon in the oesophagus indicates that some patients have a low threshold for the sensation of pain (visceral hypersensitivity), and this itself may reflect local or central neuronal dysfunction. In practice, the difficulty is in understanding the relative

Table 59.3 Classification of oesophageal motility disorders

Disorders of the pharyngo-oesophageal junction

Neurological – stroke, motor neurone disease, multiple sclerosis, Parkinson's disease

 Non-specific oesophageal dysmotility

Disorders of the lower oesophageal sphincter

Achalasia
 Incompetent lower sphincter (i.e. GORD)

CREST, calcinosis, Raynaud's syndrome, (o)esophageal motility disorders, sclerodactyly and telangiectasia.
 GORD, gastro-oesophageal reflux disease.

contributions of these elements, so that a logical treatment might follow.

Achalasia

Pathology and aetiology

Achalasia (Greek 'failure to relax') is uncommon, but merits prominence because it is reasonably understood and responds to treatment. It is due to loss of the ganglion cells in the myenteric (Auerbach's) plexus, the cause of which is unknown. In South America, chronic infection with the parasite *Trypanosoma cruzi* causes Chagas' disease, which has marked clinical similarities to achalasia. Achalasia differs from Hirschsprung's disease of the colon because the dilated oesophagus usually contains few ganglion cells, whereas the dilated colon contains normal ganglion cells proximal to a constricted, aganglionic segment. Histology of muscle specimens generally shows a reduction in the number of ganglion cells (and mainly inhibitory neurones) with a variable degree of chronic inflammation. In so called 'vigorous achalasia', which may be an early stage of the disease, there is inflammation and neural fibrosis, but normal numbers of ganglion cells (Summary box 59.18).

Summary box 59.18

Achalasia

- Is uncommon
- Is due to selective loss of inhibitory neurones in the lower oesophagus
- The causes dysphagia and carcinoma must be excluded
- Treatment is by either endoscopic dilatation or surgical myotomy

The physiological abnormalities are a non-relaxing LOS and absent peristalsis in the body of the oesophagus. In its earliest stages, the oesophagus is of normal calibre and still exhibits contractile (although non-peristaltic) activity. In some patients, these uncoordinated contractions result in pain as much as a sense of food sticking. With time, the oesophagus dilates and contractions disappear, so that the oesophagus empties mainly by the hydrostatic pressure of its contents. This is nearly always incomplete, leaving residual food and fluid. The gas bubble in the stomach is frequently absent, as no bolus with its accompanying normal gas passes through the sphincter. The 'megaesophagus' becomes tortuous with a persistent retention oesophagitis due to fermentation of food residues (Fig. 59.55), and this may account for the increased incidence of carcinoma of the oesophagus (Summary box 59.19).

Summary box 59.19

Lower oesophageal stricture

- Beware pseudoachalasia; look for tumour

Pseudoachalasia is an achalasia-like disorder that is usually produced by adenocarcinoma of the cardia (Fig. 59.56), but has also

Harald Hirschsprung, 1831–1916, Physician, The Queen Louise Hospital for Children, and Professor of Paediatrics, Copenhagen, Denmark, described congenital megacolon in 1888.

been described in relation to benign tumours at this level. It has been presumed that the inability of the sphincter to relax is linked to the loss of body peristalsis, but other cancers outside the oesophagus (bronchus, pancreas) have also been associated with pseudoachalasia.

Clinical features

The disease is most common in middle life, but can occur at any age. It typically presents with dysphagia, although pain (often mistaken for reflux) is common in the early stages. Patients often present late and, having had relatively mild symptoms, remain untreated for many years. Regurgitation is frequent, and there may be overflow into the trachea, especially at night.

Diagnosis

Achalasia may be suspected at endoscopy by finding a tight cardia and food residue in the oesophagus. Barium radiology may show hold-up in the distal oesophagus, abnormal contractions in the oesophageal body and a tapering stricture in the distal oesophagus, often described as a 'bird's beak' (see Fig. 59.55). The gastric gas bubble is usually absent. These typical features of well-developed achalasia are often absent, and endoscopy and radiology can be normal. A firm diagnosis is established by oesophageal manometry. Classically, the LOS does not relax completely on swallowing, there is no peristalsis and there is a raised resting pressure in the oesophagus (Fig. 59.57). The LOS pressure may be elevated, but is often normal.

Treatment

Alone among motility disorders, achalasia responds well to treatment. The two main methods are forceful dilatation of the cardia and Heller's myotomy.

Pneumatic dilatation

This involves stretching the cardia with a balloon to disrupt the muscle and render it less competent. The treatment was first described by Plummer. Many varieties of balloon have been used but, nowadays, plastic balloons with a precisely controlled external diameter are used. If the pressure in the balloon is too high, the balloon is designed to split along its length rather than expanding further. Balloons of 30–40 mm in diameter are available and are inserted over a guidewire (Fig. 59.58). Perforation is the major complication. With a 30-mm balloon, the incidence of perforation should be less than 0.5%. The risk of perforation increases with bigger balloons, and they should be used cautiously for progressive dilatation over a period of weeks. Forceful dilatation is curative in 75–85% of cases. The results are best in patients aged more than 45 years (Summary box 59.20).

Summary box 59.20

Achalasia

- Beware perforation due to dilatation of achalasia
- Beware postoperative reflux

Ernst Heller, 1877–1964, Surgeon, St. George's Krankenhaus, Leipzig, Germany.
Henry Stanley Plummer, 1874–1937, Physician, The Mayo Clinic, Rochester, MN, USA.

Figure 59.55 Achalasia of the oesophagus. (a) Barium swallow showing the smooth outline of the stricture, which narrows to a point at its lower end. (b) Tortuosity and sigmoid appearance of the lower oesophagus. (c) Mediastinal shadow due to a large, fluid-filled oesophagus.

Heller's myotomy

This involves cutting the muscle of the lower oesophagus and cardia (Fig. 59.59). The major complication is gastro-oesophageal reflux, and most surgeons therefore add a partial anterior fundoplication (Heller–Dor's operation). The procedure is ideally

suited to a minimal access laparoscopic approach, and most surgeons use intraoperative endoscopy to judge the extent of the myotomy and to ensure that the narrow segment is abolished.

It is successful in more than 90% of cases and may be used after failed dilatation.

Figure 59.56 Almost achalasia, but note the irregularity of the taper, which indicates carcinoma of the cardia.

Figure 59.57 Manometry in achalasia, showing simultaneous contractions in the body of the oesophagus and incomplete relaxation of the lower oesophageal sphincter (LOS) in response to swallowing.

Figure 59.58 Balloon dilator for the treatment of achalasia by forceful dilatation.

Figure 59.59 Heller's myotomy. The incision should not go too far on to the stomach. The lateral extent must enable the mucosa to pout out, to prevent the edges healing together.

Botulinum toxin

This is done by endoscopic injection into the LOS. It acts by interfering with cholinergic excitatory neural activity at the LOS. The effect is not permanent, and the injection usually has to be repeated after a few months. For this reason, its use is restricted to elderly patients with other comorbidities.

Drugs

Drugs such as calcium channel antagonists have been used but are ineffective for long-term use. However, sublingual nifedipine may be useful for transient relief of symptoms if definitive treatment is postponed.

Other oesophageal motility disorders

Disorders of the pharyngo-oesophageal junction

With the exception of Zenker's diverticulum (see below), most patients with oropharyngeal dysphagia have generalised neurological or muscular disorders with pharyngeal involvement. A small number of patients who have sustained a cerebrovascular accident benefit from myotomy of the cricopharyngeus to alleviate pooling of saliva and nocturnal aspiration, but they should

Friedrich Albert Zenker, 1825–1898, Professor of Pathology, Dresden, Germany.

have good deglutition and phonation before this is performed. The operation is also effective in patients with oculopharyngeal muscular dystrophy.

Disorders of the body of the oesophagus

Diffuse oesophageal spasm and nutcracker oesophagus

Diffuse oesophageal spasm is a condition in which there are incoordinate contractions of the oesophagus, causing dysphagia and/or chest pain. The condition may be dramatic, with spastic pressures on manometry of 400–500 mmHg, marked hypertrophy of the circular muscle and a corkscrew oesophagus on barium swallow (Fig. 59.60). These abnormal contractions are more common in the distal two-thirds of the oesophageal body, and this may have some relevance to treatment. Making the diagnosis when chest pain is the only symptom may be difficult. Prolonged ambulatory oesophageal manometry that correlates episodes of chest pain with manometric abnormalities may establish the diagnosis.

There is no proven pharmacological or endoscopic treatment. Calcium channel antagonists, vasodilators and endoscopic dilatation have only transient effects. While the severity and frequency of symptoms may be tolerated by most patients, sometimes the combination of chest pain and dysphagia is sufficiently severe that malnutrition begins. In these patients, extended oesophageal myotomy up to the aortic arch may be required. Surgical treatment of diffuse spasm is more successful in improving dysphagia than chest pain, and caution should be exercised in patients in whom chest pain is the only symptom.

Nutcracker oesophagus is a condition in which peristaltic pressures of more than 180 mmHg develop. It is said to cause chest pain, but there is still some debate as to whether it is a real disorder.

Oesophageal involvement in autoimmune disease

Oesophageal involvement is mainly seen in systemic sclerosis, but may be a feature of polymyositis, dermatomyositis, systemic lupus erythematosus, polyarteritis nodosa or rheumatoid disease. While most involve weak peristalsis, swallowing difficulties may be compounded by pharyngeal problems in the disorders that primarily affect skeletal muscle (e.g. polymyositis) or extraoesophageal

Figure 59.60 Corkscrew oesophagus in diffuse oesophageal spasm.

problems such as involvement of the cricoarytenoid joint in rheumatoid disease or dry mouth in Sjögren's syndrome. In systemic sclerosis, smooth muscle atrophy causes hypoperistalsis (Fig. 59.61). The LOS is involved, leading to a loss of the anti-reflux barrier. A wide range of symptoms can follow from mild to severe dysphagia accompanied by regurgitation and aspiration. Reflux can be severe and is exacerbated by weak acid clearance so that strictures can occur. There are no drugs that specifically correct the motor disorder, and medical treatment is mainly directed at minimising reflux-induced damage with PPIs. A small number of patients may require anti-reflux surgery.

Eosinophilic oesophagitis is a disorder that occurs in children and adults either alone or as a manifestation of eosinophilic gastroenteritis. It is characterised by eosinophilic infiltration of the oesophageal wall, presumably of allergic or idiopathic origin. The commonest presenting symptom is dysphagia, and more than half have some history of atopy. The oesophagus often seems narrow and friable on endoscopy and may include mucosal rings. The most important feature is the development of deep ulcers leading to stricture development, especially in the proximal oesophagus. The diagnosis is established by endoscopic biopsy.

Elimination diets, topical and systemic steroids all seem to be helpful in the short term, but there is scant information on the long-term impact of any particular approach. Immunotherapy directed against interleukin (IL)-5, which has a major role in eosinophil recruitment, seems to be a promising innovative approach. Although endoscopic dilatation has been recommended, this can create deep ulcers and further scarring, so should be used with caution and only when the above therapies fail.

Pharyngeal and oesophageal diverticula

Most oesophageal diverticula are *pulsion* diverticula that develop at a site of weakness as a result of chronic pressure against an

Figure 59.61 Advanced scleroderma of the oesophagus. The oesophagus dilates, and the lower oesophageal sphincter is widely incompetent.

Henrik Samuel Conrad Sjogren, 1899–1986, Professor of Ophthalmology, Gothenburg, Sweden.

obstruction. Symptoms are mostly caused by the underlying disorder unless the diverticulum is particularly large. *Traction* diverticula (Fig. 59.62) are much less common. They are mostly a consequence of chronic granulomatous disease affecting the tracheobronchial lymph nodes due to tuberculosis, atypical mycobacteria or histoplasmosis. Fibrotic healing of the lymph nodes exerts traction on the oesophageal wall and produces a focal outpouching that is usually small and has a conical shape. There may be associated broncholithiasis, and additional complications may occur, such as aerodigestive fistulation (Fig. 59.63) and bleeding.

Zenker's diverticulum (*pharyngeal pouch*) is not really an oesophageal diverticulum as it protrudes posteriorly above the cricopharyngeal sphincter through the natural weak point (the dehiscence of Killian) between the oblique and horizontal (cricopharyngeus) fibres of the inferior pharyngeal constrictor (Figs 59.64 and 59.65). The exact mechanism that leads to its formation is unknown, but it involves loss of the coordination between pharyngeal contraction and opening of the upper sphincter. When the diverticulum is small, symptoms largely reflect this incoordination with predominantly pharyngeal dysphagia. As the pouch enlarges, it tends to fill with food on eating, and the fundus descends into the mediastinum. This leads to halitosis and oesophageal dysphagia. Treatment can be undertaken endoscopically with a linear cutting stapler to divide the

Figure 59.62 Mid-oesophageal traction diverticulum with the mouth facing downwards.

Gustav Killian, 1860–1921, Professor of Laryngology at Freiburg, and later at Berlin, Germany.

Figure 59.63 Mid-oesophageal diverticulum with a tracheo-oesophageal fistula.

septum between the diverticulum and the upper oesophagus, producing a diverticulo-oesophagostomy, or can be done by open surgery involving pouch excision, pouch suspension (diverticulopexy) and/or myotomy of the cricopharyngeus. All techniques have good results.

Mid-oesophageal diverticula are usually small pulsion diverticula of no particular consequence. The underlying motility disorder does not usually require treatment. Some pulsion diverticula may fistulate into the trachea (Fig. 59.63), but this is more common with traction diverticula in granulomatous disease.

Epiphrenic diverticula are pulsion diverticula situated in the lower oesophagus above the diaphragm (Fig. 59.66). They may be quite large, but cause surprisingly few symptoms. They again probably reflect some loss of coordination between an incoming pressure wave and appropriate relaxation of the LOS. This needs to be acknowledged in the surgical management of the patient. The diverticulum, in isolation, should not be assumed to account for a patient's illness just because it looks dramatic on a radiograph. Large diverticula may be excised, and this should be combined with a myotomy from the site of the diverticulum down to the cardia to relieve functional obstruction (Summary box 59.21).

Summary box 59.21

Oesophageal diverticula

- Diverticula are indicators of a motor disorder and not necessarily the cause of symptoms

Figure 59.64 The typical appearances of: (a) a small pharyngeal pouch with a prominent cricopharyngeal impression and 'streaming' of barium, indicating partial obstruction; and (b) a large pouch extending behind the oesophagus towards the thoracic inlet.

Figure 59.65 The endoscopic appearance of the mouth of a pharyngeal pouch posterior to the normal opening (left) of the oesophagus.

Diffuse intramural pseudodiverticulosis is a rare condition in which there are multiple tiny outpouchings from the lumen of the oesophagus. The pseudodiverticula are dilated excretory ducts of oesophageal sebaceous glands. It is questionable whether the condition produces any symptoms in its own right.

OTHER NON-NEOPLASTIC CONDITIONS

Schatzki's ring

Schatzki's ring is a circular ring in the distal oesophagus (Fig. 59.67), usually at the squamocolumnar junction. The cause is obscure, but there is a strong association with reflux disease. The core of the ring consists of variable amounts of fibrous tissue and cellular infiltrate. Most rings are incidental findings. Some are associated with dysphagia and respond to dilatation in conjunction with medical anti-reflux therapy.

Oesophageal infections

Bacterial infection of the oesophagus is rare, but fungal and viral infections do occur. They are particularly important in immunocompromised patients

Oesophagitis due to *Candida albicans* is relatively common in patients taking steroids (especially transplant patients) or those undergoing cancer chemotherapy. It may present with dysphagia or odynophagia. There may be visible thrush in the throat. Endoscopy shows numerous white plaques that cannot be moved, unlike food residues (Fig. 59.68). Biopsies are diagnostic. In severe cases, a barium swallow may show dramatic mucosal ulceration and irregularity that is surprisingly similar to the appearance of oesophageal varices (Figs 59.69 and 59.70). Treatment is with a topical antifungal agent.

Dysphagia and odynophagia can also be caused by herpes simplex virus and cytomegalovirus (CMV). With the former, there may be a history of a herpetic lesion on the lip some days earlier, and endoscopy may reveal vesicles or small ulcers with raised margins, usually in the upper half of the oesophagus. CMV

Richard Schatzki, 1901–1992, American Radiologist.

Figure 59.66 Epiphrenic diverticulum proximal to the gastro-oesophageal sphincter. (a) Small and asymptomatic; (b) large, symptomatic and appearing as a gas-filled bubble on the chest radiograph.

Figure 59.67 Schatzki's ring, a thin submucosal web completely encircling the whole of the lumen, usually situated at the squamocolunar junction.

infection may be apparent in graft-versus-host disease following bone marrow transplantation. It has a characteristic endoscopic appearance with a geographical, serpiginous border. In both cases, endoscopic biopsy is diagnostic.

Chagas' disease

This condition is confined to South American countries, but is of interest because oesophageal symptoms occur that are similar to severe achalasia. It is caused by a protozoan, *Trypanosoma cruzi*, transmitted by an insect vector. Parasites reach the bloodstream and, after a long latent period, there is damage particularly to cardiac and smooth muscle. Destruction of both Auerbach's and Meissner's plexuses leads to acquired megaesophagus.

Crohn's disease

The oesophagus is not commonly affected by symptomatic Crohn's disease. However, pathological studies indicate that it may be present in 20% of patients without symptoms. Symptoms are often severe, and a diagnosis of reflux oesophagitis is usually made on the basis of retrosternal pain and dysphagia. Endoscopy shows extensive oesophagitis that extends much further proximally than reflux oesophagitis. Biopsies may be diagnostic, but may show only non-specific inflammation. In severe cases, deep

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Figure 59.68 Endoscopic appearance of oesophageal candidiasis.

sinuses occur, and fistulation has been described. Crohn's oesophagitis is said to respond poorly to medical treatment and, although balloon dilatation of strictures and surgical resection for multiple internal fistulae have both been described, these interventions should be used with great caution.

Figure 59.69 Oesophageal candidiasis with shaggy appearance of mucosal defects.

Plummer–Vinson syndrome

This is also called the Paterson–Kelly syndrome or *sideropenic dysphagia*. The original descriptions are vague and poorly supported by evidence of a coherent syndrome. Dysphagia is said to occur because of the presence of a post-cricoid web that is associated with iron deficiency anaemia, glossitis and koilonychia. The classical syndrome is rarely complete. Some patients may have oropharyngeal leucoplakia, and this may account for an alleged increased risk of developing hypopharyngeal cancer.

Webs certainly occur in the upper and middle oesophagus, usually without any kind of associated syndrome. They are nearly always thin diaphanous membranes identified coincidentally by contrast radiology. Even symptomatic webs that cause a degree of obstruction may be inadvertently ruptured at endoscopy. Few require formal endoscopic dilatation.

Vascular abnormalities affecting the oesophagus

Several congenital vascular anomalies may produce dysphagia by compression of the oesophagus. Classically, this results from an

Figure 59.70 Oesophageal varices with smooth outline of the filling defects.

Porter Paisley Vinson, 1890–1959, Physician, The Mayo Clinic, Rochester, MN, who later practiced in Richmond, VA, USA.

Donald Rose Paterson, 1863–1939, Surgeon, The Ear, Nose and Throat Department, The Royal Infirmary, Cardiff, Wales.

Vinson, Kelly and Paterson all described this syndrome independently in 1919.

aberrant right subclavian artery (arteria lusoria). However, the oesophagus is more commonly compressed by vascular rings, such as a double aortic arch. Dysphagia occurs in only a minority of cases and usually presents early in childhood, although it can occur in the late teens. Treatment is usually by division of the non-dominant component of the ring.

In adults, acquired causes include aneurysm of the aorta, diffuse cardiac enlargement and pressure from the left common carotid or vertebral arteries. It is rare that symptom severity justifies surgical intervention.

Mediastinal fibrosis

This rare condition can occur alone or in conjunction with retroperitoneal fibrosis. The cause is unknown and, while the major consequences are usually cardiovascular as a result of caval compression, dysphagia can occur. The existence of irreparable

cardiovascular problems usually precludes surgical intervention on the oesophagus.

Stomach and duodenum

LEARNING OBJECTIVES

To recognise and understand:

- The anatomy and pathophysiology of the stomach in relation to disease
- The most appropriate investigations for gastroduodenal symptoms
- The importance of gastritis and *Helicobacter pylori*
- The investigations and treatment of peptic ulcer disease and its complications
- The presentation and treatment of gastric cancer
- The causes of duodenal obstruction and presentation of duodenal tumours

INTRODUCTION

The function of the stomach is to act as a reservoir for ingested food. It also serves to break down foodstuffs mechanically and commence the processes of digestion before these products are passed into the duodenum.

GROSS ANATOMY OF THE STOMACH AND DUODENUM

Blood supply

Arteries

The stomach has an arterial supply on both the lesser and greater curves (Fig. 60.1). On the lesser curve, the left gastric artery, a

branch of the coeliac axis, forms an anastomotic arcade with the right gastric artery, which arises from the common hepatic artery. Branches of the left gastric artery pass up towards the cardia. The gastroduodenal artery, which is also a branch of the hepatic artery, passes behind the first part of the duodenum, highly relevant to the bleeding duodenal ulcer. Here it divides into the superior pancreaticoduodenal artery and the right gastroepiploic artery. The superior pancreaticoduodenal artery supplies the duodenum and pancreatic head, and forms an anastomosis with the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery. The right gastroepiploic artery runs along the greater curvature of the stomach, eventually forming an anastomosis with the left gastroepiploic artery, a branch of the splenic artery. This vascular arcade, however, is often variably incomplete. The fundus of the stomach is supplied by the vasa brevia (or short gastric arteries), which arise near the termination of the splenic artery.

Veins

In general, the veins are equivalent to the arteries, with those along the lesser curve ending in the portal vein and those on the greater curve joining via the splenic vein. On the lesser curve the coronary vein is particularly important. It runs up the lesser curve towards the oesophagus and then passes left to right to join the portal vein; it becomes markedly dilated in portal hypertension.

Lymphatics

The lymphatics of the stomach are of considerable importance in the surgery of gastric cancer and are described in detail in that section.

Nerves

As with all of the gastrointestinal tract, the stomach and duodenum possess both intrinsic and extrinsic nerve supplies. The intrinsic nerves exist principally in two plexuses, the myenteric

Figure 60.1 The arterial blood supply of the stomach.

plexus of Auerbach and the submucosal plexus of Meissner. Compared with the rest of the gut, the submucosal plexus of the stomach contains relatively few ganglionic cells, as does the myenteric plexus in the fundus. However, in the antrum, the ganglia of the myenteric plexus are well developed. The extrinsic supply is derived mainly from the vagus nerves, fibres of which originate in the brainstem. The vagal plexus around the oesophagus condenses into bundles that pass through the oesophageal hiatus (Fig. 60.2), the posterior bundle usually being identifiable as a large nerve trunk. Vagal fibres are both afferent (sensory) and efferent. The efferent fibres are involved in the receptive relaxation of the stomach and the stimulation of gastric motility, as well as having a secretory function. The sympathetic supply is derived mainly from the coeliac ganglia.

MICROSCOPIC ANATOMY OF THE STOMACH AND DUODENUM

The gastric epithelial cells are mucus producing and are turned over rapidly. In the pyloric part of the stomach, and also the duodenum, mucus-secreting glands are found. Most of the specialised cells of the stomach (parietal and chief cells) are found in the gastric crypts (Fig. 60.3). The stomach also has numerous endocrine cells.

Parietal cells

These are in the body (acid-secreting portion) of the stomach and line the gastric crypts, being more abundant distally. They are responsible for the production of hydrogen ions used to form hydrochloric acid. The hydrogen ions are actively pumped by the proton pump, a hydrogen–potassium-ATPase (Sachs), which exchanges intraluminal potassium for hydrogen ions. The potassium ions enter the lumen of the crypts passively, but the hydrogen ions are pumped against an immense concentration gradient (1 000 000:1).

Chief cells

These lie principally proximally in the gastric crypts and produce pepsinogen. Both forms of pepsinogen, pepsinogen I and II, are produced by chief cells, but pepsinogen I is produced only in the stomach. The ratio between pepsinogens I and II in the serum decreases with gastric atrophy. Pepsinogen is activated in the stomach to produce pepsin, the active enzyme.

Endocrine cells

The stomach has numerous endocrine cells, which are critical to its function. In the gastric antrum the mucosa contains G cells, which produce gastrin. Throughout the body of the stomach, enterochromaffin-like (ECL) cells are abundant and produce histamine, a key factor in driving gastric acid secretion. There are also large numbers of somatostatin-producing D cells throughout the stomach, and somatostatin has a negative regulatory role. The peptides and neuropeptides produced in the stomach are discussed later.

Duodenum

The duodenum is lined by a mucus-secreting columnar epithelium. In addition, Brunner's glands lie beneath the mucosa and are similar to the pyloric glands in the pyloric part of the stomach. Endocrine cells in the duodenum produce cholecystokinin and secretin.

PHYSIOLOGY OF THE STOMACH AND DUODENUM

The stomach mechanically breaks up ingested food and, together with the actions of acid and pepsin, forms chyme that passes into the duodenum. In contrast to the acidic environment of the stomach, that of the duodenum is alkaline, because of the secretion of bicarbonate ions from both the pancreas and the duodenum. This neutralises the acid chyme and adjusts the osmolarity

Figure 60.2 The anatomy of the anterior and posterior vagus nerves in relation to the stomach.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany, (now Wrocław, Poland), described the myenteric plexus in 1862.

Georg Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany, described the submucosal plexus in 1852.

George Sachs, Professor of Medicine, CURE, Los Angeles, CA, USA.

Johann Conrad Brunner, 1653–1729, Professor of Anatomy, at Heidelberg, Germany and later at Strasbourg, France, described these glands in 1687.

to approximately that of plasma. Endocrine cells in the duodenum produce cholecystokinin, which stimulates the pancreas to produce trypsin and the gall bladder to contract. Secretin, produced by the endocrine cells of the duodenum, inhibits gastric acid secretion and promotes production of bicarbonate by the pancreas.

Gastric acid secretion

The secretion of gastric acid and pepsin tends to run in parallel, although the understanding of the mechanisms of gastric acid secretion is considerably greater than that of pepsin. Numerous factors are involved in gastric acid production. These include neurotransmitters, neuropeptides and peptide hormones, and several other factors. This complexity need not detract from the fact that there are basic principles which are easily understood (Fig. 60.4). Hydrogen ions are exported from parietal cells via the proton pump. Although numerous factors can act on parietal cells, the most important is histamine, which acts via the H_2 -receptor. Histamine is produced, in turn, by the ECL cells of the stomach and acts in a paracrine (local) fashion on parietal cells. These relationships explain why proton pump inhibitors can abolish gastric acid secretion, as they act on the final common pathway of gastric secretion, and why H_2 -receptor antagonists

have such profound effects on gastric acid secretion, even though this is not insurmountable (Fig. 60.4). The ECL cell produces histamine in response to a number of stimuli that include the vagus and gastrin. Gastrin is released by G cells in response to the presence of food in the stomach. The production of gastrin is inhibited by acid, hence creating a negative-feedback loop. Various other peptides, including secretin, inhibit gastric acid secretion.

Classically, three phases of gastric secretion are described. The *cephalic phase* is mediated by vagal activity, secondary to sensory arousal as first demonstrated by Pavlov. The *gastric phase* is a response to food within the stomach, which is mediated principally, but not exclusively, by gastrin. In the *intestinal phase*, the presence of chyme in the duodenum and small bowel inhibits gastric emptying and the acidification of the duodenum leads to the production of secretin, which also inhibits gastric acid secretion, along with numerous other peptides originating from the gut. The stomach also possesses somatostatin-containing D cells. Somatostatin is released in response to a number of factors including acidification. This peptide acts probably on the G cell, the ECL cell and the parietal cell itself to inhibit acid production.

Gastric mucus and the gastric mucosal barrier

The gastric mucus layer is essential to the integrity of the gastric mucosa. It is a viscid layer of mucopolysaccharides produced by the mucus-producing cells of the stomach and the pyloric glands. Gastric mucus is an important barrier that protects the gastric mucosa from mechanical damage and also from the effects of acid and pepsin. Its considerable buffering capacity is enhanced by the presence of bicarbonate ions within the mucus. Many factors can lead to the breakdown of this gastric mucous barrier. These include bile, non-steroidal anti-inflammatory drugs (NSAIDs), alcohol, trauma and shock. Tonometry studies have shown that, of all the gastrointestinal tract, the stomach is the most sensitive to ischaemia following a hypovolaemic insult and also the slowest

Figure 60.4 The parietal cell in relation to the mechanism of gastric acid secretion. ECL, enterochromaffin-like; G, gastrin receptor; H, histamine receptor; M, muscarinic receptor.

to recover. This may explain the high incidence of stress ulceration (Summary box 60.1).

Summary box 60.1

The anatomy and physiology of the stomach

- The stomach acts as a reservoir for food and commences the process of digestion
- Gastric acid is produced by a proton pump in the parietal cells, which in turn is controlled by histamine acting on the H₂-receptors
- Histamine is produced by the endocrine gastric ECL cells in response to a number of factors, particularly gastrin and the vagus
- Proton pump inhibitors abolish gastric acid production, whereas H₂-receptor antagonists only markedly reduce it
- The gastric mucous layer is essential to the integrity of the gastric mucosa

Peptides and neuropeptides in the stomach and duodenum

As with most of the gastrointestinal tract, the endocrine cells of the stomach produce peptide hormones and neurotransmitters. Previously, nerves and endocrine cells were considered distinct in terms of their products. However, it is increasingly realised that there is enormous overlap within these systems. Many peptides recognised as hormones may also be produced by neurones, hence the term neuropeptides. The term 'messenger' can be used to describe all such products. There are three conventional modes of action that overlap:

1. *Endocrine*. The messenger is secreted into the circulation where it affects tissues that may be remote from the site of origin (Bayliss and Starling).
2. *Paracrine*. Messengers are produced locally and have local effects on tissues. Neurones and endocrine cells both act in this way.
3. *Neurocrine* (classic neurotransmitter). Messengers are produced by the neurone via the synaptic knob and pass across the synaptic cleft to the target.

Many peptide hormones act on the intrinsic nerve plexus of the gut (see later) and influence motility. Similarly, neuropeptides may influence the structure and function of the mucosa. Some of these peptides, neuropeptides and neurotransmitters are shown in Table 60.1.

Gastroduodenal motor activity

The motility of the entire gastrointestinal tract is modulated to a large degree by its intrinsic nervous system. The migrating motor complex (MMC) is critical in this respect. In the small bowel in the fasted state, and after food has cleared, there is a period of quiescence lasting approximately 40 min (phase I). There follows a series of waves of electrical and motor activity, also lasting for about 40 min, propagated from the fundus of the stomach in a caudal direction at a rate of about three per minute (phase II). These pass as far as the pylorus but not beyond. Duodenal slow

waves are generated in the duodenum at a rate of about 10 per minute, which propagate down the small bowel. The amplitude of these contractions increases to a maximum in phase III, which lasts for about 10 min. This 90-min cycle of activity is then repeated. From the duodenum, the MMC moves distally at 5–10 cm min⁻¹, reaching the terminal ileum after 1.5 hours.

Following a meal, the stomach exhibits receptive relaxation, which lasts for a few seconds. Following this, adaptive relaxation occurs, which allows the proximal stomach to act as a reservoir. Most of the peristaltic activity is found in the distal stomach (the antral mill) and the proximal stomach demonstrates only tonic activity. The pylorus, which is most commonly open, contracts with the peristaltic wave and allows only a few millilitres of food through at a time. The antral contraction against the closed sphincter is important in the milling activity of the stomach. Although the duodenum is capable of generating 10 waves per minute, after a meal it only contracts after an antral wave reaches the pylorus. The coordination of the motility of the antrum, pylorus and duodenum means that only small quantities of food reach the small bowel at a time. Motility is influenced by numerous factors, including mechanical stimulation and neuronal and endocrine influences (Table 60.1).

Table 60.1 Function and source of peptides and neuropeptides in the stomach

Function	Source
Stimulate secretion	
Gastrin	G cells
Histamine	ECL cells
Acetylcholine	Neurones
Gastrin-releasing peptide	Neurones and mucosa
Cholecystokinin	Duodenal endocrine cells
Inhibit secretion	
Somatostatin	D cells and neurones
Secretin	Duodenal endocrine cells
Enteroglucagon	Small intestinal endocrine cells
Prostaglandins	Mucosa
Neurotensin	Neurones
GIP	Duodenal and jejunal endocrine cells
PYY	Small intestinal endocrine cells
Stimulate motility	
Acetylcholine	Neurones
5-HT	Neurones
Histamine	ECL cells
Substance P	Neurones
Substance K	Neurones
Motilin	Neurones
Gastrin	G cells
Angiotensin	
Inhibit motility	
Somatostatin	D cells and neurones
VIP	Neurones
Nitric oxide	Neurones and smooth muscle
Noradrenaline	Neurones
Enkephalin	Neurones
Dopamine	Neurones

ECL, enterochromaffin-like; GIP, gastric inhibitory polypeptide; PYY, peptide YY; VIP, vasoactive intestinal peptide.

Sir William Maddock Baylis, 1860–1924, Professor of Physiology, University College, London, England.

Ernest Henry Starling, 1866–1927, Professor of Physiology, University College, London, England.

INVESTIGATION OF THE STOMACH AND DUODENUM

Flexible endoscopy

Among all of the methods used to investigate and image the stomach and duodenum, flexible endoscopy is now the 'gold standard'. The original flexible gastroscopes were fiberoptic (Hirschowitz), but now most use a solid-state camera mounted at the instrument's tip (Figs 60.5 and 60.6). Other members of the endoscopy team are able to see the image and this is useful when taking biopsies or performing interventional techniques, and also facilitates teaching and training.

Flexible endoscopy is more sensitive than conventional radiology in the assessment of the majority of gastroduodenal conditions. This is particularly the case with peptic ulceration, gastritis and duodenitis. In upper gastrointestinal bleeding, endoscopy is far superior to any other investigation and, in most circumstances, is the only imaging required.

Figure 60.5 A video gastroscopy [courtesy of KeyMed (Medical and Industrial Equipment) Ltd]. (a) The camera stack. (b) The gastroscopy and biopsy forceps in the working channel.

Basil I. Hirschowitz, Professor of Medicine, Birmingham, AL, USA.

Figure 60.6 A view of the normal stomach during endoscopy (courtesy of G.N.J. Tytgat, Amsterdam, The Netherlands).

Fiberoptic endoscopy is generally a safe investigation but it is important that all personnel undertaking this procedure are adequately trained and that resuscitation facilities are always available. Although morbidity and mortality are extremely low, the technique is not without hazard. Careless and rough handling of the endoscope during intubation of a patient may result in perforations of the pharynx and oesophagus. An inadequately performed endoscopy is also dangerous as a serious condition may be overlooked. This is particularly the case in early and curable gastric cancer, the appearance of which may often be subtle and which therefore may be missed by inexperienced endoscopists. A more experienced endoscopist will have a higher index of suspicion for any mucosal abnormalities and will take more biopsies. Spraying the mucosa with dye endoscopically may allow better discrimination between normal and abnormal mucosa, allowing small cancers to be more easily seen. In the future, advances in technology may allow 'optical biopsy' to determine the nature of mucosal abnormalities in real time.

Upper gastrointestinal endoscopy is normally carried out under sedation, usually with incremental doses of a benzodiazepine until the patient is adequately sedated. Sedation is of particular concern in the case of gastrointestinal bleeding as it may have a more profound effect on cardiovascular stability. It has now become the standard to use pulse oximetry to monitor patients during upper gastrointestinal endoscopy, and nasal oxygen is also often administered. Buscopan is useful to abolish duodenal motility for examinations of the second and third parts of the duodenum. Examinations of this type are best carried out using a side-viewing endoscope.

Some patients are relatively resistant to sedation with benzodiazepines, particularly those who are accustomed to alcohol. Increasing the dose of benzodiazepines in these patients may not result in any useful sedation, but merely make the patient more restless and confused. Such patients are sometimes better endoscoped fully awake using a local anaesthetic throat spray and a narrow-gauge endoscope. Whatever the circumstances, it is

important that resuscitation facilities are available, including agents that reverse the effects of benzodiazepines, such as flumazenil.

The technology associated with upper gastrointestinal endoscopy is continuing to advance. Instruments that allow both endoscopy and endoluminal ultrasound to be performed simultaneously (see later) are used routinely. Bleeding from the stomach and duodenum can be treated with a number of haemostatic measures. These include injection with various substances, diathermy, heater probes and lasers. These approaches appear to be useful in the treatment of bleeding ulcers, although there are few good controlled trials in this area. Currently, there is no good evidence that such interventional procedures work in patients who are bleeding from very large vessels, such as the gastroduodenal artery or splenic artery, although technology may overcome this problem in future.

Contrast radiology

Upper gastrointestinal radiology is now less frequently used as endoscopy is a more sensitive investigation for most gastric problems. Computerised tomography (CT) imaging with oral contrast has also replaced contrast radiology in areas where anatomical information is sought, e.g. large hiatus hernias of the rolling type and chronic gastric volvulus. In these conditions it may be difficult for the endoscopist to determine exactly the anatomy or, indeed, negotiate the deformity to see the distal stomach.

Ultrasonography

Standard ultrasound imaging can be used to investigate the stomach, but used conventionally it is less sensitive than other modalities. In contrast, endoluminal ultrasound and laparoscopic ultrasound are probably the most sensitive techniques available in the preoperative staging of gastric cancer. In endoluminal ultrasound, the transducer is usually attached to the distal tip of the instrument. However, devices have been developed that may be passed down the biopsy channel, albeit with poorer image quality. Five layers (Fig. 60.7) of the gastric wall may be identified on endoluminal ultrasound and the depth of invasion of a tumour can be assessed with exquisite accuracy [90% accuracy for the 'T' tumour component of the staging]. Enlarged lymph nodes can also be identified and the technique's accuracy in this situation is about 80%. Finally, it may be possible to identify liver metastases not seen on axial imaging. Laparoscopic ultrasound is also very

Figure 60.7 Endoscopic ultrasound of the stomach. Five layers can be identified in the normal stomach. A gastric cancer is shown invading the muscle of the gastric wall [courtesy of KeyMed (Medical and Industrial Equipment) Ltd].

sensitive and is one of the most sensitive methods of detecting liver metastases from gastric cancer.

An additional use of ultrasound is in the assessment of gastric emptying. Swallowed contrast is utilised, which is designed to be easily seen using an ultrasound transducer. The emptying of this contrast is then followed directly. The accuracy of the technique is similar to that of radioisotope gastric emptying studies.

Computerised tomography scanning and magnetic resonance imaging

The resolution of CT scanners continues to improve and multi-slice CT is of increasing value in the investigation of the stomach, especially malignancies (Fig. 60.8). The presence of gastric wall thickening associated with a carcinoma of any reasonable size can be easily detected by CT, but the investigation lacks sensitivity in detecting smaller and curable lesions. It is much less accurate in 'T' staging than endoluminal ultrasound. Lymph node enlargement can be detected and, based on the size and shape of the lymph nodes, it is possible to be reasonably accurate in detecting nodal involvement with tumour. However, as with all imaging techniques, it is limited. Microscopic tumour deposits cannot be detected when the node is not enlarged and, in contrast, nodes may undergo reactive enlargement but not contain tumour. These problems apply to all imaging techniques.

The detection of small liver metastases is improving although, in general terms, metastases from gastric cancer are less easy to detect using CT than those, for instance, from colorectal cancer. This is because metastases from gastric cancer may be of the same density as liver and may not handle the intravenous contrast any differently. At present, magnetic resonance imaging (MRI) scanning does not offer any specific advantage in assessing the stomach, although it has a higher sensitivity for the detection of gastric cancer liver metastases than conventional CT imaging.

Computerised tomography/positron emission tomography

Positron emission tomography (PET) is a functional imaging technique that relies on the uptake of a tracer, in most cases by metabolically active tumour tissue. Fluorodeoxyglucose (FDG) is the most commonly used tracer. This tracer has a short half-life,

Figure 60.8 A computerised tomography scan of the abdomen showing a gastric cancer arising in the body of the stomach.

so manufacture and use have to be carefully coordinated. To be of value, anatomical and functional information need to be linked, hence CT/PET is now used universally. It is increasingly being used in the preoperative staging of gastro-oesophageal cancer, as it will often demonstrate occult spread, which renders the patient surgically incurable (Fig. 60.9).

Laparoscopy

This technique is now well used in the assessment of patients with gastric cancer. Its particular value is in the detection of peritoneal disease, which is difficult by any other technique unless the patient has ascites or bulky intraperitoneal disease. Its main limitation is in the evaluation of posterior extension but other techniques are available, especially CT and endoluminal ultrasound. Usually, laparoscopy is combined with peritoneal cytology unless laparotomy follows immediately.

Gastric emptying studies

These are useful for studying gastric dysmotility problems, particularly those that follow gastric surgery. The principle of the examination is that a radioisotope-labelled liquid and solid meal is ingested and the emptying of the stomach is followed on a gamma camera. This allows the proportion of activity in the remaining stomach to be assessed numerically, and it is possible to follow liquid and solid gastric emptying independently (Fig. 60.10).

Angiography

Angiography is used most commonly in the investigation of upper gastrointestinal bleeding that is not identified using endoscopy. Therapeutic embolisation may also be of value in the treatment of bleeding in patients in whom surgery is difficult or inadvisable (Summary box 60.2).

Summary box 60.2

The investigation of gastric disorders

- Flexible endoscopy is the most sensitive and commonly used technique
- Great care is necessary in performing endoscopy to avoid complications and missing important pathology
- Axial imaging, particularly multislice CT, is useful in the staging of gastric cancer, although it may be less sensitive in the detection of liver metastases than other modalities
- CT/PET is useful in staging gastric cancer
- Endoscopic ultrasound is the most sensitive technique in the evaluation of the 'T' stage of gastric cancer and in the assessment of duodenal tumours
- Laparoscopy is sensitive in detecting peritoneal metastases, and laparoscopic ultrasound provides an accurate evaluation of lymph node and liver metastases

PAEDIATRIC DISORDERS

Hypertrophic pyloric stenosis of infancy and duodenal atresia (see Chapter 6)

HELICOBACTER PYLORI

Over the last 20 years this organism has proved to be of overwhelming importance in the aetiology of a number of common gastroduodenal diseases, such as chronic gastritis, peptic ulceration and gastric cancer. The organism had unquestionably been observed by a number of workers since Bircher's first description in 1874, but it was not until 1980 that Warren and Marshall, with enthusiasm but perhaps a lack of caution, ingested the organism

Figure 60.9 Computerised tomography/positron emission tomography of a patient with gastric cancer. The middle pair of images shows the primary tumour. The two images on the left show unsuspected liver metastases, whereas the two on the right show a left cervical node positive for metastases.

J. Robin Warren, B. 1937, Pathologist, The Royal Perth Hospital, Perth, WA, Australia.
Barry J. Marshall, B. 1931, Physician, The Royal Perth Hospital, WA, Australia.

Figure 60.10 Dual-phase solid and liquid gastric emptying. The use of two isotopic labels allows the liquid and solid phases of the emptying to be followed separately. (a) Image acquisition. (b) Gastric emptying curves in a normal individual showing the typical lag period in the solid phase before linear emptying (courtesy of Dr V. Lewington, Southampton, England).

to confirm that Koch's postulates could be fulfilled with respect to the gastritis that they succeeded in causing in themselves. Eradication therapy was then employed with mixed success, but both received the Nobel Prize for Medicine and Physiology in 2005. The organism is spirally shaped and is fastidious in its requirements, being difficult to culture outside the mucus layer of the stomach.

One of the characteristics of the organism is its ability to hydrolyse urea, resulting in the production of ammonia, a strong alkali. The effect of ammonia on the antral G cells is to cause the release of gastrin via the previously described negative-feedback

Robert Koch, 1843–1910, Professor of Hygiene and Bacteriology, Berlin, Germany, stated his 'postulates' in 1882. These define the conditions which must be met before an organism can be shown to be the causal agent for a particular disease.

loop. This is probably responsible for the modest, but inappropriate, hypergastrinaemia in patients with peptic ulcer disease, which, in turn, may result in gastric acid hypersecretion. The organism's obligate urease activity is utilised by various tests designed to detect the presence of the organism, including the ^{13}C and ^{14}C breath tests and the CLO test (a commercially available urease test kit), which is performed on gastric biopsies. The organism can also be detected histologically (Fig. 60.11), using the Giemsa or the Ethin–Starey silver stains, and cultured using appropriate media. Previous or current infection with the organism may also be detected serologically.

After infection with *H. pylori*, enzymes produced by the organism disrupt the gastric mucous barrier and the inflammation induced in the gastric epithelium is the basis of many of the associated disease processes. The association of the organism with chronic (type B) gastritis is not in doubt as Koch's postulates have been fulfilled. Some strains of *H. pylori* produce cytotoxins, notably the *cagA* and *vacA* gene products, and the production of cytotoxins seems to be associated with the ability of the organism to cause gastritis, peptic ulceration and cancer. The effect of the organism on the gastric epithelium is to incite a classic inflammatory response that involves the migration and degranulation of acute inflammatory cells, such as neutrophils, and also the accumulation of chronic inflammatory cells, such as macrophages and lymphocytes.

It is evident how *H. pylori* infection results in chronic gastritis and also how this may progress to gastric ulceration, but for a while it remained an enigma as to how the organism could be involved in duodenal ulceration, as the normal duodenum is not colonised. As mentioned above, the production of ammonia does increase the level of circulating gastrin and it has been subsequently shown that eradication of the organism in patients with duodenal ulcer disease will reduce the acid levels to normal. However, the overlap in gastric acid secretion between normal subjects and those with duodenal ulcers is considerable and the modestly increased acid levels in patients with *Helicobacter*-associated antral gastritis are insufficient to explain the aetiology of duodenal ulceration.

Figure 60.11 Antral mucosa showing colonisation with *Helicobacter pylori* (modified Giemsa stain).

Gustav Giemsa, 1867–1948, a Bacteriologist who became Privatdozent in Chemotherapy at The University of Hamburg, Hamburg, Germany.

The explanation can probably be found in the phenomenon of duodenal gastric metaplasia. Gastric metaplasia is the normal response of the duodenal mucosa to excess acidity. It can be thought of in the same way as any other metaplasia in the gastrointestinal tract: an attempt by the mucosa to resist an injurious stimulus. Although normal duodenal mucosa cannot be infected with *H. pylori*, gastric metaplasia in the duodenum is commonly infected and this infection results in the same inflammatory process that is observed in the gastric mucosa. The result is duodenitis, which is almost certainly the precursor of duodenal ulceration.

Infection with *H. pylori* may be the most common human infection. The incidence of infection within a population increases with age and, in many populations, infection rates of 80–90% are not unusual. It appears that most infection is acquired in childhood and the probability of infection is inversely related to socio-economic group. The means of spread has not been identified but the organism can occur in the faeces and faeco-oral spread seems most likely. The organism is not normally found in saliva or dental plaque. There is evidence in different environments and in different population groups that the manifestations of the infection may be different. Predominantly antral gastritis, which is commonly seen in the west, results initially in increased levels of acid production and peptic ulcer disease, whereas gastritis affecting the body of the stomach, common in the developing world, may lead to hypochlorhydria and gastric neoplasia.

It has been known since 1984 that *Helicobacter* infection is amenable to treatment with antibiotics. The profound hypochlorhydria produced by proton pump inhibitors combined with antibiotics is also effective in eradicating the organism. Commonly used eradication regimes include a proton pump inhibitor and two antibiotics, such as metronidazole and amoxicillin. Very high eradication rates, in the region of 90%, can be achieved with combinations that include the antibiotic clarithromycin, although it may be that, in the future, antibiotic resistance will become a problem. Reinfection following successful eradication appears rare but incomplete eradication is a more important clinical problem.

At present, eradication therapy is recommended for patients with duodenal ulcer disease but not for patients with non-ulcer dyspepsia or in asymptomatic patients who are infected. However, recent data show that a proportion of patients with non-ulcer dyspepsia do respond to treatment. *Helicobacter pylori* is now classed by the World Health Organization as a class 1 carcinogen and it may be that further epidemiological studies on the risk of gastric cancer change the current advice on treatment.

GASTRITIS

The understanding of gastritis has increased markedly following elucidation of the role of *H. pylori* in chronic gastritis.

Type A gastritis

This is an autoimmune condition in which there are circulating antibodies to the parietal cell. This results in the atrophy of the parietal cell mass, resulting in hypochlorhydria and ultimately achlorhydria. As intrinsic factor is also produced by the parietal cell there is malabsorption of vitamin B12, which, if untreated, may result in pernicious anaemia. In type A gastritis, the antrum is not affected and the hypochlorhydria leads to the production of
