high levels of gastrin from the antral G cells. This results in chronic hypergastrinaemia. This, in turn, results in hypertrophy of the ECL cells in the body of the stomach, which are not affected by the autoimmune damage. Over time it is apparent that microadenomas develop in the ECL cells of the stomach, sometimes becoming identifiable tumour nodules. Very rarely, these tumours can become malignant. Patients with type A gastritis are predisposed to the development of gastric cancer, and screening such patients endoscopically may be appropriate.

Type B gastritis

There are abundant epidemiological data to support the association of this type of gastritis with *H. pylori* infection. Most commonly, type B gastritis affects the antrum, and it is these patients who are prone to peptic ulcer disease. *Helicobacter*-associated pangastritis is also a very common manifestation of infection, but gastritis affecting the corpus alone does not seem to be associated. However, there are some data to suggest that *Helicobacter* may be involved in the initiation of the process. Patients with pangastritis seem to be most prone to the development of gastric cancer.

Intestinal metaplasia is associated with chronic pangastritis with atrophy. Although intestinal metaplasia per se is common, intestinal metaplasia associated with dysplasia has significant malignant potential and, if this condition is identified, endoscopic screening may be appropriate.

Reflux gastritis

This is caused by enterogastric reflux and is particularly common after gastric surgery. Its histological features are distinct from those of other types of gastritis. Although commonly seen after gastric surgery, it is occasionally found in patients with no previous surgical intervention or who have had a cholecystectomy. Bile-chelating or prokinetic agents may be useful in treatment and as a temporising measure to avoid the consideration of revisional surgery. Operation for this condition should be reserved for the most severe cases.

Erosive gastritis

This is caused by agents that disturb the gastric mucosal barrier; NSAIDs and alcohol are common causes. The NSAID-induced gastric lesion is associated with inhibition of the cyclo-oxygenase type 1 (COX-1) enzyme, hence reducing the production of cytoprotective prostaglandins in the stomach. Many of the beneficial anti-inflammatory activities of NSAIDs are mediated by COX-2, and the use of specific COX-2 inhibitors reduces the incidence of these side-effects. However, taken in the long term, COX-2 inhibitors appear to be associated with cardiovascular complications, in common with many NSAIDs.

Stress gastritis

This is a common sequel of serious illness or injury and is characterised by a reduction in the blood supply to superficial mucosa of the stomach. Although common, it is not usually recognised unless stress ulceration and bleeding supervene, in which case treatment can be extremely difficult. The condition also sometimes follows cardiopulmonary bypass. Prevention of the stress bleeding from the stomach is much easier than treating it, hence the routine use of H₂-receptor antagonists, with or without barrier agents such as sucralfate, in patients who are in intensive care. These measures have been shown to reduce the incidence of bleeding from stress ulceration.

Ménétrier's disease

This is an unusual condition characterised by gross hypertrophy of the gastric mucosal folds, mucus production and hypochlorhydria. The condition is pre-malignant and may present with hypoproteinaemia and anaemia. There is no treatment other than a gastrectomy. The disease seems to be caused by over-expression of transforming growth factor alpha (TGF α). Like epidermal growth factor (EGF), this peptide also binds to the EGF receptor. The histological features of Ménétrier's disease may be reproduced in transgenic mice overexpressing TGF α .

Lymphocytic gastritis

This type of gastritis is seen rarely. It is characterised by the infiltration of the gastric mucosa by T cells and is probably associated with *H. pylori* infection. The pattern of inflammation resembles that seen in coeliac disease or lymphocytic colitis.

Other forms of gastritis

Eosinophilic gastritis appears to have an allergic basis and is treated with steroids and cromoglycate. Granulomatous gastritis is seen rarely in Crohn's disease and may also be associated with tuberculosis. Acquired immunodeficiency syndrome (AIDS) gastritis is secondary to infection with *Cryptosporidium*. Phlegmonous gastritis is a rare bacterial infection of the stomach found in patients with severe intercurrent illness. It is usually an agonal event (Summary box 60.3).

Summary box 60.3

Gastritis

- The spiral bacterium *H. pylori* is critical in the development of type B gastritis, peptic ulceration and gastric cancer
- Infection appears to be acquired mainly in childhood and the infection rate is inversely associated to socio-economic status
- Eradication, recommended specifically in patients with peptic ulcer disease, can be achieved in up to 90% of patients with a combination of a proton pump inhibitor and antibiotics, and reinfection is uncommon
- Erosive gastritis is usually related to the use of non-steroidal anti-inflammatory drugs (NSAIDs)
- Type A gastritis is an autoimmune process and is associated with the development of gastric cancer

PEPTIC ULCERS

Although the name 'peptic' ulcer suggests an association with pepsin, this is essentially unimportant as in the absence of acid, for instance in type A gastritis with atrophy, peptic ulcers do not occur. All peptic ulcers can be healed by using proton pump inhibitors, which can render a patient virtually achlorhydric.

Common sites for peptic ulcers are the first part of the duodenum and the lesser curve of the stomach, but they also occur on the stoma following gastric surgery, the oesophagus and even in a

Pierre Eugene Menetrier, 1859–1935, a French Histopathologist who later became Professor of Medical History in the Faculty of Medicine, Paris, France.
Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA described regional ileitis in 1932.

Meckel's diverticulum, which contains ectopic gastric epithelium. In general, the ulcer occurs at a junction between different types of epithelium, the ulcer occurring in the epithelium least resistant to acid damage.

In the past, much distinction has been made between acute and chronic peptic ulcers, but this difference can sometimes be difficult to determine clinically. It is probably best to consider that there is a spectrum of disease, from superficial gastric and duodenal ulcers, frequently seen at endoscopy, to deep chronic penetrating ulcers. This does not minimise the importance of acute stress ulceration; these ulcers can both perforate and bleed.

For many years, the cause of peptic ulceration remained an enigma. When comparing groups of patients having duodenal and pre-pyloric peptic ulcers with normal subjects, gastric acid levels are higher in the ulcer group, but the overlap is very considerable. Patients with gastric ulceration have relatively normal levels of gastric acid secretion. As peptic ulceration will occur in the presence of very high acid levels, such as those found in patients with a gastrinoma (Zollinger–Ellison syndrome), and as all ulcers can be healed in the absence of acid, it is clear that acid is important. In patients with a gastrinoma it may be the only aetiological factor, but this is not the case in the majority of patients. As with many diseases, genetic factors may be involved to a limited degree and social stress has also been implicated, although this has been shown to be false (Asher).

It is now widely accepted that infection with *H. pylori* is the most important factor in the development of peptic ulceration. The other factor of major importance at present is ingestion of NSAIDs. Cigarette smoking predisposes to peptic ulceration and increases the relapse rate after treatment with gastric anti-secretory agents or, as carried out in the past, elective surgery. Multiple other factors may be involved in the transition between the superficial and the deep penetrating chronic ulcer, but they are of lesser importance.

Duodenal ulceration

Incidence

There have been marked changes in the last two decades in the demography of patients presenting with duodenal ulceration in the west. First, even before the introduction of H₂-receptor antagonists, the incidence of duodenal ulceration and the frequency of elective surgery for the condition were falling. This trend has continued and now, in the west, dyspeptic patients presenting with a duodenal ulcer at gastroscopy are uncommon. In part, this may relate to the widespread use of gastric anti-secretory agents and eradication therapy for patients with dyspepsia. Second, the peak incidence is now in a much older age group than previously and, although it is still more common in men, the difference is less marked. These changes mirror the changes, at least in part, in the epidemiology of *H. pylori* infection. In Eastern

Johann Friedrich Meckel, (The Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.

Zollinger and Ellison described this condition in a joint paper in 1955 when they were both working at The Ohio State University.

Richard Asher, 1912–1969, Physician, The Central Middlesex Hospital, London, England.

Europe the disease remains common and, although previously uncommon, it is now observed more frequently in some developing nations. Again, the relationship with *H. pylori* appears convincing.

Pathology

Most duodenal ulcers occur in the first part of the duodenum (Figs 60.12 and 60.13). A chronic ulcer penetrates the mucosa and into the muscle coat, leading to fibrosis. The fibrosis causes deformities such as pyloric stenosis. When an ulcer heals, a scar can be observed in the mucosa. Sometimes there may be more than one duodenal ulcer. The situation in which there is both a posterior and an anterior duodenal ulcer is referred to as 'kissing ulcers'. Anteriorly placed ulcers tend to perforate and, in contrast, posterior duodenal ulcers tend to bleed, sometimes by eroding a large vessel such as the gastroduodenal artery. Occasionally, the ulceration may be so extensive that the entire duodenal cap is ulcerated and devoid of mucosa. With respect to the giant duodenal ulcer, malignancy in this region is so

Figure 60.12 Duodenal ulcer at gastroduodenoscopy (courtesy of Dr G.N.J. Tytgat, Amsterdam, The Netherlands).

Figure 60.13 Duodenal ulcer shown by barium meal.

uncommon that, in normal circumstances, surgeons can be confident that they are dealing with benign disease, even though from external palpation it may not appear so. In the stomach the situation is different.

Histopathology

Microscopically, destruction of the muscular coat is observed and the base of the ulcer is covered with granulation tissue, with the arteries in this region showing the typical changes of endarteritis obliterans. Sometimes the terminations of nerves can be seen among the fibrosis. The pathological appearance of the healing ulcer must be carefully observed as some of the epithelial downgrowths can be misinterpreted as invasion. This is unlikely to be important in duodenal ulcers when malignancy rarely, if ever, occurs, but it is much more important in gastric ulcers.

Gastric ulceration

Incidence

As with duodenal ulceration, *H. pylori* and NSAIDs are the important aetiological factors in gastric ulceration. Gastric ulceration is also associated with smoking; other factors are of lesser importance.

There are marked differences between the populations affected by chronic gastric ulceration and those affected by duodenal ulceration. First, gastric ulceration is substantially less common than duodenal ulceration. The incidence of gastric ulcers is equal between the sexes and the population with gastric ulcers tends to be older. They are more prevalent in low socioeconomic groups and considerably more common in the developing world than in the west.

Pathology

The pathology of gastric ulcers is essentially similar to that of duodenal ulcers, except that gastric ulcers tend to be larger. Fibrosis, when it occurs, may result in the now rarely seen hour-glass contraction of the stomach. Large chronic ulcers may erode posteriorly into the pancreas and, on other occasions, into major vessels such as the splenic artery. Less commonly, they may erode into other organs such as the transverse colon. Chronic gastric ulcers are much more common on the lesser curve (especially at the incisura angularis; Figs 60.14 and 60.15) than on the greater curve and, even when high on the lesser curve, they tend to be at the boundary between the acid-secreting and the non-acid-secreting epithelia. With atrophy of the parietal cell mass, non-acid-secreting epithelium migrates up the lesser curvature.

Malignancy in gastric ulcers

Chronic duodenal ulcers are not associated with malignancy but, in contrast, gastric ulcers are. Widely varying estimates are made of the incidence of gastric malignancy in gastric ulcers. The reason for this is that the authors reporting such diverse incidences are describing different clinical situations. Two clinical extremes must be distinguished to understand this problem. First, there is the situation in which a benign chronic gastric ulcer undergoes malignant transformation. This is known to happen, albeit rarely. The contrasting clinical extreme is the patient identified as having an ulcer in the stomach, either endoscopically or on contrast radiology, which is assessed as benign but biopsies reveal malignancy. In this situation the patient does not have, and probably never has had, chronic peptic ulceration in the stomach but has

Figure 60.14 Benign incisural gastric ulcer shown at gastroscopy (courtesy of Dr G.N.J. Tytgat, Amsterdam, The Netherlands).

Figure 60.15 Benign gastric ulcer shown by barium meal. (a) Radiograph. (b) Diagrammatic outline.

presented with an ulcerated cancer. This situation is common, although whether a lesion found in the stomach is described as being benign or malignant on clinical grounds depends very much on the experience of the endoscopist or radiologist.

It is fundamental that any gastric ulcer should be regarded as being malignant, no matter how classically it resembles a benign gastric ulcer. Multiple biopsies should always be taken, perhaps as many as 10 well-targeted biopsies, before an ulcer can be tentatively accepted as being benign. Even then it is important that further biopsies are taken while the ulcer is healing and when healed. Modern anti-secretory agents can frequently heal the ulceration associated with gastric cancer but, clearly, are ineffective in treating the malignancy itself. At operation, even experienced surgeons may have difficulty distinguishing between the gastric cancer and a benign ulcer. Operative strategies differ so radically that it is essential, if at all possible, that a confident diagnosis is made before operation. The petechial haemorrhages found on the serosa of the patient with peptic ulceration are a

useful sign, but not entirely reliable. If at operation it is determined that the ulcer is probably benign, it should nonetheless be completely excised, if possible, and submitted for histological examination. It is not known whether a patient's survival is compromised by this approach if the ulcer turns out to be malignant on biopsy, as convincing data are not available.

Other peptic ulcers

The pre-pyloric gastric ulcer was difficult to treat in the past, a problem that has been overcome with the introduction of proton pump inhibitors. Pyloric channel ulcers are similar to duodenal ulcers. Both pre-pyloric and pyloric ulcers may be malignant, and biopsy is essential. Stomal ulcers occur after a gastroenterostomy or a gastrectomy of the Billroth II type. The ulcer is usually found on the jejunal side of the stoma.

Clinical features of peptic ulcers

Although many textbooks try to create differences in the clinical features of gastric and duodenal ulceration, detailed analysis has shown that they cannot be differentiated on the basis of symptoms. The demographic characteristics of groups of patients with gastric and duodenal ulceration do differ but this does not allow discrimination.

Pain

The pain is epigastric, often described as gnawing, and may radiate to the back. Eating may sometimes relieve the discomfort. The pain is normally intermittent rather than intractable.

Periodicity

One of the classic features of untreated peptic ulceration is periodicity. Symptoms may disappear for weeks or months to return again. This periodicity may be related to the spontaneous healing of the ulcer.

Vomiting

Although this occurs, it is not a notable feature unless stenosis has occurred.

Alteration in weight

Weight loss or, sometimes, weight gain may occur. Patients with gastric ulceration are often underweight but this may precede the occurrence of the ulcer.

Bleeding

All peptic ulcers may bleed. The bleeding may be chronic and presentation with anaemia is not uncommon. Acute presentation with haematemesis and melaena is discussed later.

Clinical examination

Examination of the patient may reveal epigastric tenderness but, except in extreme cases (for instance gastric outlet obstruction), there is unlikely to be much else to find.

Investigation of the patient with suspected peptic ulcer

Gastroduodenoscopy

This is the investigation of choice in the management of suspected peptic ulceration and, in the hands of a well-trained operator, is highly accurate.

In the stomach, any abnormal lesion should be multiply biopsied and, in the case of a suspected benign gastric ulcer, numerous biopsies must be taken to exclude, as far as possible, the presence of a malignancy. Commonly, biopsies of the antrum will be taken to see whether there is histological evidence of gastritis and a CLO test performed to determine the presence of *H. pylori*. A 'U' manoeuvre should be performed to exclude ulcers around the gastro-oesophageal junction. This is important as the increasing incidence of cancer at the gastro-oesophageal junction requires that all mucosal abnormalities in this region should undergo multiple biopsy. Similarly, if a stoma is present, for instance after gastroenterostomy or Billroth II gastrectomy, it is important to enter both afferent and efferent loops. Almost all stomal ulcers will be very close to the junction between the jejunal and gastric mucosa. Attention should be given to the pylorus to note whether there is any pre-pyloric or pyloric channel ulceration, and also whether it is deformed, which is often the case with chronic duodenal ulceration. In the duodenum, care must be taken to view all of the first part. It is not infrequent for an ulcer to be just beyond the pylorus and easily overlooked.

Treatment of peptic ulceration

The vast majority of uncomplicated peptic ulcers are treated medically. Surgical treatment of uncomplicated peptic ulceration has decreased markedly since the 1960s and is now seldom performed in the west. Surgical treatment was aimed principally at reducing gastric acid secretion and, in the case of gastric ulceration, removing the diseased mucosa. When originally devised, medical treatment also aimed to reduce gastric acid secretion, initially using highly successful H_2 -receptor antagonists and, subsequently, proton pump inhibitors. This has now largely given way to eradication therapy.

Medical treatment

It is reasonable that a doctor managing a patient with an uncomplicated peptic ulcer should suggest modifications to the patient's lifestyle, particularly the cessation of cigarette smoking. This advice is rarely followed and pharmacological measures form the mainstay of treatment.

H_2 -receptor antagonists and proton pump inhibitors

H_2 -receptor antagonists (Black) revolutionised the management of peptic ulceration; most duodenal ulcers and gastric ulcers can be healed by a few weeks of treatment with these drugs provided that they are taken and absorbed. There remain, however, a group of patients who are relatively refractory to conventional doses of H_2 -receptor antagonists. This is largely now irrelevant as proton pump inhibitors can effectively render a patient achlorhydric and all benign ulcers will heal using these drugs, the majority within 2 weeks. Symptom relief is impressively rapid, most patients being asymptomatic within a few days. Like H_2 -receptor antagonists, proton pump inhibitors are safe and relatively devoid of serious side-effects. The problem with all gastric anti-secretory agents is that, following cessation of therapy, relapse is almost universal.

Sir James Whyte Black, 1924–2002, Professor of Analytical Pharmacology, King's College Hospital Medical School, London, England, introduced beta blockers and H_2 receptor antagonists. For this work he shared the 1988 Nobel Prize for Physiology or Medicine with Gertrude Elion and George Hitchings.

Eradication therapy

Eradication therapy is now routinely given to patients with peptic ulceration, and this is described earlier in this chapter (see *Helicobacter pylori*, p. 1051). Evidence suggests that if a patient has a peptic ulcer and *H. pylori* is the principal aetiological factor (essentially the patient not taking NSAIDs), complete eradication of the organism will cure the disease and reinfection as an adult is uncommon. Eradication therapy is therefore the mainstay of treatment for peptic ulceration. It is extremely economical by comparison with prolonged courses of anti-secretory agents or surgery. It is also considerably safer than surgical treatment.

There are some patients with peptic ulcers in whom eradication therapy may not be appropriate and this includes patients with NSAID-associated ulcers. Such patients should avoid these drugs if possible and, if not, they should be co-prescribed with a potent anti-secretory agent. Similarly, patients with stomal ulceration are not effectively treated with eradication therapy and require a prolonged course of anti-secretory agents. Patients with Zollinger–Ellison syndrome should be treated in the long term with proton pump inhibitors unless the tumour can be adequately managed by surgery.

Surgical treatment of uncomplicated peptic ulceration

From its peak in the 1960s, the incidence of surgery for uncomplicated peptic ulceration has fallen markedly, to the extent that peptic ulcer surgery is now of little more than historical interest. A description of operations used in the treatment of peptic ulcers is still necessary because surgery is commonly employed for the complicated ulcer and, in addition, many patients are left suffering from the consequences of the more destructive operations.

Operations for duodenal ulceration

Duodenal ulcer surgery (rationale)

Procedures devised for the treatment of duodenal ulcers have the common aim of excluding the damaging effects of acid from the duodenum. This has been achieved by diversion of the acid away from the duodenum, reducing the secretory potential of the stomach, or both. All of the operations devised achieved their aim to some extent, but with varying degrees of morbidity, mortality and postoperative side-effects. There is now no role for acid-reducing operations in the routine management of peptic ulcer disease but, occasionally, operations that involve gastrectomy have to be performed in the emergency situation. In addition, many patients have had such operations performed and suffer from the sequelae. Hence, it is important for the clinician to understand the anatomical and physiological consequences of surgery. The operations are described in historical sequence.

Billroth II gastrectomy

The first successful gastrectomy was performed by Billroth in January 1881, and Wolfler performed the first gastroenterostomy in the same year. The original Billroth operation consisted of a gastric resection with gastroduodenal anastomosis (Billroth I technique) (Fig. 60.16). The Billroth II operation was devised more by accident than design (Fig. 60.17). A gastroenterostomy (Fig. 60.18) was performed on a gravely ill patient with a pyloric

cancer, who was not expected to survive. Contrary to expectations, the patient improved and the stomach distal to the anastomosis was resected. It soon became evident that the use of gastrojejunal anastomosis after gastric resection could be safer and easier than the Billroth I procedure, and it became popular and effective in the surgical treatment of duodenal ulcer. Because of its disadvantages, such as higher operative mortality and morbidity, it has not been used for many years in the patient with an uncomplicated ulcer, but it is still used occasionally in the treatment of a complicated ulcer with a 'difficult' duodenum. In Billroth II gastrectomy, or its close relation Pólya gastrectomy, the

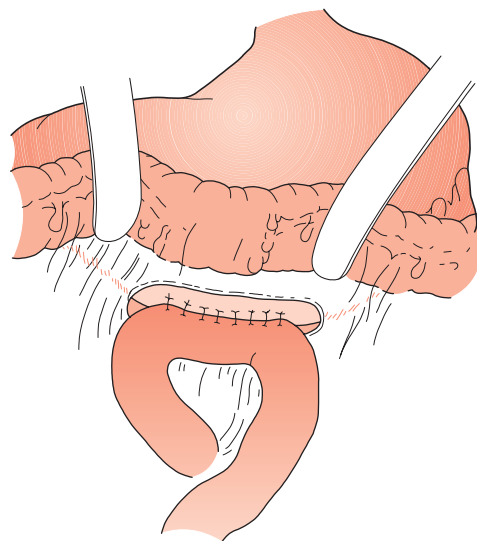

Figure 60.18 Gastroenterostomy. The jejunum is anastomosed to the posterior, dependent wall of the stomach.

antrum and distal body of the stomach are mobilised by opening the greater and lesser omentum and dividing the gastroepiploic arteries, right gastric artery and left gastric artery arcade at the limit of the resection. The duodenum is closed off either by suture or using staples, sometimes with difficulty in patients with a very deformed duodenum. Various techniques are available to close the difficult duodenum and, *in extremis*, a catheter may be placed in the duodenal stump, the duodenum closed around it and the catheter brought out through the abdominal wall. Following resection, the distal end of the stomach is narrowed by the closure of the lesser curve aspect of the remnant. The greater curve aspect is then anastomosed, usually in a retrocolic fashion, to the jejunum, leaving as short an afferent loop as feasible (see Fig. 60.17). Even when well performed, this procedure has an operative mortality rate of a few per cent and morbidity is not unusual. A common cause of morbidity is leakage from the duodenal stump, which is particularly associated with kinking of the afferent loop. Leakage from the gastrojejunal anastomosis is unusual unless it is under tension or the stomach has been devascularised during the mobilisation. The incidence of side-effects following gastrectomy is considerable, as shown in Table 60.2. Recurrence of the ulcer at the stoma is uncommon but can occur, especially as this procedure is traditionally not combined with vagotomy.

Gastrojejunostomy

Because of the potential for mortality after gastrectomy, the use of gastrojejunostomy alone in the treatment of duodenal ulceration was developed (Fig. 60.18). Reflux of alkali from the small bowel into the stomach reduced duodenal acid exposure and was often successful in healing the ulcer. However, because the jejunal loop was exposed directly to gastric acid, stomal ulceration was extremely common, hence the procedure in isolation was ineffective.

Truncal vagotomy and drainage

Truncal vagotomy was first introduced in 1943 by Dragstedt and, for many years, combined with drainage, was the mainstay of

Lester Reynold Dragstedt, 1893–1975, Professor of Surgery, Chicago, IL, USA.

Table 60.2 Operative mortality, side effects and incidence of recurrence following duodenal ulcer operations

Operation	Operative mortality (%)	Significant side-effects (%)	Recurrent ulceration (%)
Gastrectomy	1–2	20–40	1–4
Gastroenterostomy alone	< 1	10–20	50
Truncal vagotomy and drainage	< 1	10–20	2–7
Selective vagotomy and drainage	< 1	10–20	5–10
Highly selective vagotomy	< 0.2	< 5	2–10
Truncal vagotomy and antrectomy	1	10–20	1

treatment of duodenal ulceration (Fig. 60.19). The principle of the operation is that section of the vagus nerves, which are critically involved in the secretion of gastric acid, reduces the maximal acid output by approximately 50%. Because the vagal nerves are conductors of motor impulses to the stomach, denervation of the antropyloroduodenal segment results in gastric stasis in a substantial proportion of patients on whom truncal vagotomy alone is performed. This was first noted by Dragstedt, who did not perform a drainage procedure when he first introduced the operation. The most popular drainage procedure was the Heineke–Mikulicz pyloroplasty (Fig. 60.20). It was simple to perform and involved the longitudinal section of the pyloric ring. The incision was closed transversely. Gastrojejunostomy (see Fig. 60.18) was the alternative drainage procedure to pyloroplasty. This was performed by opening the lesser sac and performing an anastomosis between the most dependent part of the antrum and the first jejunal loop. An isoperistaltic anastomosis was most commonly performed. The operation of truncal vagotomy and drainage was substantially safer than gastrectomy (Table 60.2). However, the side-effects of surgery were, in fact, little different from those that follow gastrectomy.

Highly selective vagotomy

In 1968 Johnston and Amdrup independently devised the operation of highly selective vagotomy in which only the parietal cell mass of the stomach was denervated (Fig. 60.21). This proved to be the most satisfactory operation for duodenal ulceration, with a low incidence of side-effects and acceptable recurrence rates when performed to a high technical standard. This operation became the 'gold standard' for the treatment of duodenal ulceration in the 1970s. The operative mortality rate was lower than

any other definitive operation for duodenal ulceration, in all probability because the gastrointestinal tract was not opened during this procedure. The unpleasant effects of surgery were largely avoided, although loss of receptive relaxation of the stomach did occur, leading to epigastric fullness and sometimes mild dumping. However, the severe symptoms that are seen after other more destructive gastric operations did not occur. It is often said that recurrent ulceration was the Achilles heel of this operation although, when performed well, recurrence was no more common than after truncal vagotomy. The operation disappeared from routine use with the advent of anti-secretory agents and eradication therapy.

Truncal vagotomy and antrectomy

For completeness this operation should be mentioned because at one stage it was popular in the USA. In addition to a truncal vagotomy, the antrum of the stomach was removed, thus eradicating the source of gastrin, and the gastric remnant was joined to the duodenum. The recurrence rates after this procedure were exceedingly low. However, the operative mortality rate was higher than after vagotomy and drainage (Table 60.2) and the incidence of unpleasant side-effects was similar.

Operations for gastric ulcer

In contrast to duodenal ulcer surgery, in which the principal objective was to reduce duodenal acid exposure, in gastric ulceration, the diseased tissue is usually removed as well. This has the advantage that malignancy can then be confidently excluded. As with duodenal ulceration, such surgery is not now performed except for complications of gastric ulcer.

Billroth I gastrectomy

This was the standard operation (see Fig. 60.16) for gastric ulceration until medical treatments became prevalent. The distal stomach is mobilised and resected in the same way as in the Billroth II gastrectomy. This resection should include the ulcer, which is usually situated on the lesser curve. The cut edge of the remnant is then partially closed from the lesser curve aspect, leaving a stoma at the greater curve aspect, which should be similar in size to the duodenum. Reconstruction may be facilitated by mobilising the duodenum using Kocher's manoeuvre. The incidence of recurrent ulceration after this operation is low, but it carries with it the morbidity and mortality rates associated with any gastric resection.

Sequelae of peptic ulcer surgery

There are a number of sequelae of peptic ulcer surgery, which include recurrent ulceration, small stomach syndrome, bilious vomiting, early and late dumping, diarrhoea and malignant transformation. These sequelae principally follow the more destructive

operations, which are now seldom performed. However, a substantial number of patients suffer from side-effects from operations undertaken in the past. Approximately 30% of patients can expect to suffer a degree of dysfunction following peptic ulcer surgery (Table 60.2) and, in about 5% of such patients, the symptoms will be intractable.

Recurrent ulceration

Although mentioned first, this is by far the easiest problem to treat. Just as all peptic ulcers will heal with potent anti-secretory agents, so will ulcers that are recurrent after ulcer surgery.

As with other peptic ulcers, recurrent ulcers may present with complications, particularly bleeding and perforation. In this respect, the complication of gastrojejunal colic fistula requires a particular mention. In this rare condition, the anastomotic ulcer penetrates into the transverse colon. Patients suffer from diarrhoea that is severe and follows every meal. They have foul breath and may vomit formed faeces. Severe weight loss and dehydration are rapid in onset and, for this reason, the condition may be mistaken for malignancy. The major factor producing the nutritional disturbance is the severe contamination of the jejunum with colonic bacteria. A number of imaging techniques can be used to detect the fistula, most commonly CT with oral contrast or, indeed, a barium enema. Endoscopy may not convincingly demonstrate the fistula and, in about one-half of such cases, the barium meal will not reveal the problem. The treatment of gastrocolic fistula consists of first correcting the dehydration and malnutrition and then performing revisional surgery.

Small stomach syndrome

Early satiety follows most ulcer operations to some degree, including highly selective vagotomy, in which, although there is no anatomical disturbance of the stomach, there is a loss of receptive relaxation. Fortunately, this problem does tend to get better with time and revisional surgery is not necessary.

Bile vomiting

Bile vomiting can occur after any form of vagotomy with drainage or gastrectomy. Commonly, the patient presents with vomiting of a mixture of food and bile or sometimes bile alone after a meal. Often, eating will precipitate abdominal pain and reflux symptoms are common. Bile-chelating agents can be tried but are usually ineffective. In intractable cases, revisional surgery may be indicated. The nature of the revision depends very much on the original operation. Following gastrectomy, Roux-en-Y diversion is probably the best treatment. In patients with a gastroenterostomy, the drainage may be taken down and, in most circumstances, a small pyloroplasty can be performed. In patients with a pyloroplasty, reconstruction of the pylorus has been attempted but, in general terms, the results have been rather poor. Antrectomy and Roux-en-Y reconstruction may be the better option.

Early and late dumping

Although considered together because the symptoms are similar, early and late dumping have different aetiologies. A common feature, however, is early rapid gastric emptying. Many patients have both early and late dumping.

Emil Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland.

Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.

Early dumping

Early dumping consists of abdominal and vasomotor symptoms, which are found in about 5–10% of patients following gastrectomy or vagotomy and drainage. It also affects a small percentage of patients following highly selective vagotomy because of the loss of receptive relaxation of the stomach. The small bowel is filled with foodstuffs from the stomach, which have a high osmotic load, and this leads to the sequestration of fluid from the circulation into the gastrointestinal tract. This can be observed by the rise in the packed cell volume while the symptoms are present. All of the symptoms shown in Table 60.3 can be related to this effect on the gut and the circulation.

Treatment The principal treatment is dietary manipulation. Small, dry meals are best, and avoiding fluids with a high carbohydrate content also helps. Fortunately, following operation, the syndrome tends to improve with time. For some reason, however, there is a group of patients who suffer intractable dumping regardless of any of these measures. The somatostatin analogue octreotide, given before meals, has been shown to be useful in some individuals and the long-acting preparation may also be useful. However, this treatment can lead to the development of gallstones and it does not help the diarrhoea from which many patients with dumping also suffer.

Revisional surgery may be occasionally required. In patients with a gastroenterostomy, the drainage may be taken down or, in the case of a pyloroplasty, repaired. Alternatively, antrectomy with Roux-en-Y reconstruction is often effective, although the procedure is of greater magnitude; following gastrectomy, it is the revisional procedure of choice.

Late dumping

This is reactive hypoglycaemia. The carbohydrate load in the small bowel causes a rise in the plasma glucose level, which, in turn, causes insulin levels to rise, causing a secondary hypoglycaemia. This can be easily demonstrated by serial measurements of blood glucose in a patient following a test meal. The treatment is essentially the same as for early dumping. Octreotide is very effective in dealing with this problem.

Post-vagotomy diarrhoea

This can be the most devastating symptom to afflict patients having peptic ulcer surgery. Most patients will suffer looseness of bowel action to some degree (with the exception of highly selective vagotomy) but, in about 5%, it may be intractable. Despite much investigation, the precise aetiology of the problem is uncertain. It is partly related to rapid gastric emptying. In all probability, the denervation of the upper gastrointestinal

tract as a result of the vagotomy is also important. Exaggerated gastrointestinal peptide responses may also aggravate the condition.

The diarrhoea may take several forms. It may be severe and explosive, with the patient experiencing a considerable degree of urgency. The patient sometimes describes the diarrhoea as feeling like passing boiling water. At the other extreme, some patients only have minor episodes of diarrhoea, which are not as directly related to food.

Many authors regard diarrhoea and dumping as being essentially the same problem. However, many patients with severe diarrhoea do not have any of the other symptoms of dumping and, likewise, some patients with dumping do not experience any significant diarrhoea.

The condition is difficult to treat. The patient should be managed as for early dumping and anti-diarrhoeal preparations may be of some value. Octreotide is not effective in treating this condition and the results of revisional surgery are too unpredictable to make this an attractive option.

Malignant transformation

Many large studies now confirm that operations such as gastrectomy or vagotomy and drainage are independent risk factors for the development of gastric cancer. The increased risk appears to be approximately four times that of the control population.

It is not difficult to understand the increased incidence of gastric cancer, as bile reflux gastritis, intestinal metaplasia and gastric cancer are linked. The lag phase between operation and the development of malignancy is at least 10 years. Highly selective vagotomy does not seem to be associated with an increased incidence.

Nutritional consequences

Nutritional disorders are more common after gastrectomy than after vagotomy and drainage. Weight loss is common after gastrectomy and the patient may never return to their original weight. Eating small meals often may help.

Anaemia may result from either iron or vitamin B12 deficiency. Iron-deficiency anaemia occurs after both gastrectomy and vagotomy and drainage and is multifactorial in origin. Reduced iron absorption is probably the most important factor, although the loss of blood from the gastric mucosa may also be important. Vitamin B12 deficiency is prone to occur after total gastrectomy. However, because of the very large vitamin B12 stores, this may be very late in occurring. Vitamin B12 supplementation after total gastrectomy is essential. Rarely, vitamin B12 deficiency may occur after lesser forms of gastrectomy. The cause

Table 60.3 Features of early and late dumping

	Early	Late
Incidence	5–10%	5%
Relation to meals	Almost immediate	Second hour after meal
Duration of attack	30–40 min	30–40 min
Relieved by	Lying down	Food
Aggravated by	More food	Exercise
Precipitating factor	Food, especially carbohydrate-rich and wet	As for early dumping
Major symptoms	Epigastric fullness, sweating, light-headedness, tachycardia, colic, sometimes diarrhoea	Tremor, faintness, prostration

is a combination of reduced intrinsic factor production and, in some patients, bacterial colonisation, which results in the destruction of vitamin B12.

Bone disease is seen principally after gastrectomy and mainly in women. The condition is essentially indistinguishable from the osteoporosis commonly seen in post-menopausal women; it is only the frequency and magnitude of the disorder that distinguish it. Treatment is through dietary supplementation with calcium and vitamin D, and with exercise.

Gallstones

The development of gallstones is strongly associated with truncal vagotomy, in which the biliary tree as well as the stomach is denervated, leading to stasis and, hence, stone formation. Patients developing symptomatic gallstones will require cholecystectomy. However, this may induce or worsen other post-peptic ulcer surgery syndromes such as bilious vomiting and post-vagotomy diarrhoea.

The complications of peptic ulceration

The common complications of peptic ulcer are perforation, bleeding and stenosis. Bleeding and stenosis are considered below in the relevant sections.

Perforated peptic ulcer

Epidemiology

Despite the widespread use of gastric anti-secretory agents and eradication therapy, the incidence of perforated peptic ulcer has changed little. However, there has been a considerable change in the epidemiology of perforated peptic ulcer in the west over the last two decades. Previously, most patients were middle aged, with a ratio of 2:1 of men:women. With time, however, there has been a steady increase in the age of the patients suffering from this complication and an increase in the number of women affected, such that perforations now occur most commonly in elderly female patients. NSAIDs appear to be responsible for most of these perforations.

Clinical features

The classic presentation is instantly recognisable (Fig. 60.22). The patient, who may have a history of peptic ulceration, develops sudden-onset, severe, generalised abdominal pain as a result of the irritant effect of gastric acid on the peritoneum. Although the contents of an acid-producing stomach are relatively low in bacterial load, bacterial peritonitis supervenes over a few hours, usually accompanied by a deterioration in the patient's condition.

Figure 60.22 A sketch of Mr Hamilton Bailey watching for abdominal movement on respiration. In the case of a classically presenting perforated ulcer, the abdominal movement is restricted or absent.

Initially, the patient may be shocked with a tachycardia but a pyrexia is not usually observed until some hours after the event. The abdomen exhibits a board-like rigidity and the patient is disinclined to move because of the pain. The abdomen does not move with respiration. Patients with this form of presentation need an operation, without which they will deteriorate with a septic peritonitis.

This classic presentation of the perforated peptic ulcer is observed less commonly than in the past. Very frequently, the elderly patient who is taking NSAIDs will have a less dramatic presentation, perhaps because of the use of potent anti-inflammatory drugs. The board-like rigidity seen in the abdomen of younger patients may also not be observed and a higher index of suspicion is necessary to make the correct diagnosis. In other patients, the leak from the ulcer may not be massive. They may present only with pain in the epigastrium and right iliac fossa as the fluid may track down the right paracolic gutter. Sometimes perforations will seal as a result of the inflammatory response and adhesion within the abdominal cavity, and so the perforation may be self-limiting. All of these factors may combine to make the diagnosis of perforated peptic ulcer difficult.

By far the most common site of perforation is the anterior aspect of the duodenum. However, the anterior or incisural gastric ulcer may perforate and, in addition, gastric ulcers may perforate into the lesser sac, which can be particularly difficult to diagnose. These patients may not have obvious peritonitis.

Investigations

An erect plain chest radiograph will reveal free gas under the diaphragm in more than 50% of cases (Fig. 60.23) but CT imaging is more accurate (see below). All patients should have serum amylase levels tested, as distinguishing between peptic ulcer perforation and pancreatitis can be difficult. Measuring the serum amylase, however, may not remove the diagnostic difficulty; it can be elevated following perforation of a peptic ulcer although, fortunately, the levels are not usually as high as the levels commonly seen in acute pancreatitis. Several other investigations are useful if doubt remains. A CT scan will normally be diagnostic in both conditions.

Treatment

The initial priorities are resuscitation and analgesia. Analgesia

Figure 60.23 Plain abdominal radiograph of a perforated ulcer, showing air under the diaphragm.

should not be withheld for fear of removing the signs of an intra-abdominal catastrophe. In fact, adequate analgesia makes the clinical signs more obvious. It is important, however, to titrate the analgesic dose. Following resuscitation, the treatment is principally surgical. Laparotomy is performed, usually through an upper midline incision if the diagnosis of perforated peptic ulcer can be made with confidence. This is not always possible and, hence, it may be better to place a small incision around the umbilicus to localise the perforation with more certainty. Alternatively, laparoscopy may be used. The most important component of the operation is a thorough peritoneal toilet to remove all of the fluid and food debris. If the perforation is in the duodenum it can usually be closed by several well-placed sutures, closing the ulcer in a transverse direction as with a pyloroplasty. It is important that sufficient tissue is taken in the suture to allow the edges to be approximated, and the sutures should not be tied so tight that they tear out. It is common to place an omental patch over the perforation in the hope of enhancing the chances of the leak sealing. Gastric ulcers should, if possible, be excised and closed, so that malignancy can be excluded. Occasionally, a patient is seen who has a massive duodenal or gastric perforation such that simple closure is impossible; in these patients, a Billroth II gastrectomy is a useful operation.

All patients should be treated with systemic antibiotics in addition to a thorough peritoneal lavage. In the past, many surgeons performed definitive procedures such as either truncal vagotomy and pyloroplasty or, more recently and probably more successfully, highly selective vagotomy during the course of an operation for a perforation. Studies show that in well-selected patients and in expert hands this is a very safe strategy. However, nowadays, surgery is most commonly confined to first-aid measures and the peptic ulcer is treated medically, as described earlier in this chapter. Following operation, gastric anti-secretory agents should be started immediately.

Perforated peptic ulcers can often be managed by minimally invasive techniques if the expertise is available. The principles of operation are, however, the same; thorough peritoneal toilet is performed and the perforation is closed by intracorporeal suturing. Whichever technique is used, it is important that the stomach is kept empty postoperatively by nasogastric suction and that gastric anti-secretory agents are commenced to promote healing in the residual ulcer.

A great deal has been written about the conservative management of perforated ulcer. Some writers say that virtually all patients can be managed conservatively, whereas most surgeons have difficulty in understanding how a patient who is ill with widespread peritonitis and who has food debris widely distributed through the abdominal cavity will improve without an operation. There are undoubtedly patients who have small leaks from a perforated peptic ulcer and relatively mild peritoneal contamination who may be managed with intravenous fluids, nasogastric suction and antibiotics; however, these patients are in the minority.

Patients who have suffered one perforation may suffer another one. Therefore, they should be managed aggressively to ensure that this does not happen. In patients with *Helicobacter*-associated ulcers, eradication therapy is appropriate. Lifelong treatment with proton pump inhibitors is a reasonable option, especially in those who have to continue with NSAID treatment (Summary box 60.4).

Summary box 60.4

Peptic ulceration

- Most peptic ulcers are caused by *H. pylori* or NSAIDs and changes in epidemiology mirror changes in these principal aetiological factors
- Duodenal ulcers are more common than gastric ulcers, but the symptoms are indistinguishable
- Gastric ulcers may become malignant and an ulcerated gastric cancer may mimic a benign ulcer
- Gastric anti-secretory agents and *H. pylori* eradication therapy are the mainstay of treatment, and elective surgery is rarely performed now
- The long-term complications of peptic ulcer surgery may be difficult to treat
- The common complications of peptic ulcers are perforation, bleeding and stenosis
- The treatment of the perforated peptic ulcer is primarily surgical, although some patients may be managed conservatively

HAEMATEMESIS AND MELAENA

Upper gastrointestinal haemorrhage remains a major medical problem. Despite improvements in diagnosis and the proliferation in treatment modalities over the last few decades, an in-hospital mortality rate of 5% can be expected. In patients in whom the cause of bleeding can be found, the most common causes are bleeding peptic ulcer, erosions, Mallory–Weiss tear and bleeding oesophageal varices (Table 60.4).

Whatever the cause, the principles of management are identical. The patient should be first resuscitated and then investigated urgently to determine the cause of the bleeding. Only then should definitive treatment be instituted. For any significant gastrointestinal bleed, intravenous access should be established

Table 60.4 Causes of upper gastrointestinal bleeding

Condition	Incidence (%)
Ulcers	60
Oesophageal	6
Gastric	21
Duodenal	33
Erosions	26
Oesophageal	13
Gastric	9
Duodenal	4
Mallory–Weiss tear	4
Oesophageal varices	4
Tumour	0.5
Vascular lesions, e.g. Dieulafoy's disease	0.5
Others	5

Soma Weiss, 1898–1942, Professor of Medicine, Harvard University Medical School, Boston, MA, USA.

and, for those with severe bleeding, central venous pressure monitoring should be set up and bladder catheterisation performed. Blood should be cross-matched and the patient transfused as clinically indicated. As a general rule, most gastrointestinal bleeding will stop, albeit temporarily, but there are sometimes instances when this is not the case. In these circumstances, resuscitation, diagnosis and treatment should be carried out in quick succession. There are occasions when life-saving manoeuvres have to be undertaken without the benefit of an absolute diagnosis. For instance, in patients with known oesophageal varices and uncontrollable bleeding, a Sengstaken–Blakemore tube may be inserted before an endoscopy has been carried out. This practice is not to be encouraged, except *in extremis*. In some patients bleeding is secondary to a coagulopathy. The most important current causes of this are liver disease and inadequately controlled warfarin therapy. In these circumstances, the coagulopathy should be corrected, if possible, with fresh-frozen plasma.

Upper gastrointestinal endoscopy should be carried out by an experienced operator as soon as practicable after the patient has been stabilised. In patients in whom the bleeding is relatively mild, endoscopy may be carried out on the morning after admission. In all cases of severe bleeding it should be carried out immediately.

Bleeding peptic ulcers

The epidemiology of bleeding peptic ulcers exactly mirrors that of perforated ulcers. In recent years, the population affected has become much older and the bleeding is commonly associated with the ingestion of NSAIDs. Diagnosis can normally be made endoscopically although, occasionally, the nature of the blood loss precludes accurately identifying the lesion. However, the more experienced the endoscopist, the less likely this is to be a problem.

Medical and minimally interventional treatments

Medical treatment has limited efficacy. All patients are commonly started on a proton pump antagonist, but well-performed studies have failed to show that such treatments influence rebleeding, operation rate or mortality. However, meta-analyses of studies does suggest that tranexamic acid, an inhibitor of fibrinolysis, reduces the rebleeding rate.

Numerous endoscopic devices are now available that can be used to achieve haemostasis, ranging from expensive lasers and argon diathermy to inexpensive injection apparatus. There are few conclusive studies available but a review of the literature suggests that these treatments may have some value, although they will probably never be effective in patients who are bleeding from large vessels, with which the majority of the mortality is associated.

Surgical treatment

Criteria for surgery are well worked out. A patient who continues to bleed requires surgical treatment. The same applies to a significant rebleed. Patients with a visible vessel in the ulcer base, a spurting vessel or an ulcer with a clot in the base are statistically likely to require surgical treatment. Elderly and unfit patients are

more likely to die as a result of bleeding than younger patients; ironically, they should have early surgery. In general, a patient who has required more than 6 units of blood needs surgery. Various scoring systems have been devised, which predict the probability of rebleeding and mortality with some degree of accuracy.

The aim of the operation is to stop the bleeding. The advent of endoscopy has greatly helped in the management of upper gastrointestinal bleeding as a surgeon can usually be confident about the site of bleeding prior to operation. The most common site of bleeding from a peptic ulcer is the duodenum. In tackling this, it is essential that the duodenum is fully mobilised. This should be done before the duodenum is opened as it makes the ulcer much more accessible and also allows the surgeon's hand to be placed behind the gastroduodenal artery, which is commonly the source of major bleeding. Following mobilisation, the duodenum, and usually the pylorus, are opened longitudinally as in a pyloroplasty. This allows good access to the ulcer, which is usually found posteriorly or superiorly. Accurate haemostasis is important. It is the vessel within the ulcer that is bleeding and this should be controlled using well-placed sutures that under-run the vessel. The placing of more and more inaccurately positioned sutures is counter-productive. Following under-running, it is often possible to close the mucosa over the ulcer. The pyloroplasty is then closed with interrupted sutures in a transverse direction in the usual fashion.

The principles of management of bleeding gastric ulcers are essentially the same. The stomach is opened at an appropriate position anteriorly and the vessel in the ulcer under-run. If the ulcer is not excised then a biopsy of the edge needs to be taken to exclude malignant transformation. Sometimes the bleeding is from the splenic artery and if there is a lot of fibrosis then the operation may be challenging. However, most patients can be managed by conservative surgery. Gastrectomy for bleeding has been widely practised in the past but is associated with a high perioperative mortality, even if the incidence of recurrent bleeding is less.

Bearing in mind that most patients nowadays are elderly and unfit, the minimum surgery that stops the bleeding is optimal. Acid can be inhibited by pharmacological means and appropriate eradication therapy will prevent ulcer recurrence. Definitive acid lowering surgery is not now required. Patients on long-term NSAIDs can be managed as outlined earlier.

Stress ulceration

This commonly occurs in patients who have a major injury or illness, who have undergone major surgery or who have a major comorbidity. Many such patients are found in intensive care units. There seems little doubt that the incidence of this problem has reduced in recent years because of the widespread use of prophylaxis. Acid inhibition and the nasogastric or oral administration of sucralfate has been shown to reduce the incidence of stress ulceration. There is no doubt that it is far better to prevent this condition than to try to treat it once it occurs. Endoscopic treatment may be ineffective and operation may be required. The principles of management are the same as for the chronic ulcer.

Gastric erosions

Erosive gastritis has a variety of causes, especially the use of NSAIDs. Fortunately, most such bleeding settles spontaneously but when it does not it can be a major problem to treat. In

Robert William Sengstaken, B. 1923, Surgeon, Garden City, New York, NY, USA.
Arthur Hendley Blakemore, Associate Professor of Surgery, The Columbia College of Physicians and Surgeons, New York, NY, USA.

general terms, although there is a diffuse erosive gastritis, there is one (or more) specific lesion that has a significant-sized vessel within it. This should be dealt with appropriately, preferably endoscopically, although sometimes surgery is necessary.

Mallory–Weiss tear

This is a longitudinal tear below the gastro-oesophageal junction, which is induced by repetitive and strenuous vomiting. Doubtless, many such lesions occur and do not cause bleeding. When it is a cause of haematemesis, the lesion may often be missed; it can be difficult to see as it is just below the gastro-oesophageal junction, a position that can be difficult for the inexperienced endoscopist. Occasionally these lesions continue to bleed and require surgical treatment. Often, the situation arises in which the surgeon does not have guidance from the endoscopists regarding the site of bleeding, and a high index of suspicion in such circumstances is important. The stomach is opened by longitudinal gastrotomy and the upper section is carefully inspected. It is normally possible to palpate the longitudinal mucosal tear with a little induration at the edges, which gives a clue to the lesion's location. Under-running is all that is required.

Dieulafoy's disease

This is essentially a gastric arterial venous malformation that has a characteristic histological appearance. Bleeding as a result of this malformation is one of the most difficult types of upper gastrointestinal bleeding to treat. The lesion itself is covered by normal mucosa and, when not bleeding, it may be invisible. If it can be seen during the bleeding, all that may be visible is profuse bleeding coming from an area of apparently normal mucosa. If this occurs, the cause is instantly recognisable. If the lesion can be identified endoscopically there are various means of dealing with it, including the injection of sclerosant. If it is identified at operation then only a local excision is necessary. Occasionally, a lesion is only recognised after gastrectomy and sometimes not even then. The pathologist, as well as the endoscopist, may have difficulty in finding it.

Tumours

All of the gastric tumours described below may present with chronic or acute upper gastrointestinal bleeding. Bleeding is not normally torrential but can be unremitting. Gastric stromal tumours commonly present with bleeding and have a characteristic appearance, as the mucosa breaks down over the tumour in the gastric wall (Fig. 60.24). Whatever the nature, the tumours should be dealt with as appropriate.

Portal hypertension and portal gastropathy

The management of bleeding gastric varices is very challenging. Fortunately, most bleeding from varices is oesophageal and this is much more amenable to sclerotherapy, banding and balloon tamponade. Gastric varices may also be injected, although this is technically more difficult. Banding can also be used, again with difficulty. The gastric balloon of the Sengstaken–Blakemore tube can be used to arrest the haemorrhage if it is occurring from the fundus of the stomach. Octreotide reduces portal pressure in

Figure 60.24 Gastric gastrointestinal stromal tumour with ulceration.

patients with varices, and trials suggest that it is of value in arresting haemorrhage in these patients, although its overall effect on mortality remains in doubt. Glypressin is also said to be of use.

Most surgeons prefer to avoid acute surgery on bleeding varices as, in contrast with elective operations for portal hypertension, acute shunts are attended by considerable operative mortality. For this reason, the acute TIPSS procedure (transjugular intrahepatic portosystemic shunt; see Chapter 61) can be an extremely useful, although technically demanding, procedure.

Portal gastropathy

Portal gastropathy is essentially the same disease process as described above. The mucosa is affected by the increased portal pressure and may exude blood, even in the absence of well-developed visible varices. The treatment is as above.

Aortic enteric fistula

This diagnosis should be considered in any patient with haematemesis and melaena that cannot be otherwise explained. Contrary to expectation, the bleeding from such patients is not always massive, although it can be. Very often there is nothing much to distinguish between the bleeding from the aortic enteric fistula and any other recurrent upper gastrointestinal bleeding. The vast majority of patients will have had an aortic graft and, in the absence of this, the diagnosis is unlikely. However, it is occasionally seen in patients with an untreated aortic aneurysm. A well-performed CT scan will commonly allow the diagnosis to be made with certainty. The condition should be managed by an expert vascular surgeon as, whether secondary or primary, the morbidity and mortality rates are high.

GASTRIC OUTLET OBSTRUCTION

The two common causes of gastric outlet obstruction are gastric cancer and pyloric stenosis secondary to peptic ulceration. Previously, the latter was more common. Now, with the decrease in the incidence of peptic ulceration and the advent of potent

Georges Dieulafoy, 1939–1911, Professor of Medicine, and Chief of Medical Services at the Hôtel Dieu, Paris, France.

medical treatments, gastric outlet obstruction should be considered malignant until proven otherwise, at least in the west.

The term 'pyloric stenosis' is normally a misnomer as the stenosis is seldom at the pylorus. Commonly, when the condition is due to underlying peptic ulcer disease the stenosis is found in the first part of the duodenum, the most common site for a peptic ulcer. True pyloric stenosis can occur as a result of fibrosis around a pyloric channel ulcer. However, in recent years, the most common cause of gastric outlet obstruction has been gastric cancer. In this circumstance, the metabolic consequences may be somewhat different from those of benign pyloric stenosis because of the relative hypochlorhydria found in patients with gastric cancer.

Clinical features

In benign gastric outlet obstruction there is usually a long history of peptic ulcer disease. Nowadays, as most patients with peptic ulcer symptoms are treated medically, it is easy to understand why the condition is becoming much less common. In some patients the pain may become unremitting and in other cases it may largely disappear. The vomitus is characteristically unpleasant in nature and is totally lacking in bile. Very often it is possible to recognise foodstuff taken several days previously. The patient commonly loses weight, and appears unwell and dehydrated. On examination it may be possible to see the distended stomach and a succussion splash may be audible on shaking the patient's abdomen.

Metabolic effects

These are most interesting as the metabolic consequences of benign pyloric stenosis are unique. The vomiting of hydrochloric acid results in hypochlorhaemic alkalosis but, initially, sodium and potassium levels may be relatively normal. However, as dehydration progresses, more profound metabolic abnormalities arise, partly related to renal dysfunction. Initially, the urine has a low chloride and high bicarbonate content, reflecting the primary metabolic abnormality. This bicarbonate is excreted along with sodium and so, with time, the patient becomes progressively hyponatraemic and more profoundly dehydrated. Because of the dehydration, a phase of sodium retention follows and potassium and hydrogen are excreted in preference. This results in the urine becoming paradoxically acidic and hypokalaemia ensues. Alkalosis leads to a lowering of the circulating ionised calcium, and tetany can occur.

Management

Treating the patient involves correcting the metabolic abnormality and dealing with the mechanical problem. The patient should be rehydrated with intravenous isotonic saline with potassium supplementation. Replacing the sodium chloride and water allows the kidney to correct the acid–base abnormality. Following rehydration it may become obvious that the patient is also anaemic, the haemoglobin being spuriously high on presentation.

It is notable that the metabolic abnormalities may be less if the obstruction is due to malignancy, as the acid–base disturbance is less pronounced.

The stomach should be emptied using a wide-bore gastric tube. A large nasogastric tube may not be sufficiently large to deal with the contents of the stomach and it may be necessary to pass an orogastric tube and lavage the stomach until it is completely emptied. This then allows investigation of the patient with

endoscopy and contrast radiology. Biopsy of the area around the pylorus is essential to exclude malignancy. The patient should also have an anti-secretory agent, initially given intravenously to ensure absorption.

Early cases may settle with conservative treatment, presumably as the oedema around the ulcer diminishes as the ulcer is healed. Traditionally, severe cases are treated surgically, usually with a gastroenterostomy rather than a pyloroplasty. Endoscopic treatment with balloon dilatation has been practised and may be most useful in early cases. However, this treatment is not devoid of problems. Dilating the duodenal stenosis may result in perforation, and the dilatation may have to be performed several times and may not be successful in the long term (Summary box 60.5).

Summary box 60.5

Gastric outlet obstruction

- Gastric outlet obstruction is most commonly associated with longstanding peptic ulcer disease and gastric cancer
- The metabolic abnormality of hypochlorhaemic alkalosis is usually only seen with peptic ulcer disease and should be treated with isotonic saline with potassium supplementation
- Endoscopic biopsy is essential to determine whether the cause of the problem is malignancy
- Endoscopic dilatation of the gastric outlet may be effective in the less severe cases of benign stenosis
- Operation is normally required, with a drainage procedure being performed for benign disease and appropriate resectional surgery if malignant

Other causes of gastric outlet obstruction

Adult pyloric stenosis

This is a rare condition and its relationship to the childhood condition is unclear, although some patients have a long history of problems with gastric emptying. It is commonly treated by pyloroplasty rather than pyloromyotomy.

Pyloric mucosal diaphragm

The origin of this rare condition is unknown. It usually does not become apparent until middle life. When found, simple excision of the mucosal diaphragm is all that is required.

GASTRIC POLYPS

A number of conditions manifest as gastric polyps. Their main importance is that they may actually represent early gastric cancer. Biopsy is essential.

The most common type of gastric polyp is metaplastic. These are associated with *H. pylori* infection and regress following eradication therapy. Inflammatory polyps are also common. Fundic gland polyps deserve particular attention; they seem to be associated with the use of proton pump inhibitors and are also found in patients with familial polyposis.

None of the above polypoid lesions has proven malignant potential. True adenomas have malignant potential and should be removed, but they account for only 10% of polypoid lesions. Gastric carcinoids arising from ECL cells are seen in patients with pernicious anaemia and usually appear as small polyps.

GASTRIC CANCER

Carcinoma of the stomach is a major cause of cancer mortality worldwide. Its prognosis tends to be poor with cure rates little better than 5–10%, although better results are obtained in Japan where the disease is common. Gastric cancer is actually an eminently curable disease provided that it is detected at an appropriate stage and treated adequately. It rarely disseminates widely before it has involved the lymph nodes and, therefore, there is an opportunity to cure the disease prior to dissemination. Early diagnosis is therefore the key to success. Unfortunately, the late presentation of many cases is the cause of the poor overall survival figures. The only treatment modality able to cure the disease is resectional surgery.

Incidence

There are marked variations in the incidence of gastric cancer worldwide. In the UK the incidence is approximately 15 cases per 100 000 population per year, in the USA 10 cases per 100 000 population per year and in Eastern Europe 40 cases per 100 000 population per year. In Japan the disease is much more common, with an incidence of approximately 70 cases per 100 000 population per year, and there are small geographical areas in China where the incidence is double that in Japan. These underlying epidemiological data make it clear that this is an environmental disease. In general, men are more affected by the disease than women and, as with most solid organ malignancies, the incidence increases with age.

At present, marked changes are being observed in the west in terms of the incidence and sites of gastric cancer and the population affected, changes that to date have not been observed in Japan. First, the incidence of gastric cancer is continuing to fall, at a rate of about 1% per year, with the reduction exclusively affecting carcinomas arising in the body of the stomach and the distal stomach. In contrast, the incidence of carcinoma in the proximal stomach, particularly the oesophagogastric junction, appears to be increasing. Carcinoma of the distal stomach and body of the stomach is most common in low socio-economic groups, whereas the increase in proximal gastric cancer seems to affect principally higher socio-economic groups. Proximal gastric cancer does not seem to be associated with *H. pylori* infection, in contrast with carcinoma of the body of the stomach and the distal stomach.

Aetiology

Gastric cancer is a multifactorial disease (Correa). Epidemiological studies point to a role for *H. pylori*, although its importance is disputed. Studies reveal a correlation between the incidence of gastric cancer in various populations and the prevalence of *H. pylori* infection, but other factors are also important. There is insufficient evidence at the moment to support eradication programmes in asymptomatic patients who are infected with *H. pylori*, with a view to reducing the population incidence of gastric cancer. However, clinical trials may subsequently change this view. As mentioned above, *H. pylori* seems to be principally associated with carcinoma of the body of the stomach and the distal stomach rather than the proximal stomach. As *Helicobacter* is associated with gastritis, gastric atrophy and intestinal metaplasia, the association with malignancy is perhaps not surprising.

P. Correa, a Pathologist of New Orleans, LA, USA.

Several other risk factors have been identified as being important in the aetiology of gastric cancer. Patients with pernicious anaemia and gastric atrophy are at increased risk, as are those with gastric polyps. Patients who have had peptic ulcer surgery, particularly those who have had drainage procedures such as Billroth II or Pólya gastrectomy, gastroenterostomy or pyloroplasty, are at approximately four times the average risk. Presumably, duodenogastric reflux and reflux gastritis are related to the increased risk of malignancy in these patients. Intestinal metaplasia is a risk factor. Carcinoma is associated with cigarette smoking and dust ingestion from a variety of industrial processes. Diet appears to be important, as illustrated by the often quoted example of the change in the incidence of gastric cancer in Japanese families living in the USA. The high incidence of gastric cancer in some pockets in China is probably environmental and probably diet related. The ingestion of substances such as spirits may induce gastritis and, in the long term, cancer. Excessive salt intake, deficiency of antioxidants and exposure to *N*-nitroso compounds are also implicated. The aetiology of proximal gastric cancer remains an enigma. It is not associated with *Helicobacter* but is associated with obesity and higher socio-economic status. Genetic factors are also important but imperfectly elucidated (see below).

Clinical features

The features of advanced gastric cancer are usually obvious. However, curable gastric cancer has no specific features to distinguish it symptomatically from benign dyspepsia. The key to improving the outcome of gastric cancer is early diagnosis and, although in Japan there is a screening programme, most curable cases are picked up by the liberal use of gastroscopy in patients with dyspepsia. In the west, early diagnosis is much more difficult as the population incidence is much lower and, hence, the cost-effectiveness of performing gastroscopy for mild dyspeptic symptoms is low. However, a high index of suspicion is necessary, as endoscopy only patients with symptoms of advanced cancer is unlikely to be beneficial because such patients are not surgically curable. It is important to note that gastric anti-secretory agents will improve the symptoms of gastric cancer so the disease should be excluded preferably before therapy is started.

In advanced cancer, early satiety, bloating, distension and vomiting may occur. The tumour frequently bleeds, resulting in iron-deficiency anaemia. Obstruction leads to dysphagia, epigastric fullness or vomiting. With pyloric involvement the presentation may be of gastric outlet obstruction, although the alkalosis is usually less pronounced or absent compared with cases of duodenal ulceration leading to obstruction. Metastatic lymph nodes may be palpable, most notably in the left supraclavicular fossa (Virchow's node, Troisier's sign). In recent years, gastric outlet obstruction has been more commonly associated with malignancy than benign disease. Non-metastatic effects of malignancy are seen, particularly thrombophlebitis (Trousseau's sign) and deep venous thrombosis. These features result from the effects of the tumour on thrombotic and haemostatic mechanisms.

Rudolf Ludwig Carl Virchow, 1821–1902, Professor of Pathology, Berlin, Germany.
Charles Emil Troisier, 1844–1919, Professor of Pathology, Paris, France.
Armand Trousseau, 1801–1867, Physician, Hôtel Dieu, Paris. The sign led him to suspect that he had gastric cancer himself. He actually had pancreatic cancer which was diagnosed at post-mortem.

Site

The proximal stomach is now the most common site for gastric cancer in the west. Because so many malignancies occur at the oesophagogastric junction, and because the lower oesophagus is also a very common site of adenocarcinoma, it is artificial to separate the stomach from the oesophagus. Therefore, it is best to consider the whole of the upper gastrointestinal tract from the cricopharyngeus to the pylorus. The incidence of cancer at these various sites is shown in Fig. 60.25. It can be seen that just under 60% of all of the malignancies occurring in the oesophagus and stomach occur in proximity to the oesophagogastric junction. This high prevalence of proximal gastric cancer is not seen in Japan, where distal cancer still predominates, as it does in most of the rest of the world.

Pathology

The most useful classification of gastric cancer is the Lauren classification. In this system there are principally two forms of gastric cancer: intestinal gastric cancer and diffuse gastric cancer. In intestinal gastric cancer, the tumour resembles carcinomas found elsewhere in the tubular gastrointestinal tract and forms polypoid tumours or ulcers. It probably arises in areas of intestinal metaplasia. In contrast, diffuse gastric cancer infiltrates deeply into the stomach without forming obvious mass lesions but spreading widely in the gastric wall. Not surprisingly, this has a much worse prognosis. A small proportion of gastric cancers are of mixed morphology.

Gastric cancer can be divided into early gastric cancer and advanced gastric cancer. Early gastric cancer can be defined as cancer limited to the mucosa and submucosa with or without lymph node involvement (T1, any N); this classification is shown in Figs 60.26 and 60.27. In the Japanese classification, early gastric cancer can be protruding, superficial or excavated. Early gastric cancer is eminently curable, and even early gastric cancers associated with lymph node involvement have 5-year survival rates in the region of 90%. In Japan, approximately one-third of gastric cancers diagnosed are in this stage. However, in the UK it is uncommon to detect gastric cancers at this stage. A number of reasons probably still accounts for this. First, because gastric cancer is less common in the UK, dyspeptic patients are not always

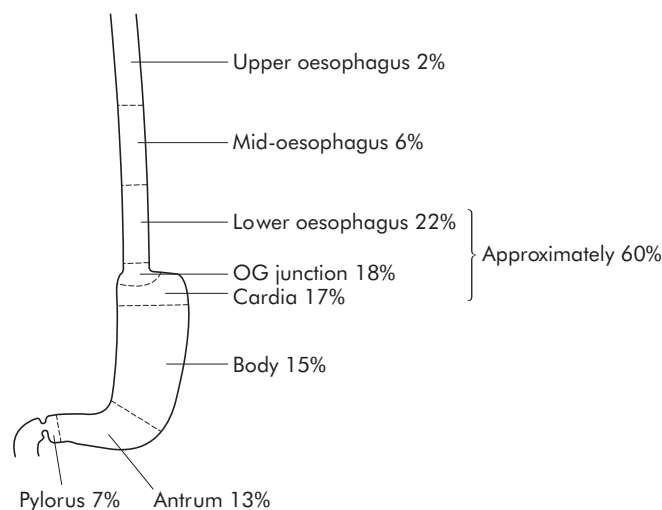

Figure 60.25 The incidence of cancer in the various parts of the upper gastrointestinal tract in the UK. OG, oesophagogastric.

Figure 60.26 Japanese classification of early gastric cancer.

referred for endoscopy at an appropriate stage. Second, endoscopists are unfamiliar with the appearances of early gastric cancer and in all probability many such cases are missed.

Advanced gastric cancer involves the muscularis. Its macroscopic appearances have been classified by Bormann into four types (Figs 60.28 and 60.29). Types III and IV are commonly incurable.

The molecular pathology of gastric cancer

Although the molecular pathology of gastric cancer is less well worked out than that of colorectal cancer, several genetic events have been established, some of which have clinical relevance. Mutation or loss of heterozygosity in the APC gene or in the associated gene coding for β -catenin is found in approximately 50% and 30%, respectively, of cases of intestinal-type cancer. APC mutations are found less frequently in diffuse gastric cancer and not at all in patients with β -catenin mutations. In contrast, another related gene, E-cadherin, is mutated in 50% of cases of diffuse cancer. In some families, inherited diffuse gastric cancer has been shown to be related to a germline mutation in the E-cadherin gene. Inactivation of *p53*, a tumour-suppressor gene, is found in around 30% of both intestinal and diffuse gastric cancers. These findings serve to illustrate that there are important differences between the two types of cancer at a molecular level.

Errors in DNA replication manifesting as microsatellite instability (MSI) have been demonstrated in approximately 15% of cases of gastric cancer, with little distinction between the intestinal or diffuse types. This genetic phenotype is associated with the inherited cancer syndrome, hereditary non-polyposis colorectal cancer (HNPCC) or Lynch's syndrome. However, most cases of MSI are a result of an acquired mutation in the tumour itself.

Several growth factor receptors are overexpressed/amplified in gastric cancer; these include c-Met, k-Sam and c-ErbB2. Similarly, several growth factors may be overexpressed, including TGF α , EGF and vascular endothelial growth factor (VEGF).

Lastly, loss of heterozygosity in the *BCL2* gene, an inhibitor of apoptosis, is associated with intestinal-type cancer.

Henry T. Lynch, an Oncologist at the Creighton School of Medicine, Omaha, NE, USA.

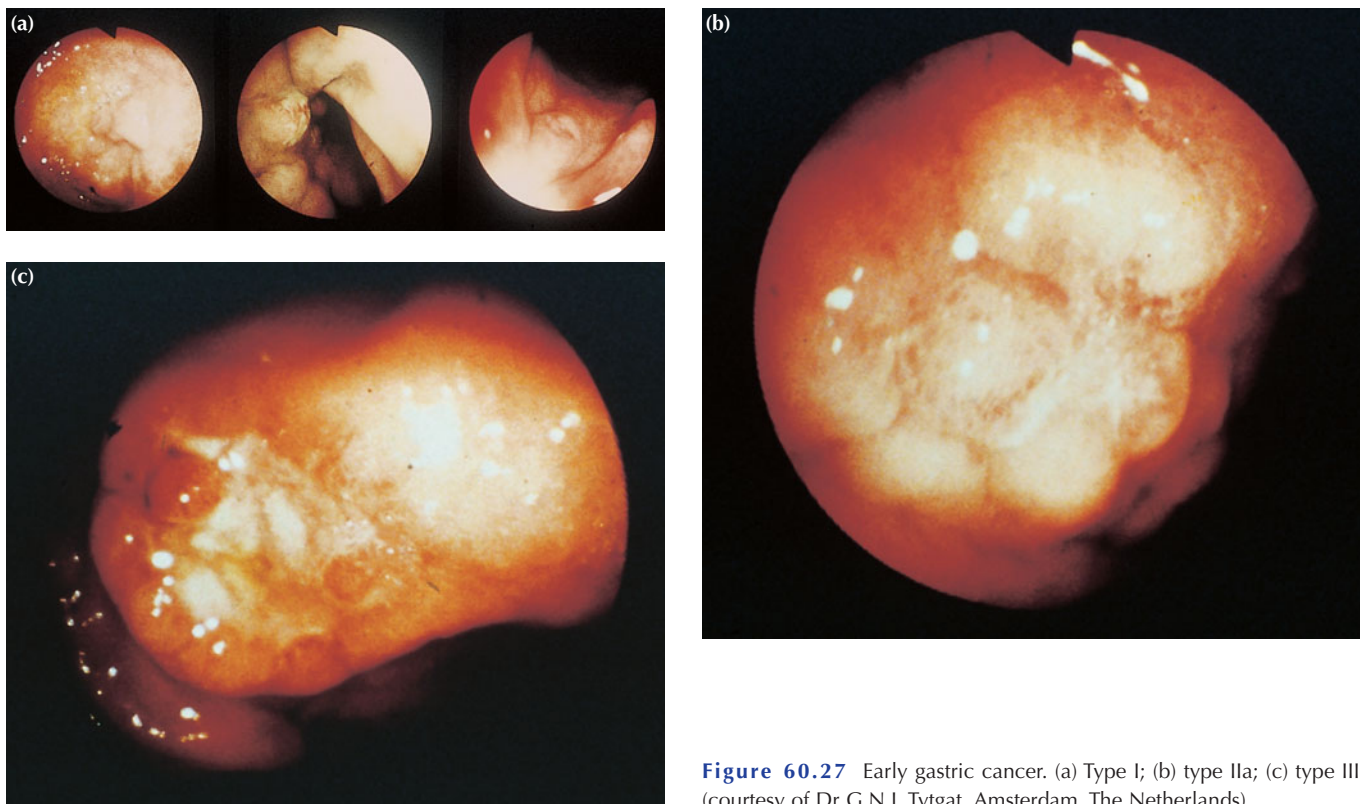

Figure 60.27 Early gastric cancer. (a) Type I; (b) type IIa; (c) type III (courtesy of Dr G.N.J. Tytgat, Amsterdam, The Netherlands).

These genetic changes may be involved in the familial predisposition to gastric cancer. Well-known syndromes such as HNPCC have gastric cancer as part of their spectrum.

Staging

The International Union Against Cancer (UICC) staging system is shown in Table 60.5.

Spread of carcinoma of the stomach

No better example of the various modes by which carcinoma spreads can be given than the case of stomach cancer. It is important to note that this distant spread is unusual before the disease spreads locally, and distant metastases are uncommon in the absence of lymph node metastases. The intestinal and diffuse

types of gastric cancer spread differently. The diffuse type spreads via the submucosal and subserosal lymphatic plexus and it penetrates the gastric wall at an early stage.

Direct spread

The tumour penetrates the muscularis, serosa and ultimately adjacent organs such as the pancreas, colon and liver.

Lymphatic spread

This is by both permeation and emboli to the affected tiers (see below) of nodes. This may be extensive, with the tumour even appearing in the supraclavicular nodes (Troisier's sign). Unlike malignancies such as breast cancer, nodal involvement does not imply systemic dissemination.

Figure 60.28 Borrmann classification of advanced gastric cancer.

Figure 60.29 Advanced gastric cancer. (a) Type I; (b) type II; (c) type III; (d) type IV (linitis plastica) (courtesy of Dr G.N.J. Tytgat, Amsterdam, The Netherlands).

Blood-borne metastases

Blood-borne metastases occur first to the liver and subsequently to other organs, including lung and bone. They are uncommon in the absence of nodal disease.

Transperitoneal spread

This is a common mode of spread once the tumour has reached the serosa of the stomach and indicates incurability. Tumours can manifest anywhere in the peritoneal cavity and commonly give rise to ascites. Advanced peritoneal disease may be palpated either abdominally or rectally as a tumour 'shelf'. The ovaries may sometimes be the sole site of transcoelomic spread

(Krukenberg's tumours). Tumour may spread via the abdominal cavity to the umbilicus (Sister Joseph's nodule). Transperitoneal spread of gastric cancer can be detected most effectively by laparoscopy and cytology.

Lymphatic drainage of the stomach

Understanding the lymphatic drainage of the stomach is the key to comprehending the radical surgery of gastric cancer. The

lymphatics of the antrum drain into the right gastric lymph node superiorly and the right gastroepiploic and subpyloric lymph nodes inferiorly. The lymphatics of the pylorus drain into the right gastric suprapyloric nodes superiorly and the subpyloric lymph nodes situated around the gastroduodenal artery inferiorly. The efferent lymphatics from the suprapyloric lymph nodes converge on the para-aortic nodes around the coeliac axis, whereas the efferent lymphatics from the subpyloric lymph nodes pass up to the main superior mesenteric lymph nodes situated around the origin of the superior mesenteric artery. The lymphatic vessels related to the cardiac orifice of the stomach communicate freely with those of the oesophagus.

The prognosis of operable cases of carcinoma of the stomach depends on whether or not there is histological evidence of regional lymph node involvement. Retrograde (downwards) spread may occur if the upper lymphatics are blocked. In Japan, lymph node dissection is highly advanced and the Japanese Research Society for Gastric Cancer has assigned a number to each lymph node station to aid the pathological staging (Fig. 60.30). Many centres in the west now perform surgery that involves a radical lymphadenectomy but, in other centres, both the staging and surgery are less developed.

Operability

It is important that patients with incurable disease are not subjected to radical surgery that cannot help them, hence the value of CT/PET (see Fig 60.9, p. 1051). Unequivocal evidence of incurability is haematogenous metastases, involvement of the distant peritoneum, N4 nodal disease and disease beyond the N4 nodes, and fixation to structures that cannot be removed. It is important to note that involvement of another organ per se does

Figure 60.30 Lymphatic drainage of the stomach and nodal stations according to the Japanese classification. (a) The anterior view of the stomach. (b) The posterior view.

not imply incurability, provided that it can be removed. Controversies with respect to operability include N3 nodal involvement and involvement of the adjacent peritoneum; such surgery is performed in Japan but seldom elsewhere. Curative resection should be considered on the remaining patients.

Most operable patients should have neoadjuvant chemotherapy as described below, as this improves survival.

Total gastrectomy

This is best performed through a long upper midline incision. The stomach is removed *en bloc*, including the tissues of the entire greater omentum and lesser omentum (Fig. 60.31). In commencing the operation, the transverse colon is completely separated from the greater omentum. The dissection may then be commenced either proximally or, more usually, distally. The subpyloric nodes are dissected and the first part of the duodenum is divided, usually with a surgical stapler. The hepatic nodes are dissected down to clear the hepatic artery; this dissection also includes the suprapyloric nodes. The right gastric artery is taken on the hepatic artery. The lymph node dissection is continued to the origin of the left gastric artery, which is divided flush with its origin. The dissection is continued along the splenic artery,

Figure 60.31 Radical total gastrectomy. (a) Dissection of omentum of the transverse colon; (b) exposure of the lesser sac; (c) splenectomy; (d) division and oversewing of the duodenum; (e) dissection of the left gastric artery nodes (group 17); (f) mobilisation of the oesophagus.

taking all of the nodes at the superior aspect of the pancreas and in the splenic hilum. Separation of the stomach from the spleen, if this organ is not going to be removed, is carried out and this then allows access to the nodal tissues around the upper stomach and oesophagogastric junction. The oesophagus can then be divided at an appropriate point using a combination of stay sutures and a soft non-crushing clamp, usually of the right-angled variety. It is important that the resection margins are well clear of the tumour. Involvement of either the proximal or distal resection margin carries an appalling prognosis and, if in doubt, frozen section should be performed. There is some controversy regarding the management of the spleen and distal pancreas in this procedure and this is discussed below.

Gastrointestinal continuity is reconstituted by means of a Roux loop. Other methods of reconstruction should be discouraged because of poor functional results. The Roux loop should be at least 50 cm long to avoid bile reflux oesophagitis. The simplest means of effecting the oesophagojejunostomy is to place a purse-string in the cut end of the oesophagus and, using a circular stapler introduced through the blind end of the Roux loop, staple the end of the oesophagus onto the side of the Roux loop. The blind open end of the Roux loop may then be closed either with sutures or, alternatively, with a linear stapler. The anastomosis can also be fashioned end-to-end. The Roux loop may be placed in either an anticolic or retrocolic position. The jejunojunos-tomy is undertaken at a convenient point in the usual fashion (end-to-side, Fig. 60.32).

There remains some controversy about the extent of the lymphadenectomy required for the optimal treatment of curable gastric cancers. In Japan, at least a D2 gastrectomy (removal of the second tier of nodes) is performed on all operable gastric cancers and some centres are practising more radical surgery (D3 and even D4 resections). Certainly, the results of surgical treatment stage for stage in Japan are much better than those

Figure 60.32 Oesophagojejunostomy Roux-en-Y.

commonly reported in the west, and the Japanese contention is that the difference is principally related to the staging and the quality of the surgery. It is observed that the physical proportions of the average Japanese patient, compared with the average patient in the west, favour the performance of more radical procedures. However, radical lymphadenectomies above D2 have not been subjected to any randomised controlled trials. In the UK and Europe, randomised trials have been set up to compare D1 and D2 gastrectomy but the results are difficult to interpret. One of the problems relates to standardisation of the operation. Overall, it seems that the oncological outcome may be better following a D2 gastrectomy, but this operation is associated with higher levels of morbidity and perioperative mortality. It is clear that most of this morbidity and mortality relates to the removal of the spleen with or without the distal pancreas. The traditional radical gastrectomy removes the spleen and distal pancreas *en bloc* with the stomach and, although this is indeed an adequate means of performing clearance of the lymph nodes around the splenic artery, there now seems little doubt that this substantially increases the complication rate. The Japanese D2 gastrectomy will commonly preserve the spleen and pancreas.

The differentiation between a D1 and a D2 operation depends upon the tiers of nodes removed. Different tiers need to be removed depending on the position of the primary tumour and this is outlined in Table 60.6. In general, a D1 resection involves the removal of the perigastric nodes and a D2 resection involves the clearance of the major arterial trunks.

Subtotal gastrectomy

For tumours distally placed in the stomach it appears unnecessary to remove the whole stomach. However, a subtotal gastrectomy is very similar to a total gastrectomy except that the proximal stomach is preserved, the blood supply being derived from the short gastric arteries. Following the resection, the simplest form of reconstruction is to close the stomach from the lesser curve, near the oesophagogastric junction, with either sutures or staples and

then perform an anastomosis of the greater curve to the jejunum. Although the reconstruction can be performed as in a Billroth II-/Pólya-type gastrectomy, this may result in quite marked entero-gastric reflux and bile reflux oesophagitis, and it is preferred to perform the reconstruction using a Roux loop.

Palliative surgery

In patients suffering from significant symptoms of either obstruction or bleeding, palliative resection is appropriate. A palliative gastrectomy need not be radical and it is sufficient to remove the tumour and reconstruct the gastrointestinal tract. Sometimes it is impossible to resect an obstructing tumour in the distal stomach and other palliative procedures need to be considered, although the prognosis in such patients, even in the short term, is poor. A high gastroenterostomy is a poor operation that very frequently does not allow the stomach to empty adequately and may produce the additional problem of bile reflux. A Roux loop with a wide anastomosis between the stomach and jejunum may be a better option, although even this may not allow the stomach to empty particularly well. Gastric exclusion and oesophagojejunostomy are practised by some surgeons. For inoperable tumours situated in the cardia, either palliative intubation, stenting or another form of recanalisation can be used (see Chapter 59). Recanalisation appears to offer better functional results.

Postoperative complications of gastrectomy

Radical gastrectomy is complex major surgery and predictably there are a large number of potential complications. Leakage of the oesophagojejunostomy should be uncommon in experienced hands. When it does occur it can often be managed conservatively as the Roux-en-Y reconstruction means that it is mainly saliva and ingested food that leaks. Some patients may establish a fistula from the wound or drain site and others may need radiological or surgically placed drains. It is unclear whether a nasogastric tube should be used routinely; many surgeons do use such tubes routinely but this is not supported by any evidence base. It

The nodes in stations 12–18 are not routinely removed in a D1 or D2 gastrectomy.

is common practice to perform a water-soluble contrast swallow 5–7 days after the operation to determine whether the anastomosis is intact, and it is not uncommon to find a small radiological leak. It is unusual to detect a major leak in the absence of clinical signs.

As with any gastrectomy, leakage from the duodenal stump can occur. This is usually due to a degree of distal obstruction and care must be taken when performing the Roux-en-Y anastomosis that there is no kinking. Paraduodenal collections can be drained radiologically, which will often convert the collection into an external fistula. Biliary peritonitis requires a laparotomy and peritoneal toilet, and in this circumstance it is best to leave a Foley catheter in the duodenum to establish a controlled duodenal fistula. If it is established that there is no distal obstruction, or if any such obstruction is managed, then with time the fistula will close.

The presence of septic collections along with a very radical vascular dissection may lead to catastrophic secondary haemorrhage from the exposed or divided blood vessels. This situation may be very difficult to manage, whether or not reoperation or interventional radiology is employed.

Long-term complications of surgery

Considering the radical nature of the total gastrectomy it is surprising that many patients, particularly younger ones, have good functional results. However, most patients will have a reduced capacity, particularly in the short term. They need to be given detailed nutritional advice, the substance of which is to eat small meals often while the jejunum or small gastric remnant adapts. In fact, there is very little functional difference between patients who have a total gastrectomy and those who have a subtotal gastrectomy. Various attempts have been made to try and improve the short-term functional results by forming a jejunal pouch and attaching this to the oesophagus; however, most surgeons do not perform this because, in the long term, there seems to be little functional advantage. It is surprising that these patients only infrequently suffer from the complications of gastric surgery, such as dumping and diarrhoea. Nutritional deficiencies may occur and the patient should be monitored with this in mind. The loss of the parietal mass leads to vitamin B12 deficiency and replacement should be given routinely.

Outlook after surgical treatment

The outlook after surgical treatment varies considerably between the west and Japan. In Japan, approximately 75% of patients will have a curative resection and, of these, the overall 5-year survival rate will be in the region of 50–70%. In contrast, in the west, most series show that only 25–50% of patients undergoing surgery will have a curative operation and the 5-year survival rate in such patients is only about 25–30%, although in some series it does approach Japanese levels. A combination of differences in staging and a higher standard of surgery in Japan probably accounts for these results. Staging is clearly crucial when survival figures are being compared. The more thorough the staging, the higher the stage is likely to be and, therefore, stage for stage, the outcome seems better in patients who are adequately staged pathologically. This phenomenon is termed ‘stage migration’.

Frederic Eugene Basil Foley, 1891–1966, Urologist, Anker Hospital, St. Paul, MN, USA.

Other treatment modalities

Because of the failure of radical surgery to cure advanced gastric cancer, there has been interest in the use of radiotherapy and chemotherapy.

Radiotherapy

The routine use of radiotherapy is controversial as the results of clinical trials are inconclusive. There are a number of radiosensitive tissues in the region of the gastric bed, which limits the dose that can be given. Radiotherapy has a role in the palliative treatment of painful bony metastases.

Chemotherapy

Gastric cancer may respond well to combination cytotoxic chemotherapy and neoadjuvant chemotherapy improves the outcome following surgery. Therefore, most patients should have chemotherapy before surgery. There are a number of well-investigated regimes but the best results are currently obtained using a combination of epirubicin, cis-platinum and infusional 5-fluorouracil (5-FU) or an oral analogue such as capecitabine. The same regimen is used as first line for patients with inoperable disease although oxaliplatin is being substituted for cis-platinum as it has fewer side-effects. Second-line treatment using combinations that include taxotere are increasingly being used. Chemotherapy for advanced disease is palliative.

Pattern of relapse following surgical treatment

As might be expected, the most common site of relapse following radical gastrectomy is the gastric bed, representing inadequate extirpation of the primary tumour. Widespread nodal intraperitoneal metastases, distant nodal metastases and liver metastases are all common. Dissemination to the lung and bones usually only occurs after liver metastases are already established (Summary box 60.6).

Summary box 60.6

Gastric cancer

- Gastric cancer is one of the most common causes of cancer death in the world
- The outlook is generally poor because of the advanced stage at presentation
- Better results are obtained in Japan, which has a high population incidence, screening programmes and high-quality surgical treatment
- The aetiology of gastric cancer is multifactorial; *H. pylori* is an important factor for distal but not proximal gastric cancer
- Early gastric cancer is associated with very high cure rates
- Gastric cancer can be classified into intestinal and diffuse types, the latter having a worse prognosis
- In the west, proximal gastric cancer is now more common than distal cancer and is usually of the diffuse type
- Spread may be by lymphatics, blood, transcoelomic or direct, but distant metastases are uncommon in the absence of lymph node involvement
- The treatment of curable cases is by radical surgery, and removal of the second tier of nodes (around the principal arterial trunks) may be advantageous
- Gastric cancer is chemosensitive and chemotherapy improves survival both in patients having curative surgery and with advanced disease

GASTROINTESTINAL STROMAL TUMOURS

Gastrointestinal stromal tumours (GISTs) commonly occur in the stomach and duodenum. Previously named leiomyoma and leiomyosarcoma, the term GIST is now used, recognising their particular distinct phenotype. The tumours are universally associated with a mutation in the tyrosine kinase *c-kit* oncogene. These tumours are sensitive to the tyrosine kinase antagonist imatinib, and an 80% objective response rate can be observed. Tumours with mutations in exon 11 of *c-kit* are particularly sensitive to this drug. The biological behaviour of these tumours is unpredictable but size and mitotic index are the best predictors of metastasis. Peritoneal and liver metastases are most common; spread to lymph nodes is extremely rare.

The incidence of the condition is unclear; small stromal tumours of the stomach are probably quite common but remain unnoticed. Clinically obvious tumours are considerably less common than gastric cancer.

The only way that many stromal tumours are recognised is either that the mucosa overlying the tumour ulcerates (see Fig. 60.24, p. 1065), leading to bleeding, or that they are noticed incidentally at endoscopy. Because the mucosa overlying the tumour is normal, endoscopic biopsy can be uninformative unless the tumour has ulcerated. Larger tumours present with non-specific gastric symptoms and, in many instances, it may initially be thought that they are gastric cancers (Fig. 60.33).

As the biological behaviour is difficult to predict, the best guide is to consider the size of the tumour. If easily resectable, surgery is the primary mode of treatment. Smaller tumours can be treated by wedge excision although the appropriate management of asymptomatic diminutive tumours found incidentally at endoscopy is unclear. Larger tumours may require a gastrectomy or duodenectomy (see Chapter 64) but lymphadenectomy is not required. Larger tumours that require multivisceral resection may be better treated for 3–6 months with imatinib before

Figure 60.33 Computerised tomography (CT) of the upper abdomen showing a 3.5 cm gastrointestinal stromal tumour (GIST) arising from the gastric wall.

operation as this will usually radically reduce their size and vascularity.

The prognosis of advanced metastatic GIST has been dramatically improved with imatinib chemotherapy but resection of metastases, especially from the liver, still has an important role.

GASTRIC LYMPHOMA

Gastric lymphoma is an interesting disease and some aspects of the management are controversial. It is first important to distinguish primary gastric lymphoma from involvement of the stomach in a generalised lymphomatous process. This latter situation is more common than the former. Unlike gastric carcinoma, the incidence of lymphoma seems to be increasing. Primary gastric lymphoma accounts for approximately 5% of all gastric neoplasms.

Gastric lymphoma is most prevalent in the sixth decade of life. The presentation is no different from gastric cancer, the common symptoms being pain, weight loss and bleeding. Acute presentations of gastric lymphoma such as haematemesis, perforation or obstruction are not common. Primary gastric lymphomas are B cell-derived, the tumour arising from the mucosa-associated lymphoid tissue (MALT). Primary gastric lymphoma remains in the stomach for a prolonged period before involving the lymph nodes. At an early stage, the disease takes the form of a diffuse mucosal thickening, which may ulcerate. Diagnosis is made as a result of the endoscopic biopsy and seldom on the basis of the endoscopic features alone, which are not specific.

Following diagnosis, adequate staging is necessary, primarily to establish whether the lesion is a primary gastric lymphoma or part of a more generalised process. CT scans of the chest and abdomen and bone marrow aspirate are required, as well as a full blood count.

Although the treatment of primary gastric lymphoma is somewhat controversial, it seems most appropriate to use surgery alone for the localised disease process. No benefit has been shown from adjuvant chemotherapy, although some oncologists contend that primary gastric lymphoma can be treated by chemotherapy alone. Chemotherapy alone is appropriate for patients with systemic disease.

Some of the more controversial aspects of gastric lymphoma concern the role of *H. pylori*. Lymphocytes are not found to any degree in normal gastric mucosa but are found in association with *Helicobacter* infection. It has also been shown that early gastric lymphomas may regress and disappear when the *Helicobacter* infection is treated (Isaacson).

Gastric involvement with the diffuse lymphoma

These patients are treated with chemotherapy, sometimes with dramatic and rapid responses. Surgeons are frequently asked to deal with the complications of gastric involvement. The two common complications are bleeding and perforation; both may occur at presentation, but more usually they may follow chemotherapy when there is rapid regression and necrosis of the tumour. These operations can be technically very challenging and normally require gastrectomy.

Peter Gersohn Isaacson, Professor of Morbid Anatomy, University College, London, England.

DUODENAL TUMOURS

Benign duodenal tumours

Duodenal villous adenomas occur principally in the periampullary region. Although generally uncommon, they are often found in patients with familial adenomatous polyposis. The appearances are similar to those of adenomas arising in the colon and, as they have malignant potential, they should be locally excised with histologically clear margins.

Duodenal adenocarcinoma

Although uncommon, this is the most common site for adenocarcinoma arising in the small bowel. Most tumours originate in the periampullary region and commonly arise in pre-existing villous adenomas. Patients present with anaemia because of ulceration of the tumour or obstruction as the polypoid neoplasm begins to obstruct the duodenum. Direct involvement in the ampulla leads to obstructive jaundice. Histologically, the lesion is a typical adenocarcinoma and the metastases are commonly to regional lymph nodes and the liver. At presentation, about 70% of the patients have resectable disease and, for those who survive operation, the 5-year survival rate is in the region of 20%, this approximately equating to cure. Poor prognostic features in the resected specimen include regional lymph node metastases, transmural involvement and perineural invasion. Curative surgical treatment will normally involve a pancreaticoduodenectomy (Whipple's procedure). Patients with familial polyposis, which is due to a mutation in the APC gene on chromosome 5, are predisposed to periampullary cancer, which is one of the most common causes of death in patients who have had their colon removed. Other duodenal malignancies include GISTs (see above) and neuroendocrine tumours.

Neuroendocrine tumours

A number of neuroendocrine neoplasms occurs in the duodenum. It is a common site for primary gastrinoma (Zollinger–Ellison syndrome). Non-functioning neuroendocrine tumours (usually called carcinoid tumours) also occur but uncommonly in comparison with the ileum.

Zollinger–Ellison syndrome

This syndrome is mentioned here because the gastrin-producing endocrine tumour is often found in the duodenal loop, although it also occurs in the pancreas, especially the head. It is a cause of persistent peptic ulceration. Before the development of potent gastric anti-secretory agents, the condition was recognised by the sometimes fulminant peptic ulceration that did not respond to gastric surgery short of total gastrectomy. It was also recognisable from gastric secretory studies in which the patient had a very high basal acid output but no marked response to pentagastrin, as the parietal cell mass was already nearly maximally stimulated by pathological levels of gastrin. The advent of proton pump inhibitors has rendered this extreme endocrine condition fully controllable, but also less easily recognised.

Gastrinomas may be either sporadic or associated with the autosomal dominantly inherited multiple endocrine neoplasia (MEN) type I (in which a parathyroid adenoma is almost

invariably present). The tumours are most commonly found in the 'gastrinoma triangle' (Passaro) defined by the junction of the cystic duct and common bile duct superiorly, the junction of the second and third parts of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially (essentially the superior mesenteric artery). Many are found in the duodenal loop, presumably arising in the G cells found in Brunner's glands. It is extremely important that the duodenal wall is very carefully inspected endoscopically and also at operation. Very often all that can be detected is a small nodule that projects into the medial wall of the duodenum.

Even malignant sporadic gastrinomas may have a very indolent course. The palliative resection of liver metastases may be beneficial and, as for other gut endocrine tumours, liver transplantation is practised in some centres with reasonable long-term results. However, the minority of tumours that are found to the left of the superior mesenteric artery (outside the 'triangle') seem to have a worse prognosis, with more having liver metastases at presentation. In MEN type I, the tumours may be multiple and the condition is incurable. Even in this situation, as with sporadic gastrinoma, surgical treatment should be employed to remove any obvious tumours and associated lymphatic metastases, as the palliation achieved may be good.

Duodenal obstruction

Duodenal obstruction in the adult is usually due to malignancy, and cancer of the pancreas is the most common cause. About one-fifth of patients with pancreatic cancer treated with endoscopic stenting will develop obstruction. Treatment is usually by gastroenterostomy but duodenal stenting is increasingly being used. In patients having a surgical biliary bypass for pancreatic cancer, gastric drainage may be necessary.

A variety of other malignancies can cause duodenal obstruction, including metastases from colorectal and gastric cancer. Primary duodenal cancer is much less common as a cause of obstruction than these other malignancies.

An annular pancreas may rarely cause duodenal obstruction. Obstruction usually follows an attack of pancreatitis and, on occasions, the obstruction may be mistaken for malignancy.

Arterioesophageal compression is an ill-defined condition in which it is proposed that the fourth part of the duodenum is compressed between the superior mesenteric artery and the vertebral column; when it is convincingly demonstrated and causing weight loss, duodenojejunostomy may be performed (Summary box 60.7).

Summary box 60.7

Duodenal tumours

- Duodenal villous adenomas are commonly found around the ampulla of Vater and are pre-malignant
- Duodenal carcinoma is uncommon, but the commonest site for adenocarcinoma in the small intestine
- Both adenoma and carcinoma occur commonly in patients with familial polyposis and screening these patients is advised
- Pancreatic cancer is the most common cause of duodenal obstruction

Allen Oldfather Whipple, 1881–1963, Director of Surgical Services, The Presbyterian Hospital, and Professor of Surgery, The College of Physicians and Surgeons, Columbia University, New York, NY, USA.

Edward Passaro, Professor of Surgery, Los Angeles, CA, USA.

GASTRIC OPERATIONS FOR MORBID OBESITY

Morbid obesity is defined as being 100% over the ideal weight for height or having a body mass index [(weight in kg)/(height in m)²] of greater than 45. It is an increasing and major health problem in the west, especially in the USA. A number of surgical treatments have been devised for morbid obesity, but none is free of problems. Selection of patients for operation should ideally be made by a team that includes a nutritionist/endocrinologist and a psychiatrist, as well as a surgeon, because it is important that major metabolic problems and severe psychiatric disorders are elucidated before operation. Morbidly obese patients as defined above have an excessive morbidity and mortality. The patient will often already have morbidity associated with severe obesity, such as hypertension, diabetes or osteoarthritis. Preoperative counselling should include discussion of the possibility of perioperative mortality. This is very much an elective procedure and the patient is at risk of postoperative respiratory problems and pulmonary thromboembolism. Thromboembolic prophylaxis is essential, as are antibiotics.

Increasingly, surgery is performed laparoscopically. The two most commonly performed procedures are the Lap Band procedure and gastric bypass. In the Lap Band procedure an inflatable cuff is placed laparoscopically just below the oesophagogastric junction (Fig. 60.34). The inflation of the band determines the level of restriction. However, very small differences in volume may result in complete dysphagia on the one hand and no significant weight loss on the other. Perioperative mortality is less than 1%. Band slippage may cause problems and the long-term results seem inferior to conventional surgery.

The operation that has the best long-term results is gastric bypass. This operation can be performed laparoscopically and, although technically difficult, it is becoming a standard procedure

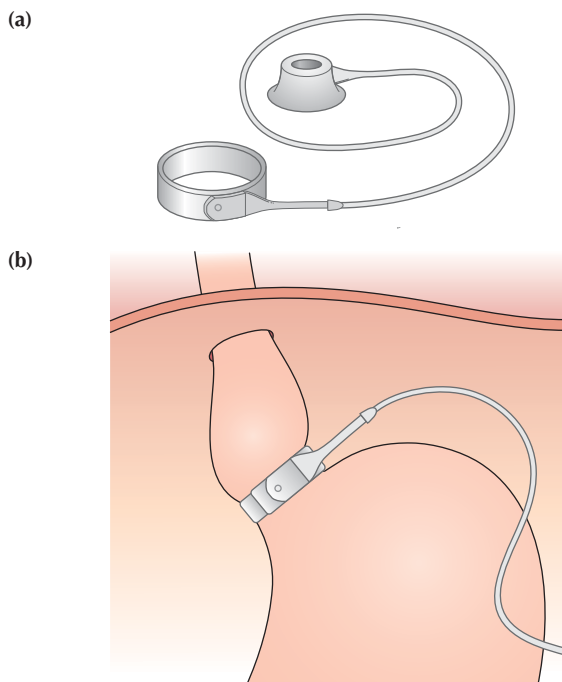

Figure 60.34 A gastric band (a) showing the cuff and injectable port and (b) in position around the upper part of the stomach.

for the severely obese (Fig. 60.35). Using a combination of circular and linear staplers, a gastric pouch is created as shown. The pouch has no connection to the rest of the stomach but is drained by a 70-cm Roux loop. The operative mortality is in the region of 2%.

After both procedures the patient must be managed in a high-dependency care unit until the possibility of apnoea and other complications are diminished. Epidural anaesthesia is useful as it decreases opiate requirements. The patient may be introduced to fluids and some food on the first postoperative day. Dietary advice is important; the patient must understand that liquidised food or high-calorie supplements are to be avoided. The patient should lose between one-third and one-half of their body weight over 2 years. Vomiting is common and vitamin supplementation is advised.

OTHER GASTRIC CONDITIONS

Acute gastric dilatation

This condition usually occurs in association with pyloroduodenal disorders or after surgery without nasogastric suction. The stomach, which may also be atonic, dilates enormously. Often the patient is also dehydrated and has electrolyte disturbances. Failure to treat this condition can result in a sudden massive vomit with aspiration into the lungs. The treatment is nasogastric suction with a large-bore tube, fluid replacement and treatment of the underlying condition.

Trichobezoar and phytobezoar

Trichobezoars (hair balls) (Fig. 60.36) are unusual and are almost exclusively found in female psychiatric patients, often young. They are caused by the pathological ingestion of hair, which remains undigested in the stomach. The hair ball can lead to ulceration and gastrointestinal bleeding, perforation or obstruction. The diagnosis is made easily at endoscopy or, indeed, from a plain radiograph. Treatment consists of removal of the trichobezoar, which may require open surgical treatment. Phytobezoars are made of vegetable matter and are found principally in patients who have gastric stasis. Often this follows gastric surgery.

Foreign bodies in the stomach

A variety of ingested foreign bodies reach the stomach and very often these can be seen on a plain radiograph. If possible they should be removed endoscopically but, if not, most can be left to pass. Even objects such as needles, about which there is understandable anxiety, will seldom cause harm. In general, an object that leaves the stomach will pass spontaneously. In contrast, attempted removal at laparotomy can be very difficult as the object may be much more difficult to find than might be expected. Most adults who swallow foreign bodies have ill-defined psychiatric problems and may appear to relish the attention associated with serial laparotomies. The treatment should therefore be expectant and intervention reserved for patients with symptoms in whom the foreign body is failing to progress.

Volvulus of the stomach

Rotation of the stomach usually occurs around the axis and between its two fixed points, i.e. the cardia and the pylorus. In theory, rotation can occur in the horizontal (organoaxial) or vertical (mesenteroaxial) direction but, commonly, it is the

Figure 60.35 The technique of laparoscopic gastric bypass. (a) Formation of a gastric pouch; (b) anastomosis of the jejunum to the gastric pouch; (c) formation of the jejunum-jejunostomy; (d) completion of the jejunum-jejunostomy and division of the jejunum; (e) the completed procedure.

former that occurs. This condition is usually associated with a large diaphragmatic defect around the oesophagus (para-oesophageal herniation) (Fig. 60.37). What commonly happens is that the transverse colon moves upwards to lie under the left diaphragm, thus taking the stomach with it, and the stomach and colon may both enter the chest through the eventration of the diaphragm. The condition is commonly chronic, the patient presenting with difficulty in eating. An acute presentation with ischaemia may occur. It can be extremely difficult to sort out the anatomy endoscopically, and this is one situation in which contrast radiography is superior.

Treatment

If the problem is causing symptoms then surgical treatment is the only satisfactory approach. Traditionally, open surgery has been employed but this problem is suitable for laparoscopic treatment if appropriate skill is available. If there is a hernia, the sac and its contents (usually the stomach) should be reduced. The defect in the diaphragm should be closed, if necessary, with a mesh. It is advisable to separate the stomach from the transverse colon and then perform an anterior gastropexy to fix the stomach to the anterior abdominal wall. The results from this treatment are good.

Figure 60.36 Trichobezoar of the stomach in a girl aged 15 years.

The liver

CHAPTER

61

LEARNING OBJECTIVES

To understand:

- The anatomy of the liver
- The signs of acute and chronic liver disease
- The investigation of liver disease
- The management of liver trauma, infections, cirrhosis and tumours

INTRODUCTION

The liver is the largest organ in the body, weighing 1.5 kg in the average 70-kg man. The liver parenchyma is entirely covered by a thin capsule and by visceral peritoneum on all but the posterior surface of the liver, termed the 'bare area'. The liver is divided into a large right lobe, which constitutes three-quarters of the liver parenchyma, and a smaller left lobe. Surgical resection of these lobes would be termed a right or left lobectomy.

ANATOMY OF THE LIVER

Ligaments and peritoneal reflections

The liver is fixed in the right upper quadrant by peritoneal reflections that form ligaments. On the superior surface of the left lobe is the left triangular ligament. Dividing the anterior and posterior folds of this ligament allows the left lobe to be mobilised from the diaphragm and the left lateral wall of the inferior vena cava (IVC) to be exposed. The right triangular ligament fixes the entire right lobe of the liver to the undersurface of the right hemidiaphragm. Division of this ligament allows the liver to be mobilised from under the diaphragm and rotated to the left. Another major supporting structure is the falciform ligament (remnant of the umbilical vein), which runs from the umbilicus to the liver between the right and left lobes, passing into the interlobar fissure. From the fissure, it passes anteriorly on the surface of the liver, attaching it to the posterior aspect of the anterior abdominal wall. Division of the superior leaves of the falciform ligament allows exposure of the suprahepatic IVC, lying within a thin sheath of fibrous tissue. The final peritoneal reflection is between the stomach and the liver. This lesser omentum is often thin and fragile, but contains the hilar structures in its free edge.

Liver blood supply

The blood supply to the liver is unique, 80% being derived from the portal vein and 20% from the hepatic artery. The arterial blood supply in most individuals is derived from the coeliac trunk of the aorta, where the hepatic artery arises along with the splenic artery. After supplying the gastroduodenal artery, it branches at a very variable level to produce the right and left hepatic arteries.

The right artery supplies the majority of the liver parenchyma and is therefore the larger of the two arteries. There are many anatomical variations, knowledge of which is essential for safe surgery on the liver. The blood supply to the right lobe of the liver may be partly or completely supplied by a right hepatic artery arising from the superior mesenteric artery. This vessel passes posterior to the uncinate process and head of the pancreas, and runs to the liver on the posterior wall of the bile duct. Similarly, the arterial blood supply to the left lobe of the liver may be derived from the coeliac trunk via its left gastric branch. This vessel runs between the lesser curve of the stomach and the left lobe of the liver in the lesser omentum (Fig. 61.1).

Structures in the hilum of the liver

The hepatic artery, portal vein and bile duct are present within the free edge of the lesser omentum or the 'hepatoduodenal ligament'. To expose these structures requires division of the peritoneum overlying the hilar triad, followed by the division of small vessels and an extensive lymphatic plexus. The usual anatomical relationship of these structures is for the bile duct to be within the free edge, the hepatic artery to be above and medial, and the portal vein to lie posteriorly. Within this ligament, the common hepatic duct is joined by the cystic duct at a varying level to form the common bile duct. The common hepatic artery branches at a variable level within the ligament to form two, or often three, main arterial branches to the liver. The right hepatic artery often crosses the bile duct either anteriorly or posteriorly before giving rise to the cystic artery. Multiple small hepatic arterial branches provide blood to the bile duct, principally from the right hepatic artery. The portal vein arises from the confluence of the splenic vein and the superior mesenteric vein behind the neck of the pancreas. It has some important tributaries, including the left gastric vein which joins just above the pancreas.

Division of structures at the hilum

At the hilum, the major structures are divided into right and left branches. The right and left hepatic ducts arise from the hepatic parenchyma and join to form the common hepatic duct. The left duct has a longer extrahepatic course of approximately 2 cm. Once within the liver parenchyma, the duct accompanies the branches of

Figure 61.1 Hepatic angiography/conventional arterial anatomy. Arterial (a) and venous (b) phase of a selective hepatic angiogram. The hepatic artery usually arises from the coeliac trunk, along with the splenic artery, and gives rise to the gastroduodenal artery before dividing into the right and left hepatic arteries. The portal vein forms from the superior mesenteric and splenic veins, and divides into right and left branches in the hilum of the liver.

the hepatic artery and portal vein within a fibrous sheath. The portal vein often gives off two large branches to the right lobe, which are accessible outside the liver for a short length, before giving a left portal vein branch that runs behind the left hepatic duct.

Venous drainage of the liver

The venous drainage of the liver is via the hepatic veins into the IVC. The vena cava lies within a groove in the posterior wall of the liver. Above the liver, it immediately penetrates the diaphragm to join the right atrium, whereas below the liver parenchyma, there is a short length of vessel before the insertion of the renal veins. The inferior hepatic veins are short vessels that pass directly between the liver parenchyma and the anterior wall of the IVC. The major venous drainage is through three large veins that join the IVC immediately below the diaphragm. Outside the liver, these vessels are surrounded by a thin fibrous layer. The right hepatic vein can be exposed fully outside the

liver, but the middle and left veins usually join within the liver parenchyma. The right kidney and adrenal gland lie immediately adjacent to the retrohepatic IVC. The right adrenal vein drains into the IVC at this level, usually via one main branch. The IVC can be mobilised fully from the retroperitoneal tissues and, in the healthy state, there are no large vessels in this tissue plane.

THE INTERNAL ANATOMY OF THE LIVER

Understanding the internal anatomy of the liver has greatly facilitated safe liver surgery. Couinaud, a French anatomist, described the liver as being divided into eight segments (Fig. 61.2). Each of these segments can be considered as a functional unit, with a branch of the hepatic artery, portal vein and bile duct, and drained by a branch of the hepatic vein. The overall anatomy of the liver is divided into a functional right and left along the line between the gall bladder fossa and the middle hepatic vein (Cantlie's line). Liver segments (V–VIII), to the right of this line, are supplied by the right hepatic artery and the right branch of the portal vein, and drain bile via the right hepatic duct. To the

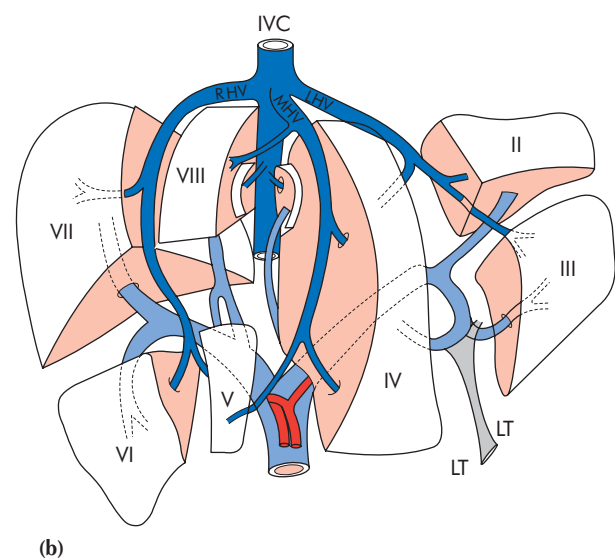

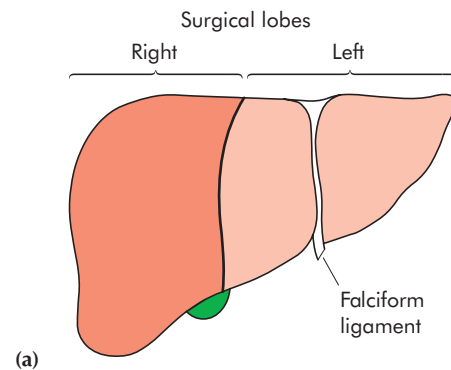

Figure 61.2 (a) The 'surgical' labels of the liver compared with the usual anatomical division into right and left lobes by the falciform ligament. (b) Segments of the liver (after Couinaud). IVC, inferior vena cava; RHV, right hepatic vein; LHV, left hepatic vein; LT, ligamentum teres; MHV, middle hepatic vein.

left of this line (segments I–IV), functionally, is the left liver, which is supplied by the left branch of the hepatic artery and the left portal vein branch, and drains bile via the left hepatic duct (Summary box 61.1).

Summary box 61.1

Liver anatomy

- The liver regenerates after partial resection
- There are two anatomical lobes with separate blood supply, bile duct and venous drainage
- Dual blood supply (20% hepatic artery and 80% portal vein)

The hepatic lobules

The functional units within the liver segments are the liver lobules. These comprise plates of liver cells separated by the hepatic sinusoids, large, thin-walled venous channels that carry blood to the central vein, a tributary of the hepatic vein, from the portal tracts, which contain branches of the hepatic artery and portal vein. During passage through the sinusoids, the many functions of the liver take place, including bile formation, which is channelled in an opposite direction to the blood flow to drain via the bile duct tributaries within the portal tracts.

Embryology

The liver is a foregut structure and forms as a small endodermal bud early in gestation. The cell population is bipotential, and cells may develop into hepatocytes or intrahepatic ductal cells. The liver endothelium is derived from the vitelline and umbilical veins, which merge with the endodermal bud to form the liver sinusoids. The supporting connective tissue, haemopoietic cells, important during intrauterine life, and Kupffer cells are derived from the mesoderm of the septum transversum.

ACUTE AND CHRONIC LIVER DISEASE

Liver function and tests

Adequate liver function is essential to survival; humans will survive for only 24–48 hours in the anhepatic state despite full supportive therapy. The liver is central to many key metabolic pathways (Summary box 61.2).

Summary box 61.2

Main functions of the liver

- Maintaining core body temperature
- pH balance and correction of lactic acidosis
- Synthesis of clotting factors
- Glucose metabolism, glycolysis and gluconeogenesis
- Urea formation from protein catabolism
- Bilirubin formation from haemoglobin degradation
- Drug and hormone metabolism
- Removal of gut endotoxins and foreign antigens

Karl Wilhelm von Kupffer, 1829–1902, Professor of Anatomy at Keil (1867), Königsberg (1875), and Munich, Germany (1880), described these ‘stellate cells’ in 1876.

An awareness of the currently available liver function tests and their significance is essential (Table 61.1).

Bilirubin is synthesised in the liver and excreted in the bile. Increased levels may be associated with increased haemoglobin breakdown, hepatocellular dysfunction resulting in impaired bilirubin transport and excretion, or biliary obstruction. In patients with known parenchymal liver disease, progressive elevation of bilirubin in the absence of a secondary complication suggests deterioration in liver function. The serum alkaline phosphatase is particularly elevated with cholestatic liver disease or biliary obstruction. The transaminase levels [aspartate transaminase (AST) and alanine transaminase (ALT)] reflect acute hepatocellular damage, as does the gamma-glutamyl transpeptidase (GGT) level, which may be used to detect the liver injury associated with acute alcohol ingestion. The synthetic functions of the liver are reflected in the ability to synthesise proteins (albumin level) and clotting factors (prothrombin time). The standard method of monitoring liver function in patients with chronic liver disease is serial measurement of bilirubin, albumin and prothrombin time.

Clinical signs of impaired liver function

These signs depend on the severity of dysfunction and whether it is acute or chronic.

Acute liver failure

Causes of acute liver failure

In the early stages there may be no objective signs, but with severe dysfunction the onset of clinical jaundice may be associated with neurological signs of liver failure, consisting of a liver flap, drowsiness, confusion and, eventually, coma (Summary box 61.3).

Summary box 61.3

Causes of acute liver failure

- Viral hepatitis (hepatitis A, B, C, D, E)
- Drug reactions [halothane, isoniazid–rifampicin, antidepressants, non-steroidal anti-inflammatory drugs, valproic acid]
- Paracetamol overdose
- Mushroom poisoning
- Shock and multiorgan failure
- Acute Budd–Chiari syndrome
- Wilson’s disease
- Fatty liver of pregnancy

Treatment of acute liver failure

The overall mortality from acute liver failure is approximately 50%, even with the best supportive therapy (Summary box 61.4).

Table 61.1 Routinely available tests of liver function

Test	Normal range
Bilirubin	5–17 $\mu\text{mol l}^{-1}$
Alkaline phosphatase (ALP)	35–130 IU l^{-1}
Aspartate transaminase (AST)	5–40 IU l^{-1}
Alanine transaminase (ALT)	5–40 IU l^{-1}
Gamma-glutamyl transpeptidase (GGT)	10–48 IU l^{-1}
Albumin	35–50 g l^{-1}
Prothrombin time (PT)	12–16 s

Summary box 61.4

Supportive therapy for acute liver failure

- Fluid balance and electrolytes
- Acid–base balance and blood glucose monitoring
- Nutrition
- Renal function (haemofiltration)
- Respiratory support (ventilation)
- Monitoring and treatment of cerebral oedema
- Treat bacterial and fungal infection

Liver transplantation is appropriate for some patients with acute liver failure (Summary box 61.5), although the overall results are poor in comparison with liver transplantation for chronic liver disease.

Summary box 61.5

King's College criteria for orthotopic liver transplantation in acute liver failure

Paracetamol induced

- pH < 7.30 irrespective of grade of encephalopathy or prothrombin time (PT) > 100 s + serum creatinine > 300 $\mu\text{mol l}^{-1}$ (with grade 3 or 4 encephalopathy)

Non-paracetamol induced (irrespective of encephalopathy)

- PT > 100 g or any three of the following:
 - Age < 10 years or > 40 years
 - Aetiology non-A, non-B, halothane or idiosyncratic drug reaction
 - More than 7 days' jaundice before encephalopathy
- PT > 50 s
- Bilirubin > 300 $\mu\text{mol l}^{-1}$

Chronic liver disease

Lethargy and weakness are common features irrespective of the underlying cause. This often precedes clinical jaundice, which indicates the liver's inability to metabolise bilirubin. The serum bilirubin level reflects the severity of the underlying liver disease. Progressive deterioration in liver function is associated with a hyperdynamic circulation involving a high cardiac output, large pulse volume, low blood pressure and flushed warm extremities. Fever is a common feature, which may be related to underlying inflammation and cytokine release from the diseased liver or may be due to bacterial infection, to which patients with chronic liver disease are predisposed. Skin changes may be evident, including spider naevi, cutaneous vascular abnormalities that blanch on pressure, palmar erythema and white nails (leuconychia). Endocrine abnormalities are responsible for hypogonadism and gynaecomastia. The mental derangement associated with chronic liver disease is termed 'hepatic encephalopathy'. This is associated with memory impairment, confusion, personality changes, altered sleep patterns and slow, slurred speech. The most useful clinical sign is the flapping tremor demonstrated by asking the patient to extend his or her arms and hyperextend the

King's College Hospital London, England, a pioneering centre for liver transplantation.

wrist joint. Abdominal distension due to ascites is a common late feature. This may be suggested clinically by the demonstration of a fluid thrill or shifting dullness. Protein catabolism produces loss of muscle bulk and wasting, and a coagulation defect is suggested by the presence of skin bruising. A patient with the typical features of end-stage chronic liver disease is shown in Figure 61.3 (Summary box 61.6).

Summary box 61.6

Features of chronic liver disease

- Lethargy
- Fever
- Jaundice
- Protein catabolism (wasting)
- Coagulopathy (bruising)
- Cardiac (hyperdynamic circulation)
- Neurological (hepatic encephalopathy)
- Portal hypertension
 - Ascites
 - Oesophageal varices
 - Splenomegaly
- Cutaneous
 - Spider naevi
 - Palmar erythema

Classifying the severity of chronic liver disease

Classification is shown in Table 61.2.

Table 61.2 Child's classification of hepatocellular function in cirrhosis (using original units of measurement)

Group designation	A	B	C
Bilirubin (mg dl ⁻¹)	< 2.0	2.0–3.0	> 3.0
Albumin (g dl ⁻¹)	> 3.5	3.0–3.5	< 3.0
Ascites	None	Easily controlled	Poorly controlled
Neurological disorder	None	Minimal	Advanced
Nutrition	Excellent	Good	Wasting

Figure 61.3 A patient with end-stage liver cirrhosis disease, demonstrating muscle wasting and gross abdominal distension due to ascites.

IMAGING THE LIVER

The major advances that have taken place over recent years in surgical approaches to the liver and the enormous improvement in the safety of liver surgery are a result of the careful individualised planning of surgery achieved through improvements in preoperative imaging. The ideal choice of imaging modality is determined by the likely liver pathology and the locally available equipment and radiological expertise (Table 61.3).

Ultrasound

This is the first-line test owing to its safety and availability. It is entirely operator dependent. It is useful for determining bile duct dilatation, the presence of gallstones (Fig. 61.4) and the presence of liver tumours. Doppler ultrasound allows flow in the hepatic artery, portal vein and hepatic veins to be assessed. In some countries, it is used as a screening test for the development of primary liver cancers in a high-risk population. Ultrasound is useful in guiding the percutaneous biopsy of a liver lesion.

Computerised tomography

The current 'gold standard' for liver imaging is triple-phase, multislice, spiral computerised tomography (CT). This provides fine detail of liver lesions down to less than 1 cm in diameter and gives information on their nature (Fig. 61.5). Oral contrast enhancement allows visualisation of the stomach and duodenum in relation to the liver hilum. The early arterial phase of the intravenous contrast vascular enhancement is particularly useful for detecting small liver cancers, owing to their preferential arterial blood supply. The venous phase maps the branches of the portal vein within the liver and the drainage via the hepatic veins. Inflammatory liver lesions often exhibit rim enhancement with intravenous contrast, whereas the common haemangioma characteristically shows late venous enhancement. The density of any liver lesion can be measured, which can be useful in establishing the presence of a cystic lesion.

Table 61.3 Imaging the liver

Imaging modality	Principal indication
Ultrasound	Standard first-line investigation
Spiral CT	Anatomical planning for liver surgery
MRI	Alternative to spiral CT
MRCP	First-line, non-invasive cholangiography
ERCP	Imaging the biliary tract when endoscopic intervention is anticipated (e.g. ductal stones)
PTC	Biliary tract imaging when ERCP impossible or failed
Angiography	To detect vascular involvement by tumour
Nuclear medicine	To quantify biliary excretion and tumour spread
Laparoscopy/ laparoscopic ultrasound	To detect peritoneal tumour spread and superficial liver metastases

CT, computerised tomography; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography; MRI, magnetic resonance imaging; PTC, percutaneous transhepatic cholangiography.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

Figure 61.4 Ultrasound scan of the upper abdomen, showing the liver on the left and a gall bladder containing multiple gallstones centrally. The stones can be seen to cast an acoustic shadow.

Figure 61.5 Computerised tomography (CT) scan of a patient with a liver tumour in the left lobe of the liver, using intravenous contrast enhancement. The vascularity of the lesion and, hence, its possible nature can be determined from the arterial (a) and venous (b) phases of the scan.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) (Fig. 61.6) would appear to be as effective an imaging modality as CT in the majority of patients with liver disease. It does, however, offer several advantages. First, the use of iodine-containing intravenous contrast agents is precluded in many patients because of a history of allergy. These patients should be offered MRI rather than contrast CT. Second, magnetic resonance cholangiopancreatography (MRCP) provides excellent quality, non-invasive imaging of the biliary tract. The image quality is currently below that available from endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC), but this is rapidly improving. It is useful for diagnostic questions when ERCP has failed or is impossible due to previous surgery. Magnetic resonance angiography (MRA) similarly provides high-quality images of the hepatic artery and portal vein, without the need for arterial cannulation. It is used as an alternative to selective hepatic angiography for diagnosis. It is

Figure 61.6 The role of magnetic resonance (MR) in liver disease. MR is increasingly used for imaging the liver. It may be used for cross-sectional imaging for staging liver cancers (MRI) (a), for non-invasive cholangiography to demonstrate a hilar stricture (magnetic resonance cholangiopancreatography, MRCP) (b) or for the non-invasive assessment of blood vessels (magnetic resonance angiography, MRA).

particularly useful in patients with chronic liver disease and a coagulopathy in whom the patency of the portal vein and its branches is in question.

Endoscopic retrograde cholangiopancreatography

ERCP (Fig. 61.7a) is required in patients with obstructive jaundice who cannot undergo MRCP because of claustrophobia or where an endoscopic intervention is anticipated based on previous imaging [endoscopic removal of common bile duct (CBD) stones or insertion of a palliative biliary tract stent]. A

Figure 61.7 (a) Endoscopic retrograde cholangiopancreatography demonstrating the biliary tract with multiple stones in the distal common bile duct. (b) Percutaneous transhepatic cholangiography. Some contrast has extravasated at the site of hepatic puncture of the percutaneously placed needle, but the biliary tract is clearly demonstrated and shows the multiple strictures typical of primary sclerosing cholangitis.

preoperative check of coagulation is essential, along with prophylactic antibiotics and an explanation of the main complications, which include pancreatitis, cholangitis and bleeding or perforation of the duodenum related to sphincterotomy.

Percutaneous transhepatic cholangiography

PTC is indicated where endoscopic cholangiography has failed or is impossible, e.g. in patients with previous pancreatoduodenectomy or Pólya gastrectomy. It is often required in patients with hilar bile duct tumours to guide external drainage of the bile ducts to relieve jaundice and to direct stent insertion (Fig. 61.7b).

Angiography

Selective visceral angiography (see Fig. 61.1, p. 1081) may be required for diagnostic purposes but, with improving cross-sectional imaging (CT and MR angiography), is usually employed for therapeutic intervention. Prior to liver resection, it may be used to visualise the anatomy of the hepatic artery to the right and left sides of the liver and to confirm patency or tumour involvement of the portal vein. It can also provide additional information on the nature of a liver nodule, as primary liver tumours have a well-developed arterial blood supply. Therapeutic interventions include the occlusion of arteriovenous malformations, the embolisation of bleeding sites in the liver and the treatment of liver tumours (transarterial embolisation, TAE).

Nuclear medicine scanning

Radioisotope scanning can provide diagnostic information that cannot be obtained by other imaging modalities. Iodoida is a technetium-99m (^{99m}Tc)-labelled radionuclide that is administered intravenously, removed from the circulation by the liver, processed by hepatocytes and excreted in the bile. Imaging under a gamma camera allows its uptake and excretion to be monitored in real time. These data are particularly useful when a bile leak or biliary obstruction is suspected and a non-invasive screening test is required. A sulphur colloid liver scan allows Kupffer cell activity in the liver to be determined. This may be particularly useful to confirm the nature of a liver lesion; adenomas and haemangiomas lack Kupffer cells and hence show no uptake of sulphur colloid.

^{18}F -2-fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) depends on the avid uptake of glucose by cancerous tissue in comparison with benign or inflammatory tissue. At present, it is mainly used to determine the nature of a mass lesion demonstrated on another form of imaging. Deoxyglucose is labelled with the positron emitter fluorine-18 (^{18}F FDG), and this is administered to the patient prior to imaging by PET. A three-dimensional image of the whole body is obtained, highlighting areas of increased glucose metabolism (Fig. 61.8).

Laparoscopy and laparoscopic ultrasound

Laparoscopy is useful for the staging of hepatopancreatobiliary cancers. Lesions overlooked by conventional imaging are mainly peritoneal metastases and superficial liver tumours. Approximately 10–30% of patients have additional lesions detected by laparoscopy, dependent on the quality of planar imaging by CT and MRI. Laparoscopic ultrasound may increase this figure and provides additional information for liver tumours on their proximity to the major vessels and bile duct branches.

LIVER TRAUMA

General

Liver injuries are fortunately uncommon because of the position of the liver under the diaphragm where it is protected by the chest wall. However, when liver injury occurs, it is serious and can be associated with significant morbidity and mortality, even with prompt and appropriate management.

Liver trauma can be divided into blunt and penetrating injuries. Blunt injury produces contusion, laceration and avulsion injuries to the liver, often in association with splenic, mesenteric or renal injury. Penetrating injuries, such as stab and gunshot wounds, are often associated with chest or pericardial involvement (Summary box 61.7).

Summary box 61.7

Management of liver trauma

- Remember associated injuries
- At-risk groups
 - Stabbing/gunshot in lower chest or upper abdomen
 - Crush injury with multiple rib fractures
- Resuscitate
 - Airway
 - Breathing
 - Circulation
- Assessment of injury
 - Spiral CT with contrast
 - Laparotomy if haemodynamically unstable
- Treatment
 - Correct coagulopathy
 - Suture lacerations
 - Resect if major vascular injury
 - Packing if diffuse parenchymal injury

Diagnosis of liver injury

The liver is an extremely well-vascularised organ, and blood loss is therefore the major early complication of liver injuries. Clinical suspicion of a possible liver injury is essential, as a laparotomy by an inexperienced surgeon with inadequate preparation preoperatively is doomed to failure. All lower chest and upper abdominal stab wounds should be suspect, especially if considerable blood volume replacement has been required. Similarly, severe crushing injuries to the lower chest or upper abdomen often combine rib fractures, haemothorax and damage to the spleen and/or liver. Patients with a penetrating wound will require a laparotomy and/or thoracotomy once active resuscitation is under way. Owing to the opportunity for massive on-going blood loss and the rapid development of a coagulopathy, the patient should be directly transferred to the operating theatre while blood products are obtained and volume replacement is taking place. Patients who are haemodynamically stable should have an oral and intravenous contrast-enhanced CT scan of the chest and abdomen. This will demonstrate evidence of parenchymal damage to the liver or spleen as well as associated traumatic injuries to their feeding vessels. Free fluid can also be clearly established and a diagnostic aspirate performed. The chest scan will help to exclude injuries to the great vessels and demonstrate damage to the lung parenchyma. Additional investigations that may be of value include peritoneal lavage, which can confirm the presence of haemoperitoneum, and laparoscopy, which can demonstrate an associated diaphragmatic rupture.

Initial management of liver injuries

Penetrating

The initial management of a patient with an upper abdominal penetrating injury is the basis of resuscitation. The initial survey assesses the patient's airway patency, breathing pattern and circulation. Peripheral venous access is gained with two large-bore cannulae and blood sent for cross-match of 10 units of blood, full blood count, urea and electrolytes, liver function tests, clotting screen, glucose and amylase. Initial volume replacement should be with colloid or O-negative blood if necessary. Arterial blood gases should be obtained and the patient intubated and ventilated if the gas exchange is inadequate. Intercostal chest drains should be inserted if associated pneumothorax or haemothorax is suspected. Once initial resuscitation has commenced, the patient should be transferred to the operating theatre, with further resuscitation performed on the operating table. The necessity for fresh frozen plasma and cryoprecipitate should be discussed with the blood transfusion service immediately the patient arrives, as these patients rapidly develop irreversible coagulopathies due to a lack of fibrinogen and clotting factors. Standard coagulation profiles are inadequate to evaluate this acute loss of clotting factors, and factors should be given empirically, aided by the results of thromboelastography (TEG), if available (Fig. 61.9).

Blunt trauma

With severe blunt injuries, the plan for resuscitation and management is as outlined above for penetrating injuries. For the patient who is haemodynamically stable, imaging by CT should be performed to further evaluate the nature of the injury. The basic surgical management differs between penetrating and blunt injuries thought to involve the liver; penetrating injuries should be explored, whereas blunt injuries can be treated conservatively.

Figure 61.9 Thromboelastography (TEG). This dynamic form of assessing the coagulation status is being used increasingly for intraoperative monitoring. The shape of the TEG trace defines the nature of the underlying coagulation deficiency as shown. A, normal; B, delayed clot formation; C, reduced clot strength; D, clot lysis; E, hypercoagulable.

The indication for discontinuing conservative treatment for blunt trauma would be evidence of on-going blood loss despite correction of any underlying coagulopathy and the development of signs of generalised peritonitis.

The surgical approach to liver trauma

Good access is vital. A rooftop incision gives excellent visualisation of the liver and spleen and, if necessary, can be extended upwards for a median sternotomy. A stab incision in the liver can be sutured with a fine absorbable monofilament suture. If necessary, this may be facilitated by producing vascular inflow occlusion by placing an atraumatic clamp across the foramen of Winslow (the Pringle manoeuvre). Lacerations to the hepatic artery should be identified by placing an atraumatic bulldog clamp on the proximal vessel prior to repair with 5/0 or 6/0 Prolene suture. If unavoidable, the hepatic artery may be ligated, although parenchymal necrosis and abscess formation will result in some individuals. Portal vein injuries should be repaired with 5/0 Prolene, again with exposure of the vessel being facilitated by the placement of an atraumatic vascular clamp.

Deceleration injuries often produce lacerations of the liver parenchyma adjacent to the anchoring ligaments of the liver. These may be amenable to suture with an absorbable monofilament suture. Again, inflow occlusion may facilitate this suturing and, if necessary, the sutures can be buttressed to prevent them cutting through the liver parenchyma. With more severe deceleration injuries, a portion of the liver may be avulsed. These injuries are more complex as they are associated with a devitalised portion of the liver and, often, major injuries to the hepatic veins and IVC. Diffuse parenchymal injuries should be treated by packing the liver to produce haemostasis. This is effective for the majority of liver injuries if the liver is packed against the natural contour of the diaphragm by packing from below. Large abdominal packs should be used to ease their removal, and the abdomen closed to facilitate compression of the parenchyma. Care should be taken to avoid overzealous packing, as this may produce pressure necrosis of the liver parenchyma.

Jacob Benignus Winslow, 1669–1760, Professor of Anatomy, Physic, and Surgery, Paris, France.
James Hogarth Pringle, 1863–1941, Surgeon, The Royal Infirmary, Glasgow, Scotland.

Crush injuries to the liver often result in large parenchymal haematomas and diffuse capsular lacerations. Suturing is usually ineffective, and packing is the most useful method of providing haemostasis. Necrotic tissue should be removed, but poorly perfused, though viable, liver left *in situ*. If packing is necessary, the patient should have the packs removed after 48 hours, and usually no further surgical intervention is required. Antibiotic cover is advisable, and full reversal of any coagulopathy is essential. If a major liver vascular injury is suspected at the time of the initial laparotomy, then referral to a specialist centre should be considered. A common surgical approach in these circumstances would be to place the patient on veno-venous bypass using cannulae in the femoral vein via a long saphenous cut-down with the blood returned, using a roller pump, to the superior vena cava (SVC) via an internal jugular line. Veno-venous bypass allows the IVC to be safely clamped to facilitate caval or hepatic vein repair. A rapid infuser blood transfusion machine facilitates the delivery of large volumes of blood instantaneously. Once prepared, the patient is re-laparotomised via the rooftop incision with a midline extension to the xiphisternum. The liver is mobilised by division of the supporting ligaments, and complete vascular isolation of the liver is achieved by occluding the hilar inflow and the IVC above the renal veins and at the level of the diaphragm with atraumatic vascular clamps. Venous return is provided by the veno-venous bypass. Warm ischaemia of the liver is tolerated for up to 45 min, allowing sufficient time in a blood-free field for repair of injuries to the IVC or hepatic veins.

Other complications of liver trauma

A subcapsular or intrahepatic haematoma requires no specific intervention and should be allowed to resolve spontaneously. Abscesses may form as a result of secondary infection of an area of parenchymal ischaemia, especially after penetrating trauma. Treatment is with systemic antibiotics and aspiration under ultrasound guidance once the necrotic tissue has liquefied. Bile collections require aspiration under ultrasound guidance or percutaneous insertion of a pigtail drain. The site of origin of a biliary fistula should be determined by endoscopic or percutaneous cholangiography, and biliary decompression achieved by nasobiliary or percutaneous transhepatic drainage or endoprosthesis insertion. If this fails to control the fistula, the affected portion of the liver may require resection. Late vascular complications include hepatic artery aneurysm and arteriovenous or arteriohepatic fistulae (Fig. 61.10). These are best treated non-surgically by a specialist hepatobiliary interventional radiologist. The feeding vessel can be embolised transarterially.

Hepatic failure may occur following extensive liver trauma. This will usually reverse with conservative supportive treatment if the blood supply and biliary drainage of the liver are intact (Summary box 61.8).

Summary box 61.8

Other complications of liver trauma

- Intrahepatic haematoma
- Liver abscess
- Bile collection
- Biliary fistula
- Hepatic artery aneurysm
- Arteriovenous fistula
- Arteriohepatic fistula
- Liver failure

Figure 61.10 Hepatic aneurysm following liver trauma. An aneurysm arising from the right hepatic artery (arrow), which can be optimally treated by the interventional radiologist using transarterial embolisation.

Long-term outcome of liver trauma

The capacity of the liver to recover from extensive trauma is remarkable, and parenchymal regeneration occurs rapidly. Late complications are rare, but the development of biliary tract strictures many years after recovery from liver trauma has been reported. The treatment depends on the mode of presentation and the extent and site of stricturing. A segmental or lobar stricture, associated with atrophy of the corresponding area of liver parenchyma and compensatory hypertrophy of the other liver lobe, may be treated expectantly. A dominant extrahepatic bile duct stricture associated with obstructive jaundice may be treated initially with endobiliary balloon dilatation or stenting, but will usually require surgical correction using a Roux-en-Y hepatochojejunostomy.

PORTAL HYPERTENSION

An elevation in portal pressure is most commonly found in the presence of liver cirrhosis, although it may be present in patients with extrahepatic portal vein occlusion, intrahepatic veno-occlusive disease or occlusion of the main hepatic veins [Budd–Chiari syndrome (BCS)]. As portal hypertension produces no symptoms, it is usually diagnosed following presentation with decompensated chronic liver disease and encephalopathy, ascites or variceal bleeding.

Management of bleeding varices

General resuscitation

Varices usually present with the acute onset of a large-volume haematemesis, the lower oesophagus being the most common site

Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.

for variceal bleeding. The diagnosis may be suspected if the patient is known to have liver cirrhosis, but it needs to be confirmed following initial resuscitation of the patient. This involves obtaining peripheral and subsequently central venous access while adequate blood is obtained (initially 10 units). Liver function tests will reveal underlying liver disease, and a coagulation profile will reveal any underlying coagulopathy. Vitamin K is administered [10 mg intravenously (i.v.)], but correction of a coagulopathy will require the administration of fresh frozen plasma (FFP). An associated thrombocytopenia is usually secondary to hypersplenism due to cirrhosis and is treated if the platelet count falls below $50 \times 10^9 \text{ l}^{-1}$. Variceal bleeding is often associated with hepatic encephalopathy and, in these circumstances, endoscopic evaluation may require sedation and mechanical ventilation. Bronchial aspiration is a frequent complication of variceal bleeding (Summary box 61.9).

Summary box 61.9

Management of bleeding oesophageal varices

- Blood transfusion
- Correct coagulopathy
- Oesophageal balloon tamponade (Sengstaken–Blakemore tube)
- Drug therapy (vasopressin/octreotide)
- Endoscopic sclerotherapy or banding
- Assess portal vein patency (Doppler ultrasound or CT)
- Transjugular intrahepatic portosystemic stent shunts (TIPSS)
- Surgery
 - Portosystemic shunts
 - Oesophageal transection
 - Splenectomy and gastric devascularisation

If the rate of blood loss prohibits endoscopic evaluation, a Sengstaken–Blakemore tube may be inserted to provide temporary haemostasis. This is shown diagrammatically in Figure 61.11. Once inserted, the gastric balloon is inflated with 300 ml of air and retracted to the gastric fundus, where the varices at the oesophagogastric junction are tamponaded by the subsequent inflation of the oesophageal balloon to a pressure of 40 mmHg. The two remaining channels allow gastric and oesophageal aspiration. A radiograph is used to confirm the position of the tube. The balloons should be temporarily deflated after 12 hours to prevent pressure necrosis of the oesophagus.

Drug treatment for variceal bleeding

This may be as effective as sclerotherapy in the initial control of variceal haemorrhage. Vasopressin has been the most extensively used drug for the initial control of variceal haemorrhage (20 U in 10 ml of 5% dextrose i.v. over 10 min). Octreotide, the long-acting somatostatin analogue, may be equally effective.

Endoscopic treatment of varices

Initial treatment of oesophageal varices in most centres is endoscopic sclerotherapy, using ethanolamine oleate or butyl

Robert William Sengstaken, B. 1923, Surgeon, Garden City, New York, NY, USA.
Arthur Hendley Blakemore, Associate Professor of Surgery, The Columbia College of Physicians and Surgeons, New York, NY, USA.

Figure 61.11 Oesophageal balloon tamponade.

cyanoacrylate. Banding may be equally effective and is associated with a lower incidence of oesophageal ulceration. The majority of variceal bleeds will respond to a single course. An early rebleed is less likely to be controlled by further sclerotherapy and a third bleed only rarely.

Transjugular intrahepatic portosystemic stent shunts

The emergency management of variceal haemorrhage has been revolutionised by the introduction of transjugular intrahepatic portosystemic stent shunts (TIPSS) in 1988. Over a short period, it has become the main treatment of variceal haemorrhage that has not responded to drug treatment and endoscopic therapy. The shunts are inserted under local anaesthetic, analgesia and sedation using fluoroscopic guidance and ultrasonography. Via the internal jugular vein and SVC, a guidewire is inserted into a hepatic vein and through the hepatic parenchyma into a branch of the portal vein. The track through the parenchyma is then dilated with a balloon catheter to allow insertion of a metallic stent, which is expanded once a satisfactory position is achieved (Fig. 61.12). A satisfactory drop in portal venous pressure is usually associated with good control of the variceal haemorrhage. The main early complication of this technique is perforation of the liver capsule, which can be associated with fatal intraperitoneal haemorrhage. TIPSS occlusion may result in further variceal haemorrhage and occurs more commonly in patients with well-compensated liver disease and good synthetic function. Post-shunt encephalopathy is the confusional state caused by the portal blood bypassing the detoxification of the liver. It occurs in about 40% of patients, a similar incidence to that found after surgical shunts. If severe, the lumen of the TIPSS can be reduced by insertion of a smaller stent. The main contraindication to TIPSS is portal vein occlusion. The main long-term complication of TIPSS is stenosis of the shunt, which is common (approximately 50% at 1 year) and may present as further variceal haemorrhage.

Figure 61.12 A check angiogram following insertion of a transjugular intrahepatic portosystemic stent shunt (open arrow). Injection of contrast into the portal vein flows through the metallic stent and outlines the right hepatic vein. Pressure measurements are taken from within the portal vein before and after insertion. Solid arrows indicate coils placed at the site of previous embolisation.

Surgical shunts for variceal haemorrhage

The increasing availability of liver transplantation and TIPSS has greatly reduced the indications for surgical shunts. It is rarely considered for the acute management of variceal haemorrhage, as the morbidity and mortality in these circumstances are high. The main current indication for a surgical shunt is a patient with Child's grade A cirrhosis, in whom the initial bleed has been controlled by sclerotherapy. Long-term β -blocker therapy and chronic sclerotherapy or banding are the main alternatives.

Surgical shunts are an effective method of preventing rebleeding from oesophageal or gastric varices, as they reduce the pressure in the portal circulation by diverting the blood into the low-pressure systemic circulation. Shunts may be divided into selective (e.g. splenorenal) and non-selective (e.g. portocaval), the former attempting to preserve blood flow to the liver while decompressing the left side of the portal circulation responsible for giving rise to the oesophageal and gastric varices. Selective shunts may be associated with a lower incidence of portal systemic encephalopathy (PSE), a confusional state commonly found in patients with chronic liver disease who have undergone radiological or surgical portosystemic shunts. The different types of surgical shunt are shown in Figure 61.13. There is no evidence that prophylactic shunting is beneficial in patients with varices that have not bled.

Oesophageal stapled transection

This technique for the management of bleeding oesophageal varices uses the circular stapling device, initially used for anastomosis of the rectum, for stapling and resecting a doughnut ring of the lower oesophagus. As with surgical shunts in the acute situation, it was associated with a high perioperative mortality and has been largely abandoned in centres where TIPSS is available.

Figure 61.13 (a–d) Surgical shunts. Surgical shunts for portal hypertension involve shunting portal blood into the systemic veins. This commonly involves a side-to-side portocaval anastomosis (a) or end-to-side portocaval (b), mesocaval (c) or splenorenal (d) anastomoses.

Management of recurrent variceal bleeds secondary to splenic or portal vein thrombosis

Treatment is by splenectomy and gastro-oesophageal devascularisation, in which the blood supply to the greater and lesser curve of the stomach and lower oesophagus is divided. Splenic vein thrombosis may be seen secondary to chronic pancreatitis, and portal vein thrombosis is a common late complication of liver cirrhosis.

Variceal bleeding and orthotopic liver transplantation

The management of variceal bleeding should always take into account the possibility of liver transplantation when this is available. Age > 65 years or a history of ischaemic heart disease, heart failure or chronic respiratory disease would contraindicate transplantation. TIPSS would be the preferred management for bleeds resistant to sclerotherapy, as long as placement is optimal. Previous surgical shunts greatly increase the morbidity associated with orthotopic liver transplantation and probably the mortality.

Ascites

The accumulation of free peritoneal fluid is a common feature of advanced liver disease independent of the aetiology. The fluid accumulation is usually associated with abdominal discomfort and a dragging sensation. Development is usually insidious. The aetiology of the ascites must be established (Summary box 61.10).

Summary box 61.10

Determining the cause of ascites

Imaging (ultrasound or CT)

- Irregular cirrhotic liver
- Portal vein patency
- Splenomegaly of cirrhosis

Aspiration

- Culture and microscopy
- Protein content
- Cytology
- Amylase level

Imaging by CT will confirm the ascites and demonstrate the irregular and shrunken nature of a cirrhotic liver and associated splenomegaly. Intravenous contrast enhancement will allow abdominal varices to be demonstrated and patency of the portal vein, as portal vein thrombosis is a common predisposing factor to the development of ascites in chronic liver disease. In patients without evidence of liver disease, malignancy is a common cause, and the primary site may also be established on CT. Aspiration of the peritoneal fluid allows the measurement of protein content to determine whether the fluid is an exudate or transudate, and an amylase estimation to exclude pancreatic ascites. Cytology will determine the presence of cancerous cells, and both microscopy and culture will exclude primary bacterial peritonitis and tuberculous peritonitis. Urinary sodium excretion is used as a guide to diuretic therapy in cirrhosis.

Treatment of ascites in chronic liver disease

The initial treatment is to restrict additional salt intake and commence diuretics using either spironolactone or furosemide. This

should be combined with advice on avoiding any precipitating factors for impaired liver function, such as alcohol intake in patients with alcoholic cirrhosis. Patients on diuretics should be monitored for the development of hyponatraemia and hypokalaemia (Summary box 61.11).

Summary box 61.11

Treatment of ascites in chronic liver disease

- Salt restriction
- Diuretics
- Abdominal paracentesis
- Peritoneovenous shunting
- TIPSS
- Liver transplantation

Abdominal paracentesis

Patients who fail to respond to diuretic treatment may require repeated percutaneous aspiration of the ascites (abdominal paracentesis), combined with volume replacement using salt-poor or standard human albumin solution, dependent on the serum sodium level. Paracentesis provides only short-term symptomatic relief.

Peritoneovenous shunting

The Le Vein shunt is designed for the relief of ascites due to chronic liver disease. One end of the silastic tube is inserted into the ascites within the peritoneal cavity and the other end is tunnelled subcutaneously to the neck, where it is inserted under direct vision into the internal jugular vein and fed into the SVC. Owing to a one-way valve within the tubing, peritoneal fluid is drawn from the abdomen and drained to the circulation due to the lower pressure in the SVC in comparison with the abdomen during the respiratory cycle. Complications include occlusion, displacement and infection. In an attempt to prevent the high occlusion rate, a further development was the insertion of a chamber placed over the costal margin to allow digital pressure and evacuation of any debris within the peritoneovenous shunt (Denver shunt).

TIPSS for ascites

The procedure and its limitations are as outlined above for the emergency treatment of bleeding varices secondary to portal hypertension. The use of TIPSS for ascites is for symptomatic relief, and the procedure is associated with considerable risks, including death from haemorrhage, renal failure or heart failure. Post-stent encephalopathy is common (about 40%), and the majority of stents will stenose on follow-up (approximately 50% by 1 year). Although a useful treatment modality, it has not become widely used because ascites is of itself not life-threatening. More encouraging results have been obtained in those with persistent chylothorax.

Liver transplantation for ascites

Diuretic-resistant ascites is an indication for liver transplantation if associated with deterioration in liver function (rising bilirubin, dropping albumin, prolonged prothrombin time). The patient's

Harry LeVeen, Professor of Surgery, The University of South Carolina, SC, USA.

age, underlying aetiology of liver disease and associated medical problems will be the major factors determining suitability for liver transplantation. In those considered inappropriate for liver transplantation, management is aimed at symptomatic control of ascites.

CHRONIC LIVER CONDITIONS

There are several chronic liver conditions, which, although rare, are important to recognise because they require a specific plan for investigation and treatment, and may present mimicking a more common clinical condition (Table 61.4).

Budd–Chiari syndrome

This is a condition principally affecting young females, in which the venous drainage of the liver is occluded by hepatic venous thrombosis or obstruction from a venous web. As a result of venous outflow obstruction, the liver becomes acutely congested, with the development of impaired liver function and, subsequently, portal hypertension, ascites and oesophageal varices. In an acute thrombosis, the patient may rapidly progress to fulminant liver failure but, in the majority of cases, abdominal discomfort and ascites are the main presenting features. If chronic, the liver progresses to established cirrhosis. The cause of the venous thrombosis needs to be established, and an underlying myeloproliferative disorder or pro-coagulant state is commonly found, such as anti-thrombin 3, protein C or protein S deficiency. The diagnosis is commonly suspected in a patient presenting with ascites, in whom a CT scan shows a large congested liver (early stage, Fig. 61.14) or a small cirrhotic liver in which there is gross enlargement of segment I (the caudate lobe). This feature results from preservation and hypertrophy of the segment with direct venous drainage to the IVC in the face of atrophy of the rest of the liver due to venous obstruction (Fig. 61.15). IVC compression or occlusion from the segment I hypertrophy is also a common feature, as is thrombosis of the portal vein. Confirmation of the suspected diagnosis is by hepatic venography via a transjugular approach, which demonstrates occlusion of the hepatic veins and may allow a transjugular biopsy.

Treatment of BCS must be tailored to the individual patient and, in particular, to the stage of disease at presentation. Patients presenting in fulminant liver failure should be considered for liver transplantation, as should those with established cirrhosis and

Table 61.4 Important chronic liver conditions

Condition	Common presentations
Budd–Chiari syndrome	Ascites
Primary sclerosing cholangitis (PSC)	Abnormal LFTs or jaundice
Primary biliary cirrhosis (PBC)	Malaise, lethargy, itching, abnormal LFTs
Caroli's disease	Abdominal pain, sepsis
Simple liver cysts	Coincidental finding, pain
Polycystic liver disease	Hepatomegaly, pain

LFTs, liver function tests.

George Budd, 1808–1882, Professor of Medicine, King's College Hospital London, England, described this syndrome in 1845.

Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany, (Strasbourg was returned to France in 1918 at the end of the First World War), gave his account of this condition in 1898.

Figure 61.14 Computerised tomography scan in early Budd–Chiari syndrome.

Figure 61.15 Segment I hypertrophy with Budd–Chiari syndrome.

the complications of portal hypertension. Those in whom cirrhosis is not established may be considered for portosystemic shunting by TIPSS, portocaval shunt or mesoatrial shunting. IVC compression may be relieved by the insertion of a retrohepatic expandable metallic stent. If the BCS is treated satisfactorily, the prognosis of this patient group is largely dependent on the underlying aetiology and whether this is amenable to treatment. Patients are usually left on lifelong anticoagulation with warfarin.

Primary sclerosing cholangitis

This condition often presents in young adults with mild non-specific symptoms, and biliary disease is suggested by the finding of abnormal liver function tests. Rarely, the first presentation is with jaundice due to biliary obstruction. The disease process results in progressive fibrous stricturing and obliteration of both

the intrahepatic and the extrahepatic bile ducts. Although the aetiology is unknown, a genetic predisposition is likely owing to its association with chronic ulcerative colitis (UC). In patients with primary sclerosing cholangitis (PSC) and UC, the condition usually progresses even if the diseased colon is removed. The diagnosis is principally based on the findings at cholangiography, in which irregular, narrowed bile ducts are demonstrated in both the intrahepatic and the extrahepatic biliary tree (Fig. 61.16). If the radiological appearances are equivocal, a liver biopsy is required to demonstrate the fibrous obliteration of the biliary tracts. There is no specific treatment that can reverse the ductal changes, and the patients usually slowly progress to progressive cholestasis and death from liver failure. There is a strong predisposition to cholangiocarcinoma, and this should be considered in any patient with PSC in whom a new or dominant stricture is demonstrated on cholangiography.

Diagnosis of cancers in PSC is greatly facilitated by biliary brush cytology, as imaging rarely shows evidence of a mass lesion even in patients with advanced cancers. Patients with good liver function, no dominant strictures and negative biliary cytology may simply be monitored for disease progression. The only useful treatment modality is liver transplantation, which is associated with excellent results if carried out before bile duct cancer has developed. Temporary relief of obstructive jaundice due to a dominant bile duct stricture can be achieved by biliary stenting, although there is considerable risk of cholangitis from the introduction of bacteria to the biliary tract.

Primary biliary cirrhosis

As with PSC, the presentation of patients with primary biliary cirrhosis (PBC) is often hidden, with general malaise, lethargy

Figure 61.16 Primary sclerosing cholangitis (PSC). Percutaneous cholangiography showing the characteristic extensive bile duct strictures and dilatations associated with PSC.

and pruritus prior to the development of clinical jaundice or the finding of abnormal liver function tests. The condition is largely confined to females. Diagnosis is suggested by the finding of circulating anti-smooth muscle antibodies and, if necessary, is confirmed by liver biopsy. The condition is slowly progressive, with deterioration in liver function resulting in lethargy and malaise. It may be complicated by the development of portal hypertension and the secondary complications of ascites and variceal bleeding. The mainstay of treatment is liver transplantation, which should be considered when the patient's general condition starts to deteriorate with inability to lead a normal lifestyle.

Caroli's disease

This is congenital dilatation of the intrahepatic biliary tree, which is often complicated by the presence of intrahepatic stone formation. Presentation may be with abdominal pain or sepsis. Imaging is usually diagnostic, with the finding on ultrasound or CT of intrahepatic biliary lakes containing stones. Biliary stasis and stone formation combine to predispose to biliary sepsis, which may be life-threatening. Another well-recognised complication is the development of carcinoma. No specific treatment is available. Acute infective episodes are treated with antibiotics. Obstructed and septic bile ducts may be drained either radiologically or surgically. Malignant change within the ductal system results in cholangiocarcinoma, which may be amenable to resection. Segmental involvement of the liver by Caroli's disease may be treated by resection of the affected part, although the ductal dilatation is usually diffuse. Transplantation is a radical but definitive treatment for a patient whose liver function is generally well preserved.

Simple cystic disease

Liver cysts are a common coincidental finding in patients undergoing abdominal ultrasound. Radiological findings to suggest that a cyst is simple are that it is regular, thin walled and unilocular, with no surrounding tissue response and no variation in density within the cyst cavity. If these criteria are confirmed and the cyst is asymptomatic, no further tests or treatment are required. Large cysts may be associated with symptoms of abdominal discomfort, possibly related to stretching of the overlying liver capsule. Aspiration of the cyst contents under radiological guidance provides a sample for culture, microscopy and cytology, and allows the symptomatic response to cyst drainage to be assessed. Aspiration alone is usually associated with cyst and symptom recurrence, in which case more definitive treatment is required. Laparoscopic de-roofing is the treatment of choice for large symptomatic cysts and is associated with good long-term symptomatic relief.

Polycystic liver disease

This is a congenital abnormality associated with cyst formation within the liver and often other abdominal organs, principally the pancreas and kidney. Those associated with renal cysts may have autosomal dominant inheritance. The cysts are often asymptomatic and incidental findings on ultrasound. They usually have no effect on organ function and require no specific treatment. Occasionally, multiple liver cysts give rise to liver discomfort. This often responds to treatment with simple analgesics. Severe

Jacques Caroli, B. 1901, Professor of Medicine, Paris, France.

pain often indicates haemorrhage into a cyst, which may be confirmed by ultrasound or CT scan. Cyst discomfort that is not adequately controlled by oral analgesics may be treated by open or laparoscopic fenestration of the liver cysts, although the results are less favourable than with simple cysts.

LIVER INFECTIONS

Viral hepatitis

Viral hepatitis is a major world health problem. In addition to the well-recognised acute and chronic liver diseases produced by hepatitis A, B and C, other hepatitis viruses have been isolated, including hepatitis D, which is usually detected only in patients with hepatitis B virus (HBV) infection, and hepatitis E, which produces a self-limiting hepatitis due to faeco-oral spread similar to hepatitis A (Table 61.5).

Hepatitis A presents with anorexia, weakness and general malaise for several weeks prior to the development of clinical jaundice, often accompanied by tenderness on palpation of an enlarged liver. The condition is spread by the faeco-oral route and often spreads rapidly in closed communities. Liver function tests will be compatible with an acute hepatitis, with elevation of bilirubin and transaminases. Diagnosis is confirmed by the antibody titre to hepatitis A. The condition is virtually always self-resolving, although rarely the viral hepatitis can lead to fulminant liver failure. Once the clinical condition resolves, the liver tends to recover fully, with no functional deficit and no long-term sequelae.

Hepatitis B is a more serious condition in most respects than hepatitis A. Although it can also produce an acute self-resolving hepatitis, the virus is often not cleared and produces long-term liver damage, with the development of liver cirrhosis and primary liver cancers. Therefore, patients may present acutely with malaise, anorexia, abdominal pain and clinical jaundice due to active hepatitis, or at a late stage owing to the complications of cirrhosis, most commonly ascites or variceal bleeding. Treatment for acute hepatitis is supportive. In patients with cirrhosis, treatment is initially dictated by the specific complication at presentation (see sections on the treatment of ascites and variceal bleeding above). In established cirrhosis, liver transplantation may be considered if viral eradication or suppression can be achieved with anti-viral agents (e.g. lamivudine). Without viral suppression, death from reinfection of the transplanted liver is common. The hepatitis virus greatly increases the risk of primary liver cancers, which usually appear at the stage when the liver

parenchyma has become cirrhotic. The assessment and management of HBV cirrhosis with hepatocellular carcinoma (HCC) is discussed in the section on 'Liver tumours' below.

Hepatitis C has become one of the most common causes of chronic liver disease worldwide and, in many countries, a large percentage of the population has been exposed; 1% of blood donors worldwide are hepatitis C virus (HCV) positive. Transmission is often related back to blood transfusion, and routine screening of blood for HCV has only recently been introduced in many countries. As with hepatitis B, it may present as an acute hepatitis or remain hidden until the development of cirrhosis and the complications of portal hypertension. Acute hepatitis C proceeds to cirrhosis in about 20% of cases. Deterioration in liver function, encephalopathy, ascites or bleeding in a patient with known HCV cirrhosis necessitates an urgent assessment for liver transplantation, if available. Although reinfection of the graft is common, it generally results in a mild hepatitis from which the graft and patient fully recover and is associated with a good long-term outcome.

Ascending cholangitis

Ascending bacterial infection of the biliary tract is usually associated with obstruction and presents with clinical jaundice, rigors and a tender hepatomegaly. The diagnosis is confirmed by the finding of dilated bile ducts on ultrasound, an obstructive picture of liver function tests and the isolation of an organism from the blood on culture. The condition is a medical emergency, and delay in appropriate treatment results in organ failure secondary to septicæmia. Once the diagnosis has been confirmed, the patient should be commenced on a first-line antibiotic (e.g. third-generation cephalosporin) and rehydrated, and arrangements should be made for endoscopic or percutaneous transhepatic drainage of the biliary tree. Biliary stone disease is a common predisposing factor, and the causative ductal stones may be removed at the time of endoscopic cholangiography by endoscopic sphincterotomy.

Pyogenic liver abscess

The aetiology of a pyogenic liver abscess is unexplained in the majority of patients. It has an increased incidence in the elderly, diabetics and the immunosuppressed, who usually present with anorexia, fevers and malaise, accompanied by right upper quadrant discomfort. The diagnosis is suggested by the finding of a multiloculated cystic mass on ultrasound or CT scan (Fig. 61.17) and is confirmed by aspiration for culture and sensitivity. The

Table 61.5 Liver infections and their treatment

Condition	Causative agent	Treatment
Viral hepatitis	Hepatitis A, B, C	Supportive, anti-viral agents (lamivudine, interferon, ribavirin) Liver transplant for cirrhosis
Ascending cholangitis	Enteric bacteria	Antibiotics (cephalosporin) Relieve obstruction
Pyogenic liver abscess	<i>Streptococcus milleri</i> <i>Escherichia coli</i> <i>Streptococcus faecalis</i>	Antibiotics Aspiration Drainage
Amoebic liver abscess	Entamoeba	Metronidazole
Hydatid liver disease	Echinococcus	Mebendazole Resection/omentoplasty

Figure 61.17 Liver abscess. Computerised tomography scan showing an air–fluid level and rim enhancement with intravenous contrast typical of a liver abscess. In the adjacent liver is a calcified hydatid cyst.

most common organisms are *Streptococcus milleri* and *Escherichia coli*, but other enteric organisms such as *Streptococcus faecalis*, *Klebsiella* and *Proteus vulgaris* also occur, and mixed growths are common. Opportunistic pathogens include staphylococci. Treatment is with antibiotics and ultrasound-guided aspiration. First-line antibiotics to be used are a penicillin, aminoglycoside and metronidazole or a cephalosporin and metronidazole. Percutaneous drainage without ultrasound guidance should be avoided as an empyema may follow drainage through the pleural space. A source for the liver abscess should be sought, particularly from the colon. Atypical clinical or radiological findings should raise the possibility of a necrotic neoplasm.

Amoebic liver abscess

Entamoeba histolytica is endemic in many parts of the world. It exists in vegetative form outside the body and is spread by the faeco-oral route. The most common presentation is with dysentery, but it may also present with an amoebic abscess, the common sites being paracaecal and in the liver. The amoebic cyst is ingested and develops into the trophozoite form in the colon, and then passes through the bowel wall and to the liver via the portal blood. Diagnosis is by isolation of the parasite from the liver lesion or the stool and confirming its nature by microscopy. Often patients with clinical signs of an amoebic abscess will be treated empirically with metronidazole (750 mg t.d.s. for 5–10 days) and investigated further only if they do not respond.

Hydatid liver disease

This is a very common condition in countries around the Mediterranean. The causative tapeworm, *Echinococcus granulosus*, is present in the dog intestine, and ova are ingested by humans and pass in the portal blood to the liver. Liver abscesses are often large by the time of presentation with upper abdominal discomfort or may present after minor abdominal trauma as an acute abdomen

due to rupture of the cyst into the peritoneal cavity. Diagnosis is suggested by the finding of a multiloculated cyst on ultrasound and is further supported by the finding of a floating membrane within the cysts on CT scan (Fig. 61.18). Active cysts contain a large number of smaller daughter cysts (Fig. 61.19), and rupture can result in these implanting and growing within the peritoneal cavity. Liver cysts can also rupture through the diaphragm, producing an empyema, into the biliary tract, producing obstructive jaundice, or into the stomach. Clinical and radiological diagnosis can be supported by serology for antibodies to hydatid antigen in the form of an enzyme-linked immunosorbent assay (ELISA). Treatment is indicated to prevent progressive enlargement and rupture of the cysts. In the first instance, a course of albendazole or mebendazole may be tried. Failure to respond to medical treatment usually requires surgical intervention, although percutaneous treatments with hypertonic saline and alcohol have been attempted. The surgical options range from liver resection or local excision of the cysts to de-roofing with evacuation of the contents.

Figure 61.18 Hydatid liver cyst. Active hydatid disease usually produces a non-calcified liver cyst and, within the cyst, floating layers of the germinal membrane can be seen.

Figure 61.19 Hydatid 'daughter' cysts. These were removed from the bile duct of a patient presenting with obstructive jaundice due to a hydatid liver cyst communicating with the bile duct. Endoscopic removal should also be considered.

Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the Bacterium Coli commune in 1886.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, in the Czech Republic; Zurich, Switzerland, and The Rush Medical College, Chicago, IL, USA.

Contamination of the peritoneal cavity at the time of surgery with active hydatid daughters should be avoided by continuing drug therapy with albendazole and adding peroperative praziquantel. This should be combined with packing of the peritoneal cavity with hypertonic (2 mol l^{-1}) saline-soaked packs and instilling 2 mol l^{-1} saline into the cyst before it is opened. A biliary communication should be actively sought and sutured. The residual cavity may become infected, and this may be reduced, as may bile leakage, by packing the space with pedicled greater omentum (an omentoplasty). Calcified cysts may well be dead. If doubt exists as to whether a suspected cyst is active, it can be followed on ultrasound, as active cysts gradually become larger and more superficial in the liver. Rupture of daughter hydatids into the biliary tract may result in obstructive jaundice or acute cholangitis. This may be treated by endoscopic clearance of the daughter cysts prior to cyst removal from the liver.

LIVER TUMOURS

Surgical approaches to resection of liver tumours

Adequate exposure of the liver is an absolute prerequisite to safe liver surgery. A rooftop or transverse abdominal incision provides excellent access to the liver if adequate retraction of the costal margin is employed using a costal margin retractor. Thoraco-abdominal incisions are no longer required. The procedure for complete mobilisation of the liver is described, although this will not be necessary in all cases. There are many variations in surgical technique.

Mobilisation of the liver

The falciform ligament is first divided and followed along the anterior surface of the liver towards the suprahepatic IVC. The left triangular ligament is divided, facilitated by placing an abdominal pack in front of the oesophagogastric junction. The right triangular ligament is then divided by retraction of the diaphragm away from the right lobe parenchyma. On exposure of the bare area of the liver, the IVC can be seen as it passes behind the liver, and this can be slung above the renal veins below the liver and at the level of the main hepatic veins. Mobilisation of the liver is completed by division of the lesser omentum. Removing the liver from the IVC is achieved by lifting the liver anteriorly to expose the multiple small veins passing between the liver parenchyma and the IVC. These should be suture ligated to ensure haemostasis. This proceeds from above the renal veins until the main hepatic veins are reached below the diaphragm.

Dissection of the hilum

The peritoneum overlying the hilar triad is divided. The CBD is then exposed on the free edge of the lesser omentum, mobilisation being facilitated by ligation and division of the cystic duct and artery followed by removal of the gall bladder. Slings the CBD with an elastic sling allows exposure of the common hepatic artery and dissection of the main right and left branches. These again may be slung to allow the remaining lymphatic tissue surrounding the portal vein to be ligated and divided. The possibility of an aberrant right hepatic artery should be sought lying posterior to the bile duct, and an accessory left hepatic artery from the left gastric artery in the lesser omentum. Dissection of the hilar bile ducts requires careful retraction on segment IV of

the liver, and division of the small vessels and bile duct branches passing between segment IV and the confluence of the right and left hepatic ducts.

Division of the parenchyma

Once the liver has been adequately mobilised and the hilar vessels have been exposed, the main inflow vessels and bile duct can be divided to the liver lobe to be resected. The arterial branch may be ligated, but the bile duct should be transected with 4/0 PDS and the portal vein branch with a 4/0 Prolene suture. Division of the inflow vessels produces a line of demarcation between the right and left liver, passing to the right of and parallel with the falciform ligament. The parenchyma is divided along this plane of demarcation commencing by diathermy of the liver capsule. The ultrasound (Cusa) dissector is the most common method used for division of the parenchyma. This allows the parenchyma to be divided, leaving the vessels and bile duct branches to be diathermied or ligated depending on their size. Dissection continues on an even plane until the hepatic vein branches are approached from within the liver parenchyma, when they are ligated and divided (Fig. 61.20).

Segmental and local resections

These are considered in patients whose liver tumours can be excised with an adequate margin (generally considered to be 1 cm) without a formal right or left lobe liver resection. The segments that can be removed individually are those shown in Figure 61.2 (p. 1081). Each carries its own blood supply, venous drainage and bile drainage. The extent of mobilisation of the liver required (described above) depends on the segment to be resected. Hilar dissection may not be necessary. Segmental resections are used particularly in patients with HCC and underlying liver disease (e.g. HBV or HCV) to minimise the risk of postoperative liver failure (Fig. 61.21). Local resections are principally used for patients with liver metastases when removal of the tumour mass with a minimum margin of 1 cm of normal liver parenchyma is required.

Blood loss and transfusion

The reduction of blood loss during liver surgery has been one of the major achievements in the last decade, and resection without

Figure 61.20 Hepatectomy post resection. Cut surface of the residual liver following a right hepatectomy in which segments V–VIII have been removed. On the lower edge, the portal vein and bile duct can be visualised.

Figure 61.21 Segmental resection. Removal of a primary liver tumour by resection of liver segment VI (a and b) in a patient with well-compensated liver cirrhosis.

blood transfusion is often possible. The ultrasound dissector has been one of the main advances. Preoperative venesection, intraoperative haemodilution, reducing central venous pressure and the intraoperative cell saver have all helped to reduce the necessity for autologous blood transfusion. Better control of the coagulation cascade has been achieved using TEG (see Fig. 61.9 p. 1087), and the anti-fibrinolytic drug aprotinin has significantly reduced bleeding in patients with liver disease and an underlying coagulopathy. Oozing from the resected surface can be reduced by the topical application of fibrin glue or fibrin-impregnated collagen fleece. The main alternative is use of the argon-beam coagulator.

Benign liver tumours

Haemangiomas

These are the most common liver lesions, and their reporting has increased with the widespread availability of diagnostic ultrasound. They consist of an abnormal plexus of vessels, and their nature is usually apparent on ultrasound. If diagnostic uncertainty exists, CT scanning with delayed contrast enhancement shows the characteristic appearance of slow contrast enhancement due to small-vessel uptake in the haemangioma. Often, haemangiomas are multiple. Lesions found incidentally require confirmation of their nature and no further treatment. The management of 'giant' haemangiomas is more controversial. Occasional reports of rupture of

haemangiomas have led some to consider resection for the large lesions, especially if they appear to be symptomatic. They have little if any malignant potential, and this is no indication for surgery. Percutaneous biopsy of these lesions should be avoided as they are vascular lesions and may bleed profusely into the peritoneal cavity.

Hepatic adenoma (Fig. 61.22)

These are rare benign liver tumours. Imaging by CT demonstrates a well-circumscribed and vascular solid tumour. They usually develop in an otherwise normal liver. Unfortunately, there are no characteristic radiological features to differentiate these lesions from malignant tumours. Angiography will demonstrate a well-developed peripheral arterialisation of the tumour. Confirmation of the nature of these lesions is required by either percutaneous biopsy or resection with histological confirmation. These tumours are thought to have malignant potential, and resection is therefore the treatment of choice. Owing to their vascularity, bleeding following percutaneous biopsy is well recognised. An association with sex hormones (including the oral contraceptive pill) is well recognised, and regression of symptomatic adenomas on withdrawal of hormone stimulation is well documented.

Focal nodular hyperplasia

This is an unusual benign condition of unknown aetiology in which there is a focal overgrowth of functioning liver tissue supported by fibrous stroma. Patients are usually middle-aged females, and there

Figure 61.22 Hepatic adenoma. Magnetic resonance imaging scan of a giant hepatic adenoma. These lesions are thought to be pre-malignant, they may haemorrhage and, in some cases, their growth is sex hormone sensitive. Withdrawal of hormone preparations may allow spontaneous regression.

is no association with underlying liver disease. Ultrasound shows a solid tumour mass but does not help in discrimination. Contrast CT may show central scarring and evidence of a well-vascularised lesion. Again, these appearances are not specific for focal nodular hyperplasia (FNH). A sulphur colloid liver scan may be useful. FNH contain both hepatocytes and Kupffer cells. The latter take up the colloid allowing differentiation of FNH from either a benign adenoma or a primary or metastatic cancer, neither of which contains a significant number of Kupffer cells.

Surgery for liver metastases

Outcome

The role of surgery in the treatment of colorectal liver metastases is now well established, based on prospective data on resected patients compared with unresected patients with a similar stage of disease. The role of resection of liver metastases from other primary sites has not been defined. The expected patient survival rate for resection of solitary colorectal metastases is approximately 35% at 5 years, with few cancer-related deaths beyond this period. Multiple unilobar and bilobar liver metastases may also be considered for resection, although cure rates are significantly lower (Summary box 61.12).

Summary box 61.12

Prognostic factors in patients undergoing resection of colorectal liver metastases

- Stage of primary
- Time from primary resection
- Carcinoembryonic antigen (CEA) level
- Size of largest lesion
- Number of lesions

Staging

This involves defining the extent of the liver involvement with metastases and excluding extrahepatic disease. A standard work-up would involve oral and intravenous contrast CT scans of the liver and abdomen, chest CT scan and colonoscopy to look for locally recurrent or synchronous colonic cancers. MRI and PET scanning are useful in the clarification of equivocal lesions. This information should be taken in parallel with a general medical evaluation before deciding on the suitability for surgery of an individual patient. The typical appearance of colorectal liver metastases on contrast CT is shown in Figure 61.23. These patients usually have normal liver parenchyma and therefore tolerate a 60–70% resection of liver parenchyma without showing evidence of liver failure (Summary box 61.13).

Summary box 61.13

Staging and assessment with colorectal liver metastases

- General medical assessment
- CT, PET-CT or MRI of the abdomen/pelvis with contrast (? resectability)
- Chest CT
- Review histology of primary (? risk of local recurrence)
- Colonoscopy
- Liver function tests and tumour markers

Figure 61.23 Colorectal liver metastases on computerised tomography (CT) scan: (a) after oral contrast CT; (b) after intravenous contrast. The colorectal liver metastasis occupying the entire right lobe of the liver is difficult to visualise on oral contrast CT. The addition of intravenous contrast shows its lack of enhancement and its relationship to the hepatic veins.

Surgical approach

The basic surgical approach to liver resection is outlined above. A search for local recurrent disease, peritoneal deposits and regional lymph node involvement should be made at the start of the laparotomy. Planar imaging often overlooks peritoneal or superficial liver metastatic deposits. Coeliac node involvement in patients with liver metastases considerably reduces the overall survival whether or not the liver and nodal disease is resected.

The treatment of unresectable disease

There have been major advances in the management of patients with colorectal liver metastases who, until recently, would have been considered 'unresectable' due to the size or distribution of their metastases. Chemotherapy with 5-fluorouracil (5FU) and folinic acid produces a response rate of approximately 30% but, when combined with oxaloplatinum, the response rate increases to 50–60%, often with a dramatic size reduction of the lesions. The combination of chemotherapy with monoclonal antibodies (mAbs) that recognise vascular endothelial growth factor (VEGF) receptor

or the epidermal growth factor receptor (EGFR) may provide additional benefit. Long-term follow-up of patients downstaged with chemotherapy, who have proceeded to resection of their cancers, have shown 5-year survival rates of 30–40%.

Patients with bilobar metastases with a lesion centrally within the right lobe and a second lesion peripherally in the left lobe may have resection of their metastases in two stages to allow for regeneration of the liver parenchyma between the procedures. Good long-term survival has been reported for this group of patients.

Portal vein embolisation is a third development to affect patients previously deemed unresectable. Patients who require a right or extended right hepatectomy and in whom the left lobe volumes are congenitally small (< 30% of functioning parenchyma) have an increased risk of post-resection liver failure. This can be reduced by preoperative (3–6 weeks) percutaneous embolisation of the right portal vein branch, which produces atrophy of the affected lobe and hypertrophy of the contralateral lobe.

In patients who cannot be rendered resectable, systemic chemotherapy has been shown to produce survival and quality of life benefit. Many techniques are now available that produce local ablation of the tumours, including interstitial laser hyperthermia, radiofrequency ablation (RFA), microwave therapy, focused ultrasound and electrolytic therapy. These techniques may produce survival benefit along with chemotherapy in the palliative setting, but there is little objective evidence of long-term survival, and they should therefore be restricted to patients who cannot be offered surgical resection (Summary box 61.14).

Summary box 61.14

Strategies for 'unresectable' colorectal liver metastases

- Neoadjuvant oxaloplatinum/5-fluorouracil systemic chemotherapy
- Anti-VEGF or EGFR monoclonal antibody therapy
- Two-stage liver resection
- Portal vein embolisation

Hepatocellular carcinoma

Primary liver cancer (HCC) is one of the world's most common cancers, and its incidence is expected to rise rapidly over the next decade due to the association with chronic liver disease, particularly HBV and HCV. Many patients known to have chronic liver disease are now being screened for the development of HCC by serial ultrasound scans of the liver or serum measurements of alphafetoprotein (AFP). Patients often present in middle age, either because of the symptoms of chronic liver disease (malaise, weakness, jaundice, ascites, variceal bleed, encephalopathy) or with the anorexia and weight loss of an advanced cancer. The surgical treatment options include resection of the tumour and liver transplantation. Which option is most appropriate for an individual patient depends on the stage of the underlying liver disease, the size and site of the tumour, the availability of organ transplantation and the management of the immunosuppressed patient.

Staging and clinical assessment of HCC

In addition to a general assessment of the patient's fitness for surgery, crucial information is the severity of the underlying liver

disease, based on Child's classification (see Table 61.2 p. 1083) and the size and site of the tumour. As chronic liver disease predisposes to these tumours, they are often multifocal by the time of diagnosis. Extensive liver resections in patients with advanced cirrhosis are associated with a high mortality due to liver failure and sepsis. In contrast, extensive resections for HCC in a non-cirrhotic liver are associated with a low risk of liver failure, and resection rather than transplantation would be the treatment option of choice. Tumours often metastasise to the lung and bone and, therefore, a chest CT scan and a bone scan are useful staging investigations. Evidence of intraperitoneal disease is difficult to determine by CT scan, and laparoscopy may be useful for this purpose. The intrahepatic distribution of HCC is equally difficult to determine within the cirrhotic liver. Ultrasound, early arterial phase enhanced spiral CT scan and contrast MRI are the most useful investigations that are currently available.

Surgical approach to HCC

The surgical approach should remove the known cancer with a 1- to 2-cm margin of unaffected liver tissue. In patients with associated chronic liver disease, the volume of liver resected should be minimised to reduce the incidence of postoperative liver failure. Local or segmental resections are preferred to major resections (see Fig. 61.21 p. 1097).

Non-surgical therapy for hepatocellular carcinoma

The majority of patients diagnosed with HCC will not be amenable to surgical resection because of the advanced stage of the cancer or the severity of the underlying liver disease. These patients can be offered local ablative treatments such as transarterial embolisation (TAE), transarterial chemoembolisation (TACE), percutaneous ethanol ablation (PEA) or RFA (Fig. 61.24).

Follow-up and adjuvant treatment

There is little evidence that adjuvant chemotherapy will improve the prognosis of patients following resection of HCC, and it may damage the function of the liver in those with underlying chronic liver disease. AFP is a clinically useful tumour marker for

Figure 61.24 Computerised tomography scan after radiofrequency ablation for hepatocellular carcinoma.

follow-up, although its low sensitivity would suggest that imaging should also be used.

Cholangiocarcinoma

Presentation, pathology and natural history

Bile duct cancers typically present with painless obstructive jaundice. Elderly patients are frequently affected, but patients with PSC may develop these tumours at a much earlier age. These tumours are typically slow growing and often arise at the confluence of the right and left hepatic ducts (Klatskin tumours), eventually invading the liver parenchyma. Cancers at this site are usually fibrous and produce tight duct strictures. Distal bile duct cholangiocarcinomas are more frequently polypoidal and obstruct the lumen of the duct. Investigation, staging and management of

bile duct and gall bladder malignancies are discussed in Chapter 63.

The spleen

LEARNING OBJECTIVES

To understand:

- The function of the spleen
- The common pathologies involving the spleen
- The principles and potential complications of splenectomy
- The potential advantages of laparoscopic splenectomy
- The importance of prophylaxis against infection following splenectomy

EMBRYOLOGY, ANATOMY AND PHYSIOLOGY

Embryology

Fetal splenic tissue develops from condensations of mesoderm in the dorsal mesogastrium. This peritoneal fold attaches the dorsal body wall to the fusiform swelling in the foregut that develops into the stomach. This condensation divides the mesogastrium into two parts, one between the fetal splenic tissue and the stomach to form the gastrosplenic ligament and the other between it and the left kidney to form the lienorenal ligament.

Anatomy

The weight of the normal adult spleen is 75–250 g. It lies in the left hypochondrium between the gastric fundus and the left hemidiaphragm, with its long axis lying along the 10th rib. The hilum sits in the angle between the stomach and the kidney and is in contact with the tail of the pancreas. The concave visceral surface lies in contact with these structures, and the lower pole extends no further than the mid-axillary line. There is a notch on its inferolateral border, and this may be palpated when the spleen is enlarged.

The tortuous splenic artery arises from the coeliac axis and runs along the upper border of the body and tail of the pancreas, to which it gives small branches. The short gastric and left gastroepiploic branches pass between the layers of the gastrosplenic ligament. The main splenic artery generally divides into superior and inferior branches, which, in turn, subdivide into several segmental branches.

The splenic vein is formed from several tributaries that drain the hilum. The vein runs behind the pancreas, receiving several small tributaries from the pancreas before joining the superior mesenteric vein at the neck of the pancreas to form the portal vein.

The lymphatic drainage comprises efferent vessels in the white pulp that run with the arterioles and emerge from nodes at the hilum. These nodes and lymphatics drain via retropancreatic nodes to the coeliac nodes.

Sympathetic nerve fibres run from the coeliac plexus and innervate splenic arterial branches.

Physiology

The splenic parenchyma consists of white and red pulp that is surrounded by serosa and a collagenous capsule with smooth muscle fibres. These penetrate the parenchyma as trabeculae of dense connective tissue fibres rich in collagen and elastic tissue. These, with the reticular framework, support the cells of the spleen and surround the vessels in the splenic pulp. The white pulp comprises a central trabecular artery surrounded by nodules with germinal centres and periarterial lymphatic sheaths that provide a framework filled with lymphocytes and macrophages. Arteries from the central artery and the peripheral 'penicillar' arteries pass into the marginal zone that lies at the edge of the white pulp. Plasma-rich blood that has passed through the central lymphatic nodules is filtered as it passes through the sinuses within the marginal zone, and particles are phagocytosed. Immunoglobulins produced in the lymphatic nodules enter the circulation through the sinuses in the marginal zone, beyond which lies the red pulp, which consists of cords and sinuses. Cell-concentrated blood passes in the trabecular artery through the centre of the white pulp to the red pulp cords. Red cells must elongate and become thinner to pass from the cords to the sinuses, a process that removes abnormally shaped cells from the circulation (Fig. 62.1). As 90% of the blood passing through the spleen moves through an open circulation in which blood flows from arteries to cords, and thence sinuses, splenic pulp pressure reflects the pressure throughout the portal system. The remaining 10% of the blood flow through the spleen bypasses the cords and sinuses by direct arteriovenous communications, and the overall flow rate is about 300 ml min⁻¹.

FUNCTIONS OF THE SPLEEN

Although the spleen was previously thought to be dispensable, increasing knowledge of its function has led to a conservative approach in the management of conditions involving the spleen.

Figure 62.1 A central trabecular artery passing through the white pulp into the surrounding red pulp. A blood flow skimming effect results in most of the plasma passing down the branches of the artery while the cells pass in the central trabecular artery directly into the red pulp (courtesy of Professor T.G. Allen-Mersh, Westminster and Charing Cross Hospitals, London, UK).

It is now recognised that an incidental splenectomy during the course of another operative procedure increases the risk of complication and death. The surgeon should normally endeavour to preserve the spleen to maintain the following functions:

- **Immune function.** The spleen processes foreign antigens and is the major site of specific immunoglobulin M (IgM) production. The non-specific opsonins, properdin and tuftsin, are synthesised. These antibodies are of B- and T-cell origin and bind to the specific receptors on the surface of macrophages and leucocytes, stimulating their phagocytic, bactericidal and tumoricidal activity.
- **Filter function.** Macrophages in the reticulum capture cellular and non-cellular material from the blood and plasma. This will include the removal of effete platelets and red blood cells. This process takes place in the sinuses and the splenic cords by the action of the endothelial macrophages. Iron is removed from the degraded haemoglobin during red cell breakdown and is returned to the plasma. Removed non-cellular material may include bacteria and, in particular, pneumococci.
- **Pitting.** Particulate inclusions from red cells are removed, and the repaired red cells are returned to the circulation. These include Howell–Jolly and Heinz bodies, which represent nuclear remnants and precipitated haemoglobin or globin subunits respectively.
- **Reservoir function.** This function is less marked than in other species, but the spleen does contain approximately 8% of the red cell mass. An enlarged spleen may contain a much larger proportion of the blood volume.

- **Cytopenia.** From the fourth month of intrauterine life, some degree of haemopoiesis occurs in the fetal spleen. Stimulation of the white pulp may occur following antigenic challenge, resulting in the proliferation of T and B cells and macrophages. This may also occur in myeloproliferative disorders, thalassaemias and chronic haemolytic anaemias (Summary box 62.1).

Summary box 62.1

Functions of the spleen

- Immune
- Filter function
- Pitting
- Reservoir
- Cytopenia
- Splenectomy harms the patient

INVESTIGATION OF THE SPLEEN

Conditions that result in splenomegaly can be diagnosed on the basis of the history and examination findings and from laboratory examination. In haemolytic anaemia, a full blood count, reticulocyte count and tests for haemolysis will determine the cause of the anaemia. Splenomegaly associated with portal hypertension caused by cirrhosis is diagnosed on the history, physical signs of liver dysfunction, abnormal tests of liver function and endoscopic evidence of oesophageal varices. Sinistral or segmental portal hypertension may result from isolated occlusion of the splenic vein by pancreatic inflammation or tumour. As many conditions that cause splenomegaly are associated with lymphadenopathy, investigation should be directed at those disease processes known to be associated with both physical signs. Lymph node biopsy may be required.

William Henry Howell, 1860–1945, Professor of Physiology, Johns Hopkins University, Baltimore, MD, USA.

Justin Marie Jules Jolly, 1870–1953, Professor of Histopathology, Collège de France, Paris, France.

Robert Heinz, 1865–1924, Professor of Pharmacology and Toxicology, Erlangen, Germany.

Radiological imaging

Plain radiology is rarely used in investigation, but the incidental finding of calcification of the splenic artery or spleen may raise the possible diagnosis of a splenic artery aneurysm, an old infarct, a benign cyst or hydatid disease. Multiple areas of calcification may suggest splenic tuberculosis. Ultrasonography can determine the size and consistency of the spleen, and whether a cyst is present. However, a computerised tomography (CT) scan with contrast enhancement is more commonly undertaken to better characterise the nature of the suspected splenic pathology and to exclude other intra-abdominal pathology. Magnetic resonance image (MRI) scanning may be similarly useful. Radioisotope scanning is used occasionally to provide information about the spleen. The use of technetium-99m (^{99m}Tc)-labelled colloid is normally restricted to determining whether the spleen is a significant site of destruction of red blood cells.

CONGENITAL ABNORMALITIES OF THE SPLEEN

Splenic agenesis is rare but is present in 10% of children with congenital heart disease. Polysplenia is a rare condition resulting from failure of splenic fusion.

Splenunculi are single or multiple accessory spleens that are found in approximately 10–30% of the population. They are located near the hilum of the spleen in 50% of cases and are related to the splenic vessels or behind the tail of the pancreas in 30%. The remainder are located in the mesocolon or the splenic ligaments. Their significance lies in the fact that failure to identify and remove these at the time of splenectomy may give rise to persistent disease.

Hamartomas are rarely found in life and vary in size from 1 cm in diameter to masses large enough to produce an abdominal swelling. One form is mainly lymphoid and resembles the white pulp, whereas the other resembles the red pulp.

Non-parasitic *splenic cysts* are rare. True cysts form from embryonal rests and include dermoid and mesenchymal inclusion cysts (Fig. 62.2). These are lined by flattened epithelium and should be differentiated from false cysts that may result from trauma and contain serous or haemorrhagic fluid. The walls of

such degenerative cysts may be calcified and therefore resemble the radiological appearances of a hydatid cyst. The spleen is also a common site for pseudocyst development following a severe attack of pancreatitis (Fig. 62.3). Pseudocysts can easily be diagnosed on scanning, and intervention is normally required for symptomatic lesions that persist following a period of observation.

SPLENIC ARTERY ANEURYSM, INFARCT AND RUPTURE

Splenic artery aneurysm

Aneurysms involving the splenic artery are estimated to occur at 0.04–1% of post-mortem examinations. They are twice as common in the female and are usually situated in the main arterial trunk. Although these are generally single, more than one aneurysm is found in a quarter of cases. These may be a consequence of intra-abdominal sepsis and pancreatic necrosis in particular. They are more likely to be associated with arteriosclerosis in elderly patients.

The aneurysm is symptomless unless it ruptures and is more likely to be detected on a plain abdominal radiograph or scan. It is unlikely to be palpable, although a bruit may be present. Rupture is unsuspected in the majority of cases and, as it will generally rupture into the peritoneal cavity, the symptoms mimic those of splenic rupture. Almost half the cases of rupture occur in patients younger than 45 years of age, and a quarter are in pregnant women, usually in the third trimester of pregnancy or at labour.

The treatment of choice previously consisted of splenectomy and removal of the diseased artery. Some surgeons advocate ligation of the proximal and distal ends of the sac to allow thrombosis of the aneurysm and partial or complete splenectomy if necessary. The procedure has been performed laparoscopically. Embolisation or endovascular stenting following selective splenic artery angiography can be considered. In the younger patient with an asymptomatic splenic artery aneurysm, surgery or interventional radiology is indicated depending on local expertise after CT scan, MRI or selective coeliac angiography has confirmed the diagnosis (Fig. 62.4). In the elderly patient with a calcified

Figure 62.3 Computerised tomographic scan showing a large pseudocyst involving the spleen. There is displacement of the stomach medially, and a trace of ascitic fluid is present above the liver.

Figure 62.4 Computerised tomographic scan showing a pool of contrast in a pseudoaneurysm situated in the tail of the pancreas adjacent to the spleen.

aneurysm, there is less risk of rupture, and observation may be preferred. In patients with pancreatic necrosis, the treatment will include drainage of the septic focus.

Splenic infarction

This condition commonly occurs in patients with a massively enlarged spleen from myeloproliferative syndrome, portal hypertension or vascular occlusion produced by pancreatic disease, splenic vein thrombosis or sickle cell disease. The infarct may be asymptomatic or give rise to left upper quadrant and left shoulder tip pain. A contrast-enhanced CT scan will show the characteristic perfusion defect in the enlarged spleen (Fig. 62.5). Treatment is conservative, and splenectomy should be considered only when a septic infarct causes an abscess.

Splenic rupture

Splenic rupture (see Chapter 26) should be considered in any case of blunt abdominal trauma, particularly when the injury

Figure 62.5 Computerised tomographic scan showing a splenic infarct (arrows) in a patient with splenomegaly and hypersplenism secondary to portal hypertension and portal vein thrombosis. The varices are evident at the hilus and at the greater curvature of the stomach.

occurs to the left upper quadrant of the abdomen. Iatrogenic injury to the spleen remains a frequent complication of any surgical procedure, particularly those in the left upper quadrant when adhesions are present.

Rupture of a malarial spleen

In tropical countries, this is not uncommon, and the delayed type of presentation following 'trivial' injury is not infrequent. In such patients, splenectomy should be considered before a perisplenic haematoma ruptures, a complication that is associated with a worse prognosis.

Surgery in such patients is challenging, and early ligation of the splenic vessels along the superior border of the pancreatic body should be considered before disturbing the haematoma.

SPLENOMEGALY AND HYPERSPLENISM

Splenomegaly is a common feature of many disease processes (Table 62.1). It should be borne in mind, however, that many conditions affecting the spleen, such as idiopathic thrombocytopenic purpura, may be associated with enlargement, but the gland is seldom palpable. Few of the conditions causing splenomegaly will require splenectomy as part of their treatment.

Hypersplenism is an indefinite clinical syndrome that is characterised by splenic enlargement, any combination of anaemia, leucopenia or thrombocytopenia, compensatory bone marrow hyperplasia and improvement after splenectomy. Careful clinical judgement is required to balance the long- and short-term risks of splenectomy against continued conservative management.

Splenic abscess

Splenic abscess may arise from an infected splenic embolus or in association with typhoid and paratyphoid fever, osteomyelitis, otitis media and puerperal sepsis. In general surgical practice, it may be associated with pancreatic necrosis or other intra-abdominal infection (Fig. 62.6). An abscess may rupture and form a left subphrenic abscess or result in peritonitis. The treatment involves that of the underlying cause and drainage of the splenic abscess by percutaneous means under radiological guidance.

Figure 62.6 Computerised tomographic scan showing a multiloculated abscess in the enlarged spleen. This was managed successfully by percutaneous drainage under ultrasound guidance.

Tuberculosis

The diagnosis of tuberculosis should be considered in young adults with splenomegaly presenting with asthenia, loss of weight and fever. Tuberculosis of the spleen may produce portal hypertension or, rarely, cold abscess. Treatment with anti-tuberculous drugs will normally produce improvement. Splenectomy is not

Adolph Weil, 1848–1916, Physician, Dorpat (now Tartu), Estonia, described leptospirosis icterohaemorrhagica in 1886.
Sir George Frederic Still, 1868–1941, Professor of Diseases of Children, King's College Hospital, London, UK, described chronic articular rheumatism in children in 1896.

normally required and is made difficult by the inflammatory adhesions.

Tropical splenomegaly

Massive splenic enlargement frequently occurs in the tropics from malaria, kala-azar and schistosomiasis. Occasionally, splenomegaly cannot be fully attributed to these diseases. It may result from occult infection or be related to malnutrition. The massive splenomegaly observed in this condition may require removal for those patients disabled by anaemia or local symptoms. Lifelong antimalarial therapy is indicated in malaria-endemic areas.

Schistosomiasis

This condition is prevalent in Africa, Asia and South America. It is caused by infection with *Schistosoma mansoni* in 75% of cases and by *Schistosoma haematobium* in the remainder. The splenic enlargement may result from portal hypertension associated with hepatic fibrosis, but can result from hyperplasia induced by the phagocytosis of disintegrated worms, ova and toxin. The splenomegaly can occur at any age. The diagnosis is based on examination of the urine and faeces for ova, abnormal liver function tests and the presence of hypochromic anaemia.

Successful medical treatment of established cases does not result in regression of splenomegaly, and removal of the painful and bulky spleen is indicated where there is no evidence of hepatic or renal insufficiency.

Leukaemia

This condition should be considered in the differential diagnosis of splenomegaly and is made by examining a blood or marrow film. Splenectomy is reserved for hypersplenism that occurs during the chronic phase of chronic granulocytic leukaemia.

Idiopathic thrombocytopenic purpura

In most cases of idiopathic thrombocytopenic purpura (ITP), the low platelet count results from the development of antibodies to specific platelet membrane glycoproteins that damage the patient's own platelets. It is also known as immune and auto-immune thrombocytopenic purpura. It is defined as isolated thrombocytopenia with normal bone marrow and the absence of other causes of thrombocytopenia. Two distinct clinical types are evident: the acute condition in the child and a chronic condition in the adult. Acute ITP often follows an acute infection and has a spontaneous resolution within 2 months. Chronic ITP persists longer than 6 months without a specific cause being identified. Approximately 50–75 cases per million arise each year in adults compared with 50 cases per million each year in children.

Clinical features

The adult form normally affects females between the ages of 15 and 50 years, although it can be associated with other conditions, including systemic lupus erythematosus, chronic lymphatic leukaemia and Hodgkin's disease. The childhood form is distributed equally between males and females and commonly presents before the age of 5 years. Purpuric patches (ecchymoses) occur on the skin and mucous membranes. Following trauma or pressure, examination often reveals numbers of petechial haemorrhages in the skin. There is a tendency to spontaneous bleeding from mucous membranes (e.g. epistaxis); in women, menorrhagia and the prolonged bleeding of minor wounds are common. Haemorrhage from the urinary and gastrointestinal tracts and haemarthrosis are rare. Although intracranial haemorrhage is also uncommon, it is the most frequent cause of death. The diagnosis is made based upon the presence of cutaneous ecchymoses and a positive tourniquet test. The spleen is palpable in fewer than 10% of patients, and the presence of gross splenic enlargement should raise the suspicion of an alternative diagnosis.

Sir Patrick Manson, 1844–1922, practised in Formosa (now Taiwan) and Hong Kong before becoming Physician to the Dreadnought Hospital, Greenwich, London, UK. He is regarded as 'The Father of Tropical Medicine'.
Thomas Hodgkin, 1798–1866, Lecturer in Morbid Anatomy and Curator of the Museum, Guy's Hospital, London, UK, described lymphadenoma in 1832.

Investigations

Coagulation studies are normal, and a bleeding time is not helpful in diagnosis. Platelet count in the peripheral blood film is reduced (usually $< 60 \times 10^9 l^{-1}$). Bone marrow aspiration reveals a plentiful supply of platelet-producing megakaryocytes.

Treatment

The course of the disease differs in children and adults. The disease regresses spontaneously in 75% of paediatric cases following the initial attack. Short courses of corticosteroids in both adult and child are usually followed by recovery. Prolonged steroid therapy should not be continued if this does not produce remission. Splenectomy is usually recommended if a patient has two relapses on steroid therapy or if the platelet count remains low. Generally, this is indicated where the ITP has persisted for more than 6–9 months.

Up to two-thirds of patients will be cured by surgical intervention, and 15% will be improved, but no benefit will be derived in the remainder. The response to steroids predicts a good response to splenectomy. In the acute setting, if severe bleeding has not been controlled by steroid therapy, fresh blood transfusion or transfusion with platelet concentrates before operation is necessary, although these are generally withheld until the splenic vessels have been controlled at operation.

Haemolytic anaemias

There are four causes of haemolytic anaemia that are generally amenable to splenectomy.

Hereditary spherocytosis

This autosomal dominant hereditary disorder is characterised by the presence of spherocytic red cells. Four abnormalities in red cell membrane proteins have been identified, but spectrin deficiency is the most common. Spherocytosis arises essentially from an increase in permeability of the red cell membranes to sodium. As this ion leaks into the cell, the osmotic pressure rises, resulting in swelling and increased fragility of the spherocyte. As the sodium pump has to work harder to rid the cells of sodium, there is greater loss of membrane phospholipid, resulting in an increased fragility of the membrane, and the energy and oxygen requirements increase. A large number of red cells are destroyed in the spleen, where there is a relative deficiency of both glucose and oxygen.

The clinical presentation is generally in childhood but may be delayed until later life. Mild intermittent jaundice is associated with mild anaemia, splenomegaly and gallstones. The circulating bilirubin is not conjugated with glucuronic acid, and is not therefore excreted in the urine as it is bound to albumin. Excretion of the resulting bilirubin complex by the liver favours the formation of pigment gallstones. Once the disease manifests itself, spontaneous remissions are uncommon; the patient is often pale and jaundiced at presentation and, in established cases, lassitude and undue fatigue are present.

In some families, the disease is characterised by a severe crisis of red blood cell destruction, during which the erythrocyte count may fall from 4.5×10^6 to $1.5 \times 10^6 ml^{-1}$ within a week. Such crises are characterised by the onset of pyrexia, abdominal pain, nausea, vomiting and extreme pallor followed by increased jaundice. These episodes may be precipitated by acute infection. Any child with gallstone disease should be investigated for hereditary spherocytosis and a family history sought.

Examination reveals splenomegaly, and the liver may also be palpable. Chronic leg ulcers may arise in adults with the disease.

Haematological investigations include the fragility test. Erythrocytes begin to haemolyse in 0.47% saline solution but, in this condition, haemolysis may occur in 0.6% or even stronger solutions. Immature red blood cells (reticulocytes), which differ from adult cells by possessing a reticulum, are discharged into the circulation by the bone marrow to compensate for the loss of erythrocytes by haemolysis.

Faecal urobilinogen is increased as this route excretes most of the urobilinogen.

Radioactive chromium (^{51}Cr) labelling of the patient's own red cells will demonstrate the severity of red cell destruction. Daily scanning over the spleen will show the degree of red cell sequestration by the spleen. The presence of high levels of splenic radioactivity generally predicts a good response to splenectomy, but this test is used less commonly.

All patients with hereditary spherocytosis should be treated by splenectomy but, in juvenile cases, this is generally delayed until 6 years of age to minimise the risk of post-splenectomy infection, but before gallstones have had time to form. Ultrasonography should be performed preoperatively to determine the presence or absence of gallstones.

Acquired autoimmune haemolytic anaemia

This condition may arise following exposure to agents such as chemicals, infection or drugs, e.g. alpha-methyldopa, or be associated with another disease (e.g. systemic lupus erythematosus). In most instances, the cause is unknown, and red cell survival is reduced because of an immune reaction triggered by immunoglobulin or complement on the red cell surface. This condition is more common in women after the age of 50 years. In half the patients, the spleen is enlarged and, in 20% of cases, pigment gallstones are present.

Anaemia is invariably present and may be associated with spherocytosis because of red cell membrane damage. Antibody, which coats the red cells, can be detected by agglutination when anti-human globulin is added to a suspension of the patient's erythrocytes (Coombs test positive). The disease runs an acute self-limiting course, and no treatment is necessary. Splenectomy should, however, be considered if corticosteroids are ineffective, when the patient is developing complications from long-term steroid treatment or if corticosteroids are contraindicated. Eighty per cent of patients respond to splenectomy.

Thalassaemia (synonyms: Cooley's anaemia, Mediterranean anaemia)

This condition results from a defect in haemoglobin peptide chain synthesis and is transmitted as a dominant trait. The disease is really a group of related diseases, alpha, beta and gamma, depending upon which haemoglobin peptide chain's rate of synthesis is reduced. Most patients suffer from beta-thalassaemia, in which a reduction in the rate of beta-chain synthesis results in a decrease in haemoglobin A. Intracellular precipitates (Heinz bodies) contribute to premature red cell destruction.

Robin Royston Amos Coombs, 1921–2006, Quick Professor of Immunology, University of Cambridge, Cambridge, UK, described this test in 1945.
Thomas Benton Cooley, 1871–1945, Professor of Pediatrics, Wayne University, Detroit, MI, USA, described this type of anaemia in 1927.

Graduations of the disease range from heterozygous thalassaemia minor to homozygous thalassaemia major, which is associated with chronic anaemia, jaundice and splenomegaly. Patients with homozygous thalassaemia major frequently develop clinical signs in the first year of life, and these include retarded growth, enlarged head with slanting eyes and depressed nose, leg ulcers, jaundice and abdominal distension secondary to splenomegaly.

Red cells are small, thin and misshapen and have a characteristic resistance to osmotic lysis. In the more severe forms, nucleated red cells and other immature blood cells are seen. The final diagnosis is by haemoglobin electrophoresis.

Blood transfusion may be required to correct profound anaemia, but the patient may become transfusion dependent because of the development of hypersplenism. Splenectomy is therefore of benefit in patients who require frequent blood transfusion and if haemolytic antibodies have developed as a result.

Sickle cell disease

Sickle cell disease is a hereditary haemolytic anaemia occurring mainly among those of African origin in whom the normal haemoglobin A is replaced by haemoglobin S (HbS). The HbS molecule crystallises when the blood oxygen tension is reduced, thus distorting and elongating the red cell. The resulting increased blood viscosity may obstruct the flow of blood in the spleen. Splenic microinfarcts are therefore common.

The sickle cell trait can be detected in 9% of those of African origin, but most are asymptomatic; sickle cell disease occurs in about 1% of Africans. Depending upon the vessels affected by vascular occlusion, patients may complain of bone or joint pain, priapism, neurological abnormalities, skin ulcers or abdominal pain due to visceral blood stasis. The diagnosis is made by the finding of characteristic sickle-shaped cells on blood film, although this investigation has largely been replaced by haemoglobin electrophoresis.

Hypoxia that provokes a sickling crisis should be avoided and is particularly relevant in patients undergoing general anaesthesia. Adequate hydration and partial exchange transfusion may help in a crisis. Splenectomy is of benefit in a few patients in whom excessive splenic sequestration of red cells aggravates the anaemia. Chronic hypersplenism usually occurs in late childhood or adolescence, although *Streptococcus pneumoniae* infection may precipitate an acute form in the first 5 years of life.

Porphyria

Porphyria is a hereditary error of haemoglobin catabolism in which porphyrinuria occurs. Abdominal crises characterised by severe intestinal colic and constipation can be precipitated by the administration of barbiturates. The patient is anaemic and may suffer from photosensitivity; in advanced forms of the disease, neurological and mental symptoms are present. The splenomegaly associated with this condition may be overlooked. The urine may be orange and develops a port-wine colour after a few hours of exposure to the air. Splenectomy has little role to play in the management of this condition.

Gaucher's disease

This lipid storage disease is characterised by storage of glucocerebroside in the reticuloendothelial system and in the spleen.

Philippe Charles Ernest Gaucher, 1854–1918, Physician, Hôpital St Louis, Paris, France, described familial splenic anaemia in 1882.

Enormous splenic enlargement may be associated with yellowish-brown discolouration of the skin on the hands and face, anaemia and conjunctival thickening (pinguecula). Slavonic and Jewish races are more prone to the disease, and the detection of Gaucher cells in the bone marrow confirms the diagnosis. Splenectomy is indicated only for severe symptoms related to the splenomegaly.

Hypersplenism due to portal hypertension

Splenomegaly is an invariable feature of portal hypertension (Fig. 62.7) and results in the thrombocytopenia and granulocytopenia observed in these patients. These may be improved if the portal hypertension is relieved by shunt surgery or liver transplantation. Splenectomy would normally be required only in those patients whose segmental portal hypertension has resulted in symptomatic oesophagogastric varices.

Felty's syndrome

Patients with rheumatoid arthritis may develop leucopenia. This is referred to as Felty's syndrome if it is extreme and associated with splenomegaly. There is no definite relationship between the severity of the arthritic changes and the leucopenia and splenomegaly. Splenectomy produces only a transient improvement in the blood picture, but rheumatoid arthritis may respond to steroid therapy to which it had previously become resistant.

NEOPLASMS

Haemangioma is the most common benign tumour of the spleen and may rarely develop into a haemangiosarcoma that is managed by splenectomy. The spleen is rarely the site of metastatic disease. Lymphoma is the most common cause of neoplastic enlargement, and splenectomy may play a part in its management. Splenectomy may be required to achieve a diagnosis in the absence of palpable lymph nodes or to relieve the symptoms of gross splenomegaly. However, the need for staging laparoscopy

has largely receded with the advent of CT scanning. Its use has been restricted to those patients in whom a definite histological diagnosis of intra-abdominal disease will affect management. Thus, selected patients with stage IA or IIA Hodgkin's disease may be candidates for staging laparotomy or laparoscopy. In the absence of obvious liver or intra-abdominal nodal disease, splenectomy is an integral part of the staging procedure to exclude splenic involvement, which would alter the method of treatment.

Myelofibrosis results from an abnormal proliferation of mesenchymal elements in the bone marrow, spleen, liver and lymph nodes. Most patients present over the age of 50 years, and the spleen may produce pain owing to its gross enlargement (Fig. 62.8) or from splenic infarcts. Splenectomy reduces the need for transfusion and may relieve the discomfort resulting from the splenomegaly.

SPLENECTOMY

The common indications for splenectomy are:

- trauma resulting from an accident or during a surgical procedure, as for example during mobilisation of the oesophagus, stomach, distal pancreas or splenic flexure of the colon;
- removal *en bloc* with the stomach as part of a radical gastrectomy or with the pancreas as part of a distal or total pancreatectomy;
- to reduce anaemia or thrombocytopenia in spherocytosis, idiopathic thrombocytopenic purpura or hypersplenism;
- in association with shunt or variceal surgery for portal hypertension (Summary box 62.2).

Summary box 62.2

Indications for splenectomy

Trauma

- Accidental
- Operative

Oncological

- Part of *en bloc* resection
- Diagnostic
- Therapeutic

Haematological

- Spherocytosis
- Purpura (ITP)
- Hypersplenism

Portal hypertension

- Variceal surgery

Figure 62.7 Computerised tomographic scan showing an enlarged spleen in a patient with portal hypertension secondary to portal vein thrombosis. Clot is evident within the lumen of the portal vein (black arrow), and large varices (white arrows) are present at the splenic hilus.

Augustus Roi Felty, 1895–1964, Physician, Hartford Hospital, Hartford, CT, USA, described this disease in 1924.

Preoperative preparation

In the presence of a bleeding tendency, transfusion of blood, fresh-frozen plasma, cryoprecipitate or platelets may be required. Coagulation profiles should be as near normal as possible at operation, and platelets should be available for patients with thrombocytopenia at operation and in the early postoperative period.

Antibiotic prophylaxis appropriate to the operative procedure should be given, and consideration should be given to the risk of post-splenectomy sepsis (see below).

Figure 62.8 Magnetic resonance imaging (MRI) scan showing massive hepatosplenomegaly secondary to myelofibrosis. Note the prominent portal system and the left kidney, which is superimposed over the grossly enlarged spleen.

Technique of open splenectomy

Most surgeons use a midline or transverse left subcostal incision for open splenectomy. Rarely, a thoracoabdominal incision may be necessary for a massive spleen that is adherent to the diaphragm. Passage of a nasogastric tube following induction of the anaesthetic enables the stomach to be emptied.

In elective splenectomy, the gastrosplenic ligament is opened up, and the short gastric vessels are divided. The splenic vessels at the superior border of the pancreas are suture-ligated. The posterior surface of the spleen is exposed, the posterior leaf of the lienorenal ligament divided with long curved scissors, and the spleen rotated medially along with the tail and body of the pancreas (Fig. 62.9). The pancreas is separated from the hilar vessels, which are ligated and divided. Accessory splenic tissue in the splenic hilum or omentum should be excluded by a careful search at operation. There is no need to drain the wound if haemostasis is secured adequately.

Technique of laparoscopic splenectomy

The patient is placed on the right side with the space between the left ilium and costal margin exposed. Placement of access ports is often determined by the size of the patient and the spleen. Insufflation of the abdomen can be performed once access is obtained through an incision 1 cm from the costal margin at the left mid-clavicular line. A further trocar is inserted close to the costal margin below the xiphoid. A 12-mm trocar is inserted at a similar distance from the costal margin at the posterior axillary line. The splenocolic ligament is divided to give access to the lower splenic pole. The spleen is separated from the kidney and diaphragm before the gap between the splenic hilum and the tail of the pancreas is enlarged. The spleen is elevated to expose the splenic hilum, which is secured and divided with an endoscopic vascular stapler (Fig. 62.10). Two or three applications of the instrument may be required to secure the hilum and the short

Figure 62.9 Diagrammatic view of the approach required to divide the short gastric vessels anteriorly and the lienorenal ligament posteriorly.

Figure 62.10 Photograph showing a stapling gun across the hilus of spleen for division of the splenic vessels during laparoscopic splenectomy.

gastric vessels. Any remaining attachments to the diaphragm are divided before a self-retaining opening bag is introduced through the incision of the open laparoscopy after removal of the 12-mm port. The spleen is placed in the bag, the mouth of which is pulled out of the abdominal opening before the spleen is crushed and retrieved with an instrument. The operation may be undertaken as a hand-assisted procedure.

Postoperative complications

Immediate complications specific to splenectomy include haemorrhage resulting from a slipped ligature. Haematemesis from gastric mucosal damage and gastric dilatation is uncommon. Left basal atelectasis is common, and a pleural effusion may be present. Adjacent structures at risk during the procedure include the stomach and pancreas. A fistula may result from damage to the greater curvature of the stomach during ligation of the short gastric vessels. Damage to the tail of the pancreas may result in

pancreatitis, a localised abscess or a pancreatic fistula. The blood platelet count may rise and, if this exceeds $1 \times 10^6 \text{ ml}^{-1}$, prophylactic aspirin is recommended to prevent axillary or other venous thrombosis.

Post-splenectomy septicaemia may result from *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae* and *Escherichia coli*. The risk is greater in the young patient, in splenectomised patients treated with chemoradiotherapy and in patients who have undergone splenectomy for thalassaemia, sickle cell disease and autoimmune anaemia or thrombocytopenia.

Opportunist post-splenectomy infection (OPSI) is a major concern. Published guidelines emphasise that most infections after splenectomy could be avoided through measures that include offering patients appropriate and timely immunisation, antibiotic prophylaxis, education and prompt treatment of infection. The benefit of prophylactic antibiotics in this setting remains controversial. It is thought that children who have undergone splenectomy before the age of 5 years should be treated with a daily dose of penicillin until the age of 10 years. Prophylaxis in older children should be continued at least until the age of 16 years, but its use is less well defined in adults. Furthermore, compliance is problematic in the long term but, as the risk of overwhelming sepsis is greatest within the first 2–3 years after splenectomy, it seems reasonable to give prophylaxis during this time. However, all patients with compromised immune function should receive prophylaxis. Satisfactory oral prophylaxis can be obtained with penicillin, erythromycin or amoxicillin, or co-amoxiclav. Suspected infection can be treated intravenously with these same antibiotics and cefotaxime, ceftriaxone or chloramphenicol in patients allergic to penicillin and cephalosporins.

If elective splenectomy is planned, consideration should be given to vaccinating against pneumococcus, meningococcus (both repeated every 5 years) and *H. influenzae* (repeated every 10 years). Yearly influenza vaccination has been recommended as there is some evidence that it may reduce the risk of secondary bacterial infection. Such vaccinations should be administered at least 2 weeks before elective surgery and as soon as possible after recovery from surgery but before discharge from hospital in all other cases. Pneumococcal vaccination is recommended in those patients aged over 2 years. *Haemophilus influenzae* type b vaccination is recommended irrespective of age. Meningococcal vaccination is not recommended routinely unless the individual is considering travel to areas where there is a risk of group A infection, in local outbreaks and for contacts with infected cases.

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wrocław, Poland).
Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria.

Meningococcal vaccination only offers protection of short duration, and group B and C infection is commoner. The improved immunogenic properties of the newer group C conjugate vaccine may confer greater protection to the patient. It is also recommended that influenza vaccine be given to asplenic patients as influenza has been implicated as a risk factor for secondary bacterial infection in both general and meningococcal disease.

In the trauma victim, vaccination can be given in the postoperative period, and the resulting antibody levels will be protective in the majority of cases. Antibody levels are, however, less than 50% of those achieved if vaccination is given in the presence of an intact spleen. Protection following vaccination is not always guaranteed (Summary box 62.3).

Summary box 62.3

Splenectomy

- Remember preoperative immunisation
- Prophylactic antibiotics in the long term
- OPSI is a real clinical danger

Patients who have undergone splenectomy and are travelling to countries where malaria is present are strongly advised to use all physical anti-mosquito barriers as well as antimalarial therapy.

The gall bladder and bile ducts

LEARNING OBJECTIVES

To understand:

- The techniques used for imaging the biliary tree
- The management of gallstones

- Unusual disorders of the biliary tree
- Malignant disease of the biliary tree

SURGICAL ANATOMY AND PHYSIOLOGY

The gall bladder lies on the underside of the liver in the main liver scissura at the junction of the right and left lobes of the liver. The relationship of the gall bladder to the liver varies between being embedded within the liver substance to suspended by a mesentery. It is a pear-shaped structure, 7.5–12 cm long, with a normal capacity of about 35–50 ml. The anatomical divisions are a fundus, a body and a neck that terminates in a narrow infundibulum. The muscle fibres in the wall of the gall bladder are arranged in a criss-cross manner, being particularly well developed in its neck. The mucous membrane contains indentations of the mucosa that sink into the muscle coat; these are the crypts of Luschka.

The *cystic duct* is about 3 cm in length but variable. Its lumen is usually 1–3 mm in diameter. The mucosa of the cystic duct is arranged in spiral folds known as the valves of Heister. Its wall is surrounded by a sphincteric structure called the sphincter of Lütken. While the cystic duct joins the common hepatic duct in its supraduodenal segment in 80% of cases, it may extend down into the retroduodenal or even retropancreatic part of the bile duct before joining. Occasionally, the cystic duct may join the right hepatic duct or even a right hepatic sectorial duct.

The *common hepatic duct* is usually less than 2.5 cm long and is formed by the union of the right and left hepatic ducts. The *common bile duct* is about 7.5 cm long and is formed by the junction of the cystic and common hepatic ducts. It is divided into four parts:

- the *supraduodenal portion*, about 2.5 cm long, running in the free edge of the lesser omentum;
- the *retroduodenal portion*;
- the *infraduodenal portion*, which lies in a groove, but at times in a tunnel, on the posterior surface of the pancreas;
- the *intraduodenal portion*, which passes obliquely through the wall of the second part of the duodenum, where it is surrounded by the sphincter of Oddi, and terminates by opening on the summit of the ampulla of Vater.

Hubert von Luschka, 1820–1875, Professor of Anatomy, Tübingen, Germany.
Ruggero Oddi, 1845–1906, Physiologist, Perugia, who later worked in Rome, Italy, described this sphincter in 1887.
Abraham Vater, 1684–1751, Professor of Anatomy and Botany, (1719) and later of Pathology and Therapeutics, Wittenburg, Germany.

The cystic artery, a branch of the right hepatic artery, is usually given off behind the common hepatic duct (Fig. 63.1). Occasionally, an accessory cystic artery arises from the gastroduodenal

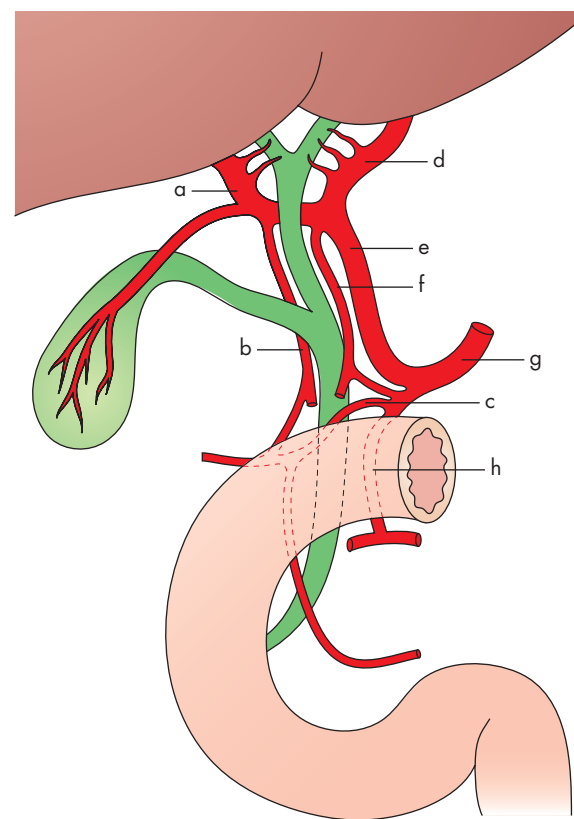

Figure 63.1 The anatomy of the gall bladder and bile ducts. Note the arrangement of the arterial tree: (a) right hepatic artery; (b) right choledochal artery; (c) retroduodenal artery; (d) left branch of hepatic artery; (e) hepatic artery; (f) left choledochal artery; (g) common hepatic artery; (h) gastroduodenal artery.

artery. In 15% of cases, the right hepatic artery and/or the cystic artery cross in front of the common hepatic duct and the cystic duct. The most dangerous anomalies are where the hepatic artery takes a tortuous course on the front of the origin of the cystic duct, or the right hepatic artery is tortuous and the cystic artery short. The tortuosity is known as the 'caterpillar turn' or 'Moynihan's hump' (Fig. 63.2). This variation is the cause of many problems during a difficult cholecystectomy with inflammation in the region of the cystic duct. Inadvertent damage to the right hepatic artery is most difficult to control laparoscopically.

Lymphatics

The lymphatic vessels of the gall bladder (subserosal and submucosal) drain into the cystic lymph node of Lund (the sentinel lymph node). This lies in the fork created by the junction of the cystic and common hepatic ducts. Efferent vessels from this lymph node go to the hilum of the liver and to the coeliac lymph nodes. The subserosal lymphatic vessels of the gall bladder also connect with the subcapsular lymph channels of the liver, and this accounts for the frequent spread of carcinoma of the gall bladder to the liver.

Surgical physiology

Bile, as it leaves the liver, is composed of 97% water, 1–2% bile salts and 1% pigments, cholesterol and fatty acids. The liver excretes bile at a rate estimated to be approximately 40 ml h⁻¹. The rate of bile secretion is controlled by cholecystikinin (CCK),

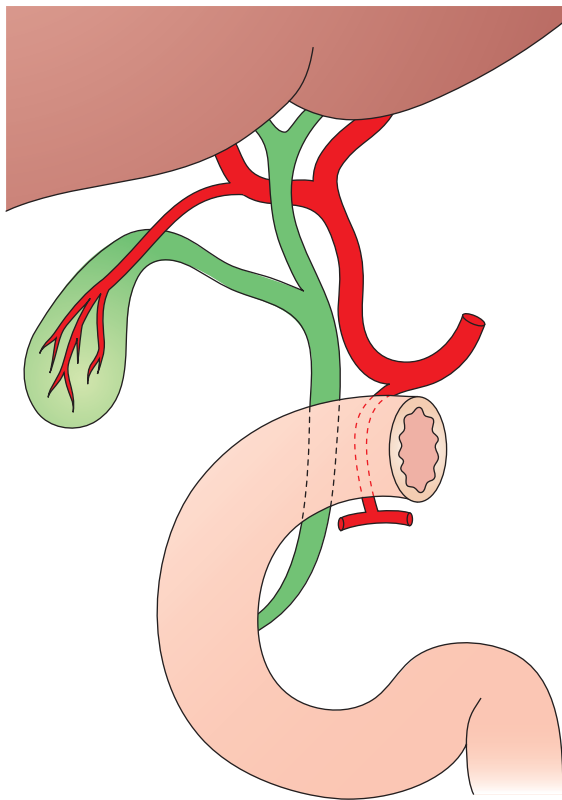

Figure 63.2 Tortuous hepatic artery (so called 'caterpillar turn' or 'Moynihan's hump'), a frequent cause of inadvertent arterial damage or bleeding during cholecystectomy.

Fred Bates Lund, 1865–1950, Surgeon, the Boston City Hospital, Boston, MA, USA.

which is released from the duodenal mucosa. With feeding, there is increased production of bile.

FUNCTIONS OF THE GALL BLADDER

The gall bladder is a reservoir for bile. During fasting, resistance to flow through the sphincter is high, and bile excreted by the liver is diverted to the gall bladder. After feeding, the resistance to flow through the sphincter of Oddi is reduced, the gall bladder contracts, and the bile enters the duodenum. These motor responses of the biliary tract are in part effected by the hormone CCK.

The second main function of the gall bladder is concentration of bile by active absorption of water, sodium chloride and bicarbonate by the mucous membrane of the gall bladder. The hepatic bile that enters the gall bladder becomes concentrated 5–10 times, with a corresponding increase in the proportion of bile salts, bile pigments, cholesterol and calcium.

The third function of the gall bladder is the secretion of mucus – approximately 20 ml is produced per day. With total obstruction of the cystic duct in a healthy gall bladder, a mucocele develops on account of this function of the mucosa of the gall bladder.

RADIOLOGICAL INVESTIGATION OF THE BILIARY TRACT

Plain radiograph

A plain radiograph of the gall bladder will show radio-opaque gallstones in 10% of patients with gallstones (Fig. 63.3). Rarely, the centre of a stone may contain radiolucent gas in a triradiate or biradiate fissure, and this gives rise to characteristic dark shapes on a radiograph – the 'Mercedes-Benz' or 'seagull' sign.

Figure 63.3 Plain radiograph showing radio-opaque stones in the gall bladder. Radio-opaque stones are uncommon (10%).

The Mercedes-Benz sign takes its name from the insignia displayed on the bonnet of a Mercedes-Benz car.
A Seagull is a medium sized bird related to the Terns and Skuas, which is found world-wide and scavenges for its food.

A plain X-ray may also show the rare cases of calcification of the gall bladder, a so called 'porcelain' gall bladder (Fig. 63.4). The importance of this appearance is an association with carcinoma in up to 25% of patients. It is therefore an indication for cholecystectomy. Gas may be seen in the wall of the gall bladder (emphysematous cholecystitis). Gas in the biliary tree may be seen after endoscopic sphincterotomy or surgical anastomosis (Summary box 63.1).

Summary box 63.1

Investigation of the biliary tree

- Ultrasound: stones and biliary dilatation
- Plain radiograph: calcification
- Magnetic resonance cholangiopancreatography: anatomy and stones
- Multidetector row computerised tomography scan: anatomy, liver, gall bladder and pancreas cancer
- Radioisotope scanning: function
- Endoscopic retrograde cholangiopancreatography: anatomy, stones and biliary strictures
- Percutaneous transhepatic cholangiography: anatomy and biliary strictures
- Endoscopic ultrasound: anatomy and stones

Oral cholecystography and intravenous cholangiography

Oral and intravenous cholecystography are of historical interest only as they are relatively inaccurate and have been discarded and replaced by more accurate imaging modalities.

Ultrasonography

Transabdominal ultrasonography (Figs 63.5–63.8) is the initial imaging modality of choice as it is accurate, readily available, inexpensive and quick to perform. However, it is operator dependent and may be suboptimal due to excessive body fat and intraluminal bowel gas. It can demonstrate biliary calculi, the size of the gall bladder, the thickness of the gall bladder wall, the presence of inflammation around the gall bladder, the size of the

Figure 63.4 Porcelain gall bladder.

common bile duct and, occasionally, the presence of stones within the biliary tree. It may even show a carcinoma of the pancreas occluding the common bile duct.

In the patient who presents with obstructive jaundice, ultrasonography is particularly helpful as it can identify intra- and

Figure 63.8 Ultrasound examination. Dilatation of the intrahepatic and common bile ducts due to a calculus impacted at the sphincter of Oddi. There are calculi visible in the gall bladder (courtesy of James McIvor, FDS, FRCR, London, UK).

extrahepatic biliary dilatation and the level of obstruction. In addition, the cause of the obstruction may also be identified, such as gallstones in the gall bladder, common hepatic or common bile duct stones or lesions in the wall of the duct suggestive of a cholangiocarcinoma or enlargement of the pancreatic head indicative of a pancreatic carcinoma.

Endoscopic ultrasonography (Figs 63.9 and 63.10) uses a specially designed endoscope with an ultrasound transducer at its tip, which allows visualisation of the liver and biliary tree from within the stomach and duodenum. It provides accurate imaging of the common bile duct and is particularly useful in detecting stones within the bile ducts, choledocholithiasis. In addition, it has been shown to be highly accurate in diagnosing and staging both pancreatic and periampullary cancers.

Radioisotope scanning

Technetium-99m (^{99m}Tc)-labelled derivatives of iminodiacetic acid (HIDA, IODIDA) are, when injected intravenously, selectively taken up by the retroendothelial cells of the liver and excreted into bile. This allows visualisation of the biliary tree and gall bladder. The gall bladder is visualised within 30 min of isotope injection in 90% of normal individuals and within 1 hour in the remainder (Fig. 63.11). The bowel is usually seen within 1 hour in the majority of patients. Non-visualisation of the gall bladder is suggestive of acute cholecystitis. If the patient has a

Figure 63.9 Endoscopic ultrasonography demonstrating the common bile duct and pancreatic duct.

Figure 63.10 Endoscopic ultrasound showing the junction of the cystic duct with the common bile duct.

Figure 63.11 Dimethyl iminodiacetic acid (HIDA) scan demonstrating at 20 min non-visualisation of the gall bladder (arrow), suggestive of acute cholecystitis.

contracted gall bladder, as often occurs in chronic cholecystitis, gall bladder visualisation may be reduced or delayed.

Biliary scintigraphy may also be helpful in diagnosing bile leaks and iatrogenic biliary obstruction. When there is a suspicion of a bile leak following a cholecystectomy, radioisotope imaging should be performed. Scintigraphy can confirm the presence and quantify the leak, thus helping the surgeon to determine whether or not an operative or conservative approach is warranted.

Computerised tomography

This imaging modality allows visualisation of the liver, bile ducts, gall bladder and pancreas. It is particularly useful in detecting hepatic and pancreatic lesions and is the modality of choice in the staging of cancers of the liver, gall bladder, bile ducts and pancreas. It can identify the extent of the primary tumour and defines its relationship to other organs and blood vessels (Fig. 63.12). In addition, the presence of enlarged lymph nodes or metastatic disease can be seen.

For benign biliary diseases, standard computerised tomography (CT) is not that useful an investigation. Gallstones are

Figure 63.12 Computerised tomography scan demonstrating a hilar mass (thick arrow) and biliary dilation (thin arrow).

often not visualised, and cholecystitis is underdiagnosed. However, improvements in CT technology such as multidetector helical scanners that allow for three-dimensional reconstruction of the biliary tree have led to greater diagnostic accuracy and may increase the use of this modality in the future.

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) is an imaging technique based on the principles of nuclear magnetic resonance used to image the gall bladder and biliary system. It is non-invasive and can provide either cross-sectional (Fig. 63.13) or projection (Fig. 63.14) images. Contrast is not required and, using appropriate techniques, excellent images can be obtained of the biliary tree that demonstrate ductal obstruction, strictures or other intraductal abnormalities. The images obtained are comparable to those from endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) without the potential complications of either technique.

Endoscopic retrograde cholangiopancreatography

This technique remains widely used. Using a side-viewing endoscope, the ampulla of Vater can be identified and cannulated. Injection of water-soluble contrast directly into the bile duct provides excellent images of the ductal anatomy (Fig. 63.15) and can identify causes of obstruction such as stones (Fig. 63.16) or

Figure 63.13 Cross-sectional magnetic resonance image demonstrating a hilar mass (thick arrow) (same as Fig. 63.12) and associated gallstones (thin arrow).

Figure 63.14 Magnetic resonance cholangiopancreatography demonstrating hilar obstruction as seen in Figures 63.12 and 63.13.

Figure 63.15 Endoscopic retrograde cholangiopancreatography: normal cholangiogram.

Figure 63.16 Endoscopic retrograde cholangiopancreatography demonstrating stone obstructing the common bile duct (arrow).

malignant strictures (Fig. 63.17). While the widespread availability of ultrasound and MRCP has limited the diagnostic use of ERCP, the technique has a role in the assessment of the jaundiced patient. In this group, it is especially useful in determining the cause and level of obstruction. Bile can be sent for cytological and

Figure 63.17 Endoscopic retrograde cholangiopancreatography: partial occlusion of the bile duct by a malignant stricture (arrow).

microbiological examination, and brushings can be taken from strictures for cytological studies. Therapeutic interventions such as stone removal or stent placement to relieve the obstruction can be performed. Thus, ERCP has evolved into a mainly therapeutic rather than a diagnostic technique.

Percutaneous transhepatic cholangiography

This is an invasive technique in which the bile ducts are cannulated directly. It is only undertaken once a bleeding tendency has been excluded and the patient's prothrombin time is normal. Antibiotics should be given prior to the procedure. Usually, under fluoroscopic control, a needle (the Chiba or Okuda needle) is introduced percutaneously into the liver substance. Under

Figure 63.18 Transhepatic cholangiogram showing a stricture of the common hepatic duct (courtesy of Miss Phyllis George, FRCS, London, UK).

Kunio Okuda, Professor of Medicine, The University of Chiba, East Honshu, Japan.

radiological control (either ultrasound or CT), a bile duct is cannulated. Successful entry is confirmed by contrast injection or aspiration of bile. Water-soluble contrast medium is injected to demonstrate the biliary system. Multiple images can be taken demonstrating areas of strictures or obstruction (Fig. 63.18). Bile can be sent for cytology. In addition, PTC enables the placement of a catheter into the bile ducts to provide external biliary drainage or the insertion of indwelling stents. The scope of this procedure can be further extended by leaving the drainage catheter *in situ* for a number of days and then dilating the track sufficiently for a fine flexible choledochoscope to be passed into the intrahepatic biliary tree in order to diagnose strictures, take biopsies or remove stones.

In general, in the jaundiced patient, if a malignant stricture at the level of the confluence of the right and left hepatic ducts or higher is suspected, a PTC is preferred to an ERCP as successful drainage is more likely.

Peroperative cholangiography

During open or laparoscopic cholecystectomy, a catheter can be placed in the cystic duct and contrast injected directly into the biliary tree. The technique defines the anatomy and is mainly used to exclude the presence of stones within the bile ducts (Figs 63.19–63.21). A single X-ray plate or image intensifier can be used to obtain and review the images intraoperatively.

Figure 63.19 Peroperative cholangiography using a radiolucent table-top

Figure 63.20 Peroperative cholangiography. Technique of introducing contrast.

Figure 63.21 Peroperative cholangiography. (a) A normal duct: contrast passes without hindrance into the duodenum. (b) Dilated biliary system with multiple stones in the common bile duct and reflux of contrast into the pancreatic duct. Sphincterotomy was performed.

Irrespective of the technique used, the operating table should be tilted head down approximately 20° to facilitate filling of the intrahepatic ducts. In addition, care should be taken when injecting contrast not to introduce air bubbles into the system, as these may give the appearance of stones and lead to a false-positive result.

Operative biliary endoscopy (choledochoscopy)

At operation, a flexible fiberoptic endoscope can be passed down the cystic duct into the common bile duct enabling stone identification and removal under direct vision. The technique can be combined with an X-ray image intensifier to ensure complete clearance of the biliary tree. After exploration of the bile duct, a tube can be left in the cystic duct remnant or in the common bile duct (a T-tube) and drainage of the biliary tree established. After 7–10 days, a track will be established. This track can be used for the passage of a choledochoscope to remove residual stones in the awake patient in an endoscopy suite. This technique is invaluable in the management of difficult stone disease and prevents the excessive prolongation of an operative exploration of the common bile duct.

CONGENITAL ABNORMALITIES OF THE GALL BLADDER AND BILE DUCTS

Embryology

The hepatic diverticulum arises from the ventral wall of the foregut and elongates into a stalk to form the choledochus. A lateral bud is given off, which is destined to become the gall bladder and cystic duct. The embryonic hepatic duct sends out many branches, which join up the canaliculi between the liver cells. As is usual with embryonic tubular structures, hyperplasia obliterates the lumina of this ductal system; normally, recanalisation subsequently occurs and bile begins to flow. During early fetal life, the gall bladder is entirely intrahepatic.

Absence of the gall bladder

Occasionally, the gall bladder is absent. Failure to visualise the gall bladder is not necessarily a pathological problem.

The Phrygian cap

The Phrygian cap (Fig. 63.22) is present in 2–6% of cholecystograms and may be mistaken for a pathological deformity of the organ. ‘Phrygian cap’ refers to hats worn by the people of Phrygia, an ancient country of Asia Minor; it was rather like a liberty cap of the French Revolution.

Figure 63.22 The main variations in gall bladder and cystic duct anatomy. (a) Double gall bladder. (b) Septum of the gall bladder; 1 is the most common, the so called ‘Phrygian cap’. (c) Diverticulum of the gall bladder. (d) Variations in cystic duct insertion.

Floating gall bladder

The organ may hang on a mesentery, which makes it liable to undergo torsion.

Double gall bladder

Rarely, the gall bladder is duplicated. One may be intrahepatic.

Absence of the cystic duct

This is usually a pathological, as opposed to an anatomical, anomaly and indicates the recent passage of a stone or the presence of a stone at the lower end of the cystic duct, which is ulcerating into the common bile duct. The main danger at surgery is damage to the bile duct, and particular care to identify the correct anatomy is essential before division of any duct.

Low insertion of the cystic duct

The cystic duct opens into the common bile duct near the ampulla. All variations of this anomaly can occur (Fig. 63.23). At operation, they are not important. Dissection of a cystic duct that is inserted low in the bile duct should be avoided, as removal will damage the blood supply to the common bile duct and can lead to stricture formation.

An accessory cholecystohepatic duct

Ducts passing directly into the gall bladder from the liver do occur and are probably not uncommon. Nevertheless, larger ducts should be closed but, before doing so, the precise anatomy should be carefully ascertained (Fig. 63.23).

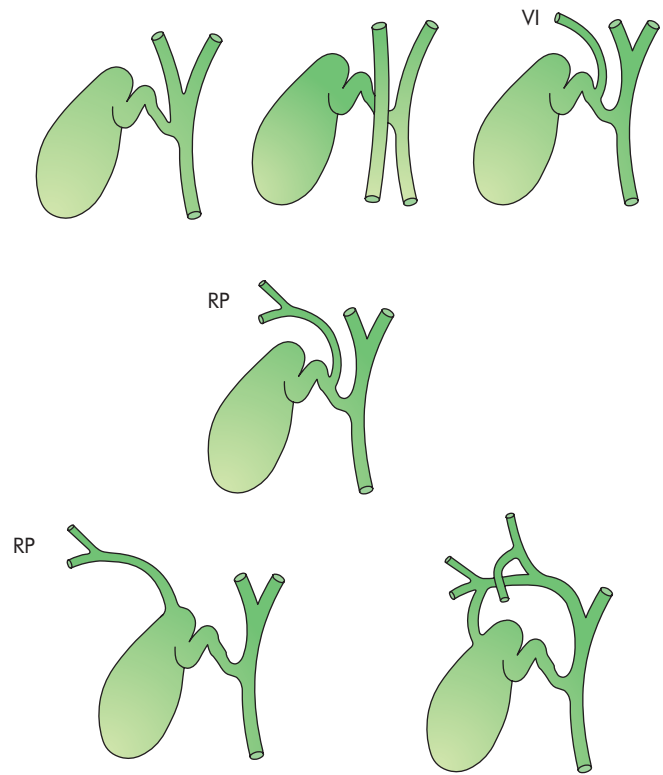

Figure 63.23 Patterns of cystic duct anatomy – note segment VI drainage into the cystic duct and the drainage of the right posterior sectorial duct (RP) into the neck of the gall bladder, or an accessory duct, the so called duct of Luschka.

EXTRAHEPATIC BILIARY ATRESIA

Aetiology and pathology

Atresia is present in approximately 1:12 000 live births and affects males and females equally. The extrahepatic bile ducts are progressively destroyed by an inflammatory process, which starts around the time of birth. The aetiology is unclear. Intrahepatic changes also occur and eventually result in biliary cirrhosis and portal hypertension. Untreated, death from the consequences of liver failure occurs before the age of 3 years.

The inflammatory destruction of the bile ducts has been classified into three main types (Fig. 63.24):

- type I: atresia restricted to the common bile duct;
- type II: atresia of the common hepatic duct;
- type III: atresia of the right and left hepatic ducts.

Associated anomalies include, in about 20% of cases, cardiac lesions, polysplenia, situs inversus, absent vena cava and a preduodenal portal vein.

Clinical features

About one-third of patients are jaundiced at birth. In all, however, jaundice is present by the end of the first week and deepens progressively. The meconium may be a little bile-stained, but later the stools are pale and the urine is dark. Prolonged steatorrhoea gives rise to osteomalacia (biliary rickets). Pruritus is severe. Clubbing and skin xanthomas, probably related to a raised serum cholesterol, may be present.

Differential diagnosis

This includes any form of jaundice in a neonate giving a cholestatic picture. Examples are alpha-1-antitrypsin deficiency, cholestasis

associated with intravenous feeding, choledochal cyst and inspissated bile syndrome. Neonatal hepatitis is the most difficult to differentiate. Both extrahepatic biliary atresia and neonatal hepatitis are associated with giant cell transformation of the hepatocytes. Liver biopsy and radionuclide excretion scans are essential.

Treatment

Patent segments of proximal bile duct are found in 10% of type I lesions. A direct Roux-en-Y hepaticojejunostomy will achieve bile flow in 75%, but progressive fibrosis results in disappointing long-

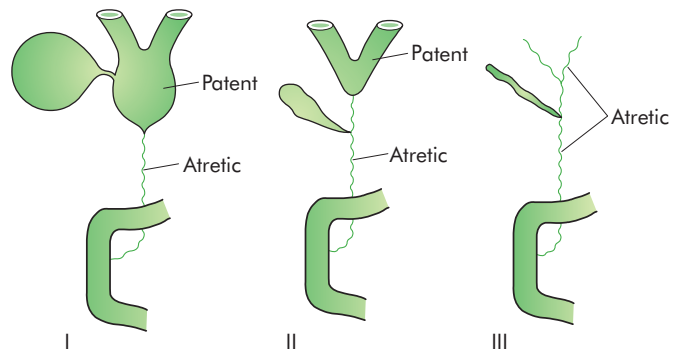

Figure 63.24 Classification of biliary atresia. Gall bladder filling provides a clue to the type of atresia.

Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.

term results. A simple biliary–enteric anastomosis is not possible in the majority of cases in which the proximal hepatic ducts are either very small (type II) or atretic (type III). These are treated by the Kasai procedure, in which radical excision of all bile duct tissue up to the liver capsule is performed. A Roux-en-Y loop of jejunum is anastomosed to the exposed area of liver capsule above the bifurcation of the portal vein creating a portoenterostomy. The chances of achieving effective bile drainage after portoenterostomy are maximal when the operation is performed before the age of 8 weeks. Approximately 90% of children whose bilirubin falls to within the normal range can be expected to survive 10 years or more. Early referral for surgery is critical.

Postoperative complications include bacterial cholangitis, which occurs in 40% of patients. Repeated attacks lead to hepatic fibrosis, and 50% of long-term survivors develop portal hypertension, with one-third having variceal bleeding.

Liver transplantation should be considered in children in whom a portoenterostomy is unsuccessful. Results are improving with 70–80% alive 2–5 years following transplantation.

CONGENITAL DILATATION OF THE INTRAHEPATIC DUCTS (CAROLI'S DISEASE)

This rare condition is characterised by multiple irregular saccular dilatations of the intrahepatic ducts separated by segments of normal or stenotic ducts with a normal extrahepatic biliary system. The aetiology is unknown, but it is considered to be hereditary. It can be divided into a simple and a periportal fibrotic type. The periportal fibrotic type presents in childhood and is associated with biliary stasis, stone formation and cholangitis. In contrast, the simple type presents later with episodes of abdominal pain and biliary sepsis. Associated conditions include congenital hepatic fibrosis, polycystic liver and, rarely, cholangiocarcinoma. The mainstays of treatment are antibiotics for the cholangitis and the removal of calculi. As the condition can be limited to one lobe of the liver, lobectomy may be indicated.

Choledochal cyst

Cystic disease of the biliary system is rare. Choledochal cysts are congenital dilatations of the intra- and/or extrahepatic biliary system. The pathogenesis is unclear. Anomalous junctions of the biliary pancreatic junction are frequently observed, but whether or not these play a role in the pathogenesis of the condition is unclear. Todani and colleagues proposed a classification of cystic disease of the biliary tract (Fig. 63.25). Type I cysts are the most common and account for approximately 75% of patients.

Patients may present at any age with jaundice, fever, abdominal pain and a right upper quadrant mass on examination. However, 60% of cases are diagnosed before the age of 10 years. Pancreatitis is a not infrequent presentation in adults. Patients with choledochal cysts have an increased risk of developing cholangiocarcinoma with the risk varying directly with the age at diagnosis.

Ultrasonography will confirm the presence of an abnormal cyst and magnetic resonance imaging (MRI/MRCP) will reveal the anatomy, in particular the relationship between the lower end of the bile duct and the pancreatic duct. CT is also useful for delineating the extent of the intra- or extrahepatic dilatation.

Radical excision of the cyst is the treatment of choice with

Figure 63.25 Classification of types of choledochal cyst. Type Ia and b: diffuse cystic. Note extension into the pancreas of type Ib. Type II: diverticulum of the common bile duct. Type III: diverticulum within the pancreas. Type IV: extension into the liver. Type V: cystic dilatation only of the intrahepatic ducts.

reconstruction of the biliary tract using a Roux-en-Y loop of jejunum. Complete resection of the cyst is important because of the association with the development of cholangiocarcinoma. Resection and Roux-en-Y reconstruction is also associated with a reduced incidence of stricture formation and recurrent cholangitis.

TRAUMA

Injuries to the gall bladder and extrahepatic biliary tree are rare. They occur as a result of blunt or penetrating abdominal trauma. Operative trauma is perhaps more frequent than external trauma. The physical signs are those of an acute abdomen. Management depends on the location and extent of the biliary and associated injury. In the stable patient, a transected bile duct is best repaired by a Roux-en-Y choledochojejunostomy. Injuries to the gall bladder can be dealt with by cholecystectomy.

TORSION OF THE GALL BLADDER

This is very rare and requires a long mesentery. It occurs most often in an older patient with a large mucocele of the gall bladder. The patient presents with extreme pain and an acute abdomen. Immediate exploration and cholecystectomy are indicated.

GALLSTONES (CHOLELITHIASIS)

Gallstones are the most common biliary pathology. It is estimated that gallstones are present in 10–15% of the adult population in the USA. They are asymptomatic in the majority (> 80%). In the UK, the prevalence of gallstones at the time of death is estimated to be 17% and may be increasing. Approximately 1–2% of asymptomatic patients will develop symptoms requiring cholecystectomy per year, making cholecystectomy one of the most common operations performed by general surgeons.

Aetiology of gallstones

Gallstones can be divided into three main types: cholesterol, pigment (brown/black) or mixed stones. In the USA and Europe,

80% are cholesterol or mixed stones, whereas in Asia, 80% are pigment stones. Cholesterol or mixed stones contain 51–99% pure cholesterol plus an admixture of calcium salts, bile acids, bile pigments and phospholipids.

Cholesterol, which is insoluble in water, is secreted from the canalicular membrane in phospholipid vesicles. Whether cholesterol remains in solution depends on the concentration of phospholipids and bile acids in bile and the type of phospholipid and bile acid. Micelles formed by the phospholipid hold cholesterol in a stable thermodynamic state. When bile is supersaturated with cholesterol or bile acid concentrations are low, unstable unilamellar phospholipid vesicles form, from which cholesterol crystals may nucleate, and stones may form. The process of gallstone formation is complex (Fig. 63.26). Obesity, high-calorie diets and certain medications can increase the secretion of cholesterol and supersaturate the bile, increasing the lithogenicity of bile. Nucleation of cholesterol monohydrate crystals from multilamellar vesicles is a crucial step in gallstone formation. Abnormal emptying of the gall bladder may promote the aggregation of nucleated cholesterol crystals; hence, removing gallstones without removing the gall bladder inevitably leads to gallstone recurrence.

Pigment stone is the name used for stones containing less than 30% cholesterol. There are two types – black and brown. Black stones are largely composed of an insoluble bilirubin pigment polymer mixed with calcium phosphate and calcium bicarbonate. Overall, 20–30% of stones are black. The incidence rises with age. Black stones accompany haemolysis, usually hereditary spherocytosis or sickle cell disease. For unclear reasons, patients with cirrhosis have a higher instance of pigmented stones.

Brown pigment stones contain calcium bilirubinate, calcium palmitate and calcium stearate, as well as cholesterol. Brown stones are rare in the gall bladder. They form in the bile duct and are related to bile stasis and infected bile. Stone formation is related to the deconjugation of bilirubin deglucuronide by bacterial β -glucuronidase. Insoluble unconjugated bilirubinate precipitates. Brown pigment stones are also associated with the presence of foreign bodies within the bile ducts such as endopro-

Figure 63.26 Factors associated with gallstone formation.

thesis (stents) or parasites such as *Clonorchis sinensis* and *Ascaris lumbricoides*.

Clinical presentation

Patients typically complain of right upper quadrant or epigastric pain, which may radiate to the back. This may be described as colicky, but more often is dull and constant. Other symptoms include dyspepsia, flatulence, food intolerance, particularly to fats, and some alteration in bowel frequency. Biliary colic is typically present in 10–25% of patients. This is described as a severe right upper quadrant pain that ebbs and flows associated with nausea and vomiting. Pain may radiate to the chest. The pain is usually severe and may last for minutes or even several hours. Frequently, the pain starts during the night, waking the patient. Minor episodes of the same discomfort may occur intermittently during the day. Dyspeptic symptoms may coexist and be worse after such an attack. As the pain resolves, the patient is able to eat and drink again, often only to suffer further episodes. It is of interest that the patient may have several episodes of this nature over a period of a few weeks and then no more trouble for some months (Summary box 63.2).

Summary box 63.2

Natural history of gallstones

The natural history of gallstones is shown in Summary box 63.3. Jaundice may result if a stone migrates from the gall bladder and obstructs the common bile duct. Rarely, a gallstone can lead to bowel obstruction (gallstone ileus).

Summary box 63.3

Effects and complications of gallstones

In the gallbladder

- Biliary colic
- Acute cholecystitis
- Chronic cholecystitis
- Empyema of the gall bladder
- Mucocele
- Perforation

In the bile ducts

- Biliary obstruction
- Acute cholangitis
- Acute pancreatitis

In the intestine

- Intestinal obstruction (gallstone ileus)

When symptoms do not resolve, but progress to continued pain with fever and leucocytosis, the diagnosis of acute cholecystitis should be considered. The differential diagnosis is given in Summary box 63.4.

Summary box 63.4

Differential diagnosis of cholecystitis

Common

- Appendicitis
- Perforated peptic ulcer
- Acute pancreatitis

Uncommon

- Acute pyelonephritis
- Myocardial infarction
- Pneumonia – right lower lobe

Ultrasound scan aids diagnosis

Uncertain diagnosis – do CT scan

Diagnosis

A diagnosis of gallstone disease is based on the history and physical examination with confirmatory radiological studies such as transabdominal ultrasonography and radionuclide scans (see above). In the acute phase, the patient may have right upper quadrant tenderness that is exacerbated during inspiration by the examiner's right subcostal palpation (Murphy's sign). A positive Murphy's sign suggests acute inflammation and may be associated with a leucocytosis and moderately elevated liver function tests. A mass may be palpable as the omentum walls off an inflamed gall bladder. Fortunately, in the majority of cases, this process is limited by the stone slipping back into the body of the gall bladder and the contents of the gall bladder escaping by way of the cystic duct. This achieves adequate drainage of the gall bladder and enables the inflammation to resolve.

If resolution does not occur, an empyema of the gall bladder may result. The wall may become necrotic and perforate, with the development of localised peritonitis. The abscess may then perforate into the peritoneal cavity with a septic peritonitis – however, this is uncommon, because the gall bladder is usually localised by omentum around the perforation.

A palpable, non-tender gall bladder (Courvoisier's sign) portends a more sinister diagnosis. This usually results from a distal common duct obstruction secondary to a peripancreatic malignancy. Rarely, a non-tender, palpable gall bladder results from complete obstruction of the cystic duct with reabsorption of the intraluminal bile salts and secretion of uninfected mucus secreted by the gall bladder epithelium, leading to a mucocele of the gall bladder.

Treatment

Most authors would suggest that it is safe to observe patients with asymptomatic gallstones, with cholecystectomy only being performed for those patients who develop symptoms or complications of their gallstones. However, prophylactic cholecystectomy

should be considered in diabetic patients, those with congenital haemolytic anaemia and those due to undergo bariatric surgery for morbid obesity, as these groups are at increased risk of complications from gallstones.

For patients with biliary colic or cholecystitis, cholecystectomy is the treatment of choice in the absence of medical contraindications. The timing of surgery in acute cholecystitis remains controversial. Many units favour early intervention, whereas others suggest that a delayed approach is preferable.

Conservative treatment followed by cholecystectomy

Experience shows that, in more than 90% of cases, the symptoms of acute cholecystitis subside with conservative measures. Non-operative treatment is based on four principles:

- 1 Nil per mouth (NPO) and intravenous fluid administration.
- 2 Administration of analgesics.
- 3 Administration of antibiotics. As the cystic duct is blocked in most instances, the concentration of antibiotic in the serum is more important than its concentration in bile. A broad-spectrum antibiotic effective against Gram-negative aerobes is most appropriate (e.g. cefazolin, cefuroxime or gentamicin).
- 4 Subsequent management. When the temperature, pulse and other physical signs show that the inflammation is subsiding, oral fluids are reinstated followed by regular diet. Ultrasonography is performed to ensure that no local complications have developed, that the bile duct is of a normal size and that no stones are contained in the bile duct. Cholecystectomy may be performed on the next available list, or the patient may be allowed home to return later when the inflammation has completely resolved.

Conservative treatment must be abandoned if the pain and tenderness increase; depending on the status of the patient, operative intervention and cholecystectomy should be performed (Fig. 63.27). If the patient has serious comorbid conditions, a percutaneous cholecystostomy can be performed under ultrasound control, which will rapidly relieve symptoms. A subsequent cholecystectomy is usually required.

Routine early operation

As noted above, some surgeons advocate urgent operation as a routine measure in cases of acute cholecystitis. Provided that the

Figure 63.27 Gas in the gall bladder and gall bladder wall (*Clostridium perfringens*). Emergency surgery is indicated.

John Benjamin Murphy, 1857–1916, Professor of Surgery, The Northwestern University, Chicago, IL, USA.
Ludwig Courvoisier, 1843–1918, Professor of Surgery, Basle, Switzerland.

operation is undertaken within 5–7 days of the onset of the attack, the surgeon is experienced and excellent operating facilities are available, good results are achieved. Nevertheless, the conversion rate in laparoscopic cholecystectomy is five times higher in acute than in elective surgery. If an early operation is not indicated, one should wait approximately 6 weeks for the inflammation to subside before proceeding to operate.

EMPHYEMA OF THE GALL BLADDER

The gall bladder appears to be filled with pus. It may be a sequel of acute cholecystitis or the result of a mucocele becoming infected. The treatment is drainage and, later, cholecystectomy.

Acalculous cholecystitis

Acute and chronic inflammation of the gall bladder can occur in the absence of stones and give rise to a clinical picture similar to calculous cholecystitis. Some patients have non-specific inflammation of the gall bladder, whereas others have one of the cholecystoses. Acute acalculous cholecystitis is seen particularly in patients recovering from major surgery (e.g. coronary artery bypass), trauma and burns. In these patients, the diagnosis is often missed, and the mortality rate is high.

THE CHOLECYSTOSES (CHOLESTEROSIS, POLYPOSIS, ADENOMYOMATOSIS AND CHOLECYSTITIS GLANDULARIS PROLIFERANS)

This is a not uncommon group of conditions affecting the gall bladder, in which there are chronic inflammatory changes with hyperplasia of all tissue elements.

Cholesterosis ('strawberry gall bladder')

In the fresh state, the interior of the gall bladder looks something like a strawberry; the yellow specks (submucous aggregations of cholesterol crystals and cholesterol esters) correspond to the seeds (Fig. 63.28). It may be associated with cholesterol stones.

Cholesterol polyposis of the gall bladder

Cholecystography shows negative shadows in a functioning gall bladder, or there is a well-defined polyp present on ultrasound.

Figure 63.28 The interior of a strawberry gall bladder (cholesterosis) (courtesy of Dr Sanjay P. Thakur, Patna, India).

These are either cholesterol polyposis or adenomatous change. With improving ultrasonography, they are seen more frequently, and surgery is advised only if they change in size or are longer than 1 cm.

Cholecystitis glandularis proliferans (polyp, adenomyomatosis and intramural diverticulosis)

Figure 63.29 summarises the varieties of this condition. A polyp of the mucous membrane is fleshy and granulomatous. All layers of the gall bladder wall may be thickened, but sometimes an incomplete septum forms that separates the hyperplastic from the normal. Intraparietal 'mixed' calculi may be present. These can be complicated by an intramural, and later extramural, abscess. If symptomatic, the patient is treated by cholecystectomy.

Diverticulosis of the gall bladder

Diverticulosis of the gall bladder is usually manifest as black pigment stones impacted in the outpouchings of the lacunae of Luschka. Diverticulosis of the gall bladder may be demonstrated by cholecystography, especially when the gall bladder contracts after a fatty meal. There are small dots of contrast medium just within and outside the gall bladder (Fig. 63.30). A septum may

Figure 63.29 Types of cholecystitis glandularis proliferans (polypus, intramural or diverticular stones and fistula).

Figure 63.30 Cholecystogram showing diverticulosis with dots of contrast medium in the gall bladder wall.

also be present [to be distinguished from the Phrygian cap (see Fig. 63.22, p. 1117)]. The treatment is cholecystectomy.

Typhoid gall bladder

Salmonella typhi ('Typhoid Mary', a cook-general who passed *Salmonella typhi* in her faeces and urine, was responsible for nearly a score of epidemics of typhoid in and around New York City) or, occasionally, *Salmonella typhimurium* can infect the gall bladder. Acute cholecystitis can occur. More frequently, chronic cholecystitis occurs, and the patient, being a typhoid carrier, excretes the bacteria in the bile. Gallstones may be present (surgeons should not give patients their stones after their operation if there is any suspicion of typhoid!). It is debatable whether the stones are secondary to the *Salmonella* cholecystitis or whether pre-existing stones predispose the gall bladder to chronic infection. *Salmonellae* can, however, frequently be cultured from these stones. Ampicillin and cholecystectomy are indicated.

CHOLECYSTECTOMY

Preparation for operation

An appropriate history is taken, and the patient's fitness for the procedure is assessed. This includes investigation of the cardiovascular and respiratory systems, and a full blood count and biochemical profile are performed to exclude anaemia or abnormal liver function. Blood coagulation is checked if there is a history of jaundice. The patient is given prophylactic antibiotics either with pre-medication or at the time of anaesthetic induction. A second-generation cephalosporin is appropriate. Subcutaneous heparin or anti-embolic stockings are prescribed. The patient must sign a consent form to indicate that he or she is fully aware of the procedure being undertaken, the risks involved and the complications that may occur (Summary box 63.5).

Figure 63.31 Operative image of a laparoscopic cholecystectomy. Forceps (arrowed) are dissecting the cystic duct.

The *Phrygian Cap* refers to the hats worn by the people of Phrygia, an ancient country of Asia Minor. The cap was like the *Liberté Cap* of the French Revolutionaries.

Typhoid Mary was the name given to a cook-general who passed *Salmonella typhi* in her faeces and urine, and was responsible for nearly twenty epidemics of typhoid in, and around, New York City, in the United States.

Summary box 63.5

Preparation for operation

- Full blood count
- Renal profile and liver function tests
- Prothrombin time
- Chest X-ray and electrocardiogram (if over 45 years or medically indicated)
- Antibiotic prophylaxis
- Deep vein thrombosis prophylaxis
- Informed consent

Laparoscopic cholecystectomy

The preparation and indications for cholecystectomy are the same whether it is performed by laparoscopy or by open techniques. Laparoscopic cholecystectomy is the procedure of choice for the majority of patients with gall bladder disease (Fig. 63.31). The key, as in open surgery, is identification and safe dissection of Calot's triangle.

The patient is placed supine on the operating table. Following induction and maintenance of a general anaesthetic, the abdomen is prepared in a standard fashion. Pneumoperitoneum is established. A number of techniques are described. The author's preference is to use an open subumbilical cut-down with direct visualisation of the peritoneum to place the initial port. This port will function as the camera port. Many surgeons use a 'closed' technique using a Verres needle to establish pneumoperitoneum prior to placing the initial trocar.

Additional operating ports are inserted in the subxiphoid area and in the right subcostal area. The patient is placed in a reverse Trendelenburg position, slightly rotated to the left. This exposes the fundus of the gall bladder, which is retracted towards the diaphragm. The neck of the gall bladder is then retracted towards the right iliac fossa exposing Calot's triangle. This area is laid wide open by dividing the peritoneum on the posterior and anterior aspects. The cystic duct is carefully defined, as is the cystic artery. The gall bladder is separated from the liver bed for about 2 cm to allow for confirmation of the anatomy. Unless there are specific indications (see below), a routine cholangiogram is not performed. However, if doubt exists regarding the anatomy, a cholangiogram is warranted. Once the anatomy is clearly defined and the triangle of Calot has been laid wide open, the cystic duct and artery are clipped and divided. The gall bladder is then removed from the gall bladder bed by sharp dissection and, once free, removed via the umbilicus. An endobag may be used for extraction of the gall bladder to prevent contamination of the umbilical wound. Recovery after laparoscopic cholecystectomy is rapid – 80% of patients are discharged within 24 hours and the remainder by day 2. Any untoward symptoms require immediate investigation (Summary box 63.6).

Jean Francois Calot, 1861–1944, Surgeon, The Rothschild Hospital, Berck-sur-Mer, Pas-de-Calais, France.

Janos Verres, 1903–1979, Chest Physician, and Chief of the Department of Internal Medicine, The Regional Hospital, Kapuvar, Hungary.

Friedrich Trendelenburg, 1844–1924, Professor of Surgery, Rostock (1875–1882), Bonn, (1882–1895), and Leipzig, (1895–1911), Germany. The Trendelenburg position was first described in 1885.

Summary box 63.6

Post-cholecystectomy discomfort

- If there is a delay in recovery after cholecystectomy, exclude bile duct or bowel injury
- Incidence of bile duct injury is 0.05%

Serious complications of laparoscopic cholecystectomy fall into two major areas: access complications or bile duct injuries. In the main, access complications occur during the insertion of the Verres needle to establish pneumoperitoneum or the insertion of trocars. If insertion is performed blindly or is found to be difficult, visceral injury should be excluded. If either a visceral or a bile duct injury is suspected, conversion to an open technique is recommended by most surgeons.

Open cholecystectomy

For patients in whom a laparoscopic approach is not indicated or in whom conversion from a laparoscopic approach is required, an open cholecystectomy is performed.

A short right upper transverse incision is made centred over the lateral border of the rectus muscle. The gall bladder is appropriately exposed, and packs are placed on the hepatic flexure of the colon, the duodenum and the lesser omentum to ensure a clear view of the anatomy of the porta hepatis. These packs may be retracted using the hand of the assistant ('It is the left hand of the assistant that does all the work' – Moynihan), or a stabilised ring retractor is used to keep the packs in position. A Duval forceps is placed on the infundibulum of the gall bladder, and the peritoneum overlying Calot's triangle is placed on a stretch. The peritoneum is then divided close to the wall of the gall bladder, and the fat in Calot's triangle is carefully dissected away to expose the cystic artery and the cystic duct. The cystic duct is dissected to the common bile duct, whose position is clearly ascertained. The cystic artery is tied and divided. The whole of the triangle of Calot is displayed to ensure that the anatomy of the ducts is clear, and the cystic duct is then divided between ligatures (Fig. 63.32). The gall bladder is then dissected away from the gall bladder bed.

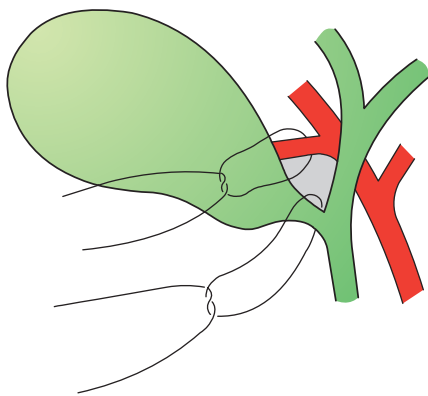

Figure 63.32 Ligatures passed and tied around the cystic artery and cystic duct. The grey shaded area represents Calot's triangle.

Pierre Duval, B. 1874, a Surgeon, of Paris, France.

Some golden rules in case of difficulty:

- When the anatomy of the triangle of Calot is unclear, blind dissection should stop.
- Bleeding adjacent to the triangle of Calot should be controlled by pressure and not by blind clipping or clamping.
- When there is doubt about the anatomy, a 'fundus-first' or 'retrograde' cholecystectomy dissecting on the gall bladder wall down to the cystic duct can be helpful.
- If the cystic duct is densely adherent to the common bile duct and there is the possibility of a Mirizzi syndrome (a gallstone ulcerating through into the common duct), the infundibulum of the gall bladder should be opened, the stone removed and the infundibulum oversewn.
- A cholecystostomy is rarely indicated but, if necessary, as many stones as possible should be extracted, and a large Foley catheter (14F) placed in the fundus of the gall bladder with a direct track externally. By so doing, should stones be left behind in the gall bladder, these can be extracted with a choledochoscope.

Indications for choledochotomy

In a situation in which sophisticated preoperative imaging or per-operative cholangiography is not available, it is well to remember the traditional indications for choledochotomy, which are:

- 1 palpable stones in the common bile duct;
- 2 jaundice, a history of jaundice or cholangitis;
- 3 a dilated common bile duct;
- 4 abnormal liver function tests, in particular a raised alkaline phosphatase.

Unless the expertise is available, it is probably inadvisable to perform a choledochotomy laparoscopically; rather, one should rely on postoperative endoscopic techniques or convert to an open operation. The incidence of symptomatic stones in the bile duct varies from 5% to 8%. These can, in the main, be dealt with endoscopically without resort to opening the duct. However, current trials suggest that, in experienced hands, the morbidity of the two techniques is similar.

Late symptoms after cholecystectomy

In 15% of patients, cholecystectomy fails to relieve the symptoms for which the operation was performed. Such patients may be considered to have a 'post-cholecystectomy' syndrome. However, such problems are usually related to the preoperative symptoms and are merely a continuation of those symptoms. Full investigation should be undertaken to confirm the diagnosis and exclude the presence of a stone in the common bile duct, a stone in the cystic duct stump or operative damage to the biliary tree. This is best performed by MRCP or ERCP. The latter has the added advantage that, if a stone is found in the common bile duct, it can be removed.

Management of bile duct obstruction following cholecystectomy

Patients with symptoms developing either immediately or delayed after a cholecystectomy, particularly if jaundice is present, need urgent investigation. This is especially true if the jaundice is associated with infection, a condition called cholangitis.

P. L. Mirizzi, an Argentinian Physician, described this syndrome in 1948.
Frederic Eugene Basil Foley, 1891–1966, Urologist, Anker Hospital, St. Paul, MN, USA.

The first step in management is to undertake an immediate ultrasound scan. This will demonstrate whether there is intra- or extrahepatic ductal dilatation. The anatomy needs to be defined by either an ERCP or an MRCP. The latter investigation will also allow for therapeutic manoeuvres such as removal of an obstructing stone or insertion of a stent across a biliary leak. If a fluid collection is present in the subhepatic space, drainage catheters may be required. These can be inserted under radiological control or, if this expertise is not available, at open operation. Small biliary leaks will usually resolve spontaneously, especially if there is no distal obstruction. Should the common bile duct be damaged, the patient should be referred to an appropriate expert for reconstruction of the duct.

About 15% of injuries to the bile ducts are recognised at the time of operation. In 85% of cases, the injury declares itself post-operatively by: (1) a profuse and persistent leakage of bile if drainage has been provided, or bile peritonitis if such drainage has not been provided; and (2) deepening obstructive jaundice. When the obstruction is incomplete, jaundice is delayed until subsequent fibrosis renders the lumen of the duct inadequate.

Any change in bilirubin or suggestion of duct damage requires investigation and the nature of the bile duct injury clarified. The surgical repair and subsequent outcome is related to the level of injury, which is determined using the Bismuth classification (Table 63.1).

Treatment

In the debilitated patient, temporary external biliary drainage may be achieved by passing a catheter percutaneously into an intrahepatic duct. Also, stents may be passed through strictures at the time of ERCP and left to drain into the duodenum. When the general condition of the patient has improved, definitive surgery can be undertaken. The principles of surgical repair are maintenance of duct length and restoration of biliary drainage. For benign stricture or duct transection, the preferred treatment is immediate Roux-en-Y choledochojejunostomy by an experienced surgeon. For a stricture of recent onset through which a guidewire can be passed, balloon dilatation with insertion of a stent is an acceptable alternative provided that the services of an experienced endoscopist are available. The outcome of such surgery is good, with 90% of patients having no further cholangitis or stricture formation.

Stones in the bile duct

Duct stones may occur many years after a cholecystectomy (Fig. 63.33) or be related to the development of new pathology, such as infection of the biliary tree or infestation by *Ascaris lumbricoides* or *Clonorchis sinensis*. Any obstruction to the flow of bile can give rise to stasis with the formation of stones within the duct. The consequence of duct stones is either obstruction to bile flow or infection. Stones in the bile ducts are more often associated with infected bile (80%) than are stones in the gall bladder.

Table 63.1 Bismuth classification

Type I	Low common bile duct; stump > 2 cm
Type II	Middle common hepatic duct; stump < 2 cm
Type III	Hilar – confluence of right and left ducts intact
Type IV	Right and left ducts separated
Type V	Involvement of the intrahepatic ducts

Figure 63.33 Endoscopic retrograde cholangiopancreatography: the patient presented with jaundice 4 days after laparoscopic cholecystectomy. The bile duct contained multiple stones.

Symptoms

The patient may be asymptomatic but usually has bouts of pain, jaundice and fever. The patient is often ill and feels unwell. The term 'cholangitis' is given to the triad of pain, jaundice and fevers, sometimes known as 'Charcot's triad'.

Signs

Tenderness may be elicited in the epigastrium and the right hypochondrium. In the jaundiced patient, it is useful to remember Courvoisier's law – in obstruction of the common bile duct due to a stone, distension of the gall bladder seldom occurs; the organ is usually already shrivelled. In obstruction from other causes, distension of the gall bladder is common by comparison.

Jean Martin Charcot, 1825–1893, Physician, La Salpêtrière, Paris, France.

Management

It is essential to determine whether the jaundice is due to liver disease, disease within the duct, such as sclerosing cholangitis, or obstruction of the biliary tree. Ultrasound scanning, liver function tests, liver biopsy (if the ducts are not dilated) and MRI or ERCP will delineate the nature of the obstruction.

The patient may be ill. Pus may be present within the biliary tree, and liver abscesses may develop. Full supportive measures are required with rehydration, correction of clotting abnormalities and treatment with appropriate broad-spectrum antibiotics. Once the patient has been resuscitated, relief of the obstruction is essential. Endoscopic papillotomy is the preferred first technique with a sphincterotomy, removal of the stones using a Dormia basket or the placement of a stent if stone removal is not possible. If this technique fails, percutaneous transhepatic cholangiography can be performed to provide drainage and subsequent percutaneous choledochoscopy. Surgery, in the form of choledochotomy, is now rarely used for this situation, as most patients can be managed by minimally invasive techniques (Figs 63.34 and 63.35).

Choledochotomy

When faced with a sick patient whose investigations show that the cause of the cholangitis is stones in the duct, and minimally invasive techniques for stone extraction are not available, the surgeon has no alternative but to undertake a laparotomy. The aim of this surgery is to drain the common bile duct and remove the stones by a longitudinal incision in the duct. When the duct is clear of stones, a T-tube is inserted and the duct closed around it; the long limb of the T-tube is brought out on the right side, and the bile is allowed to drain externally. When the bile has become clear and the patient has recovered, a cholangiogram is performed, usually 7–10 days following operation. If residual stones are found, the T-tube is left in place for 6 weeks so that the track is 'mature'. The retained stones can be removed percutaneously by an interventional radiologist (Burhenne technique) (Fig. 63.35).

Stricture of the bile duct

The causes of benign biliary stricture are given in Summary box 63.7.

Figure 63.34 (a) Endoscopic sphincterotomy; (b) extraction of a stone from the bile duct through the ampulla.

Figure 63.35 Extraction of a stone from the common bile duct by the Burhenne technique. (a) A T-tube *in situ* with a stone in the duct. (b) A steerable catheter has been manipulated into the duct and a basket placed around the stone. (c) The stone being extracted from the bile duct along the T-tube track.

Joachim Burhenne, a Radiologist of Vancouver, Canada.

Summary box 63.7

Causes of benign biliary stricture

Congenital

- Biliary atresia

Bile duct injury at surgery

- Cholecystectomy
- Choledochotomy
- Gastrectomy
- Hepatic resection
- Transplantation

Inflammatory

- Stones
- Cholangitis
- Parasitic
- Pancreatitis
- Sclerosing cholangitis
- Radiotherapy

Trauma**Idiopathic**

Bile duct strictures may be investigated radiologically (Summary box 63.8).

Summary box 63.8

Radiological investigation of biliary strictures

- Ultrasonography
- Cholangiography via T-tube, if present
- ERCP
- MRCP
- PTC (see Figs 63.20 and 63.21, pp. 1116 and 1117)
- Multidetector row CT

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis is an idiopathic fibrosing inflammatory condition of the biliary tree that affects both intrahepatic and extrahepatic ducts. It is of unknown origin, but association with hypergammaglobulinaemia and elevated markers such as smooth muscle antibodies and anti-nuclear factor suggests an immunological basis. The majority of patients are between 30 and 60 years of age. There appears to be a male predominance and a strong association with inflammatory bowel disease, especially ulcerative colitis.

Common symptoms include right upper quadrant discomfort, jaundice, pruritus, fever, fatigue and weight loss. Investigation reveals a cholestatic pattern in liver function tests with elevation of serum alkaline phosphatase and gamma-glutamyl transferase and smaller rises in the aminotransferases. Bilirubin values can be variable and may fluctuate. Imaging studies such as MRCP or ERCP may demonstrate stricturing and beading of the bile ducts (Fig. 63.36). A liver biopsy is helpful in confirming the diagnosis and may help to guide therapy by excluding cirrhosis. The important differential diagnoses are secondary sclerosing cholangitis and cholangiocarcinoma. The latter condition may be very difficult to

Figure 63.36 Sclerosing cholangitis in a patient with ulcerative colitis visualised by endoscopic retrograde cholangiopancreatography.

diagnose, and a high index of suspicion is required especially in the setting of an unexplained deterioration.

Medical management with antibiotics, vitamin K, cholestyramine, steroids and immunosuppressants such as azathioprine is generally unsuccessful. Endoscopic stenting of dominant strictures and, in selected patients with predominantly extrahepatic disease, operative resection may be worthwhile. For patients with cirrhosis, liver transplantation is the best option. Five-year survival following transplantation is in excess of 80%.

PARASITIC INFESTATION OF THE BILIARY TRACT

Biliary ascariasis

The round worm, *Ascaris lumbricoides*, commonly infests the intestine of inhabitants of Asia, Africa and Central America. It may enter the biliary tree through the ampulla of Vater and cause biliary pain. Complications include strictures, suppurative cholangitis, liver abscesses and empyema of the gall bladder. In the uncomplicated case, anti-spasmodics can be given to relax the sphincter of Oddi, and the worm will return to the small intestine to be dealt with by anthelmintic drugs. Operation may be necessary to remove the worm or deal with complications. Worms can be extracted via the ampulla of Vater by ERCP.

Clonorchiasis (Asiatic cholangiohepatitis)

The disease is endemic in the Far East. The fluke, up to 25 mm long and 5 mm wide, inhabits the bile ducts, including the intrahepatic ducts. Fibrous thickening of the duct walls occurs. Many cases are asymptomatic. Complications include biliary pain, stones, cholangitis, cirrhosis and bile duct carcinoma. Choledochotomy and T-tube drainage and, in some cases, choledochoduodenostomy are required. Because a process of recurrent stone formation is set up, a choledochojejunostomy with Roux loop affixed to the abdominal parietes is performed in some centres to allow easy subsequent access to the duct system.

Hydatid disease

A large hydatid cyst may obstruct the hepatic ducts. Sometimes, a cyst will rupture into the biliary tree and its contents cause obstructive jaundice or cholangitis, requiring appropriate surgery (see Chapters 5 and 61).

TUMOURS OF THE BILE DUCT

Benign tumours of the bile duct

These are uncommon and need to be distinguished from other benign conditions such as choledocholithiasis, sclerosing cholangitis, Caroli's disease and choledochal cysts. They account for less than 0.1% of biliary tract operations.

The duration of symptoms may vary from a few days to months, and their clinical presentation may in fact mimic the more common conditions such as cholecystitis, choledocholithiasis, cancer of the bile duct and pancreatic cancer.

Benign neoplasms causing biliary obstruction may be classified as follows:

- papilloma and adenoma;
- multiple biliary papillomatosis;
- granular cell myoblastoma;
- neural tumours;
- leiomyoma;
- endocrine tumours.

Papilloma and adenoma

The most common benign neoplasm arises from the glandular epithelium lining the bile ducts. It can occur throughout the biliary system but is more common in the periampullary area, where a papilloma or adenoma may protrude through the ampulla of Vater and be visible at endoscopy. Jaundice is the commonest symptom occurring in more than 90% of cases. Coexisting gallstones are uncommon.

Treatment depends on the age, general status of the patient and site of the disease but, in general, it should consist of total resection. In some cases, a wide local resection can be performed, particularly for periampullary lesions.

Papillomatosis

This rare condition is characterised by the presence of multiple mucus-secreting tumours of the biliary epithelium. Patients present with obstructive jaundice, which may be intermittent and often complicated by cholangitis. These tumours have a malignant potential and should be resected if possible. This may involve liver resection if the disease is confined to a hepatic lobe. If both lobes are affected, then liver transplantation may be required.

Granular cell myoblastoma, neural tumours, leiomyomata and endocrine tumours are extremely uncommon. In general, if biliary obstruction occurs, it should be relieved by resection, bypass or endoscopic stenting.

Malignant tumours of the bile duct

Carcinoma may arise at any point in the biliary tree, from the common bile duct to the small intrahepatic ducts (Summary box 63.9).

Summary box 63.9

Bile duct cancer

- Rare, but incidence increasing
- Presents with jaundice and weight loss
- Diagnosis by ultrasound and CT scanning
- Jaundice relieved by stenting
- Surgical excision possible in 5%
- Prognosis poor – 90% mortality in 1 year

Jacques Caroli, Professor of Medicine, Paris, France.

Incidence

This is a rare malignancy accounting for 1–2% of new cancers in a western practice. The overall annual incidence is 1–1.5:100 000 with two-thirds of patients being older than 65 years.

Histologically, the tumour is usually an adenocarcinoma (cholangiocarcinoma), predominantly in the extrahepatic biliary system.

Associations

Patients with a history of ulcerative colitis, hepatolithiasis, choledochal cyst or sclerosing cholangitis are at increased risk of developing the disease. It is estimated that a longstanding history of sclerosing cholangitis increases the risk of developing biliary tract cancer by 20-fold compared with the normal population. In addition, liver fluke infestations in the Far East are also associated with cholangiocarcinoma. *Opisthorchis viverrini* infestation is important in Thailand, Laos and western Malaysia. These parasites induce DNA changes and mutations through production of carcinogens and free radicals, which stimulate cellular proliferation in the intrahepatic bile ducts and can ultimately lead to invasive cancer.

Clinical features

Biliary tract cancers tend to be slow-growing tumours that invade locally and metastasise to local lymph nodes. Distant metastases to the peritoneal cavity, liver and lung do occur. Jaundice is the most common presenting feature. Abdominal pain, early satiety and weight loss are also commonly seen. On examination, jaundice is evident, cachexia often noticeable and a palpable gall bladder is present if the obstruction is in the distal common bile duct (Courvoisier's sign).

Investigations

Biochemical investigations will confirm the presence of obstructive jaundice (elevated bilirubin, alkaline phosphatase and gamma-glutamyl transferase). The tumour marker CA19-9 may also be elevated. Non-invasive studies such as ultrasound and CT scanning define the level of biliary obstruction, the locoregional extent of disease and the presence of metastases (Fig. 63.37). For proximal tumours, percutaneous transhepatic cholangiography is the most useful modality. This outlines the anatomy of the tumour and the intrahepatic biliary system. In addition, it allows percutaneous biliary drainage, and samples can be obtained for cytology to confirm the diagnosis. For distal tumours, an ERCP is preferred as an endobiliary stent can be placed across the obstructing lesion. Again, cytology or biopsies can be taken for diagnosis.

Treatment

The treatment depends on the site and extent of disease. Most patients are inoperable, but 10–15% are suitable for surgical resection, which offers the only hope for long-term survival. Depending on the site of disease, resection may involve partial hepatectomy and reconstruction of the biliary tree. The perioperative mortality rate is now less than 5%. Distal common duct tumours may require a pancreaticoduodenectomy. Overall, the median survival is 18 months, with 20% of patients surviving 5 years post resection. Survival appears to be better for distal tumours compared with those involving the upper third of the biliary tree. Adjuvant chemotherapy or radiotherapy has a limited role and is not considered standard therapy.

Figure 63.37 Computerised tomography scan demonstrating a distal common bile duct tumour with biliary obstruction (a; arrow) and duodenal infiltration (b; arrow).

Carcinoma of the gall bladder

Incidence

This is a rare disease, but extremely variable by geographical region and racial/ethnic groups. The highest incidence is in Chileans, American Indians and in parts of northern India, where it accounts for as much as 9.1% of all biliary tract disease. In western practice, gall bladder cancer accounts for less than 1% of new cancer diagnoses. The patients are usually older, in their sixties or seventies. The aetiology is unclear, but there may be an association with pre-existing gallstone disease. Calcification of the gall bladder is associated with cancer (see Fig. 63.4, p. 1113) in 10–25% cases. Infection may promote the development of cancer as the risk of carcinoma in typhoid carriers is significantly increased (Summary box 63.10).

Summary box 63.10

Gall bladder cancer

- Rare
- Presents as for benign biliary disease (gallstones)
- Diagnosis by ultrasound and CT scanning
- Excision in less than 10% – remainder palliative treatment
- Prognosis poor – 95% mortality in 1 year

Pathology

The majority of cases are adenocarcinoma (90%). Grossly, carcinomas are difficult to differentiate from chronic cholecystitis; the tumour is most commonly nodular and infiltrative, with thickening of the gall bladder wall, often extending to the whole gall bladder. The tumour spreads by direct extension into the liver, seeding of the peritoneal cavity and involvement of the perihilar lymphatics and neural plexuses. At the time of presentation, the majority of tumours are advanced.

Clinical features

Patients may be asymptomatic at the time of diagnosis. If symptoms are present, they are usually indistinguishable from benign gall bladder disease such as biliary colic or cholecystitis, particularly in the older patient. Jaundice and anorexia are late features. A palpable mass is a late sign.

Investigation

Laboratory findings may be consistent with biliary obstruction or non-specific findings such as anaemia, leucocytosis, mild elevation in transaminases and increased erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP). The level of serum CA19-9 is elevated in 80% of patients. The diagnosis is made on ultrasonography and defined by a multidetector row CT scan, with a percutaneous biopsy confirming the histological diagnosis. In selected patients, laparoscopy is useful in staging the disease, as it can detect peritoneal or liver metastases that would preclude further surgical resection.

Treatment and prognosis

Occasionally, the diagnosis is made by histological examination of a gall bladder removed for 'benign' gallstone disease. For early-stage disease confined to the mucosa or muscle of the gall bladder, no further treatment is indicated. However, for transmural disease, a radical *en bloc* resection of the gall bladder fossa and surrounding liver along with the regional lymph nodes should be performed. The disease has a very poor prognosis with the median survival less than 6 months and a 5-year survival of 5%. The value of adjuvant therapy is unproven.

The pancreas

CHAPTER 64

LEARNING OBJECTIVES

To understand:

- The anatomy and physiology of the pancreas
- Investigations of the pancreas
- Congenital abnormalities of the pancreas
- Assessment and management of pancreatitis
- Diagnosis and treatment of pancreatic cancer

ANATOMY AND PHYSIOLOGY

Anatomy

The name 'pancreas' is derived from the Greek 'pan' (all) and 'kreas' (flesh). For a long time, its glandular function was not understood, and it was thought to act as a cushion for the stomach. The pancreas is situated in the retroperitoneum. It is divided into a head, which occupies 30% of the gland by mass, and a body and tail, which together constitute 70%. The head lies within the curve of the duodenum, overlying the body of the second lumbar vertebra and the vena cava. The aorta and the superior mesenteric vessels lie behind the neck of the gland. Coming off the side of the pancreatic head and passing to the left and behind the superior mesenteric vein is the uncinate process of the pancreas. Behind the neck of the pancreas, near its upper border, the superior mesenteric vein joins the splenic vein to form the portal vein (Figs 64.1 and 64.2). The tip of the pancreatic tail extends up to the splenic hilum.

The pancreas weighs approximately 80 g. Of this, 80–90% is composed of exocrine acinar tissue, which is organised into lobules. The main pancreatic duct branches into interlobular and intralobular ducts, ductules and, finally, acini. The main duct is lined by columnar epithelium, which becomes cuboidal in the ductules. Acinar cells are clumped around a central lumen, which communicates with the duct system. Clusters of endocrine cells, known as islets of Langerhans, are distributed throughout the pancreas. Islet cells consist of differing cell types: 75% are B cells (producing insulin); 20% are A cells (producing glucagon); and the remainder are D cells (producing somatostatin) and a small number of pancreatic polypeptide cells. Within an islet, the B cells form an inner core surrounded by the other cells. Capillaries draining the islet cells drain into the portal vein, forming a pancreatic portal system.

There are nine key processes that occur during pancreatic embryogenesis (Table 64.1). Malrotation of the ventral bud in the fifth week results in an annular pancreas, while the mode of

Figure 64.1 The posterior relations of the pancreas.

Figure 64.2 Transverse section of the pancreas. Section 1, body and tail of pancreas; section 2, neck of pancreas; section 3, head of pancreas. Note the position of the uncinate process behind the vessels.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany, described the islets in 1869.

Table 64.1 Steps in the development of the pancreas

1	Day 26	Dorsal pancreatic duct arises from the dorsal side of the duodenum
2	Day 32	Ventral bud arises from the base of the hepatic diverticulum
3	Day 37	Contact occurs between the two buds. Fusion by the end of week 6
4	Week 6	Ventral bud produces the head and uncinate process
5	Week 6	Ducts fuse
6	Week 6	Ventral duct and distal portion of the dorsal duct form the main duct (duct of Wirsung)
7	Week 6	Proximal dorsal duct forms the duct of Santorini
8	Month 3	Acini appear
9	Months 3–4	Islets of Langerhans appear and become biologically active

ductule fusion in the seventh week produces the various possible ductular patterns. Between the 12th and 40th weeks of fetal life, the pancreas differentiates into exocrine and endocrine elements. The primitive ducts and their ductules are responsible for the lobular arrangement of the pancreas. Congenital anomalies of the pancreas are varied and arise during the early phase of development (Summary box 64.1). The anatomy of the pancreatic duct is variable as a result of the primordial bud development. The dorsal duct is expressed in a variable manner in the adult, as outlined in Figure 64.3. Approximately 10% of patients will have a significant flow from the main duct through the accessory papilla. The anatomy of the main duodenal papilla, also known as the ampulla of Vater, is also variable (Fig. 64.4). The outlet of each duct is protected by a complex sphincter mechanism (sphincter of Oddi) (Fig. 64.5).

Physiology

In response to a meal, the pancreas secretes digestive enzymes in an alkaline (pH 8.4) bicarbonate-rich fluid. Spontaneous secretion is minimal; the hormone secretin, which is released from the duodenal mucosa, evokes a bicarbonate-rich fluid. Cholecystokinin (CCK) (synonym: pancreozymin) is released from the duodenal mucosa in response to food. CCK is responsible for enzyme release. Vagal stimulation increases the volume of secretion. Protein is synthesised at a greater rate (per gram of tissue) in the pancreas than in any other tissue, with the possible exception of the lactating mammary gland. About 90% of this protein is exported from the acinar cells as a variety of digestive enzymes. Approximately 6–20 g of digestive enzymes enters the duodenum each day. Nascent proteins are synthesised as preproteins and undergo modification in a sequence of steps. The proteins move from the rough endothelial endoplasmic reticulum to the Golgi complex, where lysosomes and mature zymogen storage granules containing proteases are stored, and then to the ductal surface of the cell, from which they

Camillo Golgi, 1844–1926, Professor of Anatomy and Histology at Pavia, and later at Sienna, Italy.

Figure 64.4 Variations in the relation of the common bile duct and main pancreatic duct at the main duodenal papilla. In (a), there is a common channel with no sphincter mechanism protecting flow between the ducts. In (b), there is a partial common channel, while in (c), there is separation of the two channels. Gallstone pancreatitis is more likely with (a) and (b).

are extruded by exocytosis. During this phase, the proteolytic enzymes are in an inactive form, the maintenance of which is important in preventing pancreatitis.

INVESTIGATIONS (TABLE 64.2)

Estimation of pancreatic enzymes in body fluids

When the pancreas is damaged, enzymes such as amylase, lipase, trypsin, elastase and chymotrypsin are released into the serum. Measurement of serum amylase is the most widely used test of

Table 64.2 Investigation of the pancreas

Chest
Upper abdomen

pancreatic damage. The serum amylase rises within a few hours of pancreatic damage and declines over the next 4–8 days. A markedly elevated serum level is highly suspicious but not diagnostic of acute pancreatitis. Urinary amylase and amylase–creatinine clearance ratios add little to diagnostic accuracy. If confirmation of the diagnosis is required, computerised tomography (CT) of the pancreas is of greater value (Summary box 64.2).

Summary box 64.2

Causes of raised serum amylase level other than acute pancreatitis

- Upper gastrointestinal tract perforation
- Mesenteric infarction
- Torsion of an intra-abdominal viscus
- Retroperitoneal haematoma
- Ectopic pregnancy
- Macroamylasaemia
- Renal failure
- Salivary gland inflammation

Pancreatic function tests

Pancreatic exocrine function can be assessed by directly measuring pancreatic secretion in response to a standardised stimulus. The stimulus to secretion can be physiological, e.g. ingestion of a test meal, as in the Lundh test, or pharmacological, e.g. intravenous injection of a hormone such as secretin or CCK. Duodenal intubation has to be performed with a triple-lumen tube so that the gastric and duodenal juices can be aspirated, and a non-absorbable marker such as polyethylene glycol is used to assess the completeness of the aspiration. The nitroblue tetrazolium–*para*-aminobenzoic acid (NBT–PABA) test provides an indirect measure of pancreatic function. The substance is administered orally and degraded in the gut by a pancreatic enzyme, and the breakdown product (PABA) is absorbed by the intestine and excreted in the urine; its urinary level is measured. The Pancreolauryl test works on a similar principle. These tests are cheap and easy to perform, but are non-specific, especially following gastrectomy and in conditions that may alter gastrointestinal transit and intestinal absorptive capacity. Measurement of the enzyme elastase in stool is simple and specific. Absence indicates exocrine insufficiency.

Imaging investigations

Ultrasonography

Ultrasonography is the initial investigation of choice in patients with jaundice to determine whether or not the bile duct is dilated, the coexistence of gallstones or gross disease within the liver such as metastases. It may also define the presence or absence of a mass in the pancreas (Fig. 64.6). However, obesity and overlying bowel gas often make interpretation of the pancreas itself unsatisfactory.

Computerised tomography

Most significant pathologies within the pancreas can be diagnosed on high-quality CT scans, with three-dimensional reconstruction if necessary. A specific pancreatic protocol should be followed. An initial unenhanced CT scan is essential to determine the presence of calcification within the pancreas and gall bladder (Fig. 64.7). Then, following rapid injection of intravenous contrast, scanning

Figure 64.7 (a) Unenhanced computerised tomography scan of a man with chronic pancreatitis, showing a focus of calcification (marked by an arrow) in the head of the pancreas and a cyst adjacent to that. Oral contrast has been administered. (b) The same area after injection of intravenous contrast.

is performed in the arterial and venous phases. The stomach and duodenum should be outlined with water and distended to define the duodenal loop. Pancreatic carcinomas of 1–2 cm in size can usually be demonstrated whether in the head, body or tail of the pancreas (Fig. 64.8). Endocrine tumours are also well imaged on CT (Fig. 64.9). In patients with pancreatitis, necrotic areas within the gland can be identified by the absence of contrast enhancement on CT. Inflammatory collections and pseudocysts can be seen (Fig. 64.10). CT-guided drainage is helpful in the treatment of pancreatic collections, cysts and pseudocysts, and facilitates percutaneous fine-needle or Trucut biopsy.

Figure 64.8 Contrast-enhanced computerised tomography scan of a patient with a carcinoma of the pancreatic head. The main bulk of the tumour lies inferior to the section shown here. The dilated bile duct (1) and main pancreatic duct (2) can be seen, with tumour infiltration around them. There is a thrombus in the superior mesenteric vein (3). The gall bladder is distended (4).

Figure 64.9 Computerised tomography scan showing a hypervascular insulinoma adjacent to the splenic vein. Local excision of the tumour resulted in normoglycaemia.

Figure 64.10 Computerised tomography scan of a large pseudocyst in relation to the body and tail of the pancreas.

Magnetic resonance imaging

With magnetic resonance imaging (MRI), the pancreas can be clearly identified, and clear images of the bile duct and the pancreatic duct, together with fluid collections, can be defined. Magnetic resonance cholangiography and pancreatography (MRCP) may well replace *diagnostic* endoscopic cholangiography and pancreatography (ERCP) as it is non-invasive and less expensive (Fig. 64.11). Using the technique in conjunction with intravenous injection of secretin, emptying of the pancreatic duct can be demonstrated to show the absence or presence of obstruction.

Endoscopic retrograde cholangiopancreatography

ERCP is performed using a side-viewing fiberoptic duodenoscope. The ampulla of Vater is intubated, and contrast is injected into the biliary and pancreatic ducts to display the anatomy radiologically (Fig. 64.12). In pancreatic carcinoma, the main

Figure 64.11 Magnetic resonance cholangiopancreatography in a patient with obstructive jaundice. A dilated common bile duct was seen on ultrasound, but no pancreatic mass lesion was visible on computerised tomography. The bile duct and the main pancreatic duct are seen very well, with a stone visible in the lower part of the bile duct and another in the neck of the gall bladder.

Abraham Vater, 1684–1751, Professor of Anatomy and Botany, and later of Pathology and Therapeutics, Wittenberg, Germany.

pancreatic duct may be narrowed or completely obstructed at the site of the tumour (Fig. 64.13), or the distal bile duct may be narrowed. Concurrent narrowing of both ducts results in the so called double duct sign (Fig. 64.14). Changes seen in chronic pancreatitis include the presence of pancreatic duct strictures, dilatation of the main pancreatic duct with stones,

abnormalities of pancreatic duct side branches, communication of the pancreatic duct with cysts, and bile duct strictures (Figs 64.15–64.17). A plain radiograph before contrast studies is essential to delineate calcification (Fig. 64.18). In addition to imaging, bile or pancreatic fluid and brushings from duct strictures can yield cells that confirm the suspected diagnosis of carcinoma (Fig. 64.19). ERCP also allows the placement of biliary and pancreatic stents.

Endoscopic ultrasound

Endoscopic ultrasound (EUS) is performed using a special endoscope that has a high-frequency ultrasonic transducer at its tip. When the endoscope is in the lumen of the stomach or duodenum, the pancreas and its surrounding vasculature and lymph nodes can be assessed (Fig. 64.20). This is particularly useful in identifying small tumours that may not show up well on CT or MRI, and in demonstrating the relationship of a pancreatic tumour to major vessels nearby. EUS can clarify the relationship of a neuroendocrine tumour to the main pancreatic duct (important if

Figure 64.15 Endoscopic retrograde cholangiopancreatography: chronic pancreatitis. Most of the opacities lie within the duct system and are stones. Gross dilatation of ducts in the body and tail are due to obstructions by stones in the head of the pancreas.

Figure 64.16 (a) Endoscopic retrograde cholangiopancreatography: relapsing acute pancreatitis. Normal biliary tree. Pancreatogram shows stricture of the main duct in the body with distal dilatation and cyst formation. (b) Diagrammatic outline of (a). CBD, common bile duct; PD, pancreatic duct.

enucleation is being considered). It helps to distinguish cystic tumours from pseudocysts. Transduodenal or transgastric fine-needle aspiration (FNA) or Trucut biopsy performed under EUS guidance avoids spillage of tumour cells into the peritoneal cavity.

CONGENITAL ABNORMALITIES

Cystic fibrosis

This is inherited as an autosomal recessive condition. It occurs most frequently among Caucasians, in whom it is the most common inherited disorder (incidence of 1:2000 live births in the UK). Cystic fibrosis (CF) develops when there is a mutation in the *CFTR* (cystic fibrosis transmembrane conductance regulator) gene on chromosome 7. This gene creates a cell membrane protein that helps to control the movement of chloride across the cell membrane.

CF is a multisystem disorder of exocrine glands that affects the lungs, intestines, pancreas and liver, and is characterised by elevated sodium and chloride ion concentrations in sweat. The mother may notice that the child is salty when kissed.

Most of the organ damage is due to blockage of the narrow passages by thickened secretions. Chronic pulmonary disease arises from plugging of bronchi and bronchioles. CF is the most common cause of chronic lung disease among children in

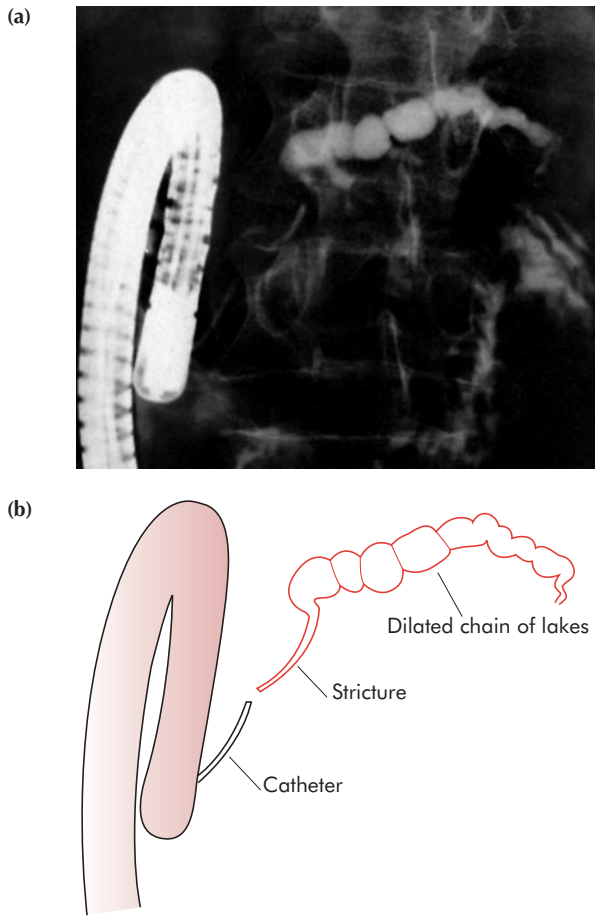

Figure 64.17 (a) Endoscopic retrograde cholangiopancreatography: chronic pancreatitis. Long stricture of the pancreatic duct in the head; distal pancreatic duct shows sacculations with intervening short strictures, 'chain of lakes'. (b) Diagrammatic outline of (a).

Figure 64.18 Plain abdominal radiograph: chronic pancreatitis. Multiple opacities can be seen in the region of the head and tail of the pancreas.

developed countries. Cor pulmonale may develop later. At birth, the meconium may set in a sticky mass and produce intestinal obstruction (meconium ileus) (see Chapter 6). Secretions precipitate in the lumen of the pancreatic duct causing blockage, which results in duct ectasia and fatty replacement of exocrine acinar tissue. Pancreatic exocrine insufficiency leads to fat malabsorption.

Figure 64.19 A group of adenocarcinoma cells identified in pancreatic juice collected at the time of endoscopic retrograde cholangiopancreatography (courtesy of Professor Roger Feakins).

Figure 64.20 (a) Carcinoma of the pancreatic head as seen on endoscopic ultrasound (EUS). (b) Aspiration biopsy carried out under EUS guidance: needle seen entering the tumour (courtesy of Dr Peter Fairclough).

tion. Steatorrhea is usually present from birth, resulting in stools that are bulky, oily and offensive. The islets of Langerhans usually appear normal, but diabetes mellitus can occur in older patients. The liver may become cirrhotic as a result of bile duct plugging, and signs of portal hypertension may appear. Infertility

is common, due to the absence of the vas deferens in men and thick cervical mucus in women.

Outside the newborn period, the earliest clinical signs of CF are poor growth, poor appetite, rancid greasy stools, abdominal distension, chronic respiratory disease and finger clubbing. The appearance of secondary sexual characteristics may be delayed. The diagnosis can be made by genetic testing (which may be part of prenatal or newborn screening) and by the sweat test. Levels of sodium and chloride ions in the sweat above 90 mmol l⁻¹ confirm the diagnosis.

Treatment is aimed at control of the secondary consequences of the disease. Pulmonary function is preserved with aggressive physiotherapy and antibiotics. Malabsorption is treated by administration of oral pancreatic enzyme preparations. The diet should be low in fat but contain added salt to replace the high losses in the sweat. With early diagnosis and optimal treatment, patients in the western world can now expect to survive to their mid-thirties. Those with end-stage lung disease may be considered for lung transplantation. Heterozygous carriers of the various gene mutations are asymptomatic but can be identified by DNA analysis. There is a suggestion that such patients may develop pancreatitis later in life.

Annular pancreas

This is the result of failure of complete rotation of the ventral pancreatic bud during development, so that a ring of pancreatic tissue surrounds the second or third part of the duodenum. It is most often seen in association with congenital duodenal stenosis or atresia and is therefore more prevalent in children with Down's syndrome. Duodenal obstruction typically causes vomiting in the neonate (see Chapter 6). The usual treatment is bypass (duodeno-oduodenostomy). The disease may occur in later life as one of the causes of pancreatitis, in which case resection of the head of the pancreas is preferable to lesser procedures.

Ectopic pancreas

Islands of ectopic pancreatic tissue can be found in the submucosa in parts of the stomach, duodenum or small intestine (including Meckel's diverticulum), the gall bladder, adjoining the pancreas, in the hilum of the spleen and within the liver. Ectopic pancreas may also be found in the wall of an alimentary tract duplication cyst (see Chapter 6).

Congenital cystic disease of the pancreas

This sometimes accompanies congenital disease of the kidneys and liver, and occurs as part of the von Hippel–Lindau syndrome.

INJURIES TO THE PANCREAS

External injury

Presentation and management

The pancreas, thanks to its somewhat protected location in the retroperitoneum, is not frequently damaged in blunt abdominal

trauma. If there is damage to the pancreas, it is often concomitant with injuries to other viscera, especially the liver, the spleen and the duodenum. Occasionally, a forceful blow to the epigastrium may crush the body of the pancreas against the vertebral column. Penetrating trauma to the upper abdomen or the back carries a higher chance of pancreatic injury. Pancreatic injuries may range from a contusion or laceration of the parenchyma *without* duct disruption to major parenchymal destruction *with* duct disruption (sometimes complete transection) and, rarely, massive destruction of the pancreatic head. The most important factor that determines treatment is whether the pancreatic duct has been disrupted.

Blunt pancreatic trauma usually presents with epigastric pain, which may be minor at first, with the progressive development of more severe pain due to the sequelae of leakage of pancreatic fluid into the surrounding tissues. The clinical presentation can be quite deceptive; careful serial assessments and a high index of suspicion are required. A rise in serum amylase occurs in most cases. A CT scan of the pancreas will delineate the damage that has occurred to the pancreas (Fig. 64.21). If there is doubt about duct disruption, an urgent ERCP should be sought. MRCP may also provide the answer, but the images can be difficult to interpret. Support with intravenous fluids and a nil by mouth regimen should be instituted while these investigations are performed. There is no need to rush to a laparotomy if the patient is haemodynamically stable, without peritonitis. It is preferable to manage conservatively at first, investigate and, once the extent of the damage has been ascertained, undertake appropriate action. Operation is indicated only if there is disruption of the main pancreatic duct; in almost all other cases, the patient will recover with conservative management.

In penetrating injuries, especially if other organs are injured and the patient's condition is unstable, there is a greater need to perform an urgent surgical exploration. Assessment of pancreatic damage and duct disruption at the time of surgery can be difficult, because the bruising associated with the retroperitoneal damage

Figure 64.21 Computerised tomography scan showing a pancreatic transection due to a bicycle handlebar injury. A distal pancreatectomy was performed.

John Langdon Haydon Down, (sometimes given as Haydon-Down), 1828–1896, Physician, The London Hospital, London, England, published his classification of aments in 1866.

Johann Friedrich Meckel (The Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany.

Eugen von Hippel, 1867–1939, Professor of Ophthalmology, Göttingen, Germany.

Arvid Lindau, 1892–1958, Pathologist, Lund, Sweden.

prevents clear visualisation of the pancreas. A patient and thorough examination of the gland should be carried out. Haemostasis and closed drainage is adequate for minor parenchymal injuries. If the gland is transected in the body or tail, a distal pancreatectomy should be performed, with or without splenectomy. If damage is purely confined to the head of the pancreas, haemostasis and external drainage is normally effective. In the emergency setting, in an unstable patient with concomitant injuries, a surgeon unaccustomed to pancreatic surgery should refrain from trying to ascertain whether the duct in the pancreatic head is intact or embarking on a major resection. However, if there is severe injury to the pancreatic head and duodenum, then a pancreatoduodenectomy may be necessary (Summary box 64.3).

Summary box 64.3

External injury to the pancreas

- Other organs are likely to be injured
- It is important to ascertain whether the pancreatic duct has been disrupted
- CT and ERCP are the most useful tests
- Surgery is indicated if the main pancreatic duct is disrupted

Prognosis

The most common cause of death in the immediate period is bleeding, usually from associated injuries. Once the acute phase has passed, the mortality and morbidity related to the pancreatic injury itself are treatable, with a complete return to normal activity the usual outcome.

Persistent drain output occurs in up to a third of patients (see the section on pancreatic fistulae below). Sometimes, in the aftermath of trauma that has been treated conservatively, duct stricture develops, leading to recurrent episodes of pancreatitis. The appropriate treatment in such cases is resection of the tail of the pancreas up to the site of duct disruption.

Also, a pancreatic pseudocyst may develop. If the main duct is intact, the cyst can be aspirated percutaneously in the first instance; it may not be necessary to undertake a cystgastrostomy. If the cyst develops in the presence of complete disruption of the pancreas, there is no alternative but to undertake a distal resection or, occasionally, a pancreatojejunostomy with a Roux-en-Y loop. In a patient who presents with a peripancreatic cyst and a history of previous blunt abdominal trauma, do not assume that it is a post-traumatic pseudocyst. The possibility of a cystic neoplasm should be considered and excluded.

Iatrogenic injury

This can occur in several ways:

- Injury to the tail of the pancreas during splenectomy, resulting in a pancreatic fistula.
- Injury to the accessory pancreatic duct (Santorini), which is the main duct in 7% of patients, during Billroth II gastrectomy.

Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.
Giandomenico (Giovanni Domenico) Santorini, 1681–1737, Professor of Anatomy and Medicine, Venice, Italy.
Christian Albert Theodor Billroth, 1829–1894, Professor of Surgery, Vienna, Austria.

A pancreatogram performed by cannulating the duct at the time of discovery of such an injury will demonstrate whether it is safe to ligate and divide the duct. If no alternative drainage duct can be demonstrated, then the duct should be reanastomosed to the duodenum.

- Enucleation of islet cell tumours of the pancreas can result in fistulae.
- Duodenal or ampullary bleeding following sphincterotomy. This injury may require duodenotomy to control the bleeding.

Pancreatic fistula

Pancreatic fistula usually follows operative trauma to the gland or may occur as a complication of acute or chronic pancreatitis. It is important to define the site of the fistula and the epithelial structure with which it communicates (e.g. externally to skin, or internally to bowel). If there is uncertainty about whether the fluid issuing from a drain site or a wound is pancreatic, measurement of the amylase content will be diagnostic.

Management includes correction of metabolic and electrolyte disturbances and adequate drainage of the fistula into a stoma bag with protection of the skin. Investigation of the cause of the fistula is required as the underlying cause must be treated before the fistula will close. Frequently, the cause is related to obstruction within the pancreatic duct, which can be overcome by the insertion of a stent or catheter endoscopically into the pancreatic duct. While waiting for closure of the fistula, the patient should be given parenteral or nasojejunal nutritional support (as opposed to nasogastric or oral feeding; the rationale is that parenteral or nasojejunal feeding reduces the volume of pancreatic secretion). The use of octreotide will also suppress pancreatic secretion (Summary box 64.4).

Summary box 64.4

Management of pancreatic fistulae

Tests

- Measure amylase level in fluid
- Determine the anatomy of the fistula
- Check whether the main pancreatic duct is blocked or disrupted

Measures

- Correct fluid and electrolyte imbalances
- Protect the skin
- Drain adequately
- Parenteral or nasojejunal feeding
- Octreotide to suppress secretion
- Relieve pancreatic duct obstruction if possible (ERCP and stent)
- Treat underlying cause

PANCREATITIS

Pancreatitis is inflammation of the gland parenchyma of the pancreas. For clinical purposes, it is useful to divide pancreatitis into acute, which presents as an emergency, and chronic, which is a prolonged and frequently lifelong disorder resulting from the development of fibrosis within the pancreas. It is probable that acute pancreatitis is but a phase of chronic pancreatitis.

Acute pancreatitis is defined as an acute condition presenting

with abdominal pain and is usually associated with raised pancreatic enzyme levels in the blood or urine as a result of pancreatic inflammation. Acute pancreatitis may recur.

The underlying mechanism of injury in pancreatitis is thought to be premature activation of pancreatic enzymes within the pancreas, leading to a process of autodigestion. Anything that injures the acinar cell and impairs the secretion of zymogen granules, or damages the duct epithelium and thus delays enzymatic secretion, can trigger acute pancreatitis. Once cellular injury has been initiated, the inflammatory process can lead to pancreatic oedema, haemorrhage and, eventually, necrosis. As inflammatory mediators are released into the circulation, systemic complications can arise, such as haemodynamic instability, bacteraemia (due to translocation of gut flora), acute respiratory distress syndrome and pleural effusions, gastrointestinal haemorrhage, renal failure and disseminated intravascular coagulation (DIC).

Acute pancreatitis may be categorised as mild or severe. *Mild acute pancreatitis* is characterised by interstitial oedema of the gland and minimal organ dysfunction. Eighty per cent of patients will have a mild attack of pancreatitis, the mortality from which is around 1%. *Severe acute pancreatitis* is characterised by pancreatic necrosis, a severe systemic inflammatory response and often multi-organ failure. In those who have a severe attack of pancreatitis, the mortality varies from 20% to 50%. About one-third of deaths occur in the early phase of the attack, from multiple organ failure, while deaths occurring after the first week of onset are due to septic complications.

Chronic pancreatitis is defined as a continuing inflammatory disease of the pancreas characterised by irreversible morphological change typically causing pain and/or permanent loss of function. Many patients with chronic pancreatitis have exacerbations, but the condition may be completely painless.

Acute pancreatitis

Incidence

Acute pancreatitis accounts for 3% of all cases of abdominal pain among patients admitted to hospital in the UK. The hospital admission rate for acute pancreatitis is 9.8 per year per 100 000 population in the UK, although worldwide, the annual incidence may range from 5 to 50 per 100 000. The disease may occur at any age, with a peak in young men and older women.

Aetiology

The two major causes of acute pancreatitis are biliary calculi, which occur in 50–70% of patients, and alcohol abuse, which accounts for 25% of cases. Gallstone pancreatitis is thought to be triggered by the passage of gallstones down the common bile duct. If the biliary and pancreatic ducts join to share a common channel before ending at the ampulla, then obstruction of this passage may lead to reflux of bile or activated pancreatic enzymes into the pancreatic duct. Patients who have small gallstones and a wide cystic duct may be at a higher risk of passing stones. The proposed mechanisms for alcoholic pancreatitis include the effects of diet, malnutrition, direct toxicity of alcohol, concomitant tobacco smoking, hypersecretion, duct obstruction or reflux, and hyperlipidaemia. The remaining cases may be due to rare causes or be idiopathic (Summary box 64.5).

Summary box 64.5

Possible causes of acute pancreatitis

- Gallstones
- Alcoholism
- Post ERCP
- Abdominal trauma
- Following biliary, upper gastrointestinal or cardiothoracic surgery
- Ampullary tumour
- Drugs (corticosteroids, azathioprine, asparaginase, valproic acid, thiazides, oestrogens)
- Hyperparathyroidism
- Hypercalcaemia
- Pancreas divisum
- Autoimmune pancreatitis
- Hereditary pancreatitis
- Viral infections (mumps, coxsackie B)
- Malnutrition
- Scorpion bite
- Idiopathic

Among patients who undergo ERCP, 1–3% develop pancreatitis, probably as a consequence of duct disruption and enzyme extravasation. Patients with sphincter of Oddi dysfunction or a history of recurrent pancreatitis, and those who undergo sphincterotomy or balloon dilatation of the sphincter, carry a higher risk of developing post-ERCP pancreatitis. Patients who have undergone upper abdominal or cardiothoracic surgery may develop acute pancreatitis in the postoperative phase, as may those who have suffered blunt abdominal trauma.

Hereditary pancreatitis is a rare familial condition associated with mutations of the cationic trypsinogen gene. Patients have a tendency to suffer acute pancreatitis while in their teens, progress to chronic pancreatitis in the next two decades and have a high risk (possibly up to 40%) of developing pancreatic cancer by the age of 70 years.

Occasionally, tumours at the ampulla of Vater may cause acute pancreatitis. It is important to check the serum calcium level, a fasting lipid profile, autoimmune markers and viral titres in patients with so called idiopathic acute pancreatitis. It is equally important to take a detailed drug history and remember the association of corticosteroids, azathioprine, asparaginase and valproic acid with acute pancreatitis. A careful search for the aetiology must be made in all cases, and no more than 20% of cases should fall into the idiopathic category (Summary box 64.6).

Summary box 64.6

Aetiology of acute pancreatitis

- It is essential to establish the aetiology
- Investigate thoroughly before labelling it as 'idiopathic'
- After the acute episode resolves, remember further management of the underlying aetiology
- If the aetiology is gallstones, cholecystectomy is desirable during the same admission

Ruggero Oddi, 1845–1906, Physiologist, Perugia, Italy.

Clinical presentation

Pain is the cardinal symptom. It characteristically develops quickly, reaching maximum intensity within minutes rather than hours and persists for hours or even days. The pain is frequently severe, constant and refractory to the usual doses of analgesics. Pain is usually experienced first in the epigastrium but may be localised to either upper quadrant or felt diffusely throughout the abdomen. There is radiation to the back in about 50% of patients, and some patients may gain relief by sitting or leaning forwards. The suddenness of onset may simulate a perforated peptic ulcer, while biliary colic or acute cholecystitis can be mimicked if the pain is maximal in the right upper quadrant. Radiation to the chest can simulate myocardial infarction, pneumonia or pleuritic pain. In fact, acute pancreatitis can mimic most causes of the acute abdomen and should seldom be discounted in differential diagnosis.

Nausea, repeated vomiting and retching are usually marked accompaniments. The retching may persist despite the stomach being kept empty by nasogastric aspiration. Hiccoughs can be troublesome and may be due to gastric distension or irritation of the diaphragm.

On examination, the appearance may be that of a patient who is well or, at the other extreme, one who is gravely ill with profound shock, toxicity and confusion. Tachypnoea is common, tachycardia is usual, and hypotension may be present. The body temperature is often normal or even subnormal, but frequently rises as inflammation develops. Mild icterus can be caused by biliary obstruction in gallstone pancreatitis, and an acute swinging pyrexia suggests cholangitis. Bleeding into the fascial planes can produce bluish discoloration of the flanks (Grey Turner's sign) or umbilicus (Cullen's sign). Neither sign is pathognomonic of acute pancreatitis; Cullen's sign was first described in association with rupture of an ectopic pregnancy. Subcutaneous fat necrosis may produce small, red, tender nodules on the skin of the legs.

Abdominal examination may reveal distension due to ileus or, more rarely, ascites with shifting dullness. A mass can develop in

the epigastrium due to inflammation. There is usually muscle guarding in the upper abdomen, although marked rigidity is unusual. A pleural effusion is present in 10–20% of patients. Pulmonary oedema and pneumonitis are also described and may give rise to the differential diagnosis of pneumonia or myocardial infarction. The patient may be confused and exhibit the signs of metabolic derangement together with hypoxaemia.

Investigations

Typically, the diagnosis is made on the basis of the clinical presentation and an elevated serum amylase level. A serum amylase level three to four times above normal is indicative of the disease. A normal serum amylase level does not exclude acute pancreatitis, particularly if the patient has presented a few days later. If the serum lipase level can be checked, it provides a slightly more sensitive and specific test than amylase. If there is doubt, and other causes of acute abdomen have to be excluded, contrast-enhanced CT is probably the best single imaging investigation (see below) (Summary box 64.7).

Summary box 64.7

Investigations in acute pancreatitis should be aimed at answering three questions:

- Is a diagnosis of acute pancreatitis correct?
- How severe is the attack?
- What is the aetiology?

Assessment of severity

On account of the difference in outcome between patients with mild and severe disease, it is important to define that group of patients who will develop severe pancreatitis. Various scoring systems have been introduced, such as the Ranson and Glasgow scoring systems (Table 64.3). The APACHE II scoring system, used in intensive care units, can also be applied. A severe attack

Table 64.3 Scoring systems to predict the severity of acute pancreatitis: in both systems, disease is classified as severe when three or more factors are present

Ranson score	Glasgow scale
On admission Age > 55 years White blood cell count > $16 \times 10^9 \text{ l}^{-1}$ Blood glucose > 10 mmol l^{-1} LDH > 700 units l^{-1} AST > 250 Sigma Frankel units per cent	On admission Age > 55 years White blood cell count > $15 \times 10^9 \text{ l}^{-1}$ Blood glucose > 10 mmol l^{-1} (no history of diabetes) Serum urea > 16 mmol l^{-1} (no response to intravenous fluids) Arterial oxygen saturation (PaO_2) < 8 kPa (60 mmHg)
Within 48 hours Blood urea nitrogen rise > 5 mg% Arterial oxygen saturation (PaO_2) < 8 kPa (60 mmHg) Serum calcium < 2.0 mmol l^{-1} Base deficit > 4 mmol l^{-1} Fluid sequestration > 6 litres	Within 48 hours Serum calcium < 2.0 mmol l^{-1} Serum albumin < 32 g l^{-1} LDH > 600 units l^{-1} AST/ALT > 600 units l^{-1}

AST, aspartate aminotransferase; ALT, alanine aminotransferase; LDH, lactate dehydrogenase; PaO_2 , arterial oxygen tension.

George Grey Turner, 1877–1951, Professor of Surgery, The University of Durham, Durham (1927–1934), and at the Postgraduate Medical School, Hammersmith, London, England (1934–1945).
 Thomas Stephen Cullen, 1868–1953, Professor of Gynecology, The Johns Hopkins University, Baltimore, MD, USA.
 John H.C. Ranson, Professor of Surgery, The New York University School of Medicine, New York, NY, USA.

may be heralded by an initial clinical impression of a very ill patient and an APACHE II score above 8. At 48 hours after the onset of symptoms, a Glasgow score of 3 or more, a C-reactive protein level greater than 150 mg l⁻¹ and a worsening clinical state with sepsis or persisting organ failure indicate a severe attack. Severity stratification should be performed in all patients within 48 hours of diagnosis. Patients with a body mass index over 30 are at higher risk of developing complications.

Imaging

Plain erect chest and abdominal radiographs are not diagnostic of acute pancreatitis, but are useful in the differential diagnosis. Non-specific findings in pancreatitis include a generalised or local ileus (sentinel loop), a colon cut-off sign and a renal halo sign. Occasionally, calcified gallstones or pancreatic calcification may be seen. A chest radiograph may show a pleural effusion and, in severe cases, a diffuse alveolar interstitial shadowing may suggest acute respiratory distress syndrome.

Ultrasound does not establish a diagnosis of acute pancreatitis. The swollen pancreas may be seen, but ultrasonography should be performed within 24 hours in *all* patients to detect gallstones as a potential cause, rule out acute cholecystitis as a differential diagnosis and determine whether the common bile duct is dilated.

CT is not necessary for all patients, particularly those deemed to have a mild attack on prognostic criteria. But a contrast-enhanced CT is indicated in the following situations:

- if there is diagnostic uncertainty;
- in patients with severe acute pancreatitis, to distinguish interstitial from necrotising pancreatitis (Fig. 64.22). In the first 72 hours, CT may underestimate the extent of necrosis. The severity of pancreatitis detected on CT may be staged according to the Balthazar criteria;

Figure 64.22 Contrast-enhanced computerised tomography scan showing acute necrotising pancreatitis. Note the area of reduced enhancement in the pancreas (marked X), the peripancreatic oedema and stranding of the fatty tissues (courtesy of Dr Niall Power).

Emil J. Balthazar, Contemporary, Professor Emeritus, The Department of Radiology, The New York University, New York, NY, USA.

- in patients with organ failure, signs of sepsis or progressive clinical deterioration;
- when a localised complication is suspected, such as fluid collection, pseudocyst or a pseudoaneurysm.

Cross-sectional MRI can yield similar information to that obtained by CT. EUS and MRCP can help in detecting stones in the common bile duct and directly assessing the pancreatic parenchyma, but are not widely available. ERCP allows the identification and removal of stones in the common bile duct in gallstone pancreatitis. In patients with severe acute gallstone pancreatitis and signs of ongoing biliary obstruction and cholangitis, an urgent ERCP should be sought (see below).

The presentation is so variable that sometimes even an experienced clinician can be mistaken. While this is not desirable, occasionally the diagnosis is only made at laparotomy. The appearances at laparotomy are characteristic (Fig. 64.23).

Management

If after initial assessment a patient is considered to have a mild attack of pancreatitis, a conservative approach is indicated with intravenous fluid administration and frequent, but non-invasive, observation. A brief period of fasting may be sensible in a patient who is nauseated and in pain, but there is little physiological justification for keeping patients on a prolonged 'nil by mouth' regimen. Antibiotics are not indicated. Apart from analgesics and anti-emetics, no drugs or interventions are warranted, and CT scanning is unnecessary unless there is evidence of deterioration. However, if a stable patient meets the prognostic criteria for a severe attack of pancreatitis, then a more aggressive approach is

Figure 64.23 Widespread fat necrosis of the omentum. A test tube has been filled with blood-stained peritoneal fluid. This specimen was rich in amylase. Fat necroses are dull, opaque, yellow-white areas suggestive of drops of wax. They are most abundant in the vicinity of the pancreas, but are widespread in the greater omentum and the mesentery. At necropsy, they can sometimes be demonstrated beneath the pleura and pericardium, and even in the subsynovial fat of the knee joint. Fat necroses consist of small islands of saponification caused by the liberation of lipase, which splits into glycerol and fatty acids. Free fatty acids combine with calcium to form soaps (fatty necrosis) (courtesy of Dr G.D. Adhia, Mumbai, India).

required, with the patient being admitted to a high-dependency or an intensive care unit and monitored invasively.

Patients with a severe attack should be admitted to an intensive care or high-dependency unit (Table 64.4). Adequate analgesia should be administered. Aggressive fluid resuscitation is important, guided by frequent measurement of vital signs, urine output and central venous pressure. Supplemental oxygen should be administered and serial arterial blood gas analysis performed. The haematocrit, clotting profile, blood glucose and serum levels of calcium and magnesium should be closely monitored.

A nasogastric tube is not essential but may be of value in patients with vomiting. Specific treatments such as aprotinin, somatostatin analogues, platelet-activating factor inhibitors and selective gut decontamination have failed to improve outcome in numerous clinical trials and should not be given. There are no data to support a practice of 'resting' the pancreas and feeding only by the parenteral or nasojejunal routes. If nutritional support is felt to be necessary, enteral nutrition (e.g. feeding via a nasogastric tube) is should be used.

There is some evidence to support the use of prophylactic antibiotics (intravenous cefuroxime, or imipenem, or ciprofloxacin plus metronidazole) in patients with severe acute pancreatitis for the prevention of local and other septic complications. The duration of antibiotic prophylaxis should not exceed 14 days. Additional antibiotic use should be guided by microbiological cultures.

If gallstones are the cause of an attack of predicted or proven severe pancreatitis, or if the patient has jaundice, cholangitis or a dilated common bile duct, urgent ERCP should be carried out within 72 hours of the onset of symptoms. There is evidence that sphincterotomy and clearance of the bile duct can reduce the incidence of infective complications in these patients. In patients with cholangitis, sphincterotomy should be carried out or a biliary stent placed to drain the duct. ERCP is an invasive procedure and carries a small risk of worsening the pancreatitis.

Systemic complications

Pancreatitis may involve all organ systems (Table 64.5) and place demands on the surgeon beyond his or her skills. Patients with systemic complications should be managed by a multidisciplinary team that includes intensive care specialists. When there is organ failure, appropriate supportive therapies may include inotropic

support for haemodynamic instability, haemofiltration in the event of renal failure, ventilatory support for respiratory failure and correction of coagulopathies (including DIC). There is no role for surgery during the initial period of resuscitation and stabilisation; surgical intervention is contemplated only in the patient who deteriorates as a result of local complications following successful stabilisation.

Local complications and their management

Once the acute phase has been survived, usually by the end of the first week, and major organ failure is under control, then local complications become pre-eminent in the management of these patients. The course of the patient should be followed carefully and, if clinical resolution does not take place or signs of sepsis develop, a CT scan should be performed. It is important to be clear about the definitions. Certain terms are confusing, such as *phlegmon*, which may refer to an abscess or to an inflammatory mass in the pancreas. Local complications in pancreatic disease are serious and carry a significant mortality. The management approach is conservative on the whole, with surgery restricted to situations in which conservative management has failed.

Acute fluid collection

This occurs early in the course of acute pancreatitis and is located in or near the pancreas. The wall encompassing the collection is ill defined. The fluid is sterile, and most such collections resolve. No intervention is necessary unless a large collection causes symptoms or pressure effects, in which case it can be percutaneously aspirated under ultrasound or CT guidance. Transgastric drainage under EUS guidance is another option. An acute fluid collection that does not resolve can evolve into a pseudocyst or an abscess if it becomes infected.

Sterile and infected pancreatic necrosis

The term pancreatic necrosis refers to a diffuse or focal area of non-viable parenchyma that is typically associated with peripancreatic fat necrosis. Necrotic areas can be identified by an absence of contrast enhancement on CT. These are sterile to begin with, but can become subsequently infected, probably due to translocation of gut bacteria. Infected necrosis is associated with a mortality rate of up to 50%. Sterile necrotic material should not be drained or interfered with. But if the patient shows signs of sepsis, then one should determine whether the

Table 64.4 Early management of severe acute pancreatitis

Admission to HDU/ICU
Analgesia
Aggressive fluid rehydration
Oxygenation
Invasive monitoring of vital signs, central venous pressure, urine output, blood gases
Frequent monitoring of haematological and biochemical parameters (including liver and renal function, clotting, serum calcium, blood glucose)
Nasogastric drainage
Antibiotic prophylaxis can be considered (imipenem, cefuroxime)
CT scan essential if organ failure, clinical deterioration or signs of sepsis develop
ERCP within 72 hours for severe gallstone pancreatitis or signs of cholangitis
Supportive therapy for organ failure if it develops (inotropes, ventilatory support, haemofiltration, etc.)
If nutritional support is required, consider enteral (nasogastric) feeding

CT, computerised tomography; ERCP, endoscopic retrograde cholangiopancreatography; HDU, high-dependency unit; ICU, intensive care unit.

ARDS, acute respiratory distress syndrome; DIC, disseminated intravascular coagulation.

necrotic pancreas or the peripancreatic fluid is infected (Fig. 64.24). A CT scan should be performed and a needle passed into the area under CT guidance, choosing a path that does not traverse hollow viscera. This may be done under ultrasonographic guidance as well. If the aspirate is purulent, percutaneous drainage of the infected fluid should be carried out. The tube drain inserted should have the widest bore possible. The aspirate should be sent for microbiological assessment, and appropriate antibiotic therapy should be commenced as per the sensitivity report. The fluid can be quite viscous with

Figure 64.24 Infected pancreatic necrosis in an elderly patient. Note the areas of reduced enhancement in the pancreas and the peripancreatic fluid collection with pockets of gas within it (arrow). This resolved after percutaneous drainage and antibiotic therapy.

particulate matter, and the drain may need regular flushing with full aseptic precautions. Often, repeated imaging and repeated insertion of drains is necessary.

If the sepsis worsens despite this, then a pancreatic necrosectomy should be considered. This is a challenging operation that carries a high morbidity and mortality, and is best carried out in a specialist unit. The overwhelming majority of patients with peripancreatic sepsis can be successfully treated by conservative means, and necrosectomy should be necessary in a very small proportion of patients. The surgical approach may be through a mid-line laparotomy, especially if the area involved is around the head of the gland. The duodenocolic and gastrocolic ligaments should be divided and the lesser sac opened. Thorough debridement of the dead tissue around the pancreas should be carried out. If the body and tail of the gland are primarily involved (Fig. 64.25), a retroperitoneal approach though a left flank incision may be more appropriate. The tissues are inevitably friable, and one should be careful not to precipitate excessive bleeding or inadvertently breach the bowel wall. Blunt dissection is preferable to sharp dissection. A feeding jejunostomy may be a useful adjunct to the procedure. If gallstones are the precipitating factor of the pancreatitis, a cholecystectomy should be included. Some prefer a minimally invasive approach to a formal laparotomy. A rigid laparoscope is inserted into the peripancreatic area through a retroperitoneal approach, and vigorous irrigation and suction is combined with a gradual nibbling away of the necrotic debris.

Once a necrosectomy has been completed, further necrotic tissue may form. There are several possible ways of dealing with this (listed below), none of which has been proved to be more effective than the others. The last two approaches make greater logistic demands as one is committed to a re-exploration every 48–72 hours.

- *Closed continuous lavage:* Tube drains are left in and the raw area flushed (Beger) (Fig. 64.26).
- *Closed drainage:* The incision is closed, but the cavity is packed with gauze-filled Penrose drains and closed suction drains. The Penrose drains are brought out through the flank and slowly pulled out and removed after 7 days.

Figure 64.25 Necrotic body and tail of the pancreas removed as an intact specimen rather than piecemeal. The patient had suffered severe necrotising gallstone pancreatitis complicated by persistent pancreatic sepsis. Necrosectomy was carried out through a left flank retroperitoneal approach.

Hans Beger, Contemporary, Emeritus Professor of Surgery, Ulm, Germany.
Charles Bingham Penrose, 1862–1925, Professor of Gynecology, The University of Pennsylvania, Philadelphia, PA, USA.

Figure 64.26 Continuous postoperative closed lavage of the lesser sac as advised by Beger. Lavage is carried out through several double-lumen and single-lumen catheters. Each time, 1 litre of saline is infused through and then drained over a period of hours, and the process is repeated.

- *Open packing:* The incision is left open, and the cavity is packed with the intention of returning to the operating room at regular intervals and repacking until there is a clean granulating cavity.
- *Closure and relaparotomy:* The incision is closed with drains with the intention of performing a series of planned relaparotomies every 48–72 hours until the raw area granulates (Bradley).

There is a sub-group of patients who respond initially to percutaneous treatment but then develop recurrent sepsis that requires repeated insertion of drains, and fail to thrive. Necrosectomy should be considered in these patients, but it can be a difficult judgement call.

Patients with peripancreatic sepsis are ill for long periods of time, and may require management in an intensive care unit. Nutritional support is essential. The parenteral and nasojejunal approaches are more popular (on the assumption that they rest the pancreas), although there is little evidence to show that nasogastric feeding, if tolerated, is harmful in any way.

Pancreatic abscess

This is a circumscribed intra-abdominal collection of pus, usually in proximity to the pancreas. It may be an acute fluid collection or a pseudocyst that has become infected. The principles of diagnosis and management are as outlined above for infected pancreatic necrosis. Percutaneous drainage with the widest possible drains placed under imaging guidance is the treatment, along with appropriate antibiotics and supportive care. Repeated scans may be required depending on the progress of the patient, and drains may need to be flushed, repositioned or reinserted. Very occasionally, open drainage of the abscess may be necessary.

Pancreatic ascites

This is a chronic, generalised, peritoneal, enzyme-rich effusion usually associated with pancreatic duct disruption. Paracentesis will reveal turbid fluid with a high amylase level. Adequate drainage with wide-bore drains placed under imaging guidance is essential. Measures that can be taken to suppress pancreatic secretion include parenteral or nasojejunal feeding and administration of octreotide. An ERCP may allow demonstration of the duct disruption and placement of a pancreatic stent.

Pancreatic effusion

This is an encapsulated collection of fluid in the pleural cavity, arising as a consequence of acute pancreatitis. Concomitant pancreatic ascites may be present, or there may be a communication with an intra-abdominal collection. Percutaneous drainage under imaging guidance is necessary.

Haemorrhage

Bleeding may occur into the gut, into the retroperitoneum or into the peritoneal cavity. Possible causes include bleeding into a pseudocyst cavity, diffuse bleeding from a large raw surface, or a pseudoaneurysm. The last is a false aneurysm of a major peripancreatic vessel confined as a clot by the surrounding tissues and often associated with infection. Recurrent bleeding is common, often culminating in fatal haemorrhage. CT, angiography or MR angiography helps to make the diagnosis. Treatment involves embolisation or surgery.

Portal or splenic vein thrombosis

This may often develop silently and is identified on a CT scan. A marked rise in the platelet count should raise suspicions. In the context of acute pancreatitis, treatment is usually conservative. The patient should be screened for pro-coagulant tendencies. If varices or other manifestations of portal hypertension develop, they will require treatment, such as endoscopic injection or banding, β -blockade, etc. Thrombocytosis may mandate the use of aspirin or other anti-platelet drugs for a period. Systemic anticoagulation, if instituted early in the process, may achieve recanalisation of the vein, but it is not routinely used as it carries considerable risks in a patient with on-going pancreatitis.

Pseudocyst

A pseudocyst is a collection of amylase-rich fluid enclosed in a wall of fibrous or granulation tissue. Pseudocysts typically arise following an attack of acute pancreatitis, but can develop in chronic pancreatitis or after pancreatic trauma. Formation of a pseudocyst requires 4 weeks or more from the onset of acute pancreatitis (Fig. 64.27; see also Fig. 64.10, p. 1134). They are often single but, occasionally, patients will develop multiple pseudocysts. If carefully investigated, more than half will be found to have a communication with the main pancreatic duct.

A pseudocyst is usually identified on ultrasound or a CT scan. It is important to differentiate a pseudocyst from an acute fluid collection or an abscess; the clinical scenario and the radiological appearances should allow that distinction to be made. Occasionally, a cystic neoplasm may be confused with a chronic pseudocyst. EUS and aspiration of the cyst fluid is very useful in such a situation. The fluid should be sent for

Figure 64.27 Barium meal. Pseudocyst displacing the stomach (courtesy of Professor V.K. Kapoor, Lucknow, India).

measurement of carcinoembryonic antigen (CEA) levels, amylase levels and cytology. Fluid from a pseudocyst typically has a low CEA level, and levels above 400 ng ml^{-1} are suggestive of a mucinous neoplasm. Pseudocyst fluid usually has a high amylase level, but that is not diagnostic, as a tumour that communicates with the duct system may yield similar findings. Cytology typically reveals inflammatory cells in pseudocyst fluid. If there is no access to EUS, then percutaneous FNA is acceptable (just aspiration, *not* percutaneous insertion of a drain). ERCP and MRCP may demonstrate communication of the cyst with the pancreatic duct system, demonstrate ductal anomalies or diagnose chronic pancreatitis and thus help in planning treatment.

Pseudocysts will resolve spontaneously in most instances, but complications can develop (Table 64.6). Pseudocysts that are thick-walled or large (over 6 cm in diameter), have lasted for a long time (over 12 weeks) or have arisen in the context of chronic pancreatitis are less likely to resolve spontaneously, but these

Table 64.6 Possible complications of a pancreatic pseudocyst

Process	Outcomes
Infection	Abscess Systemic sepsis
Rupture	
Into the gut	Gastrointestinal bleeding Internal fistula
Into the peritoneum	Peritonitis
Enlargement	
Pressure effects	Obstructive jaundice from biliary compression Bowel obstruction
Pain	
Erosion into a vessel	Haemorrhage into the cyst Haemoperitoneum

factors are not specific indications for intervention. Therapeutic interventions are advised only if the pseudocyst causes symptoms, if complications develop or a distinction has to be made between a pseudocyst and a tumour.

There are three possible approaches to draining a pseudocyst: percutaneous, endoscopic and surgical. Percutaneous drainage to the exterior under radiological guidance should be avoided. It carries a very high likelihood of recurrence. Moreover, it is not advisable unless one is absolutely certain that the cyst is not neoplastic and that it has no communication with the pancreatic duct (or else a pancreatico-cutaneous fistula will develop). A percutaneous transgastric cystgastrostomy can be done under imaging guidance, and a double-pigtail drain placed with one end in the cyst cavity and the other end in the gastric lumen. This requires specialist expertise but, in experienced hands, the recurrence rates are no more than 15%. Endoscopic drainage usually involves puncture of the cyst through the stomach or duodenal wall under EUS guidance, and placement of a tube drain with one end in the cyst cavity and the other end in the gastric lumen. The success rates depend on operator expertise. Occasionally, ERCP and placement of a pancreatic stent across the ampulla may help to drain a pseudocyst that is in communication with the duct. Surgical drainage involves internally draining the cyst into the gastric or jejunal lumen (Fig. 64.28). Recurrence rates should be no more than 5%, and this still remains the standard against which the evolving radiological and endoscopic approaches are measured. Pseudocysts that have developed complications are best managed surgically (Summary box 64.8).

Figure 64.28 Cystgastrostomy for the pancreatic pseudocyst shown in Figure 64.10 (p. 1134). The anterior wall of the stomach has been opened and the edges drawn back, held by Babcock's forceps. An opening has been made through the posterior wall of the stomach into the pseudocyst, and the tips of the dissecting forceps are in the cavity of the pseudocyst, which is lined by slough and granulation tissue. The tip of a nasogastric tube is visible. A running suture will next be placed along the edges of this opening, suturing the full thickness of the posterior gastric wall to the capsule of the pseudocyst.

William Wayne Babcock, 1872–1963, Surgeon, Philadelphia, PA, USA.

Summary box 64.8

Distinguishing a pseudocyst from a cystic neoplasm

- History
- Appearance on CT and ultrasound
- FNA of fluid, preferably under EUS guidance
 - CEA (high level in mucinous tumours)
 - Amylase (level usually high in pseudocysts, but occasionally in tumours)
 - Cytology

Outcomes and follow-up of acute pancreatitis

The overall mortality from acute pancreatitis has remained at 10–15% over the past 20 years. There is a clear responsibility before the patient is discharged to determine the aetiology of the attack of pancreatitis, and the causes listed in Summary box 64.5 (p. 1139) must be looked for and excluded. Failure to remove a predisposing factor could lead to a second attack of pancreatitis, which could be fatal. A proportion of patients in the idiopathic group who suffer repeated attacks may prove to have biliary microlithiasis, which can be identified only by bile sampling at ERCP or by endoscopic ultrasound. In a patient who has gallstone pancreatitis, the gallstones should be removed as soon as the patient is fit to undergo surgery and, preferably, before discharge from hospital.

Chronic pancreatitis

Chronic pancreatitis is a chronic inflammatory disease in which there is irreversible progressive destruction of pancreatic tissue. Its clinical course is characterised by severe pain and, in the later stages, exocrine and endocrine pancreatic insufficiency. In the early stages of its evolution, it is frequently complicated by attacks of acute pancreatitis, which are responsible for the recurrent pain that may be the only clinical symptom. The incidence of chronic pancreatitis in several European, North American and Japanese studies ranges from 2 to 10 new cases per 100 000 population per year, with a prevalence of around 13 cases per 100 000, although there are suspicions that the prevalence is actually higher. The disease occurs more frequently in men (male to female ratio of 4:1), and the mean age of onset is about 40 years.

Aetiology and pathology

High alcohol consumption is the most frequent cause of chronic pancreatitis, accounting for 60–70% of cases, but only 5–10% of people with alcoholism develop chronic pancreatitis. The exact mechanism of how alcohol causes chronic inflammation in these patients is unclear; genetic and metabolic factors may be at play.

Other causes include pancreatic duct obstruction resulting from stricture formation after trauma, after acute pancreatitis or even occlusion of the duct by pancreatic cancer. Congenital abnormalities, such as pancreas divisum and annular pancreas, if associated with papillary stenosis, are rare causes of chronic pancreatitis.

Hereditary pancreatitis, CF, infantile malnutrition and a large unexplained idiopathic group make up the remainder. Hereditary pancreatitis is an autosomal dominant disorder with an 80% penetrance, associated with mutations in the cationic trypsinogen gene on chromosome 7. Idiopathic chronic pancreatitis accounts for approximately 30% of cases and has been subdivided into early-

onset and late-onset forms. Among the idiopathic group are those who live in warm climates such as Kerala in southern India and appear to have a high incidence of pancreatitis. In this case, the pancreatitis begins at a young age and is associated with a high incidence of diabetes mellitus and stone formation. The importance of hereditary pancreatitis and pancreatitis occurring at a young age is that there is a markedly increased risk of developing pancreatic cancer, particularly if the patient smokes tobacco. Hyperlipidaemia and hypercalcaemia can lead to chronic pancreatitis.

Autoimmune pancreatitis has been described relatively recently. Features include diffuse enlargement of the pancreas, diffuse and irregular narrowing of the main pancreatic duct and a possible association with other autoimmune diseases. The changes may be confused with neoplasia. Autoantibodies may be present, and the immunoglobulin (Ig)G4 concentrations are elevated.

At the onset of the disease when symptoms have developed, the pancreas may appear normal. Later, the pancreas enlarges and becomes hard as a result of fibrosis. The ducts become distorted and dilated with areas of both stricture formation and ectasia. Calcified stones weighing from a few milligrams to 200 mg may form within the ducts. The ducts may become occluded with a gelatinous proteinaceous fluid and debris, and inflammatory cysts may form. Histologically, the lesions affect the lobules, producing ductular metaplasia and atrophy of acini, hyperplasia of duct epithelium and interlobular fibrosis.

Clinical features

Pain is the outstanding symptom in the majority of patients. The site of pain depends to some extent on the main focus of the disease. If the disease is mainly in the head of the pancreas, then epigastric and right subcostal pain is common, whereas if it is limited to the left side of the pancreas, left subcostal and back pain are the presenting symptoms. In some patients, the pain is more diffuse. Radiation to the shoulder, usually the left shoulder, occurs. Nausea is common during attacks, and vomiting may occur. The pain is often dull and gnawing. Severe flare-ups of pain may occur superimposed on background discomfort. All the complications of acute pancreatitis can occur with chronic pancreatitis. Weight loss is common, because the patient does not feel like eating. The pain prevents sleep and time off work is frequent. The number of hospital admissions for acute exacerbations is a pointer towards the severity of the disease. Analgesic use and abuse is frequent. This, too, gives an indication of the severity of the disability. The patient's lifestyle is gradually destroyed by pain, analgesic dependence, weight loss and inability to work. Loss of exocrine function leads to steatorrhoea in more than 30% of patients with chronic pancreatitis. Loss of endocrine function and the development of diabetes are not uncommon, and the incidence increases as the disease progresses. Complications frequently bring the patient to the attention of the surgeon. Infection is not infrequent, possibly related to the diabetes mellitus.

Investigations

Only in the early stages of the disease will there be a rise in serum amylase. Tests of pancreatic function merely confirm the presence of pancreatic insufficiency or that more than 70% of the gland has been destroyed.

Pancreatic calcifications may be seen on abdominal X-ray (see Fig. 64.18, p. 1136). CT or MRI scan will show the outline of the gland, the main area of damage and the possibilities for surgical correction (Fig. 64.29; see also Fig. 64.7, p. 1133). Calcification is

Figure 64.29 Computerised tomography scan in a patient with chronic pancreatitis. Stone obstructing the main pancreatic duct in the body of the gland; duct markedly dilated upstream.

seen very well on CT but not on MRI. An MRCP will identify the presence of biliary obstruction and the state of the pancreatic duct (Fig. 64.30). The use of intravenous secretin during the study may demonstrate a pancreatic duct stricture that is not apparent on a standard MRCP, but a normal-looking pancreas on CT or MRI does not rule out chronic pancreatitis. ERCP is the most accurate way of elucidating the anatomy of the duct and, in conjunction with the whole organ morphology, can help to determine the type of operation required, if operative intervention is indicated (Figs 64.15 and 64.17, p. 1136). Histologically proven chronic pancreatitis can, however, occur in the setting of normal findings on pancreatography. EUS can also be very useful. Sonographic findings characteristic of chronic pancreatitis include the presence of stones, visible side branches, cysts, lobularity, an irregular main pancreatic duct, hyperechoic foci and strands, dilation of the main pancreatic duct and hyperechoic margins of the main pancreatic duct. The presence of four or more of these features is highly suggestive of chronic pancreatitis.

Treatment

Most patients can be managed with medical measures. There is no single therapeutic agent that has been shown to relieve symptoms (Summary box 64.9).

Figure 64.30 Magnetic resonance cholangiopancreatography in a patient with chronic pancreatitis. Stricture of the pancreatic duct in the body of the gland (arrow), with dilatation upstream.

Endoscopic, radiological or surgical interventions are indicated mainly to relieve obstruction of the pancreatic duct, bile duct or the duodenum, or in dealing with complications (e.g. pseudocyst, abscess, fistula, ascites or variceal haemorrhage). Decompressing an obstructed pancreatic duct can provide pain relief in some patients (the assumption is that ductal hypertension causes the pain).

Summary box 64.9

Medical treatment of chronic pancreatitis

Treat the addiction

- Help the patient to stop alcohol consumption and tobacco smoking
- Involve a dependency counsellor or a psychologist

Alleviate abdominal pain

- Eliminate obstructive factors (duodenum, bile duct, pancreatic duct)
- Escalate analgesia in a stepwise fashion
- Refer to a pain management specialist
- For intractable pain, consider CT/EUS-guided coeliac axis block

Nutritional and digestive measures

- Diet: low in fat and high in protein and carbohydrates
- Pancreatic enzyme supplementation with meals
- Correct malabsorption of the fat-soluble vitamins (A, D, E, K) and vitamin B12
- Medium-chain triglycerides in patients with severe fat malabsorption (they are directly absorbed by the small intestine without the need for digestion)
- Reducing gastric secretions may help

Treat diabetes mellitus

Endoscopic pancreatic sphincterotomy might be beneficial in patients with papillary stenosis and a high sphincter pressure and pancreatic ductal pressure. Patients with a dominant pancreatic duct stricture and upstream dilatation may benefit by placement of a stent across the stricture. The stent should be left in for no more than 4–6 weeks as it will block. The complication rate is high, and less than two-thirds of patients experience pain relief, but those who do get relief may benefit from a surgical bypass. Pancreatic duct stones may be extracted at ERCP, and this may sometimes be combined with extracorporeal shock wave lithotripsy. Pseudocysts may be drained internally under EUS guidance. Percutaneous or transgastric drainage of pseudocysts under ultrasound or CT guidance may be performed.

The role of surgery is to overcome obstruction and remove mass lesions. Some patients have a mass in the head of the pancreas, for which either a pancreatoduodenectomy or a Beger procedure (duodenum-preserving resection of the pancreatic head) is appropriate. If the duct is markedly dilated, then a longitudinal pancreatojejunostomy or Frey procedure can be of value (Fig. 64.31). The natural evolution of the disease may not be altered significantly, but around half the patients get long-term pain relief. The rare patient with disease limited to the tail will be cured by a distal pancreatectomy. Patients with intractable pain and diffuse

Charles Frederick Frey, B. 1929, Professor of Surgery, The University of California, Davids, CA, USA.

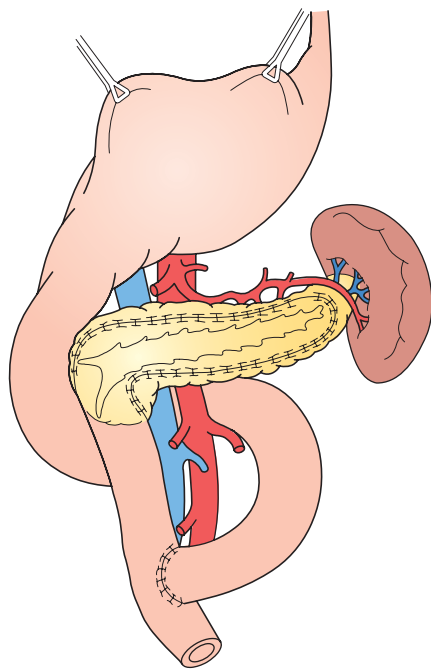

Figure 64.31 Pancreatojejunostomy. The pancreatic duct is opened longitudinally, and a loop of jejunum is sutured to the duct. In the Frey procedure, the superficial part of the head of the pancreas is removed to achieve drainage.

disease may plead for a total pancreatectomy in the expectation that removing the offending organ will relieve their pain. However, one should keep in mind that pancreatic function and quality of life are significantly impaired after this procedure, and the operative mortality rate is around 10%. Moreover, there is no guarantee of pain relief (approximately a third of patients get resolution, a third show some benefit, and a third see no benefit at all). Total pancreatectomy and islet autotransplantation has been reported in selected patients.

Prognosis

Chronic pancreatitis is a difficult condition to manage. Patients often suffer a gradual decline in their professional, social and personal lives. The pain may abate after a surgical or percutaneous intervention, but tends to return over a period of time. In a proportion of patients, the inflammation may gradually burn out over a period of years, with disappearance of the pain, leaving only the exocrine and endocrine insufficiencies. Development of pancreatic cancer is a risk in those who have had the disease for more than 20 years. New symptoms or a change in the pattern of symptoms should be investigated and malignancy excluded.

Sphincter of Oddi dysfunction

Separate mention is warranted of this condition, which should be considered in the differential diagnosis of chronic biliary or pancreatic pain. The sphincter of Oddi is 6–10 mm long and lies within the duodenal wall. A part of it encircles the common channel, and then there are separate biliary and pancreatic components (see Fig. 64.5, p. 1132). Scarring and stenosis of the sphincter can result from passage of stones, pancreatitis or prior endoscopic sphincterotomies. Sphincter of Oddi dyskinesia or dysfunction (SOD) is a clinical syndrome in which pain,

biochemical abnormalities and dilatation of the bile duct and/or pancreatic duct are attributed to abnormal function of the sphincter of Oddi. The true incidence of SOD is unknown. Females are more commonly affected than males.

There are two types of SOD. Biliary-type SOD is characterised by biliary pain, which may be accompanied by abnormally raised liver enzymes and/or dilatation of the bile duct. It may be a cause of persistent post-cholecystectomy symptoms. A predominance of pancreatic problems, especially recurrent episodes of acute pancreatitis, is known as pancreatic-type SOD. The biliary and pancreatic sphincters can be evaluated at the time of ERCP with manometry, and high sphincter pressures may be demonstrated. Sphincterotomy and/or stenting of the involved duct system may be performed if deemed appropriate. SOD is however associated with a particularly high risk of post-ERCP pancreatitis, and such treatments are best carried out in tertiary units by expert gastroenterologists.

In a small sub-group of patients who have experienced significant but short-lived relief with sphincterotomy or stenting, surgical transduodenal sphincteroplasty may be considered. Although SOD can cause severe symptoms (and the patient may therefore be keen to have something done), it is not fatal. But post-ERCP pancreatitis and surgery both carry a small but definite risk of mortality.

CARCINOMA OF THE PANCREAS

Pancreatic cancer is the sixth leading cause of cancer death in the UK, and the incidence is 10 cases per 100 000 population per year. Worldwide, it constitutes 2–3% of all cancers and, in the USA, is the fourth highest cause of cancer death. The incidence has declined slightly over the last 25 years. There is no simple screening test; however, patients with an increased inherited risk of pancreatic cancer (Table 64.7) should be referred to specialist units for screening and counselling.

Pathology

More than 85% of pancreatic cancers are ductal adenocarcinomas. The remaining tumours constitute a variety of pathologies with individual characteristics. Endocrine tumours of the pancreas are rare. They are covered in Chapter 49.

Ductal adenocarcinomas arise most commonly in the head of the gland. They are solid, scirrhous tumours, characterised by neoplastic tubular glands within a markedly desmoplastic fibrous stroma. Fibrosis is also a characteristic of chronic pancreatitis, and histological differentiation between tumour and pancreatitis can cause diagnostic difficulties. Ductal adenocarcinomas infiltrate locally, typically along nerve sheaths, along lymphatics and into blood vessels. Liver and peritoneal metastases are common. Proliferative lesions in the pancreatic ducts can precede invasive ductal adenocarcinoma. These are termed pancreatic intra-epithelial neoplasia or PanIN, and can demonstrate a range of structural complexity and cellular atypia.

Cystic tumours of the pancreas may be serous or mucinous. Serous cystadenomas are typically found in older women, and are large aggregations of multiple small cysts, almost like bubble-wrap. They are benign. Mucinous tumours, on the other hand, have the potential for malignant transformation. They include mucinous cystic neoplasms (MCNs) and intraductal papillary mucinous neoplasms (IPMNs). MCNs are seen in perimenopausal women, show up as multilocular thick-walled cysts in

the pancreatic body or tail and, histologically, contain an ovarian-type stroma. IPMNs are more common in the pancreatic head and in older men, but an IPMN arising from a branch duct can be difficult to distinguish from an MCN. IPMNs arising within the main duct are often multifocal and have a greater tendency to prove malignant. Thick mucus seen extruding from the ampulla at ERCP is diagnostic of a main duct IPMN. Mucinous tumours can be confused with pseudocysts (see Summary box 64.8, p. 1146). Occasionally, lymphoepithelial cysts, lymphangiomas, dermoid cysts and intestinal duplication cysts can show up in the pancreas. Solid pseudopapillary tumour is a rare, slowly progressive but malignant tumour, seen in women of childbearing age, and manifests as a large, part-solid, part-cystic tumour.

Tumours arising from the ampulla or from the distal common bile duct can present as a mass in the head of the pancreas, and constitute around a third of all tumours in that area. Adenomas of the ampulla of Vater are diagnosed at endoscopy as polypoid submucosal masses covered by a smooth epithelium. They can harbour foci of invasive carcinoma; the larger the adenoma, the greater the risk. Biopsies taken at endoscopy may not always include the malignant focus. Endoscopic surveillance, endoscopic resection or even surgical transduodenal ampullary excision should be considered (Fig. 64.32). Patients with familial adenomatous polyposis (FAP) can present with multiple duodenal polyps. Malignant transformation in a duodenal polyp is a significant cause of mortality in these patients, mandating endoscopic follow-up and pancreatoduodenectomy in selected patients with high-grade dysplasia within the polyp.

Ampullary adenocarcinomas often present early with biliary

Figure 64.32 A large ampullary adenoma that turned into an adenocarcinoma; the arrow indicates the ampulla. Photograph taken after resection in the form of a pancreatoduodenectomy (courtesy of Dr Joanne Chin-Aleong).

obstruction. Their natural history is distinctly more favourable compared with pancreatic ductal adenocarcinoma. Ampullary carcinomas are relatively small when diagnosed, which may account for their better prognosis. Occasionally, other malignant neoplasms can arise at the ampulla, such as carcinoid tumours and high-grade neuroendocrine carcinomas.

Clinical features

Jaundice secondary to obstruction of the distal bile duct is the most common symptom that draws attention to ampullary and pancreatic head tumours. It is characteristically painless jaundice but may be associated with nausea and epigastric discomfort. Pruritus, dark urine and pale stools with steatorrhoea are common accompaniments of jaundice. In the absence of jaundice, symptoms are often non-specific, namely vague discomfort, anorexia and weight loss, and are frequently dismissed by both patient and doctor. Upper abdominal symptoms in a recently diagnosed diabetic, especially in one above 50 years of age, with no family history or obesity, should raise suspicion. Occasionally, a patient will present with an unexplained attack of pancreatitis; all such patients should have follow-up imaging of the pancreas. Tumours of the body and tail of the gland often grow silently, and present at an advanced unresectable stage. Back pain is a worrying symptom, raising the possibility of retroperitoneal infiltration.

On examination, there may be evidence of jaundice, weight loss, a palpable liver and a palpable gall bladder. Courvoisier first drew attention to the association of an enlarged gall bladder and a pancreatic tumour in 1890, when he noted that, when the common duct is obstructed by a stone, distension of the gall bladder (which is likely to be chronically inflamed) is rare; when the duct is obstructed in some other way, such as a neoplasm, distension of the normal gall bladder is common. Other signs of intra-abdominal malignancy should be looked for with care, such as a palpable mass, ascites, supraclavicular nodes and tumour deposits in the pelvis; when present, they indicate a grim prognosis.

Ludwig Courvoisier, 1843–1918, Professor of Surgery, Basle, Switzerland.

Investigation

In a jaundiced patient, the usual blood tests and ultrasound scan should be performed. Ultrasound will determine whether or not the bile duct is dilated. If it is, and there is a genuine suspicion of a tumour in the head of the pancreas, the preferred test is a contrast-enhanced CT scan (see Fig. 64.8, p. 1133). In the majority of instances, this should establish if there is a tumour in the pancreas and if it is resectable. The presence of hepatic or peritoneal metastases, lymph node metastases distant from the pancreatic head, encasement of the superior mesenteric, hepatic or coeliac artery by tumour are clear contraindications to surgical resection. Tumour size, continuous invasion of the duodenum, stomach or colon, and lymph node metastases within the operative field are not contraindications. If the tumour abuts or minimally invades the portal or superior mesenteric vein, this is not a contraindication to surgery (as part of the vein can be resected if necessary), but complete encasement and occlusion of the vein is. MRI and MR angiography can provide information comparable to CT.

ERCP and biliary stenting should be carried out if there is any suggestion of cholangitis, if there is diagnostic doubt (small ampullary lesions may not be seen on CT, and ERCP is the best way to identify them) or if there is likely to be a delay between diagnosis and surgery and the patient is deeply jaundiced with distressing pruritus. It relieves the jaundice and can also provide a brush cytology or biopsy specimen to confirm the diagnosis (see Figs 64.13, 64.14 and 64.19, pp. 1134, 1135 and 1136). Otherwise, however, preoperative ERCP and biliary stenting is not mandatory in patients with resectable disease; there is evidence to suggest that it is associated with a slightly higher incidence of infective complications after surgery. The prothrombin time should be checked, and clotting abnormalities should be corrected with vitamin K or fresh frozen plasma prior to ERCP. If a stent is placed in a patient who may undergo resection, it should be a plastic stent rather than a metal self-expanding one.

EUS is useful if CT fails to demonstrate a tumour, if tissue diagnosis is required prior to surgery (e.g. a mass has developed on a background of chronic pancreatitis and a distinction needs to be made between inflammation and neoplasia), if vascular invasion needs to be confirmed and in separating cystic tumours from pseudocysts (Fig. 64.33; see also Fig. 64.20, p. 1136). Transduodenal or transgastric FNA or Trucut biopsy performed under EUS guidance avoids spillage of tumour cells into the peritoneal cavity. Percutaneous transperitoneal biopsy of potentially resectable pancreatic tumours should be avoided as far as possible. Histological confirmation of malignancy is desirable but not essential, particularly if the imaging clearly demonstrates a resectable tumour. The lack of a tissue diagnosis should not delay appropriate surgical therapy. In patients judged to have unresectable disease, tissue diagnosis should be obtained prior to starting palliative therapy.

Diagnostic laparoscopy prior to an attempt at resection can spare a proportion of patients an unnecessary laparotomy by identifying small peritoneal and liver metastases. It can be combined with laparoscopic ultrasonography. The tumour marker CA19-9 is not highly specific or sensitive, but a baseline level should be established; if it is initially raised, it can be useful later in identifying recurrence.

Management

At the time of presentation, more than 85% of patients with ductal adenocarcinoma are unsuitable for resection because the

Figure 64.33 (a) Carcinoma of the ampulla as seen at endoscopy. (b) Appearance of the same tumour (arrow) on endoscopic ultrasound (courtesy of Dr Peter Fairclough).

disease is too advanced. If imaging shows that the tumour is potentially resectable, the patient should be considered for surgical resection, as that offers the only (albeit small) chance of a cure. Comorbidities should be carefully taken into account. Biological rather than chronological age should be the consideration. If a cystic tumour is encountered, no matter how large, surgical resection should be considered, as it carries a reasonable chance of cure. Tumours of the ampulla have a good prognosis and should, if at all possible, be resected. Some of the rare tumours and the neuroendocrine lesions should also be resected if at all possible. For those patients who have inoperable disease, palliative treatment should be offered.

Surgical resection

The standard resection for a tumour of the pancreatic head or the ampulla is a pylorus-preserving pancreatoduodenectomy (PPPD). This involves removal of the duodenum and the pancreatic head, including the distal part of the bile duct. The original pancreatoduodenectomy as proposed by Whipple included resection of the gastric antrum. Preserving the antrum and the pylorus is thought to yield a more physiological outcome with no difference in

Allen Oldfather Whipple, 1881–1963, Director of Surgical Services, The Presbyterian Hospital, and Professor of Surgery, The College of Physicians and Surgeons, Columbia University, New York, NY, USA.

survival or recurrence rates. The Whipple procedure is now reserved for situations in which the entire duodenum has to be removed (e.g. in FAP) or where the tumour encroaches on the first part of the duodenum or the distal stomach and a PPPD would not achieve a clear resection margin. Total pancreatectomy is warranted only in situations where one is dealing with a multifocal tumour (e.g. a main duct IPMN), or the body and tail of the gland are too inflamed or too friable to achieve a safe anastomosis with the bowel. The PPPD procedure includes a local lymphadenectomy. Extended lymphadenectomy has not been shown to be beneficial in improving survival and is associated with increased morbidity. If the tumour is adherent to the portal or superior mesenteric vein, but can still be removed by including a patch or a short segment of vein in the resection, with an appropriate reconstruction of the vessel, then that should be done. This is not associated with an increase in the morbidity or mortality of the procedure, and the outcomes are similar.

For tumours of the body and tail, distal pancreatectomy with splenectomy is the standard. Infiltration of the splenic artery or vein by the tumour is not a contraindication to resection. When resecting the pancreatic tail for a benign lesion, one may attempt to preserve the spleen if possible. When removing the spleen, prior vaccinations against pneumococci, meningococci and *Haemophilus influenzae* B should be administered, and subsequent antibiotic prophylaxis given (see Chapter 62).

Attempts to downstage unresectable disease with chemotherapy or chemoradiation and render it resectable are rarely successful. Neoadjuvant chemotherapy or chemoradiation for resectable disease should only be considered within a clinical trial; it carries the risk that the disease may progress despite the neoadjuvant therapy and become unresectable.

Pancreatoduodenectomy

The clotting should be checked preoperatively and adequate hydration ensured. The patient should be aware of the diagnosis, the gravity of the operation and the risks involved. The operation has three distinct phases:

- exploration and assessment;
- resection;
- reconstruction.

A cholecystectomy is performed. The bile duct and hepatic artery are exposed, removing the lymphatic tissue in this area. Exposure of the hepatic artery enables division of the gastroduodenal artery and visualisation of the portal vein. The distal part of the gastric antrum is mobilised. The duodenum and right colon are mobilised from the retroperitoneal tissues. The superior mesenteric vein is exposed inferior to the pancreatic neck. Careful dissection into the plane between the vein and the pancreatic substance (see Fig. 64.2, p. 1130) will reveal whether the tumour is adherent to the vein. The fourth part of the duodenum is dissected and freed from the ligament of Treitz so that the upper jejunum can be brought into the supracolic compartment. At this juncture, a decision has to be made whether to proceed to the next phase of resection or not. If resection is to be performed, the jejunum is divided 20–30 cm downstream from the duodeno-jejunal flexure, and the mesentery of the proximal jejunum is

detached. The first part of the duodenum is divided. The neck of the pancreas is divided, and then the uncinate process is separated from the superior mesenteric artery and vein working up towards the upper bile duct, which is divided, releasing the specimen (Fig. 64.34). Retroperitoneal lymph nodes within the operative field are completely removed with the specimen. Reconstruction is carried out as in Figure 64.35. The pancreatic stump, the divided bile duct and the duodenal stump are anastomosed on to jejunum, in that order. Some surgeons prefer to anastomose the pancreas to the posterior wall of the stomach instead; others prefer to create a separate Roux loop of the jejunum and anastomose the pancreas to that. The operation should take between 3 and 6 hours. Blood loss should be low, and transfusion is often not necessary. The patients are usually nursed in a high-dependency area for the first 24–48 hours after surgery. Prolonged nasogastric drainage is unnecessary, and early feeding can be commenced.

Resection for pancreatic cancer should be carried out in specialist units. There is a clear correlation between higher caseload volume and lower hospital mortality and morbidity. PPPD should

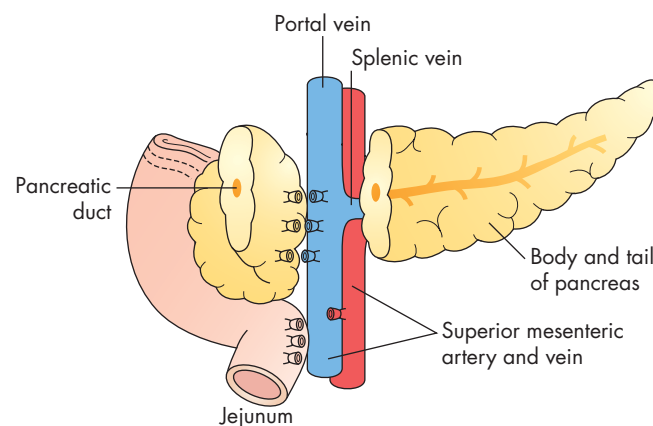

Figure 64.34 Resection of the head of the pancreas in a pylorus-preserving pancreatoduodenectomy.

Figure 64.35 Reconstruction after a pylorus-preserving pancreatoduodenectomy.

Wenzel Treitz, 1819–1872, Professor of Anatomy and Pathology, at Krakow, Poland, and later at Prague, The Czech Republic.

carry a mortality of no more than 3–5%. The morbidity remains high, with some 30–40% of patients developing a complication in the postoperative period. These complications are usually infective, but a leak from the anastomosis between the pancreas and the bowel is known to occur in at least 10% of patients, and this may give rise to major complications. Octreotide may be administered in the perioperative period to suppress secretion and reduce the likelihood of a leak, but the evidence for its efficacy is still debatable. Following surgical resection, the pathological tumour–node–metastasis stage should be documented.

Adjuvant therapy

The reported 5-year survival following resection of a pancreatic adenocarcinoma ranges from 7% to 25%. The median survival is 11–20 months. Considering that, at best, 15% of patients have resectable disease to begin with, this means only two or three out of 100 patients with this disease can expect to survive to 5 years. Moreover, recurrences can and do show up even beyond the 5-year cut-off. It should be emphasised, however, that these depressing statistics apply to ductal adenocarcinomas. Patients with resected ampullary tumours have a 5-year survival of 40%, and cystic tumours and neuroendocrine tumours can often be cured by surgical resection.

The high recurrence rate following resection has inevitably led to the consideration of adjuvant treatments to improve outcome. In a large multicentre European study (ESPAC-1), adjuvant radiotherapy or chemoradiotherapy was shown to confer no advantage, but chemotherapy with 5-fluorouracil (5-FU) provided an overall benefit (median survival with chemotherapy was 20 months compared with 16 months without). Further trials are in progress, using gemcitabine and 5-FU in combination, and other agents. Most patients with resected ductal adenocarcinoma are now offered adjuvant chemotherapy. Some centres continue to offer chemoradiotherapy, particularly in patients with involved (R1) resection margins, and further trials of adjuvant chemoradiation are also in progress.

Palliation

The median survival of patients with unresectable, locally advanced, non-metastatic pancreatic cancer is 6–10 months and, in patients with metastatic disease, it is 2–6 months.

If unresectable disease is found in the course of a laparotomy that was commenced with the intent to resect, a choledochostomy and a gastroenterostomy should be carried out to relieve (or pre-empt) jaundice and duodenal obstruction. The bile duct may be anastomosed to the duodenum, or to a loop of jejunum. It is preferable to use the bile duct rather than the gall bladder. Cholecystojejunostomy is easier to perform, but the bile must then drain through the cystic duct, which is narrow and, if the cystic duct is inserted low into the bile duct, it is vulnerable to occlusion by tumour growth. A coeliac plexus block can also be administered. A transduodenal Trucut biopsy of the tumour should be obtained.

In patients found to have unresectable disease on imaging, jaundice is relieved by stenting at ERCP (Fig. 64.36b). Stents may be made of plastic or self-expanding metal mesh. Plastic stents are cheaper but tend to occlude faster and, if the patient is likely to have a longer life expectancy, a metal stent can be used. If the patient is not a suitable candidate for endoscopic biliary stenting, a percutaneous transhepatic stent can be placed (Fig. 64.36a). Obstruction of the duodenum occurs in approximately 15% of cases. If this occurs early in the course of the disease, surgical bypass by gastrojejunostomy is appropriate but, if it is late in the

course of the disease, then the use of expanding metal stents inserted endoscopically is preferable, as many of these patients have prolonged delayed gastric emptying following surgery (Fig. 64.36c). If both biliary and duodenal metal stents are to be placed endoscopically, the biliary one should be placed first.

If no operative procedure is undertaken, an EUS-guided or percutaneous biopsy of the tumour should be performed before consideration of chemotherapy or chemoradiation. The role of chemotherapy in the management of pancreatic cancer remains ill defined. If the tumour is a lymphoma, then benefit is without doubt. Lymphomas of the pancreas are rare and constitute less than 3% of all pancreatic cancers. For patients with ductal adenocarcinoma, 5-FU or gemcitabine will produce a remission in 15–25%, while the remainder will receive no benefit from the therapy. No long-term cures have been described with chemotherapy or radiotherapy.

Steatorrhoea is treated with enzyme supplementation. Diabetes mellitus, if it develops, is treated with oral hypoglycaemics or insulin as appropriate, and pain with either analgesics or an appropriate nerve block (Summary box 64.10).

Summary box 64.10

Palliation of pancreatic cancer

Relieve jaundice and treat biliary sepsis

- Surgical biliary bypass
- Stent placed at ERCP or percutaneous transhepatic cholangiography

Improve gastric emptying

- Surgical gastroenterostomy
- Duodenal stent

Pain relief

- Stepwise escalation of analgesia
- Coeliac plexus block
- Transthoracic splanchnicectomy

Symptom relief and quality of life

- Encourage normal activities
- Enzyme replacement for steatorrhoea
- Treat diabetes

Consider chemotherapy

The small and large intestines

CHAPTER 65

LEARNING OBJECTIVES

To appreciate:

- The anatomy of the small and large intestines
- The investigation and treatment of the range of conditions that may affect the small and large intestines

To understand:

- That diseases of the intestines may involve functional or anatomical problems

- The principles behind the different types of surgery for the small and large intestines

To be able to deal with:

- Acute surgical problems of the small and large intestines

To know that:

- The surgical management of small and large intestinal disease is best conducted within a multidisciplinary team

ANATOMY OF THE SMALL AND LARGE INTESTINES

Small intestine

The small intestine starts at the pylorus and extends to the ileocaecal valve. It is approximately 7 m in length and is divided into the duodenum, jejunum and ileum. Its main function is in the breakdown and absorption of food products. The small bowel is present in the central and lower portion of the abdominal cavity. Its relations consist of the greater omentum and abdominal wall anteriorly. Posteriorly, it is fixed to the vertebral column by way of its mesentery.

The duodenum is present proximally and is about 25 cm in length. It has no mesentery and, therefore, is the most fixed part of the small bowel. It merges into the jejunum at the duodeno-jejunal flexure. The remainder of the small bowel is made up of the jejunum and ileum. The jejunum makes up the proximal two-fifths and is wider, thicker and more vascular than the ileum. It also consists of circular folds of mucous membrane (valvulae conniventes) that can be used to distinguish it from the ileum. The ileum contains larger lymph node aggregates (Peyer's patches), and these can sometimes be lead points in cases of intussusception in the young.

The arterial supply of the duodenum consists of the right gastric, the superior pancreaticoduodenal branch of the hepatic artery and the inferior pancreaticoduodenal branch of the superior mesenteric artery. The veins drain into the leinal and superior mesenteric. The nerves are supplied from the coeliac plexus. The jejunum and ileum

are vascularised by the superior mesenteric artery through a rich plexus of vessels. The veins run a similar course. The nerve supply to the small intestines arises from sympathetic nerves around the superior mesenteric artery. Pathology such as obstruction causes visceral pain, which is felt in the peri-umbilical region.

Large intestine

The large intestine extends from the ileum to the anus. Rectal anatomy is described in Chapter 68. The colon is approximately 1.5 m in length. It is relatively more fixed than the small bowel. It also differs in that it possesses appendices epiploicae on its surface, which are peritoneal folds containing fat, and the presence of taenia, which consist of longitudinal bands of the outer muscle coat. It can be divided into the caecal, ascending, transverse, descending and sigmoid colonic segments.

The blood supply of the colon is derived from ileocolic, right colic and middle colic branches of the superior mesenteric vessels. The descending colon receives its blood supply from the left colic branch from the inferior mesenteric but also communicates with the superior mesenteric system via the marginal artery of Drummond. The veins run in a similar distribution. The nerve supply is derived from the sympathetic plexus surrounding the superior and inferior mesenteric arteries. Visceral pain is felt in the peri-umbilical region in the proximal colon and in the hypogastric region in the distal colon.

FUNCTIONAL ABNORMALITIES

Megacolon and non-megacolon constipation

There is no single definition of constipation; however, a bowel frequency of less than one every 3 days would be considered

Valvulae conniventes, describes a fold of mucous membrane that passes transversely across two-thirds of the bowel circumference.
Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

Drummond, 1852–1932, English Physician.

abnormal by some. This group of conditions can be divided into:

- 1 megacolon:
 - a Hirschsprung's disease;
 - b non-Hirschsprung's megarectum and megacolon;
- 2 non-megacolon:
 - a slow transit;
 - b normal transit.

Hirschsprung's disease

See Chapter 6 for this and other congenital disorders.

Idiopathic megarectum and megacolon

This is a rare condition and the cause is not known, although in some it may result from poor toilet training during infancy and in others from a congenital abnormality of the intestinal myenteric plexus.

Clinical features

It presents usually in the first 20 years with severe constipation. Patients with idiopathic megarectum often present with faecal incontinence due to rectal faecal loading that requires manual evacuation. Patients with megacolon are more likely to present with abdominal distension and pain. On clinical examination, there may be a hard faecal mass arising out of the pelvis and, on rectal examination, there is a large faecaloma in the lumen. The anus is usually patulous, perianal soiling is common, and sigmoidoscopy is usually impossible but may show melanosis coli if the patient has been taking laxatives over many years.

Investigation

Imaging

As there is an enlarged rectum, often with distension of the colon over a variable length, a radiograph should be taken without prior bowel preparation, using a small quantity of water-soluble contrast to prevent barium impaction. There is usually gross faecal loading of the enlarged rectum and colon and, when a contrast examination is carried out, the width of the colon measured at the pelvic brim is usually more than 6.5 cm (Fig. 65.1).

Anorectal physiology tests

Anorectal physiology tests demonstrate delayed first sensation and raised maximum tolerated volume. Full-thickness rectal biopsy shows normal ganglion cells, a finding that definitively distinguishes this condition from Hirschsprung's disease.

Medical treatment

This is directed at emptying the rectum and keeping it empty with enemas, washouts and sometimes manual evacuation under anaesthesia. Thereafter, the patient is encouraged to develop a regular daily bowel habit, with the use of osmotic laxatives to help the passage of semiformed stool. Rectal evacuation with suppositories and biofeedback therapy may be useful in resistant cases.

Surgical treatment

Surgical treatment is sometimes necessary if medical therapy fails. Options that are available include:

Figure 65.1 Double-contrast barium enema showing megarectum and a huge megasigmoid with normal left colon alongside for comparison (courtesy of Dr D. Nolan, John Radcliffe Hospital, Oxford, UK).

- 1 resection of the dilated rectum and colon (Fig. 65.2) back to normal-diameter colon with normal ganglion cells confirmed by frozen section at the time of surgery, which is followed by reconstruction with a coloanal anastomosis;
- 2 colectomy with the formation of an ileorectal anastomosis;
- 3 restorative proctocolectomy;
- 4 vertical reduction rectoplasty, which is a new procedure designed to reduce the volume of the rectum by at least 50% (Williams);

Figure 65.2 Megacolon.

Harald Hirschsprung, 1830–1916, Physician, Queen Louise Hospital for Children, Copenhagen, Denmark, described congenital megacolon in 1887.

Norman Stanley Williams, Contemporary, Professor of Surgery, Barts and The London School of Medicine and Dentistry, London, UK.

- 5 stoma formation, which may be used either as a salvage operation for failure of previous surgery or as a primary intervention.

Non-megacolon constipation

Although constipation is often regarded as a trivial symptom, some patients are greatly disabled by abdominal pain, distension, reliance on laxatives and difficulty with defaecation. However, it is extremely prevalent complaint in western society. Some reports have put the annual prescription sales for laxatives in the UK at just under £50 million. These are usually otherwise healthy individuals who seek help for constipation but eat a normal diet and have a normal colon on endoscopy and barium enema.

Its cause is thought to involve slow whole-gut transit or a rectal evacuation problem. Factors influencing bowel transit time include:

- drugs: opiates, anti-cholinergics and ferrous sulphate;
- diseases: neurological conditions (Parkinson's disease, multiple sclerosis and diabetic nephropathy):
 - hypothyroidism;
 - hypercalcaemia.

Investigation

Whole-gut transit time can be measured by asking the patient to stop all laxatives and take a capsule containing radio-opaque markers (Fig. 65.3). Retention of more than 80% of the shapes, 120 hours after ingestion, is abnormal.

Defaecating proctography may be helpful if the main complaint is difficulty in evacuating stools.

Treatment

This can be done in several ways:

- 1 *Dietary fibre.* This is the first-line treatment for people with mild constipation. Constipation only resolves after several weeks of therapy and usually needs to be continued in the long term.
- 2 *Laxatives.* It is important that patients do not fall into a cycle of laxative abuse. A number of types are available which include bulk, osmotic and stimulant agents.
- 3 *Biofeedback.* This involves conditioning and coordination of the abdominal and pelvic compartments. It has been shown to be effective in those with a rectal evacuation problem and has also been used in slow transit with some response.

Idiopathic slow-transit constipation

This disorder is usually seen in women and results from infrequent bowel actions, which may have been present since childhood or may suddenly follow abdominal or pelvic surgery. Marker studies will reveal delayed transit, and the patient may or may not be able to empty the rectum normally (Fig. 65.3).

This is a difficult condition to treat medically; dietary measures are usually unsuccessful, and surgical treatment is justified only after careful studies and when medical treatment has been exhausted. Total colectomy and ileorectal anastomosis is the preferred procedure, but the results are unpredictable. Studies show complications of intermittent small bowel obstruction (60%),

Figure 65.3 Whole-gut transit studied using radio-opaque markers. More than 80% should have passed by day 5, demonstrating delayed transit here (courtesy of Dr D. Nolan, John Radcliffe Hospital, Oxford, UK).

further surgery (30%), constipation (25%), diarrhoea (25%) and incontinence (10%). This may be explained in part by the argument that colectomy does not address the functional problem of the remaining bowel. Patients need to be carefully selected for surgery. Other types of surgery performed include stoma creation and segmental resection, but results are variable.

VASCULAR ANOMALIES (ANGIODYSPLASIA)

Capillary or cavernous haemangiomas are a cause of haemorrhage from the colon at any age. In the middle-aged or elderly patient, haemangioma needs to be distinguished from other causes of sudden massive haemorrhage, such as diverticulitis, ulcerative colitis (UC) or ischaemic colitis. Angiodysplasia is a vascular malformation associated with ageing. Its true incidence is probably not known because of the spectrum of disease severity, with ranges in the literature from 5 to 25% over the age of 60 years. With the advent of more sophisticated investigative tools, this may rise. Angiodysplasias occur particularly in the ascending colon and caecum of elderly patients. The malformations consist of dilated tortuous submucosal veins and, in severe cases, the mucosa is replaced by massive dilated deformed vessels.

Clinical features

In the majority, the symptoms are subtle and patients can present with anaemia. About 10–15% can have brisk bleeds, which may

present as melaena or significant per rectum bleeding that is often intermittent.

In many patients in whom rectal bleeding has previously been attributed to diverticular disease, bleeding was probably, in fact, from angiodysplasia in the caecum. There is an association with aortic stenosis. Heyde's syndrome describes the association of aortic valve stenosis with gastrointestinal bleeding from colonic angiodysplasia. A mild form of von Willebrand's disease has been thought to be involved. This is caused by increased breakdown of von Willebrand factor by a natural enzyme called ADAMTS13 around sites of high shear stress such as a stenosed valve. The coagulation abnormality resolves after aortic valve replacement.

Investigation

Barium enema is usually unhelpful and should be avoided, not least because it may mask the lesion at subsequent endoscopy. Provided that the bleeding is not too brisk, colonoscopy may show the characteristic lesion in the right colon. The lesions are only a few millimetres in size and appear as reddish, raised areas at endoscopy. 'Pill' endoscopy is a relatively new technology that may detect small bowel lesions. Selective superior and inferior mesenteric angiography shows the site and extent of the lesion by a blush. If this fails, a radioactive test using technetium-99m (^{99m}Tc)-labelled red cells may confirm and localise the source of haemorrhage.

Treatment

The first principle is to stabilise an unstable circulation. Following this, the bleeding needs to be localised by colonoscopy. This allows simple therapeutic procedures such as cauterisation to be carried out. In severe uncontrolled bleeding, surgery becomes necessary. On-table colonoscopy is carried out to confirm the site of bleeding. Angiodysplastic lesions are sometimes demonstrated by transillumination through the caecum (Fig. 65.4). If it is still not clear exactly which segment of the colon is involved, then a total abdominal colectomy with ileorectal anastomosis may be necessary.

BLIND LOOP SYNDROME

It has been shown in dogs that, if a blind loop of the small intestine is made (Fig. 65.5), defects of absorption will appear. If this occurs in the upper intestine, the defect is chiefly of fat absorption; if in the lower intestine, there is vitamin B12 deficiency. This has been found to occur in humans and is referred to as the blind loop syndrome.

Essentially, the stasis produces an abnormal bacterial flora, which prevents proper breakdown of the food (especially fat) and mops up the vitamins that are present. Sometimes, the only manifestation is anaemia, resulting from vitamin B12 deficiency but, if steatorrhoea occurs, other serious malabsorption features follow. In general, high loops produce steatorrhoea, whereas low loops tend to produce anaemia.

Temporary improvement will follow the use of antibiotics to

Edward Heyde, American internist, published his findings on the association between aortic valve stenosis and angiodysplasia in a letter to the *New England Journal of Medicine* in 1958.

Erik Adolph von Willebrand, 1870–1949, Physician, Diakonissanstaltens Hospital, Helsinki (Helsingfors), Finland, described hereditary pseudo-haemophilia in 1926.

Figure 65.4 Angiodysplasia of the caecum demonstrated by transillumination with a colonoscope intraoperatively.

destroy the bacteria causing the trouble, but the main treatment is surgical extirpation of the cause of the stasis where applicable.

DIVERTICULAR DISEASE

Types

Diverticula can occur in a wide number of positions in the gut, from the oesophagus to the rectosigmoid. There are two varieties:

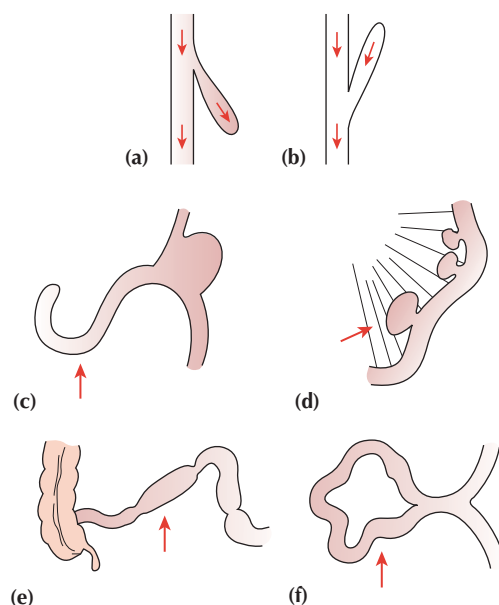

Figure 65.5 Common types of blind loop. (a) Self-filling: deficiency occurs. (b) Self-emptying: no deficiency occurs. (c) Long afferent loop stasis in Pólya gastrectomy. (d) Jejunal diverticula. (e) Intestinal stricture causing stasis. (f) 'Stenosis-anastomosis loop' syndrome.

Eugen (Janö) Alexander Pólya, 1876–1944, Surgeon, St Stephen's Hospital, Budapest, Hungary.

- 1 *Congenital*. All three coats of the bowel are present in the wall of the diverticulum, e.g. Meckel's diverticulum.
- 2 *Acquired*. The wall of the diverticulum lacks a proper muscular coat. Most alimentary diverticula are thought to be acquired.

Small intestine

Most of these diverticula arise from the mesenteric side of the bowel, probably as the result of mucosal herniation through the point of entry of blood vessels.

Duodenal diverticula

There are two types:

- 1 *Primary*. Mostly occurring in older patients on the inner wall of the second and third parts (Fig. 65.6), these diverticula are found incidentally on barium meal and are usually asymptomatic. They can cause problems locating the ampulla during endoscopic retrograde cholangiopancreatography (ERCP).
- 2 *Secondary*. Diverticula of the duodenal cap result from long-standing duodenal ulceration (Fig. 65.7).

Jejunal diverticula

These are usually of variable size and multiple (Fig. 65.8). Clinically, they may (1) be symptomless, (2) give rise to abdominal pain, (3) produce a malabsorption syndrome or (4) present as an acute abdomen with acute inflammation and occasionally perforation. They are more common in patients with connective tissue disorders. In patients with major malabsorption problems giving rise to anaemia, steatorrhoea, hypoproteinaemia or vitamin B12 deficiency, resection of the affected segment with end-to-end anastomosis can be effective.

Meckel's diverticulum

Meckel's diverticulum is present in 2% of the population; it is situated on the anti-mesenteric border of the small intestine, commonly 60 cm from the ileocaecal valve, and is usually 3–5 cm long. Many variations occur (2% – 2 feet – 2 inches is a useful aide-mémoire) (Figs 65.9 and 65.10). It represents the patent intestinal end of the vitellointestinal duct (Summary box 65.1).

Figure 65.6 Primary diverticula of the second and third parts of the duodenum.

Figure 65.7 Secondary diverticula of the duodenal cap.

Johann Friedrich Meckel (the Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany.

Figure 65.8 Jejunal diverticula.

Summary box 65.1

Meckel's diverticulum

- Occurs in 2% of patients, are usually 2 inches (5 cm) in length and are situated 2 feet (60 cm) from the ileocaecal valve
- It should be sought when a normal appendix is found at surgery for suspected appendicitis
- If a silent Meckel's is found incidentally during the course of an operation, it can be left alone provided it is wide mouthed and not thickened
- If ectopic gastric epithelium is present within the diverticulum, it may be the source of gastrointestinal bleeding

Figure 65.9 Meckel's diverticulum.

Figure 65.10 Gangrenous Meckel's diverticulitis.

A Meckel's diverticulum possesses all three coats of the intestinal wall and has its own blood supply. It is therefore vulnerable to infection and obstruction in the same way as the appendix. Indeed, when a normal appendix is found at surgery for suspected appendicitis, a Meckel's diverticulum should be sought by inspection of an appropriate length of terminal ileum. In 20% of cases, the mucosa contains heterotopic epithelium, namely gastric, colonic or sometimes pancreatic tissue. In order of frequency, these symptoms are as follows:

- 1 *Severe haemorrhage*, caused by peptic ulceration. Painless bleeding occurs per rectum and is maroon in colour. An operation is sometimes required for serious progressive gastrointestinal bleeding. When no lesion in the stomach or duodenum can be found, the terminal 150 cm of ileum should be carefully inspected.
- 2 *Intussusception*. In most cases, the apex of the intussusception is the swollen, inflamed, heterotopic epithelium at the mouth of the diverticulum.
- 3 *Meckel's diverticulitis* may be difficult to distinguish from the symptoms of acute appendicitis. When a diverticulum perforates, the symptoms may simulate those of a perforated duodenal ulcer. At operation, an inflamed diverticulum should be sought as soon as it has been demonstrated that the appendix and fallopian tubes are not at fault.
- 4 *Chronic peptic ulceration*. As the diverticulum is part of the mid-gut, the pain, although related to meals, is felt around the umbilicus.
- 5 *Intestinal obstruction*. The presence of a band between the apex of the diverticulum and the umbilicus may cause obstruction either by the band itself or by a volvulus around it.

Imaging

Meckel's diverticulum can be very difficult to demonstrate by contrast radiology; small bowel enema would be the most accurate investigation. Technetium-99m scanning may be useful in identifying Meckel's diverticulum as a source of gastrointestinal bleeding.

Gabriele Falloppio (Fallopius), 1523–1562, Professor of Anatomy, Surgery and Botany, Padua, Italy.

'Silent' Meckel's diverticulum

An aphorism attributed to Dr Charles Mayo is: 'a Meckel's diverticulum is frequently suspected, often sought and seldom found'. A Meckel's diverticulum usually remains symptomless throughout life and is found only at necropsy. When a silent Meckel's diverticulum is encountered in the course of an abdominal operation, it can be left provided it is wide mouthed and the wall of the diverticulum does not feel thickened. Where there is doubt and it can be removed without appreciable additional risk, it should be resected.

Exceptionally, a Meckel's diverticulum is found in an inguinal or a femoral hernia sac – Littre's hernia.

Meckel's diverticulectomy

A Meckel's diverticulum that is broad based should not be amputated at its base and invaginated in the same way as a vermiform appendix, because of the risk of stricture. Furthermore, this does not remove heterotopic epithelium when it is present. The steps of diverticulectomy are shown in Figure 65.11. Alternatively, a linear stapler device may be used. Where there is induration of the base of the diverticulum extending into the adjacent ileum, it is advisable to resect a short segment of ileum containing the diverticulum, restoring continuity with an end-to-end anastomosis.

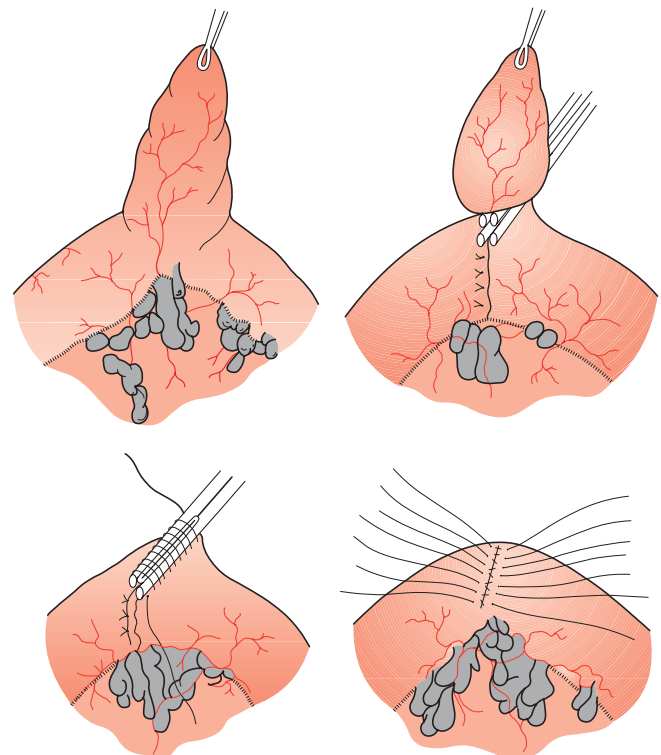

Figure 65.11 Steps in the performance of Meckelian diverticulectomy.

Charles Horace Mayo, 1865–1939, Surgeon, the Mayo Clinic, Rochester, MN, USA.
Alexis Littre, 1658–1726, Surgeon and Lecturer in Anatomy, Paris, France, described Meckel's diverticulum in a hernial sac in 1700, 81 years before Meckel was born.

Colon

Introduction

The prevalence of diverticular disease in the western world is 60% over the age of 60 years. The condition is found in the sigmoid colon in 90% of cases, but the caecum can also be involved and, on occasion, the entire large bowel can be affected. Interestingly in South-east Asia, right-sided diverticular disease is twice as common as the left. The main morbidity of the disease is due to sepsis.

Aetiology

Diverticula of the colon are acquired herniations of colonic mucosa, protruding through the circular muscle at the points where the blood vessels penetrate the colonic wall. They tend to occur in rows between the strips of longitudinal muscle, sometimes partly covered by appendices epiploicae. The rectum with its complete muscle layers is not affected. It is thought to be related to reduced fibre in the western diet. This results in low stool bulk with resulting segmentation and hypertrophy of the colonic wall musculature, thus causing increased intraluminal pressure. Diverticular disease is rare in Africans and Asians, who eat a diet that is rich in natural fibre.

Diverticulosis

It is important to distinguish between diverticulosis, which may be asymptomatic, and clinical diverticular disease in which the diverticula are causing symptoms. On histological investigation, the diverticulum consists of a protrusion of mucous membranes covered with peritoneum. There is thickening of the circular muscle fibres of the intestine, which develops a concertina or saw-tooth appearance on barium enema (Fig. 65.12).

Figure 65.12 Barium enema showing sigmoid diverticular disease 'saw-teeth' and diverticula (courtesy of Dr D. Nolan, John Radcliffe Hospital, Oxford, UK).

Diverticulitis

Diverticulitis is the result of inflammation of one or more diverticula, usually with some pericolitis. It is not a precancerous condition, but cancer may coexist (Summary box 65.2).

Summary box 65.2

Complications of diverticular disease

- Diverticulitis
- Pericolic abscess
- Peritonitis
- Intestinal obstruction
- Haemorrhage
- Fistula formation

The complications are the following:

- 1 Recurrent periodic inflammation and pain – in some patients, these episodes may be clinically silent.
- 2 Perforation leading to general peritonitis or local (pericolic) abscess formation.
- 3 Intestinal obstruction:
 - a in the sigmoid as a result of progressive fibrosis causing stenosis;
 - b in the small intestine caused by adherent loops of small intestine on the pericolitis.
- 4 Haemorrhage: diverticulitis may present with profuse colonic haemorrhage in 17% of cases, often requiring blood transfusions.
- 5 Fistula formation (vesicocolic, vaginocolic, enterocolic, colocolic) occurs in 5% of cases, with vesicocolic being the most common.

Clinical features

Elective

In mild cases, symptoms such as distension, flatulence and a sensation of heaviness in the lower abdomen may be indistinguishable from those of irritable bowel syndrome.

Emergency

Persistent lower abdominal pain, usually in the left iliac fossa, with or without peritonitis, could be caused by diverticulitis. Fever, malaise and leucocytosis can differentiate diverticulitis from painful diverticulosis. The patient may pass loose stools or may be constipated; the lower abdomen is tender, especially on the left, but occasionally also in the right iliac fossa if the sigmoid loop lies across the midline. The sigmoid colon is often palpable, tender and thickened. Rectal examination may, but does not usually, reveal a tender mass. Any urinary symptoms may herald the formation of a vesicocolic fistula, which leads to pneumaturia (flatus in the urine) and even faeces in the urine.

Classification of contamination

Studies have shown that the degree of sepsis has a major impact on outcome. Those with inflammatory masses have a lower mortality than those with perforation (3% vs. 33%). Classification systems have been developed for acute diverticulitis, of which Hinchey is the most commonly used (Table 65.1).

E.F. Hinchey, P.G.H. Schaol and G.K. Richards. Treatment of perforated diverticular disease of the colon. *Adv Surg* 1978; 12: 85–109.

Table 65.1 Classification of diverticulitis

Stage	Severity	Pain	Systemic	Investigation	Management
1	Pericolic abscess or phlegmon	LIF	Possibly no change	Delayed barium enema, endoscopy CT	Bowel rest, IV antibiotic, DVT prophylaxis and fluids Percutaneous drainage
2	Pelvic or intra-abdominal abscess	Severe, fullness in LIF	Mild toxic		
3	Non-faeculent peritonitis	Peritonitis	Toxic	CT	Resuscitation + operation
4	Faeculent peritonitis	Peritonitis	Severe toxicity, shock	Proceed to operation	Resuscitation + immediate operation

DVT, deep venous thrombosis; IV, intravenous; CT, computerised tomography; LIF, left iliac fossa.

Diagnosis

Radiology

Although the diagnosis of acute diverticulitis is made on clinical grounds, it can be confirmed during the acute phase by computerised tomography (CT). It is particularly good at identifying bowel wall thickening, abscess formation and extraluminal disease. The specificity is high and it is able to demonstrate other pathology. It has revolutionised the assessment of complicated diverticular disease. On identification of abscesses in stable patients, drainage may be carried out percutaneously. Such an option may delay or postpone further operative procedures.

Barium enemas (Fig. 65.13) and sigmoidoscopy are usually reserved for patients who have recovered from an attack of acute diverticulitis, for fear of causing perforation or peritonitis. Water-soluble contrast enemas may, however, be helpful in sorting out patients with large bowel obstruction. In the acute situation, it is good at detecting intraluminal changes and leakage. The sensitivity for this is of the order of 90%. Barium radiology is carried out to exclude a carcinoma and to assess the extent of the disease.

Figure 65.13 Barium enema showing a large filling defect in the sigmoid colon caused by a pericolic abscess (courtesy of Dr D. Nolan, John Radcliffe Hospital, Oxford, UK).

Where the sigmoid colon is thickened and narrowed, a 'saw-tooth' appearance may be seen. Some strictures can be very difficult to distinguish by radiology alone and, in those circumstances, colonoscopy will be necessary to rule out a carcinoma. Vesicocolic fistulae should be evaluated with cystoscopy and biopsy in addition to colonoscopy. Contrast examinations may show the fistula itself. The differential diagnosis for vesicocolic fistulae (and other fistulae) includes cancer, radiation damage, Crohn's disease (CD), tuberculosis and actinomycosis.

Colonoscopy

Colonoscopy may reveal the necks of diverticula within the bowel lumen (Fig. 65.14). A narrowed area of diverticulitis can be entered but, on occasion, not passed because of the severity of disease. The differential diagnosis from a carcinoma can be impossible if a tight stenosis prevents colonoscopy. In equivocal cases, biopsies may be taken.

Management

Non-complicated

Diverticulosis should be treated with a high-residue diet containing roughage in the form of wholemeal bread, flour, fruit and vegetables. The evidence for this is not of a high quality. Bulk formers such as bran, Celevac, Isogel and Fybogel may be given

Figure 65.14 Colonoscopic view of sigmoid diverticula. Note the mouths of diverticula between the hypertrophied colonic walls.

until the stools are soft. Painful diverticular disease may require antispasmodics.

Acute diverticulitis is treated by bed rest and intravenous antibiotics (usually cefuroxime and metronidazole). After the acute attack has subsided, and if the diagnosis has not already been confirmed by CT, a barium enema should be administered (Summary box 65.3).

Summary box 65.3

Principles of surgical management of diverticular disease

- In elective cases with full bowel preparation, resection and primary anastomosis is usually possible
- If there is obstruction, oedema, adhesions or perforation, Hartmann's procedure is usually the operation of choice
- In selected cases, resection and anastomosis after on-table lavage may be possible
- Laparoscopic assessment has been described but is controversial
- In cases of minimal peritoneal contamination, peritoneal lavage followed by suture of a small perforation can also be performed

Operative procedures for diverticular disease

The aim of surgery is to control sepsis in the peritoneum and circulation. Indications for operation include general peritonitis and failure to resolve on conservative treatment. Surgery, especially in the acute setting, has considerable risk. Postoperative mortality and reoperation rate for elective resection are 5% and 12%, respectively, which compares with 17% and 16% for emergency surgery. There is controversy as to whether a more radical approach should be adopted. Historically, data have shown that mortality was lower in patients in whom the inflamed colon was resected. However, two randomised comparative trials have shown that mortality is lower in the group in which a proximal defunctioning stoma is performed. The decision needs to be made by the individual surgeon based on the general state of the patient.

The risk of recurrence in patients with moderate diverticulitis is only 14%. This compares with 39% for severe diverticulitis. Therefore, a policy of monitoring can be used in elderly patients following an acute attack that settles. Younger patients unfortunately have a higher risk of recurrence (below the age of 50 years, the risk of recurrence is 25%). Surgery may be indicated for young patients with more than two attacks of inflammation. Some 10% of patients require an operation either for recurrent attacks, which make life a misery, or for the complications of diverticulitis.

- 1 The ideal operation carried out as an interval procedure after careful preparation of the gut is a one-stage resection. This involves removal of the affected segment and restoration of continuity by end-to-end anastomosis. Careful dissection will allow eventual mobilisation of the rectosigmoid out of the pelvis exposing the normal rectum, and greater mobility will allow an easier anastomosis.

- 2 If there is obstruction, inflammatory oedema and adhesions or the bowel is loaded with faeces, a Hartmann's operation is the procedure of choice (Fig. 65.15). This removes the risk of anastomotic leak. However, complications may ensue if the stoma is under tension, or the rectal stump breaks down. The involved area is resected. The rectum is closed at the peritoneal reflection, and the left colon brought out as a left iliac fossa colostomy. The once popular staged procedures using a preliminary transverse colostomy are now rarely used except by inexperienced surgeons because of the high mortality associated with them. In selected obstructed cases, the bowel can be cleaned by on-table lavage, making anastomosis much safer.
- 3 In acute perforation, peritonitis soon becomes general and may be purulent, with a mortality rate of about 15%. Gross faecal peritonitis carries a mortality rate of more than 50% and pneumoperitoneum is usually present; the diagnosis may not be confirmed until emergency laparotomy. There is a choice of procedures:
 - a primary resection and Hartmann's procedure (see above);
 - b primary resection and anastomosis after on-table lavage in selected cases;
 - c exteriorisation of the affected bowel, which is then opened as a colostomy, a procedure now rarely used.
- 4 Fistulae can be cured only by resection of the diseased bowel and closure of the fistula. In the case of a colovesical fistula, it

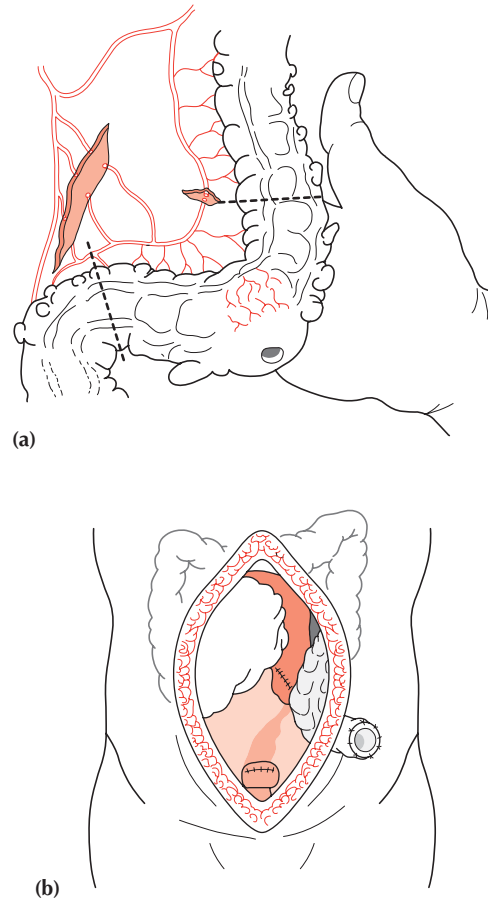

Figure 65.15 (a) Perforated sigmoid diverticular disease. (b) The Hartmann procedure – oversewn rectal stump and left iliac fossa colostomy.

Henri Albert Charles Antoine Hartmann, 1860–1952, Professor of Clinical Surgery in the Faculty of Medicine, University of Paris, France.

is usually possible to ‘pinch off’ the affected bowel from the bladder, close it and then resect the sigmoid. In very difficult cases, a staged procedure with a preliminary defunctioning stoma may be necessary.

- 5 Haemorrhage from diverticulitis must be distinguished from angiodysplasia. It usually responds to conservative management and occasionally requires resection. On-table lavage and colonoscopy may be necessary to localise the bleeding site. If the source cannot be located, then subtotal colectomy and ileostomy is the safest option.

Diverticular disease and carcinoma coexist in 12% of cases. Exploration may be necessary but, even then, differentiation may be difficult until histological investigations are available (Table 65.2). Weight loss, falling haemoglobin and persistently positive occult blood are sinister features.

Solitary diverticulum of the caecum and ascending colon is rare and congenital, and may present with symptoms and signs identical to those of acute appendicitis.

Laparoscopic surgery

In selected cases, laparoscopic surgery has been used for sigmoid resection. This has the benefit of decreased hospital stay and costs. However, there is little high-quality research in the field to advocate its true merits.

ULCERATIVE COLITIS

Aetiology

The cause of UC is unknown. There is probably a genetic contribution with no clear Mendelian pattern of inheritance. It has been shown that 15% of patients with UC have a first-degree relative with inflammatory bowel disease. UC is more common in Caucasians than in blacks or Asians. In spite of intensive bacteriological studies, no organisms or group of organisms can be incriminated. Relapse of colitis has, however, been reported in association with bacterial dysenteries. Smoking seems to have a protective effect. Patients often comment that relapses are associated with periods of stress at home or at work, but personality and psychiatric profiles are the same as those of the normal population.

Studies show that mucosal permeability increases with the presence of inflammation. This may be due to a combination of genetic susceptibility or damage by toxins. The resulting passage of antigens that trigger inflammation may cause an influx of

neutrophils and lymphocytes. This inflammation is usually dampened down in normal tissue, but this is lost in UC. There may be loss of tolerance to self-antigens. UC is thought to be an immune disorder in individuals with yet unknown susceptibility genes or a hypersensitivity reaction to an external antigen.

Epidemiology

There are 10–15 new cases per 100 000 population a year in the UK. This is higher in people of Jewish origin. The prevalence is 160 per 100 000 population. There are approximately 96 000 people with UC in the UK. The incidence has not changed over the last 20 years. The disease has been rare in eastern populations but is now being reported more commonly, suggesting an environmental cause that has developed as a result of an increasing ‘westernisation’ of diet and/or social habits and better diagnostic facilities. The sex ratio is equal in the first four decades of life. From the age of 40 years, the incidence in females falls whereas it remains the same in males. It is uncommon before the age of 10 years, and most patients are between the ages of 20 and 40 years at diagnosis.

Pathology

In 95% of cases, the disease starts in the rectum and spreads proximally. The rectum is involved in all circumstances except in those using topical rectal preparations (rectal sparing). It is a diffuse inflammatory disease, primarily affecting the mucosa and superficial submucosa, and only in severe disease are the deeper layers of the intestinal wall affected. There are multiple minute ulcers, and microscopic evidence proves that the ulceration is almost always more severe and extensive than the gross appearance indicates. When the disease is chronic, inflammatory polyps (pseudopolyps) occur in up to 20% of cases and may be numerous. In severe fulminant colitis, a section of the colon, usually the transverse colon, may become acutely dilated, with the risk of perforation (‘toxic megacolon’). On microscopic investigation, there is an increase in inflammatory cells in the lamina propria, the walls of crypts are infiltrated by inflammatory cells and there are crypt abscesses. There is depletion of goblet cell mucin. With time, these changes become severe, and precancerous changes can develop (= severe dysplasia or carcinoma *in situ*).

Symptoms

The first symptom is watery or bloody diarrhoea; there may be a rectal discharge of mucus that is either blood-stained or purulent. Pain as an early symptom is unusual. In most cases, the disease is

Table 65.2 Differentiation of diverticulitis from carcinoma of the colon

	Diverticulitis	Carcinoma
History	Long	Short
Pain	More common	25% painless
Mass	25% have tenderness	
Bleeding	17% often profuse, periodic	65% – usually small amounts persistently
Radiograph	Diffuse change	Localised: no relaxation with propantheline bromide
Sigmoidoscopy	Inflammatory change over an area	No inflammation until ulcer reached
Colonoscopy	No carcinoma seen	Carcinoma seen and biopsied

Gregor Johann Mendel, 1822–1884, an Austrian monk and naturalist who became Abbott of the Augustinian Monastery at Brunn, Czechoslovakia, and discovered the laws of inheritance by studying the edible pea.

chronic and characterised by relapses and remissions. In general, a poor prognosis is indicated by (1) a severe initial attack, (2) disease involving the whole colon and (3) increasing age, especially after 60 years. If the disease remains confined to the left colon, the outlook is better.

Proctitis

About 50% have rectal inflammation. As most of the colon is healthy, the stool is formed or semiformed, and the patient is often severely troubled by tenesmus and urgency. There is usually no systemic upset, no effect on growth in children, and extra-alimentary manifestations are rare. In 5–10%, there is spread to involve the rest of the colon.

Colitis (Fig. 65.16)

Diarrhoea usually implies that there is active disease proximal to the rectum. There is an increased tendency to systemic upset. Protein loss is associated with bleeding, which results in weight loss. There is a greater risk of extra-alimentary manifestations and cancer. Approximately 30% of patients have inflammation extending to the sigmoid colon, and spread proximal to the splenic flexure occurs in 20%. The clinical pattern is one of recurrent severe attacks of bloody diarrhoea up to 20 times a day, dehydration and fluid electrolyte losses. Anaemia and hypoproteinaemia are common.

Disease severity

Disease severity can be graded as:

- 1 mild – rectal bleeding or diarrhoea with four or fewer motions per day and the absence of systemic signs of disease;
- 2 moderate – more than four motions per day but no systemic signs of illness;
- 3 severe – more than four motions a day together with one or more signs of systemic illness: fever over 37.5°C, tachycardia more than 90 min⁻¹, hypoalbuminaemia less than 30 g l⁻¹, weight loss more than 3 kg.

Complications of severe disease

Fulminating colitis and toxic dilatation (megacolon) (Fig. 65.17)

Patients with severe disease should be admitted to hospital for intensive treatment. This occurs in 5–10% of patients. The

Figure 65.16 Extensive, active ulcerative colitis (the rectum is spared, which is unusual in the absence of treatment) (courtesy of Dr I. Talbot, St Mark's Hospital, London, UK).

Figure 65.17 Fulminating ulcerative colitis with toxic dilatation of the transverse colon.

patient will have severe rectal symptoms with systemic upset such as weight loss and dehydration. A third will come to urgent surgery. Dilatation should be suspected in patients with active colitis who develop severe abdominal pain. It is an indication that inflammation has gone through all the muscle layers of the colon. In patients on intensive treatment such as steroids, there may be few symptoms. The diagnosis is confirmed by the presence on a plain abdominal radiograph of the colon with a diameter of more than 6 cm. The condition must be differentiated from dysentery, typhoid and amoebic colitis. Plain abdominal radiographs should be obtained daily in patients with severe colitis, and a progressive increase in diameter in spite of medical therapy is an indication for surgery (Summary box 65.4; Fig. 65.18).

Summary box 65.4

Complications of UC

Acute

- Toxic dilatation
- Perforation
- Haemorrhage

Chronic

- Cancer
- Extra-alimentary manifestations: skin lesions, eye problems, liver disease

Perforation

Colonic perforation in UC is a grave complication with a mortality rate of 50% or more. Steroids may mask the physical signs. Perforation can sometimes occur without toxic dilatation. Generally, patients with severe attacks should be managed so that they do not develop these complications.

Severe haemorrhage

Severe rectal bleeding is uncommon and may occasionally require transfusion and, rarely, surgery.

Investigations

A plain abdominal film can often show the severity of disease. Faeces are present only in parts of the colon that are normal or only mildly inflamed. Mucosal islands can sometimes be seen.

Figure 65.18 Supine abdominal radiograph in toxic megacolon. The transverse colon is dilated (7 cm), there is no formed residue in the colon, and large mucosal islands are present in the ascending colon and hepatic flexure. No haustration is present in the transverse colon, which distinguishes this from ileus of obstruction. Mucosal islands are due to oedematous remnants or mucosa where there has been extensive ulceration (courtesy of Dr C. Bartram, St Mark's Hospital, London, UK).

Small bowel loops in the right lower quadrant may be a sign of severe disease.

Barium enema

The principal signs are (Fig. 65.19):

- loss of haustration, especially in the distal colon;
- mucosal changes caused by granularity;
- pseudopolyps;
- in chronic cases, a narrow contracted colon.

In some centres, an instant enema is used with a water-soluble medium for contrast instead of barium and no bowel preparation to avoid aggravating any underlying colitis (Fig. 65.20).

Sigmoidoscopy

Sigmoidoscopy is essential for diagnosis of early cases and mild disease not showing up on a barium enema. The initial findings are those of proctitis: the mucosa is hyperaemic and bleeds on touch, and there may be a pus-like exudate. Where there has been remission and relapse, there may be the presence of regeneration nodules or pseudopolyps. Later, tiny ulcers may be seen that appear to coalesce. This is different from the picture of amoebic dysentery, in which there are large, deep ulcers with intervening normal mucosa.

Figure 65.19 Double-contrast barium enema showing left-sided ulcerative colitis with a tubular left colon compared with a normal right colon (courtesy of Dr D. Nolan, John Radcliffe Hospital, Oxford, UK).

Colonoscopy and biopsy

This has an important place in management:

- 1 to establish the extent of inflammation;
- 2 to distinguish between UC and Crohn's colitis;
- 3 to monitor response to treatment;
- 4 to assess longstanding cases for malignant change.

Although it may occasionally be helpful, colonoscopy is not usually used in acute cases for fear of aggravating the disease or perforation.

Bacteriology

Campylobacter is the commonest cause of infective colitis in the UK. Pathologically, it is difficult to distinguish from UC. A stool specimen needs to be sent for microbiology analysis when UC is suspected. Other infective causes include *Shigella* and amoebiasis. Pseudomembranous colitis occurs in hospital patients on antibiotic treatment and non-steroidal anti-inflammatory drugs (NSAIDs). The causative organism is *Clostridium difficile*. Immunocompromised patients are at risk of infective proctocolitis from cytomegalovirus and cryptosporidia.

The cancer risk in colitis

Although this is an important complication, the overall risk is only about 3.5%. It is much less in early cases but increases with duration of disease. At 10 years, the risk of cancer in all patients

Burrill Bernard Crohn, 1884–1956, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.
Kiyoshi Shiga, 1870–1957, a Japanese Bacteriologist, reported his discovery of the dysentery bacillus in 1898.

Figure 65.20 Instant enema in acute ulcerative colitis. The rectum shows a granular mucosa with ulceration extending from the proximal sigmoid into the splenic flexure region. The ulcers are seen tangentially as collar-stud projections from the mucosal line. Formed residue is present in the ascending colon and hepatic flexure. The colitis extends into the mid-transverse colon but is most active in the descending colon (courtesy of Dr C. Bartram, St Mark's Hospital, London, UK).

with UC, irrespective of disease extent, is 2%. This increases to 8% at 20 years and 18% at 30 years. Carcinoma is more likely to occur if the whole colon is involved and if the disease started in early life (Fig. 65.21). Carcinomatous change, often atypical and high grade, may occur at many sites at once. The colon is involved rather than the rectum, and the maximal incidence is during the fourth decade.

The golden rule is that, when the disease has been present for 10 years or more, regular colonoscopic checks must be carried out to check for dysplasia, even if the disease is clinically quiescent. If on biopsy, there is severe epithelial dysplasia, which is a marker for impending or frank carcinomatous change, surgery is indicated. Annual colonoscopy and biopsy is then part of cancer surveillance. In the rare patients with a fibrous stricture, the stricture should be examined especially carefully for the presence of an underlying carcinoma.

Extraintestinal manifestations

Arthritis occurs in around 15% of patients and is of the large joint polyarthropathy type, affecting knees, ankles, elbows and wrists. Sacroiliitis and ankylosing spondylitis are 20 times more common in patients with UC.

Bile duct cancer is a rare complication, and colectomy does not

Figure 65.21 Resection specimen from a patient with longstanding ulcerative colitis showing a narrow tubular colon with areas of cancerous change in the rectum and sigmoid (courtesy of Dr B. Warren, John Radcliffe Hospital, Oxford, UK).

appear to reduce the risk of subsequent bile duct cancer or sclerosing cholangitis. Other manifestations include:

- *skin lesions*: erythema nodosum, pyoderma gangrenosum or aphthous ulceration;
- *eye problems*: iritis;
- *liver disease*: sclerosing cholangitis has been reported in up to 70% of cases. Diagnosis is by ERCP, which demonstrates the characteristic alternating stricturing and bleeding of the intrahepatic and extrahepatic ducts.

Treatment

It is important to appreciate the multidisciplinary approach to the management of UC. This involves the gastroenterologist, nurses, nutritionist, stomatherapist and social worker as well as the surgeon.

Medical treatment of an acute attack

Corticosteroids are the most useful drugs and can be given either locally for inflammation of the rectum or systemically when the disease is more extensive. One of the 5-aminosalicylic acid (5-ASA) derivatives can be given both topically and systemically. Their main function is in maintaining remission rather than treating an acute attack. Non-specific anti-diarrhoeal agents have no place in the routine management of UC (Summary box 65.5).

Summary box 65.5

Principles of management of UC

- Many patients can be adequately maintained for years on medical therapy
- Toxic dilatation must be suspected in any colitic patient who develops severe abdominal pain; missed colonic perforation is associated with a high mortality
- Colitic patients are at increased risk of developing cancer; those with pancolitis of long duration are most at risk

Mild attacks

Patients with a mild attack and limited disease will usually respond to rectally administered steroids. In those with more extensive disease, oral prednisolone 20–40 mg day⁻¹ is given over a 3- to 4-week period. One of the 5-ASA compounds should be given concurrently.

Moderate attacks

These patients should be treated with oral prednisolone 40 mg day⁻¹, twice-daily steroid enemas and 5-ASA. Failure to achieve remission as an out-patient is an indication for admission.

Severe attacks

These patients must be regarded as medical emergencies and require immediate admission to hospital. Their appearance is often misleading, and they must be examined at least twice a day. It is important to monitor vital signs (pulse, temperature and blood pressure). Weight needs to be recorded at admission and twice a week while in hospital. A stool chart should be kept. Increasing abdominal girth is a potential sign of megacolon developing. A plain abdominal radiograph is taken daily and inspected for dilatation of the transverse colon of more than 5.5 cm. The presence of mucosal islands or intramural gas on plain radiographs (see Fig. 65.18), increasing colonic diameter or a sudden increase in pulse and temperature may indicate a colonic perforation. Fluid and electrolyte balance is maintained, anaemia is corrected and adequate nutrition is provided, sometimes intravenously in severe cases. If the patient is not having immediate surgery, then oral nutrition is important. High calories are required. If severe malnourishment is present, then parenteral nutrition may be indicated. The patient is treated with intravenous hydrocortisone 100–200 mg four times daily. This can be supplemented with a rectal infusion of prednisolone. There is no evidence that antibiotics modify the course of a severe attack. Some patients are treated with azathioprine or ciclosporin A to induce remission. If there is failure to gain an improvement within 3–5 days, then surgery must be seriously considered. Prolonged high-dose intravenous steroid therapy is fraught with danger. Patients who have had weeks of treatment, during which the colonic wall has become friable and disintegrates at laparotomy, are now fortunately rare.

Indications for surgery

The risk of colectomy is 20% overall, ranging from 5% in those patients with proctitis to 50% in those patients with a very severe attack. The need for surgery is highest in the first year after the disease onset, for:

- severe or fulminating disease failing to respond to medical therapy;
- chronic disease with anaemia, frequent stools, urgency and tenesmus;
- steroid-dependent disease – here, the disease is not severe but remission cannot be maintained without substantial doses of steroids;
- the risk of neoplastic change: patients who have severe dysplasia on review colonoscopy;
- extraintestinal manifestations;
- rarely, severe haemorrhage or stenosis causing obstruction.

Operations

The patient is placed in a position to allow access to the rectum. In the emergency situation, the ‘first aid procedure’ is a total

abdominal colectomy and ileostomy. The rectal stump is left long but runs the risk of on-going haemorrhage. The rectum can either be brought out at the lower end of the wound as a mucous fistula or closed just beneath the skin. This has the advantage that the patient recovers quickly, the histology of the resected colon can be checked, and restorative surgery can be contemplated at a later date when the patient is no longer on steroids and in optimal nutritional condition. The alternative, division of the rectum below the sacral promontory, can result in breakdown and pelvic abscess, and makes subsequent identification of the stump more difficult. This is more likely to occur in patients in a poor condition or those on long-term steroids.

Proctocolectomy and ileostomy

This is the procedure associated with the lowest complication rate. It is indicated in patients who are not candidates for restoration. The patient is left with a permanent ileostomy. There is, however, a 20% long-term risk of adhesional obstruction (the reoperation rate is, however, very low) and 5–10% of the perineal wounds are slow to heal. The late result will be a chronic perineal sinus that may require repeated curettage or excision. The obvious disadvantage is an ileostomy and, although many patients cope remarkably well with satisfactory objective measures of quality of life, there is a psychological and social ‘cost’. Problems that may arise with a stoma include stricture formation, prolapse, retraction and herniation.

Rectal and anal dissection

Refinements of the procedure have included a close rectal dissection to minimise damage to the nervi erigenti and hence erectile dysfunction, which may occur in 0.5–2%, and intersphincteric excision of the anus, which results in a smaller perineal wound and fewer healing problems.

Restorative proctocolectomy with an ileoanal pouch (Parks)

In this operation, a pouch is made out of ileum (Fig. 65.22) as a substitute for the rectum and sewn or stapled to the anal canal. This avoids a permanent stoma. It is reserved for patients with adequate anal sphincters and should be avoided when CD is a possibility. It should not initially be considered for poorly patients. Various pouch designs have been described, but the ‘J’ is the most popular and the most easily made using staplers (Fig. 65.23). The ‘S’ (three loop) has been associated with evacuation difficulties due to the short efferent spout. The ‘W’ (four loop) pouch has a larger reservoir, which results in less bowel frequency. There is some controversy over the correct technique for ileoanal anastomosis. In the earliest operations, the mucosa from the dentate line up to midrectum was stripped off the underlying muscle, but it is now known that a long muscle cuff is not needed. A mucosectomy of the upper anal canal with an anastomosis at the dentate line is claimed to remove all of the at-risk mucosa and any problem of subsequent cancer. It may also result in imperfect continence with nocturnal seepage. The alternative is an anastomosis double-stapled to the top of the anal canal, preserving the upper anal canal mucosa. Continence appears to be better, but the theoretical risk of leaving inflamed mucosa remains. The procedure can be carried out in stages. In most cases, a covering loop

Sir Alan Guyatt Parks, 1920–1982, Surgeon, St Mark’s Hospital and the London Hospital, London, UK.

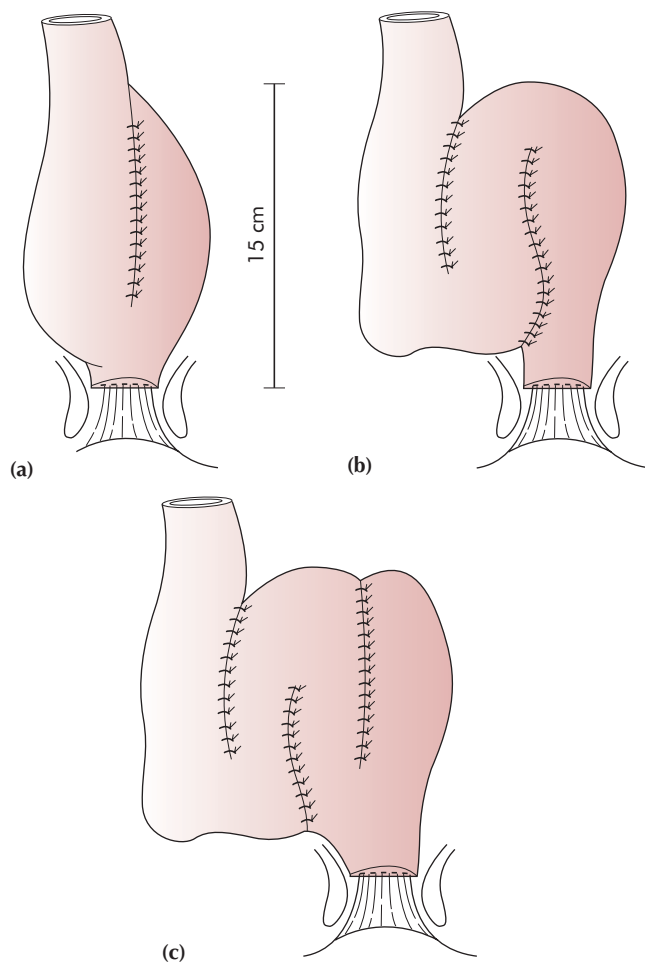

Figure 65.22 Ileoanal anastomosis with pouch. A substitute rectum is made from joined folds of ileum to form an expanded pouch of small intestine. The pouch is then joined directly to the anus at the level of the dentate line, all other rectal mucosa having been removed. Three ways of forming a pouch are illustrated: (a) a simple reversed 'J'; (b) an 'S' pouch; (c) a 'W' pouch.

ileostomy is used. Complications include pelvic sepsis – usually resulting from a leak at the ileoanal anastomosis – small bowel obstruction and pouch vaginal fistula. Frequency of evacuation is determined by pouch volume, completeness of emptying, reservoir inflammation and intrinsic small bowel motility, but can be between three and six evacuations daily. Increased frequency, urgency and faecal incontinence can be seen (20%, 5% and 5% respectively), but these reduce with time. Although associated with a higher complication rate, it is rapidly becoming the operation of choice in younger patients, avoiding a permanent ileostomy. The failure rate in the first year is 5–15%, the main reasons being pelvic sepsis (50%), poor function (30%) and pouchitis or inflammation of the pouch (10%). It is also important for women to realise that they may suffer from reduced fertility. So women yet to have children may elect for a colectomy with ileostomy or colectomy and ileorectal anastomosis if the rectum is spared in the first instance. There are much higher failure rates in CD when compared with UC (50% vs. 10%), and the operation is not to be recommended in this disease.

Figure 65.23 Stapled 'J' pouch with stapler creating a pouch–anus anastomosis.

Colectomy and ileorectal anastomosis

If there is minimal rectal inflammation, this can occasionally be used, although the surgeon should not be falsely reassured that the rectum has been relatively 'spared' in a patient using steroid enemas. If the rectum is preserved, then annual rectal inspection is advocated. Although it has the advantage of stoma avoidance and minimal risk to sexual function associated with rectal dissection, it has largely been superseded by restorative proctocolectomy. A number of series have shown low mortality and morbidity, but it has fallen out of favour due to the on-going risk of persisting inflammation and malignancy.

Ileostomy with a continent intra-abdominal pouch (Kock's procedure)

A reservoir is made from 30 cm of ileum and, just beyond this, a spout is made by inverting the efferent ileum into itself to give a continent valve just below skin level. The pouch is emptied by the patient inserting a catheter through the valve; this procedure is now rarely used. Complications include early leak with formation of fistulae, which can occur in 10–20%, and late subluxation of the valve, which can occur in 20%. Pouch survival at 10 years was 87% in one study.

Ileostomy

End-ileostomy (Brooke)

In those patients with a permanent ileostomy, there must be scrupulous attention to detail during the operation to ensure a good functional result. The position of the ileostomy should be

Nils Kock, Swedish Surgeon, pioneered the creation of artificial reservoirs within the abdomen from loops of small intestine in the 1970s.
Bryan Nicholas Brooke, 1915–1998, Professor of Surgery, St George's Hospital, London, UK.

carefully chosen by the patient with the help of a stoma care nurse specialist. There is an argument for making the trephine incision before entering the abdomen to prevent any problems of distortion of the abdominal wall after opening. The ileum is normally brought through the rectus abdominis muscle. Careful attention to the terminal ileal mesentery should be taken to ensure that it is supplied by the marginal artery in order to reduce mesenteric bulk. The use of a spout (Fig. 65.24) was originally described by Bryan Brooke; this should project some 4 cm from the skin surface. A disposable appliance is placed over the ileostomy so that it is a snug fit at skin level.

Loop ileostomy

This is often used to defunction a pouch ileoanal procedure. A knuckle of ileum is pulled out through a skin trephine in the right iliac fossa. An incision is made in the distal part of the knuckle, and this is then pulled over the top of the more proximal part to create a spout on the proximal side of the loop with a flush distal side still in continuity. This allows near-perfect defunction, but also the possibility of restoration of continuity by taking down the spout and reanastomosing the partially divided ileum.

Ileostomy care

During the first few postoperative days, fluid and electrolyte balance must be adjusted with great care. There may be an 'ileostomy flux' while the ileum adapts to the loss of the colon, and the fluid losses can amount to 4 or 5 litres day⁻¹. The stools thicken in a few weeks and are semisolid in a few months. The help, skill and advice of the stoma care nurse specialist are essential. Modern appliances have transformed stoma care, and skin problems are unusual (Fig. 65.25).

Complications of an ileostomy include prolapse, retraction, stenosis, bleeding, fistula and paraileostomy hernia.

CROHN'S DISEASE (REGIONAL ENTERITIS)

CD became widely recognised following the report in 1932 by Crohn, Ginzburg and Oppenheimer describing young adults with a chronic inflammatory disease of the ileum. It can affect any part of the gastrointestinal tract from the lips to the anal margin, but ileocolonic disease is the most common presentation.

Epidemiology

It is most common in North America and northern Europe with an incidence of 5 per 100 000. This has increased over the last 30 years but is now thought to be levelling off. Prevalence rates as high as 56 per 100 000 have been reported in the UK. Over the last four decades, there seems to have been a rise in the incidence,

Figure 65.24 Ileostomy formation. Suturing the free extremity of the proximal ileum to the skin edges after eversion to form a spout (after Brooke).

Figure 65.25 Disposable ileostomy bag (courtesy of B.N. Brooke, FRCS, London, UK).

which cannot be accounted for by increased diagnosis. It is slightly more common in women than in men, but is most commonly diagnosed in young patients between the ages of 25 and 40 years. There does, however, seem to be a second peak of incidence around the age of 70 years. Migration seems to increase the risk of developing CD as seen from the increased risk in migrant communities compared with their native countries.

Aetiology

Although CD has some features suggesting chronic infection, no causative organism has ever been found; similarities between CD and tuberculosis have focused attention on mycobacteria. Studies have found DNA of *Mycobacterium paratuberculosis* in the intestines of 60% of patients with CD as opposed to 10% of control subjects. However, no immunology reaction has been detected against this organism, and anti-tuberculosis treatment has no effect. Focal ischaemia has also been postulated as a causative factor, possibly originating from a vasculitis arising through an immunological process. A wide variety of foods has now been implicated, but none conclusively. Smoking increases the risk threefold, which is contrary to the protective effect seen in UC.

Genetic factors are thought to play a part. About 10% of patients have a first-degree relative with the disease, and concordance has been shown to approach 50% in monozygotic twins. Inheritance is thought to involve multiple genes with low

A first-degree relative, defined as the individual's parents, siblings or children.

penetrance. The *NOD2/CARD15* gene has excited some interest recently. Certain variants of this gene have been shown to have strong associations with CD.

There is an association with ankylosing spondylitis. As with UC, it is now believed that CD can predispose to cancer, although the incidence of malignant change is not nearly as high as in UC and is most manifest in the ileum.

Pathogenesis

As in UC, there is thought to be an increased permeability of the mucous membrane. This leads to increased passage of antigens, which are thought to induce a cell-mediated inflammatory response. This results in the release of cytokines, such as interleukin-2 and tumour necrosis factor, which coordinate local and systemic responses. In CD, there is thought to be a defect in suppressor T cells, which usually act to prevent escalation of the inflammatory process.

Pathology

Ileal disease is the most common, accounting for 60% of cases; 30% of cases are limited to the large intestine, and the remainder are in patients with ileal disease alone or more proximal small bowel involvement. Anal lesions are common. CD of the mouth, oesophagus, stomach and duodenum is uncommon. Resection specimens show a fibrotic thickening of the intestinal wall with a narrow lumen (Fig. 65.26). There is usually dilated gut just proximal to the stricture and, in the strictured area, there are deep mucosal ulcerations with linear or snake-like patterns. Oedema in the mucosa between the ulcers gives rise to a cobblestone appearance. The transmural inflammation leads to adhesions, inflammatory masses with mesenteric abscesses and fistulae into adjacent organs. The serosa is usually opaque, there is thickening in the mesentery, and mesenteric lymph nodes are enlarged. The condition is discontinuous, with inflamed areas separated from normal intestine, so called skip lesions. Under the microscope, there are focal areas of chronic inflammation involving all layers of the intestinal wall. There are non-caseating giant cell granulomas, but these are only found in 60% of patients. They are most common in anorectal disease. The earliest mucosal lesions are discrete aphthous ulcers. Recent studies have also shown multifocal arterial occlusions in the muscularis propria.

Figure 65.26 Crohn's disease of the ileocaecal region showing typical thickening of the wall of the terminal ileum with narrowing of the lumen (courtesy of Dr B. Warren, John Radcliffe Hospital, Oxford, UK).

Clinical features

Presentation depends upon the area of involvement.

Acute Crohn's disease

Acute CD occurs in only 5% of cases. Symptoms and signs resemble those of acute appendicitis, but there is usually diarrhoea preceding the attack. Rarely, there could be a free perforation of the small intestine, resulting in a local or diffuse peritonitis. Acute colitis with or without toxic megacolon can occur in CD but is less common than in UC.

Chronic Crohn's disease

There is often a history of mild diarrhoea extending over many months, occurring in bouts accompanied by intestinal colic. Patients may complain of pain, particularly in the right iliac fossa, and a tender mass may be palpable. Intermittent fevers, secondary anaemia and weight loss are common. A perianal abscess or fissure may be the first presenting feature of CD; the cause is often an infected anal crypt associated with concomitant diarrhoea but, as the disease becomes chronic, specific fistulae resulting from the CD itself can develop.

After months of repeated attacks with acute inflammation, the affected area of intestine begins to narrow with fibrosis, causing obstructive symptoms. Children developing the illness before puberty may have retarded growth and sexual development.

With progression of the disease, adhesions and transmural fissuring, intra-abdominal abscesses and fistula tracts can develop.

- 1 *Enterointeric fistulae* can occur into adjacent small bowel loops or the pelvic colon, and *enterovesical fistulae* may cause repeated urinary tract infections and pneumaturia.
- 2 *Enterocutaneous fistulae* rarely occur spontaneously and usually follow previous surgery.

Anal disease

In the presence of active disease, the perianal skin appears bluish. Superficial ulcers with undermined edges are relatively painless and can heal with bridging of epithelium. Deep cavitating ulcers are usually found in the upper anal canal; they can be painful and cause perianal abscesses and fistulae, discharging around the anus and sometimes forwards into the genitalia. The most distressing feature of anal disease is sepsis from secondary abscesses and perianal fistulae. Remarkably, the rectal mucosa is often spared and may feel normal on rectal examination. If it is involved, however, it will feel thickened, nodular and irregular.

Investigation

Laboratory

A full blood count needs to be performed to exclude anaemia. There is usually a fall in albumin, magnesium, zinc and selenium, especially in active disease. Protein levels that correspond to disease activity include C-reactive protein and orosomucoid.

Endoscopy

Sigmoidoscopic examination may be normal or show minimal involvement. However, ulceration in the anal canal will be readily seen.

As a result of the discontinuous nature of CD, there will be areas of normal colon or rectum. In between these, there are areas of inflamed mucosa that are irregular and ulcerated, with a mucopurulent exudate. The earliest appearances are aphthoid-like ulcers surrounded by a rim of erythematous mucosa. These become larger and deeper with increasing severity of disease. In colonic CD, there may be stricturing, and it is important to exclude malignancy in these sites (Fig. 65.27). At the ileocolic anastomosis of a patient having had previous ileocaecal resection, recurrent disease is usually seen on the ileal side of the anastomosis.

Upper gastrointestinal symptoms may have to be investigated by way of upper gastrointestinal endoscopy, which may reveal deep longitudinal ulcers and cobblestone mucosa. Capsule endoscopy may also have a useful role in those with chronic gastrointestinal bleeding.

Imaging

Barium enema will show similar features to those of colonoscopy in the colon. The best investigation of the small intestine is small bowel enema (Fig. 65.28). This will show up areas of delay and dilatation. The involved areas tend to be narrowed, irregular and, sometimes, when a length of terminal ileum is involved, there may be the string sign of Kantor. Sinograms are useful in patients with enterocutaneous fistulae. CT scans are used in patients with fistulae and those with intra-abdominal abscesses and complex involvement (Fig. 65.29).

Magnetic resonance imaging (MRI) has been shown to be useful in assessing perianal disease.

Phenotyping

The Vienna classification was introduced by the World Congress of Gastroenterology in 1998. This was born out of the observation that, following presentation, the location and behaviour of the CD varied. This has relevance in studies carrying out genetic analysis of CD as there are different sub-categories with varied disease progression. Points that are recorded

at presentation include age of onset, disease site in the gut, behaviour and data such as sex, ethnic origin, family history of inflammatory bowel disease and extraintestinal manifestations.

Figure 65.27 Colonic Crohn's disease. Note the normal mucosa on either side of the inflammatory stricture (courtesy of Dr B. Warren, John Radcliffe Hospital, Oxford, UK).

Treatment

Medical therapy

Steroids

Steroids are the mainstay of treatment. These are effective in inducing remission in moderate to severe disease in 70–80% of cases. Steroids can also be used as topical agents in the rectum with reduced systemic bioavailability, but long-term use causes adrenal suppression. They are better at inducing remission than mesalamine but has no role in maintenance. Patients suffering a relapse are treated with up to 40 mg of prednisolone orally daily, supplemented by 5-ASA compounds in those patients with colonic involvement, although there is some evidence that this may help small bowel disease as well. Meta-analysis has shown that aminosalicylates can be used after remission to reduce the absolute risk of recurrence.

Antibiotics

Those who have symptoms and signs of a mass or an abscess are also treated with antibiotics. Metronidazole is used, especially in perianal disease. Its mechanism is unknown and is thought to play a role in suppressing cell-mediated immunity. In a randomised controlled trial, it reduced disease activity in ileocolonic and colonic disease, but not small bowel disease.

Immunomodulatory agents

Azathioprine is used for its additive and steroid-sparing effect and is now standard maintenance therapy. It is a purine analogue, which is metabolised to 6-mercaptopurine and works by inhibiting cell-mediated events. It may take up to 12 weeks to have an effect. Cyclosporin acts by inhibiting cell-mediated immunity. Short-course intravenous treatment is associated with 80% remission; however, there is relapse after completion of treatment.

Monoclonal antibody

Infliximab, the murine chimeric monoclonal antibody directed towards tumour necrosis factor alpha, targets patients with severe, active disease who are refractory to 'conventional' treatments and who are at high risk of surgical interventions. A placebo-controlled trial reported the effects of single-dose infliximab on induction of remission in CD. Response after 1 month was 65% in the CD group. This compared with 17% in the placebo group. After 3 months the effects were 41% and 12% respectively. With maintenance regimes, this benefit was still apparent after a year. Infliximab is also effective in the treatment of fistulae (treatment group had a 60% reduction in fistulae compared with 26% in the placebo group). This benefit is reduced after a year. Long-term safety issues have yet to be resolved. There is a potential risk of malignancy.

Nutritional support

Nutritional support is essential. Severely malnourished people may require intravenous feeding or nasoenteric feeding regimens. Anaemia, hypoproteinaemia and electrolyte, vitamin and metabolic bone problems must all be addressed. It has been shown that parenteral nutrition can induce remission in up to 80% of patients, which is comparable to steroids, but there is no synergism or additive effect. However, relapse is high after a short duration (Summary box 65.6).

Summary box 65.6

Principles of management of CD

- Close liaison between physician and surgeon is crucial
- Medical therapy should always be considered as an alternative to surgery, although surgery should not be delayed when a clear indication for surgery exists
- Patients must be optimised as far as possible prior to surgery, and this may require preoperative total parenteral nutrition
- CD is a chronic relapsing disease with a high likelihood of reoperation; the surgeon must take every reasonable effort to preserve bowel length and sphincter function

Indications for surgery

Surgical resection will not cure CD. Surgery is therefore focused on the complications of the disease. As many of these indications for surgery may be relative, joint management by an aggressive physician and a conservative surgeon is thought to be ideal. These complications include:

- recurrent intestinal obstruction;
- bleeding;
- perforation;
- failure of medical therapy;
- intestinal fistula;
- fulminant colitis;
- malignant change;
- perianal disease.

Surgery

In patients with active CD, prompt surgery is important when medical treatment fails. The main surgical principle is to preserve functional gut length and maintain gut function. Resection is kept to a minimum so as to deal with the local problem. The whole of the gastrointestinal tract has to be examined carefully at the time of laparotomy. If, on occasion, CD is diagnosed during the course of an operation for suspected appendicitis, the appendix should be removed. If the ileum is thick, rigid and pipe-like, senior help should be sought so that an ileocaecal resection can be carried out.

The course of the disease after surgery is unpredictable, but recurrence is common. It does not seem to be related to the presence of disease at the resection line. Recurrence rates vary from site to site, but the cumulative probability of recurrence requiring surgery for ileal disease is of the order of 20%, 40%, 60% and 80% at 5, 10, 15 and 20 years, respectively, after previous resection. Restorative operations have a higher incidence of recurrence than, for example, proctocolectomy and ileostomy. Preoperative factors that are imperative include adequate bowel preparation, deep venous thrombosis prophylaxis, steroid cover, nutritional support and consideration of stoma in those who are malnourished.

- 1 *Ileocaecal resection* is the usual procedure for ileocaecal disease with a primary anastomosis between the ileum and the ascending or transverse colon depending on the extent of the disease.
- 2 *Segmental resection*. Short segments of small or large bowel involvement can be treated by segmental resection. The usual indication is stricture.

- 3 *Colectomy and ileorectal anastomosis.* In patients with widespread colonic disease with rectal sparing and a normal anus, this can be a useful option.
- 4 *Emergency colectomy.* This accounts for 8% of operations for acute colonic disease. The indications are similar to those for UC. If medical treatment induces remission, then delayed surgery is sensible because of the high risk of recurrent active disease.
- 5 *Laparoscopic surgery.* Resections and diversion are safe in uncomplicated CD. This is coupled with extracorporeal anastomosis and results in small peri-umbilical incisions. The advantages include better cosmesis and early discharge.
- 6 *Temporary loop ileostomy.* This can be used either in patients with acute distal CD, allowing remission and later restoration of continuity, or in patients with severe perianal or rectal disease.
- 7 *Proctocolectomy.* Patients with colonic and anal disease failing to respond to medical treatment or defunction will eventually require a permanent ileostomy.
- 8 *Strictureplasty.* Multiple strictured areas of CD (Fig. 65.30) can be treated by a local widening procedure, strictureplasty, to avoid excessive small bowel resection (Fig. 65.31) (Lee).
- 9 *Anal disease* is usually treated conservatively by simple drainage of abscesses, placing setons around any fistulae and, occasionally in patients with inactive disease, primary repair of a rectovaginal or high fistula-in-ano could be attempted.

The differences between UC and CD are given in Summary box 65.7.

Summary box 65.7

Differences between UC and CD

- UC affects the colon; CD can affect any part of the gastrointestinal tract, but particularly the small and large bowel
- UC is a mucosal disease whereas CD affects the full thickness of the bowel wall
- UC produces confluent disease in the colon and rectum whereas CD is characterised by skip lesions
- CD more commonly causes stricturing and fistulation
- Granulomas may be found on histology in CD but not in UC
- CD is often associated with perianal disease whereas this is unusual in UC
- CD affecting the terminal ileum may produce symptoms mimicking appendicitis, but this does not occur in UC
- Resection of the colon and rectum cures the patient with UC, whereas recurrence is common after resection in CD

INFECTIONS

Intestinal amoebiasis

Amoebiasis is an infestation with *Entamoeba histolytica*. This parasite has a worldwide distribution and is transmitted mainly in contaminated drinking water.

Emanuel Cecil Gruebel Lee, 1933–1986, Surgeon, the Radcliffe Infirmary, Oxford, UK.

Figure 65.30 Small bowel strictures in Crohn's disease with dilatation between strictures.

Figure 65.31 Strictureplasty. (1) A strictured length of intestine is incised along its length. (2) The bowel is opened and the walls are retracted as shown. (3) The bowel is resutured transversely to widen the narrowed segment.

Pathology

The ulcers, which have been described as 'bottlenecked' because of their considerably undermined edges, have a yellow necrotic floor, from which blood and pus exude. In 75%, they are confined to the lower sigmoid and upper rectum.

Biopsy

Endoscopic biopsies or fresh hot stools are examined carefully to look for the presence of amoebae. It is important to emphasise, however, that the presence of the parasite does not indicate that it is pathogenic (Fig. 65.32).

Clinical features

Dysentery is the principal manifestation of the disease, but it may come in various other guises.

Appendicitis or amoebic caecal mass

In tropical countries where amoebiasis is endemic, this is a constantly recurring problem. To operate on a patient with amoebic dysentery without precautions may prove fatal. The bowel is friable, and satisfactory closure of the appendix stump becomes difficult or impossible, especially in cases where a palpable mass is present. When there is an amoebic mass, there

Figure 65.32 An amoeba in a rectal biopsy.

tends to be tenderness on deep palpation over the caecum and the sigmoid.

Perforation

The most common sites are the caecum and rectosigmoid; usually, perforation occurs into a confined space where adhesions have formed previously, and a pericolic abscess results, which eventually needs draining. When there is sudden faecal flooding into the general peritoneal cavity, drainage of the region of the perforation, gastrointestinal aspiration, intravenous fluid, antibiotics and a full course of emetine are sometimes successful.

Severe rectal haemorrhage as a result of separation of the slough is liable to occur.

Granuloma

Progressive amoebic invasion of the wall of the rectum or colon, with secondary inflammation, can produce a granulomatous mass indistinguishable from a carcinoma.

Ulcerative colitis

A search for amoebae should always be made in the stools of patients believed to have UC.

Other

Other presentations include the following:

- Fibrous stricture may follow the healing of extensive amoebic ulcers.
- Intestinal obstruction is a common complication of amoebiasis, and the obstruction is the result of adhesions associated with pericolic abscess and large granuloma.
- Paracolic abscess, ischio-rectal abscess and fistula occur from perforation by amoebae of the intestinal wall followed by secondary infection.

Treatment

High-dose intravenous steroids in this situation can be catastrophic. Metronidazole (Flagyl) is the first-line drug, 800 mg three times daily for 7–10 days. Diloxanide furoate is best for chronic infections associated with the passage of cysts in stools. Intestinal antibiotics improve the results of the chronic stages, probably by coping with superadded infection.

Typhoid and paratyphoid

Typhoid

Paralytic ileus is the most common complication of typhoid. Intestinal haemorrhage may be the leading symptom. Other surgical complications of typhoid and paratyphoid include:

- haemorrhage;
- perforation;
- cholecystitis;
- phlebitis;
- genitourinary inflammation;
- arthritis;
- osteomyelitis.

Typhoid ulcer

Perforation of a typhoid ulcer usually occurs during the third week and is occasionally the first sign of the disease. The ulcer is parallel to the long axis of the gut and is usually situated in the lower ileum.

Paratyphoid B

Perforation of the large intestine sometimes occurs in paratyphoid B infection; vigorous intravenous antibiotic therapy is given. Occasionally, surgery may be required to defunction the colon. In cases where severely diseased bowel is present, a colectomy may be necessary, as for UC.

Tuberculosis of the intestine

Tuberculosis can affect any part of the gastrointestinal tract from the mouth to the anus. The sites affected most often are the ileum, proximal colon and peritoneum. There are two principal types.

Ulcerative tuberculosis

Ulcerative tuberculosis is secondary to pulmonary tuberculosis and arises as a result of swallowing tubercle bacilli. There are multiple ulcers in the terminal ileum, lying transversely, and the overlying serosa is thickened, reddened and covered in tubercles.

Clinical features

Diarrhoea and weight loss are the predominant symptoms, and the patient will usually be receiving treatment for pulmonary tuberculosis.

Radiology

A barium meal and follow-through or small bowel enema will show the absence of filling of the lower ileum, caecum and most of the ascending colon as a result of narrowing and hypermotility of the ulcerated segment (Fig. 65.33).

Treatment

A course of chemotherapy is given. Healing often occurs provided the pulmonary tuberculosis is adequately treated. An operation is only required in the rare event of a perforation or intestinal obstruction.

Hyperplastic tuberculosis

This usually occurs in the ileocaecal region, although solitary and multiple lesions in the lower ileum are sometimes seen. This is caused by the ingestion of *Mycobacterium tuberculosis* by patients

Figure 65.33 Ileocaecal tuberculosis; absent ascending colon and caecum with dilatation of terminal ileum (courtesy of Dr V.K. Kapoor, Delhi, India).

with a high resistance to the organism. The infection establishes itself in lymphoid follicles, and the resulting chronic inflammation causes thickening of the intestinal wall and narrowing of the lumen. There is early involvement of the regional lymph nodes, which may caseate. Unlike CD, with which it shares many similarities, abscess and fistula formation is rare.

Clinical features

Attacks of abdominal pain with intermittent diarrhoea are the usual symptoms. The ileum above the partial obstruction is distended, and the stasis and consequent infection lead to steatorrhoea, anaemia and loss of weight. Sometimes, the presenting picture is of a mass in the right iliac fossa in a patient with vague ill health. The differential diagnosis is that of an appendix mass, carcinoma of the caecum, CD, tuberculosis or actinomycosis of the caecum.

Radiology

A barium follow-through or small bowel enema will show a long narrow filling defect in the terminal ileum.

Treatment

When the diagnosis is certain and the patient has not yet developed obstructive symptoms, treatment with chemotherapy is advised and may cure the condition. Where obstruction is present, operative treatment is required and ileocaecal resection is best.

Actinomycosis of the ileocaecal region

Abdominal actinomycosis is rare. Unlike intestinal tuberculosis, narrowing of the lumen of the intestine does not occur and mesenteric nodes do not become involved. However, a local abscess spreads to the retroperitoneal tissues and the adjacent abdominal wall, becoming the seat of multiple indurated discharging sinuses. The liver may become involved via the portal vein.

Clinical features

The usual history is that appendicectomy has been carried out for an appendicitis. Some 3 weeks after surgery, a mass is palpable in the right iliac fossa and, soon afterwards, the wound begins to discharge. At first, the discharge is thin and watery, but later it becomes thicker and malodorous. Other sinuses may form and a secondary faecal fistula may develop. Pus should be sent for bacteriological examination, which will reveal the characteristic sulphur granules.

Treatment

Penicillin or cotrimoxazole treatment should be prolonged and in high dosage.

TUMOURS OF THE SMALL INTESTINE

Compared with the large intestine, the small intestine is rarely the seat of a neoplasm, and these become progressively less common from the duodenum to the terminal ileum.

Benign

Adenomas, submucous lipomas and gastrointestinal stromal tumours (GISTs) occur from time to time, and sometimes reveal themselves by causing an intussusception. The second most common complication is intestinal bleeding from an adenoma, in which event the diagnosis is frequently long delayed because the tumour is overlooked at barium radiology, endoscopy and even surgery.

Peutz–Jeghers syndrome

This is an autosomal dominant disease. The gene *STK11* on chromosome 19 has been found in a proportion of patients with this condition. This consists of:

- intestinal hamartomatosis is a polyposis affecting the whole of the small bowel and colon, where it is a cause of haemorrhage and often intussusception;
- melanosis of the oral mucous membrane and the lips.

The melanosis takes the form of melanin spots sometimes present on the digits and the perianal skin, but pigmentation of the lips is the *sine qua non* (Fig. 65.34).

Long-term follow-up of patients with Peutz–Jeghers syndrome has shown reduced survival secondary to complications of recurrent bowel cancer and the development of a wide range of cancers. These include colorectal, gastric, breast, cervical, ovarian,

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St John's Hospital, The Hague, The Netherlands.
Sine qua non, an indispensable condition, Latin for 'without which not'.

Figure 65.34 Melanin spots on the lips of a patient afflicted with Peutz–Jeghers syndrome (courtesy of Major P.C.M. Manta, Indian Medical Service).

pancreatic and testicular cancer. It is therefore important to keep these patients under surveillance. This can be done by endoscopy or contrast examinations every 3 years to detect early gastrointestinal cancers. It is also important to make sure that female patients attend cervical and breast screening programmes.

Histology

The polyps can be likened to trees. The trunk and branches are smooth muscle fibres and the foliage is virtually normal mucosa.

Treatment

As malignant change rarely occurs, resection is only necessary for serious bleeding or intussusception. Large single polyps can be removed by enterotomy, or short lengths of heavily involved intestine can be resected. The incidence of further lesions developing problems in the future can be reduced by thorough intraoperative examination at the time of the first laparotomy. Using on-table enteroscopy, polyps suitable for removal can be identified. Those lesions within reach can be snared by colonoscopy.

Malignant

Lymphoma

There are three main types, as follows:

- 1 *Western-type lymphoma*. These are annular ulcerating lesions, which are sometimes multiple. They are now thought to be non-Hodgkin's B-cell lymphoma in origin. They may present

with obstruction and bleeding, perforation, anorexia and weight loss.

- 2 *Primary lymphoma associated with coeliac disease*. There is an increased incidence of lymphoma in patients with coeliac disease; this is now regarded as a T-cell lymphoma. Worsening of the patient's diarrhoea, with pyrexia of unknown origin together with local obstructive symptoms, are the usual features.
- 3 *Mediterranean lymphoma*. This is found mostly in North Africa and the Middle East and is associated with α -chain disease.

Unless there are particular surgical complications these conditions are usually treated with chemotherapy.

Carcinoma

Like small bowel tumours, these can present with obstruction, bleeding or diarrhoea. Complete resection offers the only hope of cure (Fig. 65.35).

Carcinoid tumour

These tumours occur throughout the gastrointestinal tract, most commonly in the appendix, ileum and rectum in decreasing order of frequency. They arise from neuroendocrine cells at the base of intestinal crypts. The primary is usually small but, when they metastasise, the liver is usually involved, with numerous secondaries, which are larger and more yellow than the primary; when this has occurred, the carcinoid syndrome will become evident. The tumours can produce a number of vasoactive peptides, most commonly 5-hydroxytryptamine (serotonin), which may be present as 5-hydroxyindoleacetic acid (5-HIAA) in the urine during attacks.

The clinical syndrome itself consists of reddish-blue cyanosis, flushing attacks, diarrhoea, borborygmi, asthmatic attacks and, eventually, sometimes pulmonary and tricuspid stenosis. Classically, the flushing attacks are induced by alcohol.

Treatment

Most patients with gastrointestinal carcinoids do not have carcinoid syndrome. Surgical resection is usually sufficient. In the cases found incidentally at appendectomy, nothing further is required. In patients with metastatic disease, multiple enucleations of hepatic metastases or even partial hepatectomy can be carried out. The treatment has been transformed by the use of octreotide (a somatostatin analogue), which reduces both

Figure 65.35 Small bowel adenocarcinoma.

Thomas Hodgkin, 1798–1866, Lecturer in Morbid Anatomy and Curator of the Museum, Guy's Hospital, London, described lymphadenoma in 1832.

flushing and diarrhoea, and octreotide cover is usually used in patients with a carcinoid syndrome who have surgery to prevent a carcinoid crisis. Carcinoid tumours generally grow more slowly than most metastatic malignancies; the patients may live with the syndrome of metastatic disease for many years.

Gastrointestinal stromal tumours

These tumours can be either benign or malignant. Increased size is associated with malignant potential. GIST is a type of sarcoma that develops from connective tissue cells. It is found most commonly in the stomach but can be found in other sites of the gut. It occurs most commonly in the 50- to 70-year age group. Although its cause is unknown, patients with neurofibromatosis have an increased risk of developing these types of tumour.

Symptoms

Patients may be asymptomatic. Other symptoms include lethargy, pain, nausea, haematemesis or melaena.

Treatment

Surgery is the most effective way of removing GISTs as they are radioresistant. Glivec (imatinib) is a tyrosine kinase inhibitor that has been shown to be effective in advanced cases.

TUMOURS OF THE LARGE INTESTINE

Benign

The term 'polyp' is a clinical description of any elevated tumour. It covers a variety of histologically different tumours shown in Table 65.3.

Polyps can occur singly, synchronously in small numbers or as part of a polyposis syndrome. In familial adenomatous polyposis (FAP), more than 100 adenomas are present. It is important to be sure of the histological diagnosis because adenomas have significant malignant potential.

Adenomatous polyps

Adenomatous polyps vary from a tubular adenoma (Fig. 65.36), rather like a raspberry on a stalk, to the villous adenoma, a flat spreading lesion. Solitary adenomas are usually found during the investigation of colonic bleeding or sometimes fortuitously. Villous tumours more usually give symptoms of diarrhoea, mucus discharge and occasionally hypokalaemia. The risk of malignancy developing in an adenoma increases with increasing size of

Figure 65.36 Pedunculated adenomatous polyp of the large intestine, longitudinal section (courtesy of Dr P. Millard, John Radcliffe Hospital, Oxford, UK).

tumour; for example, in 1-cm-diameter tubular adenomas there is a 10% risk of cancer, whereas with villous adenomas over 2 cm in diameter, there may be a 15% chance of carcinoma. Adenomas larger than 5 mm in diameter are usually treated because of their malignant potential. Colonoscopic snare polypectomy or diathermy obliteration with hot biopsy forceps can be used. Huge villous adenomas of the rectum can be difficult to remove even with techniques per anus, and occasionally proctectomy is required; the anal sphincter can usually be preserved.

Familial adenomatous polyposis

FAP is clinically defined by the presence of more than 100 colorectal adenomas. Over 80% of cases come from patients with a positive family history. However, 20% arise as a result of new mutations in the adenomatous polyposis coli gene (APC). This has been identified on the short arm of chromosome 5 (Bodmer). It is less common than hereditary non-polyposis colorectal cancer (HNPCC) and accounts for less than 1% of colorectal cancer. Although the large bowel is mainly affected, polyps can occur in the stomach, duodenum and small intestine. The main risk is large bowel cancer, but duodenal and ampullary tumours have been reported. It is inherited as a Mendelian dominant condition. The risk of colorectal cancer is 100% in patients with FAP. Males and females are equally affected. It can also occur sporadically without any previous sign or history, presumably by new mutations. There is often, in these cases, a history of large bowel cancer occurring in young adulthood or middle age, suggesting pre-existing adenomatosis.

FAP can be associated with benign mesodermal tumours such as desmoid tumours and osteomas. Epidermoid cysts can also occur (Gardner's syndrome); desmoid tumours in the abdomen invade locally to involve the intestinal mesentery and, although non-metastasising, they can become unresectable (Summary box 65.8).

Table 65.3 Classification of polyps of the large intestine

Class	Varieties
Inflammatory	Inflammatory polyps
Metaplastic	Metaplastic or hyperplastic polyps
Harmartomatous	Peutz-Jeghers polyp Juvenile polyp
Neoplastic	Adenoma – Tubular – Tubulovillous – Villous Adenocarcinoma Carcinoid tumour

Sir Walter Fred Bodmer, Geneticist, University of Oxford, Director of Research, Imperial Cancer Research Fund, London, UK.
Eldon John Gardner, 1909–1989, Geneticist, the University of Utah, Salt Lake City, UT, USA, described this syndrome in 1950.

Summary box 65.8

FAP

- Autosomal dominant inherited disease due to mutation of the APC gene
- More than 100 colonic adenomas are diagnostic
- Surgery is the only means of preventing colonic cancer
- Polyps and malignant tumours can develop in the duodenum and small bowel

Clinical features

Polyps are usually visible on sigmoidoscopy by the age of 15 years and will almost always be visible by the age of 30 years. Carcinoma of the large bowel occurs 10–20 years after the onset of the polyposis. One or more cancers will already be present in two-thirds of those patients presenting with symptoms.

Symptomatic patients

These are either patients in whom a new mutation has occurred or those from an affected family who have not been screened. They may have loose stools, lower abdominal pain, weight loss, diarrhoea and the passage of blood and mucus. Polyps are seen on sigmoidoscopy, and the number and distribution of polyps, and usually cancers if they are symptomatic, are shown on a double-contrast barium enema. If in doubt, colonoscopy is performed with biopsies to establish the number and histological type of polyps. If over 100 adenomas (Fig. 65.37) are present, the diagnosis can be made confidently, but it is important not to confuse this with non-neoplastic forms of polyposis.

Asymptomatic patients

Direct genetic testing will reveal mutations in 80% of cases. In the presence of an identified mutation in a family with FAP, any resulting negative tests for this can be interpreted to mean that these individuals do not carry the mutation. They can therefore be withdrawn from surveillance programmes and warned that they are at normal population 'risk' of developing colorectal cancer. In those families where a mutation cannot be identified, then surveillance is recommended annually.

The site of the mutation within the gene has important effects on the phenotype. Truncations of the carboxy end of the APC

Figure 65.37 Familial adenomatous polyposis.

protein have a smaller effect on tumour suppressor function. This results in the attenuated FAP variant.

If there are no adenomas by the age of 30 years, FAP is unlikely. If the diagnosis is made during adolescence, operation is usually deferred to the age of 17 or 18 years or when symptoms or multiple polyps develop.

Screening policy

- 1 At-risk family members are offered genetic testing in their early teens.
- 2 At-risk members of the family should be examined at the age of 10–12 years, repeated every year.
- 3 Most of those who are going to get polyps will have them at 20 years, and these require operation.
- 4 If there are no polyps at 20 years, continue with 5-yearly examination until age 50 years; if there are still no polyps, there is probably no inherited gene. Carcinomatous change may exceptionally occur before the age of 20 years. Examination of blood relatives, including cousins, nephews and nieces, is essential, and a family tree should be constructed and a register of affected families maintained.

Treatment

Colectomy with ileorectal anastomosis has in the past been the usual operation because it avoids an ileostomy in a young patient and the risks of pelvic dissection to nerve function. The rectum is subsequently cleared of polyps by snaring or fulguration. The patients are examined by flexible sigmoidoscopy at 6-monthly intervals thereafter. In spite of this, a proportion of patients develop carcinoma in the rectal stump. The risk of carcinoma in the St Mark's series was 10% over a period of 30 years.

The alternative is a restorative proctocolectomy with an ileoanal anastomosis. This has a higher complication rate than ileorectal anastomosis. It is indicated in patients with serious rectal involvement with polyps, those who are likely to be poor at attending for follow-up and those with an established cancer of the rectum or sigmoid. However, it is now used more frequently for less severe cases. There have been reports of cancers developing after stapled anastomosis when a small remnant of rectal mucosa is left behind.

Postoperative surveillance

Because of the risk of further tumour formation, follow-up is important and takes the form of rectal/pouch surveillance. Gastroscopies are carried out to detect upper gastrointestinal tumours.

Hereditary non-polyposis colorectal cancer (Lynch's syndrome)

This syndrome is characterised by increased risk of colorectal cancer and also cancers of the endometrium, ovary, stomach and small intestines. It is an autosomal dominant condition that is caused by a mutation in one of the DNA mismatch repair genes – *MLH1*, *MSH2*, *MSH6*, *PMS1* and *PMS2*. Most people with this syndrome have mutations in the *MLH1* and *MSH2* genes.

The lifetime risk of developing colorectal cancer is 80%, and the mean age of diagnosis is 44 years. Most cancers develop in the

St. Mark's Hospital, Harrow, UK, was founded in 1835 and is recognised as a national and international referral centre for intestinal and colorectal disorders.

proximal colon. Females with HNPCC have a 30–50% lifetime risk of developing endometrial cancer. The average age of diagnosis is 46 years in this group.

Diagnosis

HNPCC can be diagnosed by genetic testing or Amsterdam criteria II:

- three or more family members with a HNPCC-related cancer, one of whom is a first-degree relative of the other two;
- two successive affected generations;
- one or more of the HNPCC-related cancers diagnosed before the age of 50 years;
- exclusion of FAP.

Malignant

Epidemiology

Colonic cancer can be diagnosed at operation as involving the large bowel proximal to where the two anti-mesenteric taenia converge (this represents the beginning of the rectum). In the UK, colorectal cancer accounted for 16 000 deaths in 2003 according to Cancer Research UK statistics. It represents a large part of the general surgeon’s elective and emergency workload. About 22 000 patients are diagnosed with colonic cancer every year. Over the last four decades, the 5-year survival rate has improved from 30% to about 45%.

Genetics

There has been an explosion of information on the molecular genetics of sporadic colorectal cancer. *APC* mutations occur in two-thirds of colonic adenomas and carcinomas and are thought to present early in the carcinogenesis pathway. *K-RAS* mutations result in activation of cell signalling pathways. They are more common in larger lesions, thus implying that they are later events in the mutagenesis pathway. Other genes involved include *p53*.

However, it must be noted that the pathway is not one of a simple stepwise progression of mutations but a complicated array of multiple gene changes, which result in an outcome of cancer. No single mutation is a common theme for all colorectal cancer cases. However, knowledge of certain mutations can be used to assess prognosis and direct adjuvant therapy.

Aetiology

Other factors that have been implicated in the development of cancer have included dietary fibre. The hypothesis is that increased roughage is associated with reduced transit times, and this in turn reduces the exposure of the mucosa to carcinogens. This has been supported by population questionnaire studies. There have also been studies linking increased dietary animal fat, smoking and alcohol to colorectal cancer. There is some evidence that links cholecystectomy, and therefore increased bile acid secretion, to an increased risk of colorectal cancer.

The role of irritable bowel disease (IBD) in colorectal cancer is discussed elsewhere in this chapter.

Adenocarcinoma of the colon

Pathology

Microscopically, the neoplasm is a columnar cell carcinoma originating in the colonic epithelium. Macroscopically, the tumour may take one of four forms (Fig. 65.38). Type 4 is the least malignant form. It is likely that all carcinomas start as a benign

Figure 65.38 The four common macroscopic varieties of carcinoma of the colon. (1) Annular; (2) tubular; (3) ulcer; (4) cauliflower.

adenoma, the so called ‘adenoma–carcinoma sequence’. This is supported by the observation that the prevalence of adenomas correlates with carcinoma. The distribution of adenoma in the colon also mirrors that of carcinoma. The annular variety tends to give rise to obstructive symptoms, whereas the others will present more commonly with bleeding. The sites and distribution of cases of cancer are shown in Figure 65.39. Tumours are more common in the left colon and rectum.

The spread of carcinoma of the colon

Generally this is a comparatively slow-growing neoplasm.

Local spread

The tumour can spread in a longitudinal, transverse or radial direction; it spreads round the intestinal wall and usually causes intestinal obstruction before it invades adjacent structures. The

Figure 65.39 Distribution of colorectal cancer by site.

ulcerative type more commonly invades locally, and an internal fistula may result, for example into the bladder. There may also be a local perforation with an abscess or even an external faecal fistula. This type of radial spread to adjacent organs has the largest impact on prognosis. The progression of invasion occurs across the submucosa into the muscularis propria and thence out into the serosa and fat, lymphatics and veins in the mesentery alongside the bowel wall.

Lymphatic spread

Lymph nodes draining the colon are grouped as follows:

- N1: nodes in the immediate vicinity of the bowel wall;
- N2: nodes arranged along the ileocolic, right colic, midcolic, left colic and sigmoid arteries;
- N3: the apical nodes around the superior and inferior mesenteric vessels where they arise from the abdominal aorta. Involvement of the lymph nodes by the tumour progresses in a gradual manner from those closest to the growth along the course of the lymphatic vessels to those placed centrally.

Bloodstream spread

This accounts for a large proportion (30–40%) of late deaths. Metastases are carried to the liver via the portal system, sometimes at an early stage before clinical or operative evidence is detected (occult hepatic metastases).

Transcoelomic spread

Rarely, colorectal cancer can spread by way of cells dislodging from the serosa of the bowel or via the subperitoneal lymphatics to other structures within the peritoneal cavity.

Staging colon cancer

There are several staging systems that are used such as Dukes, tumour–node–metastasis (TNM) and Jass. All of them can be used in order to predict prognosis and standardise treatment. Dukes' classification was originally described for rectal tumours (see Chapter 68) but has been adopted for histopathological reporting of colon cancer as well. There have been numerous modifications of the original system, leading to some confusion but, in its most basic form, Dukes' classification for colon cancer is as follows:

- A: confined to the bowel wall;
- B: through the bowel wall but not involving the free peritoneal serosal surface;
- C: lymph nodes involved.

Dukes himself never described a D stage, but this is often used to describe either advanced local disease or metastases to the liver.

TNM classification

The TNM classification is more detailed and accurate but more demanding:

- T Tumour stage;
- T1 Into submucosa;
- T2 Into muscularis propria;
- T3 Into pericolic fat but not breaching serosa;
- T4 Breaches serosa or directly involving another organ;
- N Nodal stage;

- N0 No nodes involved;
- N1 One or two nodes involved;
- N2 Three or more nodes involved;
- M Metastases;
- M0 No metastases;
- M1 Metastases;
- Ly Lymphatic invasion;
- L0 No lymphatic vessels involved;
- L1 Lymphatics involved;
- V Venous invasion;
- V0 No vessel invasion;
- V1 Vessels invaded;
- R Residual tumour;
- R0 No residual tumour;
- R1 Margins involved, residual tumour present.

Clinical features

Carcinoma of the colon usually occurs in patients over 50 years of age, but it is not rare earlier in adult life. Twenty per cent of cases present as an emergency with intestinal obstruction or peritonitis. In any case of colonic bleeding in patients over the age of 40 years, a complete investigation of the colon is required. A careful family history should be taken. Those with first-degree relatives who have developed colorectal cancer at the age of 45 years or below are at high risk and may be part of one of the colorectal cancer family syndromes.

Carcinoma of the left side of the colon

Most tumours occur in this location. They are usually of the stenosing variety.

Symptoms

The main symptoms are those of increasing intestinal obstruction. This includes lower abdominal pain, which may be colicky in nature, and abdominal distension. The patient may have a change in bowel habit with alternating diarrhoea and constipation (Summary box 65.9).

Summary box 65.9

Symptoms and signs of colorectal cancer

- Right-sided tumours: iron deficiency anaemia, abdominal mass
- Left-sided tumours: rectal bleeding, alteration in bowel habit, tenesmus, obstruction
- Metastatic disease: jaundice, ascites, hepatomegaly; other symptoms and signs from rarer sites of metastasis
- There may be considerable overlap between these symptoms

Carcinoma of the sigmoid

In addition to symptoms of intestinal obstruction, a low tumour may give rise to a feeling of the need for evacuation, which may result in tenesmus accompanied by the passage of mucus and blood. *Bladder symptoms* are not unusual and, in some instances, may herald a colovesical fistula.

Carcinoma of the transverse colon

This may be mistaken for a carcinoma of the stomach because of the position of the tumour together with anaemia and lassitude.

Cuthbert Esquire Dukes, 1890–1977, Pathologist, St Mark's Hospital, London, UK.

Carcinoma of the caecum and ascending colon

This may present with the following:

- anaemia, severe and unyielding to treatment;
- the presence of a mass in the right iliac fossa; colonoscopy may be needed to confirm the diagnosis;
- a carcinoma of the caecum can be the apex of an intussusception presenting with the symptoms of intermittent obstruction.

Metastatic disease

Patients may present for the first time with liver metastases and an enlarged liver, ascites from carcinomatosis peritonei and, more rarely, metastases to the lung, skin, bone and brain.

Methods of investigation of colon cancer

Flexible sigmoidoscopy

The 60-cm, fiberoptic, flexible sigmoidoscope is increasingly being used in the out-patient clinic or in special rectal bleeding clinics. The patient is prepared with a disposable enema and sedation is not usually necessary. This is particularly useful in supplementing barium investigations where diagnosis is difficult due to diverticular disease.

Colonoscopy

This is now the investigation of choice if colorectal cancer is suspected provided the patient is fit enough to undergo the bowel preparation. It has the advantage of not only picking up a primary cancer but also having the ability to detect synchronous polyps or even multiple carcinomas, which occur in 5% of cases. Ideally, every case should be proven histologically before surgery. Full bowel preparation and sedation are necessary. However, one must be aware of a small risk of perforation and also the failure to get to the caecum in 10% of cases, even by experienced endoscopists.

Radiology

Double-contrast barium enema is used when colonoscopy is contraindicated. It shows a cancer of the colon as a constant irregular filling defect (Fig. 65.40). False positives occur in 1–2% of cases and false negatives in 7–9% of cases.

Ultrasonography is often used as a screening investigation for liver metastases over the size of 1.5 cm, and CT is used in patients with large palpable abdominal masses, to determine local invasion, and is particularly used in the pelvis in the assessment of rectal cancer.

Spiral CT is particularly useful in elderly patients when contrast enemas or colonoscopy are not diagnostic or are contraindicated. In some centres, it is standard investigation above the age of 80 years. With the advent of technology in this field, there has been the introduction of virtual colonoscopy, which is effective in picking up polyps down to size of 6 mm (Fig. 65.41). This may even replace colonoscopy as the standard investigation in the future.

Urograms have a role in left-sided tumours where there is evidence of hydronephrosis on CT or ultrasound.

Treatment

Preoperative preparation

Recent literature has suggested that no bowel preparation is safe for right-sided colonic surgery. The most commonly used method

Figure 65.40 Barium enema showing a carcinoma of the sigmoid colon. It may have an 'apple core' appearance, i.e. a short, irregular stenosis with sharp shoulders at each end.

is dietary restriction to fluids only for 48 hours before surgery; on the day before the operation, two sachets of Picolax (sodium picosulphate) are taken to purge the colon. In addition, a rectal washout may be necessary. A stoma site is carefully discussed with the stoma care nursing specialist and anti-embolus stockings are fitted; the patient is started on prophylactic subcutaneous heparin, and intravenous prophylactic antibiotics are given at the start of surgery.

When intestinal obstruction is present, preparation in this way may precipitate abdominal pain, and it may be safer to use an on-table lavage technique at the time of the operation (Summary box 65.10).

Summary box 65.10

Principles of management of colorectal cancer

- Assessment of local and distant tumour spread should be performed both preoperatively and intraoperatively to allow planning of surgery
- Synchronous tumours occur in about 5% of patients and should be excluded preoperatively
- Operations are planned to remove the primary tumour and its draining locoregional lymph nodes
- Histological examination of resected tumours contributes to decision making regarding the need for adjuvant therapy

The test of operability

The abdomen is opened and the tumour assessed for resectability.

- 1 The liver is palpated for secondary deposits, the presence of which is not necessarily a contraindication to resection because the best palliative treatment for carcinoma of the colon is removal of the tumour.
- 2 The peritoneum, particularly the pelvic peritoneum, is

Figure 65.41 Virtual colonoscopy of the right colon. (a) Computerised tomography scan of the abdomen showing a caecal tumour. (b) Formatted 'virtual' image of the same lesion as in (a) (courtesy of Dr A. Slater, John Radcliffe Hospital, Oxford, UK).

inspected for signs of small, white, seed-like, neoplastic implantations. Similar changes can occur in the omentum.

- 3 The various groups of lymph nodes that drain the involved segment are palpated. Their enlargement does not necessarily mean that they are invaded by metastases, because the enlargement may be inflammatory.
- 4 The neoplasm is examined with a view to mobility and operability. Local fixation, however, does not always imply local invasion because some tumours excite a brisk inflammatory response.

Operations

The operations to be described are designed to remove the primary tumour and its draining locoregional lymph nodes, which may be involved by metastases. Lesser resections are indicated, however, should hepatic metastases render the condition incurable surgically. There is some evidence that early division of major blood vessels supplying the involved colon (no-touch technique – Turnbull) can slightly improve the number of curative

R. Turnbull, Irish surgeon, Cleveland Clinic, Ohio, reported the presence of cancer cells in the portal vein of patients undergoing resection for colon cancer. He then described in his Moynihan lecture a 'no-touch' isolation technique to reduce the manipulation of colonic tumours at surgery.

operations. The use of stapling and hand-suturing techniques for colonic anastomosis has been compared, and there is little difference in leak rate between the two.

Carcinoma of the caecum

Carcinoma of the caecum or ascending colon (Fig. 65.42) is treated when resectable by right hemicolectomy (Fig. 65.43).

The abdomen is opened, the peritoneum lateral to the ascending colon is incised, and the incision is carried around the hepatic flexure. The right colon is elevated, with the leaf of peritoneum containing its vessels and lymph nodes, from the posterior abdominal wall, taking care not to injure the ureter, spermatic vessels in the male or the duodenum. The peritoneum is separated medially near the origin of the ileocolic artery, which is divided together with the right colic artery when this has a separate origin from the superior mesenteric. The mesentery of the last 30 cm of ileum and the leaf of raised peritoneum attached to the caecum, ascending colon and hepatic flexure, after ligation of the mesenteric blood vessels, is divided as far as the proximal

Figure 65.42 Large villous tumour of the caecum with malignant change.

Figure 65.43 Area to be resected when the growth is situated in the caecum.

third of the transverse colon. When it is clear that there is an adequate blood supply at the resection margins, the right colon is resected, and an end-to-end anastomosis is fashioned between the ileum and the transverse colon.

Carcinoma of the hepatic flexure

When the hepatic flexure is involved, the resection must be extended correspondingly (Fig. 65.44).

Carcinoma of the transverse colon

When there is no obstruction, excision of the transverse colon and the two flexures together with the transverse mesocolon and the greater omentum, followed by end-to-end anastomosis, can be used. An alternative is an extended right hemicolectomy (Fig. 65.44).

Carcinoma of the splenic flexure or descending colon

The extent of the resection is from right colon to descending colon. Sometimes, removal of the colon up to the ileum, with an ileorectal anastomosis, is preferable.

Carcinoma of the pelvic colon

The left half of the colon is mobilised completely (Fig. 65.45). So that the operation is radical, the inferior mesenteric artery below its left colic branch, together with the related paracolic lymph nodes, must be included in the resection. This entails carrying the dissection as far as the upper third of the rectum. Many surgeons advocate flush ligation of the inferior mesenteric artery on the aorta (high ligation). Provided that there is no obstruction, primary anastomosis is the rule. Occasionally, a protecting upstream stoma may be necessary. The methods of dealing with large bowel obstruction as a result of colon cancer are described in Chapter 66.

Laparoscopic surgery

This has been heralded as the next major advance in colorectal surgery. However, its role needs to be accepted with an element of caution. It is technically demanding with a long learning curve.

Figure 65.44 Area to be resected when the growth is situated at the hepatic flexure.

Figure 65.45 Area to be resected in the case of a carcinoma of the pelvic colon.

Patients undergoing such surgery need to be entered into clinical trials. Important technical issues are traction and adequate vision, which are vital, as for open conventional procedures. Hand-assisted methods can be used in particularly difficult cases, but this takes away some of the benefits of the minimal approach. Specimen retrieval is via small incisions. Techniques and technology are rapidly evolving.

When a growth is found to be inoperable

In the upper part of the left colon, an ileostomy is performed. In the pelvic colon, a left iliac fossa colostomy is preferable. With an inoperable growth in the ascending colon, a bypass using an ileocolic anastomosis is the best procedure. A total colectomy needs to be considered for multiple tumours. Over 95% of colonic carcinomas can, however, be resected.

Adjuvant therapy

See Chapter 68.

Screening

There is now good evidence from controlled trials that regular bowel screening using faecal occult blood testing of people aged 60–69 years can reduce the mortality risk of colorectal cancer by about 15%. Those who test positive for faecal occult blood tests are then offered colonoscopy. These data have prompted the setting up of the National Health Service Bowel Cancer Screening Programme in the UK. Flexible sigmoidoscopy can also be used as the initial screening tool, and early results from a clinical trial look promising.

Hepatic metastases

It is important not to biopsy hepatic metastases as this may cause tumour dissemination (Fig. 65.46). Hepatic resection is usually performed as a staged procedure after recovery from colonic resection. Most wait 12 weeks before restaging. By doing this, those with aggressive disease are excluded from further drastic surgery. Reports have shown 30% 5-year survival following hepatectomy for colorectal cancer metastases. Radiological imaging

Figure 65.46 Computerised tomography scan of the liver showing multiple metastases from carcinoma of the colon.

will usually correctly identify colorectal metastases and assess patients suitable for liver resection. At present, the criterion for resection is fewer than three lesions in one lobe of liver. Irresectable symptomatic hepatic metastases may be suitable for other treatments including cytotoxic drugs or ablative treatments.

OTHER DISORDERS

Traumatic rupture

The intestine can be ruptured with or without an external wound – so called blunt trauma (Fig. 65.47). The most common cause of this is a blow to the abdomen that crushes the bowel against the vertebral column or sacrum; also, a rupture is more likely to occur where part of the gut has been fixed, for example in a hernia, or where a fixed part of the gut joins a mobile part such as the duodenojejunal flexure. Here, the damage may be retroperitoneal and easily overlooked.

In small perforations, the mucosa may prolapse through the hole and partly seal it, making the early signs misleading. In addition, there may be a laceration in the mesentery. The patient will then have a combination of intra-abdominal bleeding and release of intestinal contents into the abdominal cavity, giving rise to peritonitis.

Traumatic rupture of the large intestine is much less common. In blast injuries of the abdomen following the detonation of a bomb, the pelvic colon is particularly at risk of rupture. Compressed air rupture can follow the dangerous practical joke of turning on an air-line carrying compressed air near the victim's anus.

Figure 65.47 Traumatic rupture of the small intestine as a result of blunt abdominal trauma.

Rupture of the upper rectum can occur during sigmoidoscopy and occasionally during the placement of rectal catheters for barium radiology. Traumatic rupture of the colon can occur during colonoscopy. The most common site is the sigmoid colon, where the formation of a sigmoid loop pushes against the anti-mesenteric border of the sigmoid colon, stretching it out and eventually perforating it.

Gunshot wounds and impalement injuries to the bowel have more serious consequences because of the introduction of debris from the patient's clothing or the missile itself mixing with the bacteria in the patient's gut. High-velocity missiles may cause extensive damage to the bowel over a much wider area than just the entry and exit wounds.

Treatment

Where rupture is suspected, a plain radiograph in the erect or lateral decubitus position will demonstrate the presence of free air in the peritoneal cavity or indeed in the retroperitoneal tissues. In almost all cases, an abdominal exploration must be performed and, in many instances, simple closure of the perforation is all that is required. In others, for example where the mesentery is lacerated and the bowel is not viable, resection may be necessary. In the case of the large intestine, small, clean tears can be closed primarily; if there is a large tear with damage to the surrounding structures and the adjacent mesentery, resection and exteriorisation may be used. Much depends on the amount of intra-abdominal soiling.

In the case of retroperitoneal portions of the intestine, for example the duodenum, perforations can involve the front and back walls, and the duodenum in particular has to be carefully mobilised to check that a concealed tear is not overlooked. In all cases, the abdomen is washed out with saline and broad-spectrum intravenous antibiotics are given.

Enterocutaneous or faecal fistula

An external fistula communicating with the caecum sometimes follows an operation for gangrenous appendicitis or the draining of an appendix abscess. A faecal fistula can occur from necrosis of a gangrenous patch of intestine after the relief of a strangulated hernia, or from a leak from an intestinal anastomosis. The opening of an abscess connected with chronic diverticulitis or carcinoma of the colon frequently results in a faecal fistula. Radiation

damage is also another cause of fistula formation. The most common cause of enterocutaneous fistula is, however, previous surgery. This happens most often in patients with adhesions following previous operations. Damage to the small intestine occurs inadvertently during dissection of the adhesions and, because of an associated subacute obstruction or abscess, the fistula 'blows' postoperatively. Enterocutaneous fistulae can be divided into:

- those with a high output, more than 1 litre day⁻¹;
- those with a low output, less than 1 litre day⁻¹.

They can also be described anatomically as simple, with a direct communication between the gut and the skin, or complex, i.e. those with one or more tracts that are tortuous and sometimes associated with an intervening abscess cavity half way along the tract.

The discharge from a fistula connected with the duodenum or jejunum is bile-stained and causes severe excoriation of the skin. When the ileum or caecum is involved, the discharge is fluid faecal matter; when the distal colon is the affected site, it is solid or semisolid faecal matter. The site of leakage and the length of the fistula can be determined by small bowel enema and barium enema, by fistulography and, most importantly, by CT of the abdomen will show up any associated abscesses (Fig. 65.48).

Treatment

This can be very challenging in patients with a high-output fistula. Low-output fistulae can be expected to heal spontaneously, provided there is no distal obstruction. Reasons for failure of spontaneous healing also include:

- epithelial continuity between the gut and the skin;
- the presence of active disease where, for example, there is CD or carcinoma at the site of the anastomosis or in the tract;
- an associated complex abscess.

The abdominal wall must be protected from erosion by the use of appliances. The patient must remain nil by mouth; intravenous nutrition is started and signs of a decrease in fistula output are sought. The higher the fistula in the intestinal tract, the more skin excoriation must be expected, and this is worst in the case of a duodenal fistula. High-output fistulae cause rapid dehydration and hypoproteinaemia. Vigorous fluid replacement and nutritional

Figure 65.48 Computerised tomography scan in a patient with a complex enterocutaneous fistula and an intra-abdominal abscess being drained with a CT-guided catheter.

support are essential. The drainage of an intra-abdominal abscess can be life-saving. This can be achieved by either CT-guided drainage or, occasionally, laparotomy. In patients with a complex fistula, it may be necessary to bring out a defunctioning stoma upstream of the fistula site, even if this results in a high-output stoma.

Operative treatment

Operative repair should be attempted only after a trial of conservative management. The surgery can on occasion be extremely technically demanding, and an anastomosis should not be fashioned in the presence of continuing intra-abdominal sepsis or when the patient is hypoproteinaemic.

STOMAS

Colostomy

A colostomy is an artificial opening made in the large bowel to divert faeces and flatus to the exterior, where it can be collected in an external appliance. Depending on the purpose for which the diversion has been necessary, a colostomy may be temporary or permanent (Summary box 65.11).

Summary box 65.11

Stomas

- May be colostomy or ileostomy
- May be temporary or permanent
- Temporary or defunctioning stomas are usually fashioned as loop stomas
- An ileostomy is spouted; a colostomy is flush
- Ileostomy effluent is usually liquid whereas colostomy effluent is usually solid
- Ileostomy patients are more likely to develop fluid and electrolyte problems
- An ileostomy is usually sited in the right iliac fossa
- A temporary colostomy may be transverse and sited in the right upper quadrant
- End-colostomy is usually sited in the left iliac fossa
- All patients should be counselled by a stoma care nurse before operation
- Complications include skin irritation, prolapse, retraction, necrosis, stenosis, parastomal hernia, bleeding and fistulation

Temporary colostomy

A transverse loop colostomy has in the past been most commonly used to defunction an anastomosis after an anterior resection. It is now less commonly employed as it is fraught with complications and is difficult to manage; a loop ileostomy is preferred.

A loop left iliac fossa colostomy is still sometimes used to prevent faecal peritonitis developing following traumatic injury to the rectum, to facilitate the operative treatment of a high fistula-in-ano and incontinence.

A temporary loop colostomy is made, bringing a loop of colon to the surface, where it is held in place by a plastic bridge passed through the mesentery. Once the abdomen has been closed, the colostomy is opened, and the edges of the colonic incision are sutured to the adjacent skin margin (Fig. 65.49). When firm adhesion of the colostomy to the abdominal wall has taken place, the bridge can be removed after 7 days.

Figure 65.49 Usual temporary (loop) colostomy opened over a rod, and immediate suture of the colon wall to surrounding skin (many new rods are designed to lie beneath the skin's surface; alternatively, a skin bridge is used).

Following the surgical cure or healing of the distal lesion for which the temporary stoma was constructed, the colostomy can be closed. It is usual to perform a contrast examination (distal loopogram) to check that there is no distal obstruction or continuing problem at the site of previous surgery. Colostomy closure is most easily and safely accomplished if the stoma is mature, i.e. after the colostomy has been established for 2 months. Closure is usually performed by an intraperitoneal technique, which is associated with fewer closure breakdowns with faecal fistulae.

Double-barrelled colostomy

This colostomy was designed so that it could be closed by crushing the intervening 'spur' using an enterotome or a stapling device. It is rarely used now, but occasionally the colon is divided so that both ends can be brought to the surface separately, ensuring that the distal segment is completely defunctioned.

Permanent colostomy

This is usually formed after excision of the rectum for a carcinoma by the abdominoperineal technique.

It is formed by bringing the distal end (end-colostomy) of the divided colon to the surface in the left iliac fossa, where it is sutured in place, joining the colonic margin to the surrounding skin.

Figure 65.50 Usual site of a permanent (end) colostomy in the left iliac fossa. Note the distance A-B: 2.5 cm at least.

The point at which the colon is brought to the surface must be carefully selected to allow a colostomy bag to be applied without impinging on the bony prominence of the anterosuperior iliac spine. The best site is usually through the lateral edge of the rectus sheath, 6 cm above and medial to the bony prominence (Fig. 65.50).

Closure of the lateral space between the intraperitoneal segment of the sigmoid colon and the peritoneum of the pelvic wall, to prevent internal herniation or strangulation of loops of small bowel through the deficiency, has been practised, but there is no good evidence that it is effective.

Colostomy bags and appliances (Fig. 65.51)

Faeces from a permanent colostomy are collected in disposable adhesive bags. A wide range of such bags is currently available.

Figure 65.51 (a) The usual long-term backing ('stomahesive') and flange, onto which the bag is placed (b). (c) The desirable features incorporated in modern systems, e.g. the Biotrol concept as shown.

Many now incorporate a stomahesive backing, which can be left in place for several days. In most hospitals, a stoma care service is available to offer advice to patients, to acquaint them with the latest appliances and to provide the appropriate psychological and practical help.

Complications of colostomies

The following complications can occur to any colostomy but are more common after poor technique or siting of the stoma:

- prolapse;
- retraction;
- necrosis of the distal end;
- fistula formation;
- stenosis of the orifice;
- colostomy hernia;
- bleeding (usually from granulomas around the margin of the colostomy);
- colostomy 'diarrhoea': this is usually an infective enteritis and will respond to oral metronidazole 200 mg three times daily.

Many of these complications require revision of the colostomy. Sometimes, this can be achieved with an incision immediately around the stoma but, on occasion, reopening the abdomen and freeing up the colostomy may be necessary. Occasionally, transfer to the opposite side of the abdomen may be necessary.

Loop ileostomy

An ileostomy is now often used as an alternative to colostomy, particularly for defunctioning a low rectal anastomosis. The creation of a loop ileostomy from a knuckle of terminal ileum has already been described. The advantages of a loop ileostomy over a loop colostomy are the ease with which the bowel can be

brought to the surface and the absence of odour. Care is needed, when the ileostomy is closed, that suture line obstruction does not occur.

Caecostomy

This is rarely used now. In desperately ill patients with advanced obstruction, a caecostomy may be useful. In late cases of obstruction, the caecum may become so distended and ischaemic that rupture of the caecal wall may be anticipated. This can occur spontaneously, giving rise to faecal peritonitis, or at operation, when an incision in the abdominal wall reduces its supportive role and allows the caecum to expand. In such a situation, it should be decompressed by suction as soon as the abdomen is opened. In thin patients, it may then be possible to carry out direct suture of the incised or perforated caecal wall to the abdominal skin of the right iliac fossa, although a resection of this area is really the best treatment. Following on-table lavage, via the appendix stump, the irrigating catheter can be left in place as a tube caecostomy. Caecostomy is only a short-term measure to allow a few days for the condition of the patient to improve. Reoperation should normally follow soon thereafter and a definitive procedure should be carried out.

Intestinal obstruction

CHAPTER 66

LEARNING OBJECTIVES

To understand:

- The pathophysiology of dynamic and adynamic intestinal obstruction
- The cardinal features on history and examination
- The causes of small and large bowel obstruction
- The indications and contraindications for conservative management in bowel obstruction

CLASSIFICATION

Intestinal obstruction may be classified into two types:

- *Dynamic*, in which peristalsis is working against a mechanical obstruction. It may occur in an acute or a chronic form (Fig. 66.1; Summary boxes 66.1 and 66.2).
- *Adynamic*, in which peristalsis may be absent (e.g. paralytic ileus) or it may be present in a non-propulsive form (e.g. mesenteric vascular occlusion or pseudo-obstruction). In both types a mechanical element is absent (Summary box 66.1).

Summary box 66.1

Causes of intestinal obstruction

Dynamic

- Intraluminal
 - Impaction
 - Foreign bodies
 - Bezoars
 - Gallstones
- Intramural
 - Stricture
 - Malignancy
- Extramural
 - Bands/adhesions
 - Hernia
 - Volvulus
 - Intussusception

Adynamic

- Paralytic ileus
- Mesenteric vascular occlusion
- Pseudo-obstruct

Summary box 66.2

Mechanisms of obstruction

- Volvulus
- Incarceration
- Obstruction
- Intussusception

PATHOPHYSIOLOGY

Irrespective of aetiology or acuteness of onset, in dynamic (mechanical) obstruction the proximal bowel dilates and develops an altered motility. Below the obstruction the bowel exhibits normal peristalsis and absorption until it becomes empty, at which point it contracts and becomes immobile. Initially, proximal peristalsis is increased to overcome the obstruction, in direct proportion to the distance of the obstruction. If the obstruction is not relieved, the bowel begins to dilate, causing a reduction in

Figure 66.1 Pie chart showing the common causes of dynamic intestinal obstruction and their relative frequencies.

peristaltic strength, ultimately resulting in flaccidity and paralysis. This is a protective phenomenon to prevent vascular damage secondary to increased intraluminal pressure.

The distension proximal to an obstruction is produced by two factors:

- **Gas:** there is a significant overgrowth of both aerobic and anaerobic organisms, resulting in considerable gas production. Following the reabsorption of oxygen and carbon dioxide, the majority is made up of nitrogen (90%) and hydrogen sulphide.
- **Fluid:** this is made up of the various digestive juices. Following obstruction, fluid accumulates within the bowel wall and any excess is secreted into the lumen, whilst absorption from the gut is retarded. Dehydration and electrolyte loss are therefore due to:
 - reduced oral intake;
 - defective intestinal absorption;
 - losses as a result of vomiting;
 - sequestration in the bowel lumen.

STRANGULATION

When strangulation occurs, the viability of the bowel is threatened secondary to a compromised blood supply (Summary box 66.3).

Summary box 66.3

Causes of strangulation

External

- Hernial orifices
- Adhesions/bands

Interrupted blood flow

- Volvulus
- Intussusception

Increased intraluminal pressure

- Closed-loop obstruction

Primary

- Mesenteric infarction

The venous return is compromised before the arterial supply. The resultant increase in capillary pressure leads to local mural distension with loss of intravascular fluid and red blood cells intramurally and extraluminally. Once the arterial supply is impaired, haemorrhagic infarction occurs. As the viability of the bowel is compromised there is marked translocation and systemic exposure to anaerobic organisms with their associated toxins. The morbidity of intraperitoneal strangulation is far greater than with an external hernia, which has a smaller absorptive surface.

The morbidity and mortality associated with strangulation are dependent on age and extent. In strangulated external hernias the segment involved is short and the resultant blood and fluid loss is small. When bowel involvement is extensive the loss of blood and circulatory volume will cause peripheral circulatory failure.

Closed-loop obstruction

This occurs when the bowel is obstructed at both the proximal and distal points (Fig. 66.2). It is present in many cases of intestinal

Figure 66.2 Distension. Closed-loop obstruction with no proximal (A) or distal (C) distension and impending strangulation (B).

strangulation. Unlike cases of non-strangulating obstruction, there is no early distension of the proximal intestine. When gangrene of the strangulated segment is imminent, retrograde thrombosis of the mesenteric veins results in distension on both sides of the strangulated segment.

A classic form of closed-loop obstruction is seen in the presence of a malignant stricture of the right colon with a competent ileocaecal valve (present in up to one-third of individuals). The inability of the distended colon to decompress itself into the small bowel results in an increase in luminal pressure, which is greatest at the caecum, with subsequent impairment of blood supply. Unrelieved, this results in necrosis and perforation (Fig. 66.3)

SPECIAL TYPES OF MECHANICAL INTESTINAL OBSTRUCTION

Internal hernia

Internal herniation occurs when a portion of the small intestine becomes entrapped in one of the retroperitoneal fossae or in a congenital mesenteric defect.

The following are potential sites of internal herniation:

- the foramen of Winslow;
- a hole in the mesentery;

Figure 66.3 Carcinomatous stricture (X) of the hepatic flexure: closed-loop obstruction.

Jacob Benignus Winslow, 1669–1760, Professor of Anatomy, Physic and Surgery, Paris, France.

- a hole in the transverse mesocolon;
- defects in the broad ligament;
- congenital or acquired diaphragmatic hernia;
- duodenal retroperitoneal fossae – left paraduodenal and right duodenojejunal;
- caecal/appendiceal retroperitoneal fossae – superior, inferior and retrocaecal;
- intersigmoid fossa.

Internal herniation in the absence of adhesions is uncommon and a preoperative diagnosis is unusual. The standard treatment for a hernia is to release the constricting agent by division. This should not be undertaken in cases of herniation involving the foramen of Winslow, mesenteric defects and the paraduodenal/duodenojejunal fossae as major blood vessels run in the edge of the constriction ring. The distended loop in such circumstances must first be decompressed with minimal contamination and then reduced.

Obstruction from enteric strictures

Small bowel strictures usually occur secondary to tuberculosis or Crohn's disease. Malignant strictures associated with lymphoma are common, whereas carcinoma and sarcoma are rare. Presentation is usually subacute or chronic. Standard surgical management consists of resection and anastomosis. In Crohn's disease, strictureplasty may be considered in the presence of short multiple strictures without active sepsis.

Bolus obstruction

Bolus obstruction in the small bowel may be caused by food, gallstones, trichobezoar, phytobezoar, stercoliths and worms.

Gallstones

This type of obstruction tends to occur in the elderly secondary to erosion of a large gallstone through the gall bladder into the duodenum. Classically, there is impaction about 60 cm proximal to the ileocaecal valve. The patient may have recurrent attacks as the obstruction is frequently incomplete or relapsing as a result of a ball-valve effect. A radiograph will show evidence of small bowel obstruction with a diagnostic air–fluid level in the biliary tree. The stone may not be visible. At laparotomy it may be possible to crush the stone within the bowel lumen, after milking it proximally. If not, the intestine is opened and the gallstone removed. If the gallstone is faceted, a careful check for other enteric stones should be made. The region of the gall bladder should not be explored.

Food

Bolus obstruction may occur after partial or total gastrectomy when unchewed articles can pass directly into the small bowel. Fruit and vegetables are particularly liable to cause obstruction. The management is similar to that for gallstone, with intraluminal crushing usually being successful.

Trychobezoars and phytobezoars

These are firm masses of undigested hair balls and fruit/vegetable fibre respectively. The former is due to persistent hair chewing or

sucking, and may be associated with an underlying psychiatric abnormality. Predisposition to phytobezoars results from a high fibre intake, inadequate chewing, previous gastric surgery, hypochlorhydria and loss of the gastric pump mechanism. When possible, the lesion may be kneaded into the caecum, otherwise open removal is required.

Stercoliths

These are usually found in the small bowel in association with a jejunal diverticulum or ileal stricture. Presentation and management are identical to that of gallstones.

Worms

Ascaris lumbricoides may cause low small bowel obstruction, particularly in children, the institutionalised and those near the tropics (Fig. 66.4). An attack frequently follows the initiation of anti-helminthic therapy. Debility is frequently out of proportion to that produced by the obstruction. If worms are not seen in the stool or vomitus the diagnosis may be indicated by eosinophilia or the sight of worms within gas-filled small bowel loops on a plain radiograph (Naik). At laparotomy it may be possible to knead the tangled mass into the caecum; if not it should be removed. Occasionally, worms may cause a perforation and peritonitis, especially if the enteric wall is weakened by such conditions as amoebiasis.

Obstruction by adhesions and bands

Adhesions

In western countries where abdominal operations are common, adhesions and bands are the most common cause of intestinal obstruction. Furthermore, in the early postoperative period, the onset of such a mechanical obstruction may be difficult to differentiate from paralytic ileus.

The causes of intraperitoneal adhesions are shown in Table 66.1. Any source of peritoneal irritation results in local fibrin production, which produces adhesions between apposed surfaces. Early fibrinous adhesions may disappear when the cause is removed or they may become vascularised and be replaced by mature fibrous tissue.

There are several factors that may limit adhesion formation (Summary box 66.4).

Figure 66.4 Obstruction of the small intestine due to *Ascaris lumbricoides* (courtesy of Asal Y. Izzidien, Nenavah, Iraq).

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Table 66.1 The common causes of intra-abdominal adhesions

Ischaemic areas	Sites of anastomoses, reperitonealisation of raw areas, trauma, vascular occlusion
Foreign material	Talc, starch, gauze, silk
Infection	Peritonitis, tuberculosis
Inflammatory conditions	Crohn's disease
Radiation enteritis	

Summary box 66.4**Prevention of adhesions**

Factors that may limit adhesion formation include:

- Good surgical technique
- Washing of the peritoneal cavity with saline to remove clots, etc.
- Minimising contact with gauze
- Covering anastomosis and raw peritoneal surfaces

Numerous substances have been instilled in the peritoneal cavity to prevent adhesion formation, including hyaluronidase, hydrocortisone, silicone, dextran, polyvinylpropylene (PVP), chondroitin and streptomycin, anticoagulants, anti-histamines, non-steroidal anti-inflammatory drugs and streptokinase. Currently, no single agent has been shown to be particularly effective.

Adhesions may be classified into various types by virtue of whether they are early (fibrinous) or late (fibrous) or by underlying aetiology. From a practical perspective there are only two types – 'easy' flimsy ones and 'difficult' dense ones.

Postoperative adhesions giving rise to intestinal obstruction usually involve the lower small bowel. Operations for appendicitis and gynaecological procedures are the most common precursors and are an indication for early intervention.

Bands

Usually only one band is culpable. This may be:

- congenital, e.g. obliterated vitellointestinal duct;
- a string band following previous bacterial peritonitis;
- a portion of greater omentum, usually adherent to the parietes.

Acute intussusception

This occurs when one portion of the gut becomes invaginated within an immediately adjacent segment; almost invariably, it is the proximal into the distal.

The condition is encountered most commonly in children, with a peak incidence between 5 and 10 months of age. About 90% of cases are idiopathic but an associated upper respiratory tract infection or gastroenteritis may precede the condition. It is believed that hyperplasia of Peyer's patches in the terminal ileum may be the initiating event. Weaning, loss of passively acquired

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

maternal immunity and common viral pathogens have all been implicated in the pathogenesis of intussusception in infancy.

Children with intussusception associated with a pathological lead point such as Meckel's diverticulum, polyp, duplication, Henoch–Schönlein purpura or appendix are usually older than those with idiopathic disease. After the age of 2 years, a pathological lead point is found in at least one-third of affected children. Adult cases are invariably associated with a lead point, which is usually a polyp (e.g. Peutz–Jeghers syndrome), a submucosal lipoma or other tumour.

Pathology

An intussusception is composed of three parts (Fig. 66.5):

- the entering or inner tube;
- the returning or middle tube;
- the sheath or outer tube (intussuscipiens).

The part that advances is the apex, the mass is the intussusception and the neck is the junction of the entering layer with the mass.

An intussusception is an example of a strangulating obstruction as the blood supply of the inner layer is usually impaired. The degree of ischaemia is dependent on the tightness of the invagination, which is usually greatest as it passes through the ileocaecal valve.

Intussusception may be anatomically defined according to the site and extent of invagination (Table 66.2). In most children, the intussusception is ileocolic (see Chapter 6, Fig. 6.13). In adults, colocolic intussusception is common (Summary box 66.5).

Summary box 66.5**Intussusception**

- Most common in children
- Primary or secondary to intestinal pathology, e.g. polyp, Meckel's diverticulum
- Ileocolic is the commonest variety
- Can lead to an ischaemic segment
- Radiological reduction is indicated in most cases
- The remainder require surgery

Volvulus

A volvulus is a twisting or axial rotation of a portion of bowel about its mesentery. When complete it forms a closed loop of obstruction with resultant ischaemia secondary to vascular occlusion.

Volvuli may be primary or secondary. The primary form occurs secondary to congenital malrotation of the gut, abnormal mesenteric attachments or congenital bands. Examples include volvulus neonatorum, caecal volvulus and sigmoid volvulus. A secondary volvulus, which is the more common variety, is due to

Johann Friedrich Meckel, (The Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.

Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.

Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, gave his account of this disease in 1837.

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St. John's Hospital, The Hague, The Netherlands.

Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.

rotation of a piece of bowel around an acquired adhesion or stoma. (Summary box 66.6).

Summary box 66.6

Volvulus

- May involve the small intestine, caecum or sigmoid colon; neonatal midgut volvulus secondary to midgut malrotation is life-threatening
- The commonest spontaneous type in adults is sigmoid
- Sigmoid volvulus can be relieved by decompression per anum
- Surgery is required to prevent or relieve ischaemia

Volvulus neonatorum

This occurs secondary to intestinal malrotation (see Chapter 6) and is potentially catastrophic.

Sigmoid volvulus

This is rare in Europe and the USA but more common in Eastern Europe and Africa. Indeed, it is the most common cause of large bowel obstruction in the indigenous black African population. Rotation nearly always occurs in the anticlockwise direction. The predisposing medical causes are summarised in Fig. 66.6. Other predisposing factors include a high residue diet and constipation.

Compound volvulus

This is a rare condition also known as ileosigmoid knotting. The long pelvic mesocolon allows the ileum to twist around the sigmoid colon, resulting in gangrene of either or both segments of bowel. The patient presents with acute intestinal obstruction,

Table 66.2 Types of intussusception in children (after R.E. Gross) ($n = 702$)

	Percentage of series

Figure 66.6 Causes predisposing to volvulus of the sigmoid colon. Idiopathic megacolon usually precedes the volvulus in African people.

but distension is comparatively mild. Plain radiography reveals distended ileal loops in a distended sigmoid colon. At operation, decompression, resection and anastomosis are required.

CLINICAL FEATURES OF INTESTINAL OBSTRUCTION

Dynamic obstruction

The diagnosis of dynamic intestinal obstruction is based on the classic quartet of pain, distension, vomiting and absolute constipation. Obstruction may be classified clinically into two types:

- small bowel obstruction – high or low;
- large bowel obstruction (Summary box 66.7).

Summary box 66.7

Features of obstruction

- In *high small bowel obstruction*, vomiting occurs early and is profuse with rapid dehydration. Distension is minimal with little evidence of fluid levels on abdominal radiography
- In *low small bowel obstruction*, pain is predominant with central distension. Vomiting is delayed. Multiple central fluid levels are seen on radiography
- In *large bowel obstruction*, distension is early and pronounced. Pain is mild and vomiting and dehydration are late. The proximal colon and caecum are distended on abdominal radiography

The nature of the presentation will also be influenced by whether the obstruction is:

- acute;
- chronic;
- acute on chronic;
- subacute.

Acute obstruction usually occurs in small bowel obstruction, with sudden onset of severe colicky central abdominal pain, distension and early vomiting and constipation (Summary box 66.8).

Summary box 66.8

Cardinal clinical features of acute obstruction

- Abdominal pain
- Distension
- Vomiting
- Absolute constipation

Chronic obstruction is usually seen in large bowel obstruction, with lower abdominal colic and absolute constipation followed by distension. In *acute on chronic obstruction* there is a short history of distension and vomiting against a background of pain and constipation. *Subacute obstruction* implies an incomplete obstruction.

Presentation will be further influenced by whether the obstruction is:

- simple – in which the blood supply is intact;
- strangulating/strangulated – in which there is direct interference to blood flow, usually by hernial rings or intraperitoneal adhesions/bands.

The common causes of intestinal obstruction in western countries and their relative frequencies are shown in Fig. 66.1 (see page 1188). The underlying mechanisms are shown in Summary box 66.2 (see page 1188).

The clinical features vary according to:

- the location of the obstruction;
- the age of the obstruction;
- the underlying pathology;
- the presence or absence of intestinal ischaemia.

Late manifestations of intestinal obstruction that may be encountered include dehydration, oliguria, hypovolaemic shock, pyrexia, septicaemia, respiratory embarrassment and peritonism. In all cases of suspected intestinal obstruction, all hernial orifices must be examined.

Pain

Pain is the first symptom encountered; it occurs suddenly and is usually severe. It is colicky in nature and is usually centred on the umbilicus (small bowel) or lower abdomen (large bowel). The pain coincides with increased peristaltic activity. With increasing distension, the colicky pain is replaced by a mild constant diffuse pain.

The development of severe pain is indicative of the presence of strangulation. Pain may not be a significant feature in postoperative simple mechanical obstruction and does not usually occur in paralytic ileus.

Vomiting

The more distal the obstruction, the longer the interval between the onset of symptoms and the appearance of nausea and vomiting. As obstruction progresses the character of the vomitus alters from digested food to faeculent material, as a result of the presence of enteric bacterial overgrowth.

Distension

In the small bowel the degree of distension is dependent on the site of the obstruction and is greater the more distal the lesion. Visible peristalsis may be present (Fig. 66.7). Distension is delayed

Figure 66.7 Visible peristalsis. Intestinal obstruction due to a strangulated right femoral hernia, to which the arrow points.

in colonic obstruction and may be minimal or absent in the presence of mesenteric vascular occlusion.

Constipation

This may be classified as absolute (i.e. neither faeces nor flatus is passed) or relative (where only flatus is passed). Absolute constipation is a cardinal feature of complete intestinal obstruction. Some patients may pass flatus or faeces after the onset of obstruction as a result of the evacuation of the distal bowel contents. The rule that constipation is present in intestinal obstruction does not apply in:

- Richter's hernia;
- gallstone obturation;
- mesenteric vascular occlusion;
- obstruction associated with pelvic abscess;
- partial obstruction (faecal impaction/colonic neoplasm) in which diarrhoea may often occur.

Other manifestations

Dehydration

Dehydration is seen most commonly in small bowel obstruction because of repeated vomiting and fluid sequestration. It results in dry skin and tongue, poor venous filling and sunken eyes with oliguria. The blood urea level and haematocrit rise, giving a secondary polycythaemia.

Hypokalaemia

Hypokalaemia is not a common feature in simple mechanical obstruction. An increase in serum potassium, amylase or lactate dehydrogenase may be associated with the presence of strangulation, as may leucocytosis or leucopenia.

August Gottlieb Richter, 1742–1812, Lecturer in Surgery, Göttingen, Germany, described this form of hernia in 1777.

Pyrexia

Pyrexia in the presence of obstruction may indicate:

- the onset of ischaemia;
- intestinal perforation;
- inflammation associated with the obstructing disease.

Hypothermia indicates septicaemic shock.

Abdominal tenderness

Localised tenderness indicates pending or established ischaemia. The development of peritonism or peritonitis indicates overt infarction and/or perforation.

Clinical features of strangulation

It is vital to distinguish strangulating from non-strangulating intestinal obstruction because the former is a surgical emergency. The diagnosis is entirely clinical; the clinical features are shown in Summary box 66.9.

Summary box 66.9**Clinical features of strangulation**

- Constant pain
- Tenderness with rigidity
- Shock

In addition to the features above, it should be noted that:

- the presence of shock indicates underlying ischaemia;
- in impending strangulation, pain is never completely absent;
- symptoms usually commence suddenly and recur regularly;
- the presence and character of any local tenderness are of great significance and, however mild, tenderness requires frequent reassessment.

In non-strangulated obstruction there may be an area of localised tenderness at the site of the obstruction; in strangulation there is always localised tenderness associated with rigidity/rebound tenderness:

- Generalised tenderness and the presence of rigidity are indicative of the need for early laparotomy.
- In cases of intestinal obstruction in which pain persists despite conservative management, even in the absence of the above signs, strangulation should be diagnosed.
- When strangulation occurs in an external hernia, the lump is tense, tender and irreducible, there is no expansile cough impulse and it has recently increased in size.

Clinical features of intussusception

The classical presentation of intussusception is with episodes of screaming and drawing up of the legs in a previously well male infant. The attacks last for a few minutes and recur repeatedly. During attacks the child appears pale, whereas between episodes he may be listless. Vomiting may or may not occur at the outset but becomes conspicuous and bile-stained with time. Initially, the passage of stool may be normal, whereas, later, blood and mucus are evacuated – the ‘redcurrant jelly’ stool.

Whenever possible, examination should be undertaken between episodes of colic, without disturbing the child. Classically, the abdomen is not initially distended; a lump that

hardens on palpation may be discerned but this is present in only 60% of cases (Fig. 66.8). There may be an associated feeling of emptiness in the right iliac fossa (the sign of Dance). On rectal examination, blood-stained mucus may be found on the finger. Occasionally, in extensive ileocolic or colocolic intussusception, the apex may be palpable or even protrude from the anus.

Unrelieved, progressive dehydration and abdominal distension from small bowel obstruction will occur, followed by peritonitis secondary to gangrene. Rarely, natural cure may occur as a result of sloughing of the intussusception.

Differential diagnosis**Acute gastroenteritis**

Although abdominal pain and vomiting are common in acute gastroenteritis, with occasional blood and mucus in the stool, diarrhoea is a leading symptom and faecal matter or bile is always present in the stool.

Henoch–Schönlein purpura

Henoch–Schönlein purpura is associated with a characteristic rash and abdominal pain but intussusception may also occur.

Rectal prolapse

This may be easily differentiated by the fact that the projecting mucosa can be felt in continuity with the perianal skin whereas in intussusception the finger may pass indefinitely into the depths of a sulcus.

Clinical features of volvulus**Volvulus of the small intestine**

This may be primary or secondary and usually occurs in the lower ileum. It may occur spontaneously in African people, particularly following the consumption of a large volume of vegetable matter, whereas in the west it is usually secondary to adhesions passing to the parietes or female pelvic organs.

Caecal volvulus

This may occur as part of volvulus neonatorum or *de novo* and is usually a clockwise twist. It is more common in females and usually presents acutely with the classic features of obstruction. At first the obstruction may be partial, with the passage of flatus and faeces. In 25% of cases, examination may reveal a palpable tympanic swelling in the midline or left side of the abdomen.

Figure 66.8 The physical signs as recorded by Hamilton Bailey in a typical case of intussusception in an infant.

Jean Baptiste Hippolyte Dance, 1797–1832, Physician, Hôpital Cochin, Paris, France.
Henry Hamilton Bailey, 1894–1961, Surgeon, The Royal Northern Hospital, London, England.

Sigmoid volvulus

The symptoms are of large bowel obstruction, which may initially be intermittent followed by the passage of large quantities of flatus and faeces. Presentation varies in severity and acuteness, with younger patients appearing to develop the more acute form. Abdominal distension is an early and progressive sign, which may be associated with hiccough and retching; vomiting occurs late. Constipation is absolute. In the elderly, a more chronic form may be seen.

IMAGING

Erect abdominal films are no longer routinely obtained and the radiological diagnosis is based on a supine abdominal film (Fig. 66.9). An erect film may subsequently be requested when further doubt exists.

When distended with gas, the jejunum, ileum, caecum and remaining colon have a characteristic appearance in adults and older children that allows them to be distinguished radiologically. The diameter of the distended viscus is not diagnostic (Summary box 66.10).

Summary box 66.10

Radiological features of obstruction

- The obstructed small bowel is characterised by straight segments that are generally central and lie transversely. No gas is seen in the colon
- The jejunum is characterised by its valvulae conniventes, which completely pass across the width of the bowel and are regularly spaced, giving a 'concertina' or ladder effect
- Ileum – the distal ileum has been piquantly described by Wangenstein as featureless
- Caecum – a distended caecum is shown by a rounded gas shadow in the right iliac fossa
- Large bowel, except for the caecum, shows haustral folds, which, unlike valvulae conniventes, are spaced irregularly, do not cross the whole diameter of the bowel and do not have indentations placed opposite one another

In intestinal obstruction, fluid levels appear later than gas shadows as it takes time for gas and fluid to separate (Fig. 66.10). These are most prominent on an erect film. In adults, two inconstant fluid levels – one at the duodenal cap and the other in the terminal ileum – may be regarded as normal. In infants (less than 1 year old), a few fluid levels in the small bowel may be physiological. In this age group it is difficult to distinguish large from small bowel in the presence of obstruction, because the characteristic features seen in adults are not present or are unreliable.

During the obstructive process, fluid levels become more conspicuous and more numerous when paralysis has occurred. When fluid levels are pronounced, the obstruction is advanced. In the small bowel, the number of fluid levels is directly proportional to the degree of obstruction and to its site, the number increasing the more distal the lesion.

In contrast, low colonic obstruction does not commonly give rise to small bowel fluid levels unless advanced, whereas high

Owen Harding Wangenstein, 1898–1981, Professor of Surgery, The University of Minnesota, Minneapolis, MN, USA.

Figure 66.9 Gas-filled small bowel loop; patient supine.

Figure 66.10 Fluid levels with gas above; 'stepladder pattern'. Ileal obstruction by adhesions; patient erect.

colonic obstruction may do so in the presence of an incompetent ileocaecal valve. Colonic obstruction is usually associated with a large amount of gas in the caecum. A limited water-soluble enema should be undertaken to differentiate large bowel obstruction from pseudo-obstruction. A barium follow-through is contraindicated in the presence of acute obstruction and may be life-threatening.

Impacted foreign bodies may be seen on abdominal radiographs. In gallstone ileus, gas may be seen in the biliary tree, with the stone visible, usually in the right iliac fossa, in 25% of cases.

It is noteworthy that gas-filled loops and fluid levels in the

small and large bowel can also be seen in established paralytic ileus and pseudo-obstruction. The former can, however, normally be distinguished on clinical grounds whereas the latter can be confirmed radiologically. Fluid levels may also be seen in non-obstructing conditions such as inflammatory bowel disease, acute pancreatitis and intra-abdominal sepsis.

Imaging in intussusception

A plain abdominal field usually reveals evidence of small or large bowel obstruction with an absent caecal gas shadow in ileocolic cases. A soft tissue opacity is often visible in children. A barium enema may be used to diagnose the presence of an ileocolic intussusception (the claw sign) (Fig. 66.11) but does not demonstrate small bowel intussusception. An abdominal ultrasound scan has a high diagnostic sensitivity in children, demonstrating the typical doughnut appearance of concentric rings in transverse section. A computerised tomography (CT) scan is also useful in equivocal cases.

Imaging in volvulus

In *caecal volvulus*, radiography may reveal a gas-filled ileum and occasionally a distended caecum. A barium enema may be used to confirm the diagnosis, with an absence of barium in the caecum and a bird beak deformity.

In *sigmoid volvulus*, a plain radiograph shows massive colonic distension. The classic appearance is of a dilated loop of bowel running diagonally across the abdomen from right to left, with two fluid levels seen, one within each loop of bowel.

In *volvulus neonatorum*, the abdominal radiograph shows a variable appearance. Initially, it may appear normal or show evidence of duodenal obstruction but, as the intestinal strangulation progresses, the abdomen becomes relatively gasless.

TREATMENT OF ACUTE INTESTINAL OBSTRUCTION

There are three main measures used to treat acute intestinal obstruction (Summary box 66.11).

Figure 66.11 'Claw' sign of ileocolic intussusception. The barium in the intussusception is seen as a claw around a negative shadow of the intussusception (courtesy of R.S. Naik, Durg, India).

Summary box 66.11

Treatment of acute intestinal obstruction

- Gastrointestinal drainage
- Fluid and electrolyte replacement
- Relief of obstruction
- Surgical treatment is necessary for most cases of intestinal obstruction but should be delayed until resuscitation is complete, provided there is no sign of strangulation or evidence of closed-loop obstruction

The first two steps are always necessary before attempting the surgical relief of obstruction and are the mainstay of postoperative management. In a proportion of cases, particularly adhesive obstruction, they may be used exclusively.

The three principles of surgical intervention are shown in Summary box 66.12.

Summary box 66.12

Principles of surgical intervention for obstruction

Management of:

- The segment at the site of obstruction
- The distended proximal bowel
- The underlying cause of obstruction

Supportive management

Nasogastric decompression is achieved by the passage of a non-vented (Ryle) or vented (Salem) tube. The tubes are normally placed on free drainage with 4-hourly aspiration but may be placed on continuous or intermittent suction. As well as facilitating decompression proximal to the obstruction, they also reduce the risk of subsequent aspiration during induction of anaesthesia and post-extubation.

The basic biochemical abnormality in intestinal obstruction is sodium and water loss, and therefore the appropriate replacement is Hartmann's solution or normal saline. The volume required varies and should be determined by clinical haematological and biochemical criteria.

Antibiotics are not mandatory but many clinicians initiate broad-spectrum antibiotics early in therapy because of bacterial overgrowth. Antibiotic therapy is mandatory for all patients undergoing small or large bowel resection.

Surgical treatment

The timing of surgical intervention is dependent on the clinical picture. There are several indications for early surgical intervention (Summary box 66.13).

John Alfred Ryle, 1889–1950, Regius Professor of Physic, The University of Cambridge, and later Professor of Social Medicine, The University of Oxford, England, introduced the Ryle's tube in 1921.

Henri Albert Charles Antoine Hartmann, 1860–1952, Professor of Clinical Surgery, The Faculty of Medicine, The University of Paris, France.

Summary box 66.13

Indications for early surgical intervention

- Obstructed or strangulated external hernia
- Internal intestinal strangulation
- Acute obstruction

The classic clinical advice that ‘the sun should not both rise and set’ on a case of unrelieved acute intestinal obstruction is sound and should be followed unless there are positive reasons for delay. Such cases may include obstruction secondary to adhesions when there is no pain or tenderness, despite continued radiological evidence of obstruction. In these circumstances, conservative management may be continued for up to 72 hours in the hope of spontaneous resolution.

If the site of obstruction is unknown, adequate exposure is best achieved by a midline incision. Assessment is directed to:

- the site of obstruction;
- the nature of the obstruction;
- the viability of the gut.

Identification and assessment of the caecum is the best initial manoeuvre. If it is collapsed, the lesion is in the small bowel and may be identified by careful retrograde assessment. A dilated caecum indicates large bowel obstruction. To display the cause of obstruction, distended loops of small bowel should be displaced with care and covered with warm moist abdominal packs.

Operative decompression may be required if dilatation of bowel loops prevents exposure, the viability of the bowel wall is compromised or subsequent closure will be compromised. Its benefits should be balanced against the potential risk of septic complications from spillage. Decompression may be performed using Savage’s decompressor within a seromuscular purse-string suture. Alternatively, with a large-bore nasogastric tube in place, the small bowel contents may be gently milked in a retrograde manner to the stomach for aspiration. All volumes of fluid removed should be accurately measured and appropriately replaced.

The type of surgical procedure required will depend upon the cause of obstruction – division of adhesions (enterolysis), excision, bypass or proximal decompression.

Following relief of obstruction, the viability of the involved bowel should be carefully assessed (Table 66.3). Although frankly infarcted bowel is obvious, the viability status in many cases may be difficult to discern. If in doubt, the bowel should be wrapped in hot packs for 10 min with increased oxygenation and then

reassessed. The state of the mesenteric vessels and pulsation in adjacent arcades should be sought. Nevertheless, non-occlusive vascular insufficiency may occur despite adequate pulsation. In doubtful cases, following resection, both ends of the bowel should be raised as stomas. This is not only safe but also allows regular assessment of the bowel. When no resection has been undertaken or there are multiple ischaemic areas (mesenteric vascular occlusion), a second-look laparotomy at 24–48 hours may be required.

Special attention should always be paid to the sites of constriction at each end of an obstructed segment. If of doubtful viability they should be infolded by the use of a seromuscular suture and covered with omentum.

The surgical management of massive infarction in the form of superior mesenteric artery occlusion is dependent on the patient’s overall prognostic criteria. In the elderly, infarction of the small bowel from the duodenojejunal flexure and the right colon may be considered incurable, whereas in the young, with the potential for long-term intravenous alimentation and small bowel transplantation, a less conservative policy may be justified.

Whenever the small bowel is resected, the exact site of resection, the length of the resected segment and that of the residual bowel should be recorded.

Treatment of adhesions

Initial management is based on intravenous rehydration and nasogastric decompression; occasionally, this treatment is curative. Although an initial conservative regimen is considered appropriate, regular assessment is mandatory to ensure that strangulation does not occur. Conservative treatment should not be prolonged beyond 72 hours.

When, as is usual, laparotomy is required, although multiple adhesions may be found, only one may be causative. This should be divided and the remaining adhesions left *in situ* unless severe angulation is present. Division of these adhesions will only cause further adhesion formation.

When obstruction is caused by an area of multiple adhesions, the adhesions should be freed by sharp dissection. To prevent recurrence, the bare area should be covered with omental grafts.

Following the release of band obstruction, the constriction sites that have suffered direct compression should be carefully assessed and, if they show residual colour changes, invaginated.

Laparoscopic adhesiolysis may be considered in highly selected cases of chronic subacute obstruction (Summary box 66.14).

Table 66.3 Differentiation between viable and non-viable intestine

	Viable	Non-viable
Circulation	Dark colour becomes lighter Mesentery bleeds if pricked	Dark colour remains No bleeding if mesentery is pricked
Peritoneum	Shiny	Dull and lustreless
Intestinal musculature	Firm Pressure rings may or may not disappear Peristalsis may be observed	Flabby, thin and friable Pressure rings persist No peristalsis

Paul Thwaites Savage, formerly Surgeon, The Whittington Hospital, London, England.

Summary box 66.14

Treatment of adhesive obstruction

- Initially treat conservatively provided there are no signs of strangulation; should rarely continue conservative treatment for longer than 72 hours
- At operation, divide only the causative adhesion(s) and limit dissection
- Cover serosal tears; invaginate (or resect) areas of doubtful viability
- Laparoscopic adhesiolysis may have a role in chronic cases

Treatment of recurrent intestinal obstruction caused by adhesions

Several procedures may be considered in the presence of recurrent obstruction including:

- repeat adhesiolysis (enterolysis) alone;
- Noble's plication operation (Fig. 66.12);
- Charles–Phillips transmesenteric plication (Fig. 66.13);
- intestinal intubation (Fig. 66.14).

Postoperative intestinal obstruction

Differentiation between persistent paralytic ileus and early mechanical obstruction may be difficult in the early postoperative period. In practice, the latter is probably more common. Early

Figure 66.12 Noble's plication.

Figure 66.13 The Charles–Phillips procedure.

Thomas Benjamin Noble, 1895–1965, Surgeon, The Community Hospital, Indianapolis, IN, USA.
Richard V. Phillips, Surgeon, Albuquerque, NM, USA.

evidence of obstruction (days 1–5) is usually due to non-strangulating causes such as fibrinous adhesions and oedema. Obstruction is usually incomplete and the majority settle with continued conservative management. Late postoperative obstruction (> 7 days) is usually more significant in nature, and timely surgical intervention is usually required.

Treatment of intussusception

In the infant with ileocolic intussusception, after resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage, non-operative reduction can be attempted using an air or barium enema (see Chapter 6, Fig. 6.14). Successful reduction can only be accepted if there is free reflux of air or barium into the small bowel, together with resolution of symptoms and signs in the patient. Non-operative reduction is contraindicated if there are signs of peritonitis or perforation, there is a known pathological lead point or in the presence of profound shock. In experienced units, more than 70% of intussusceptions can be reduced non-operatively. Strangulated bowel and pathological lead points are unlikely to reduce. Perforation of the colon during pneumatic or hydrostatic reduction is a recognised hazard but is rare. Recurrent intussusception occurs in up to 10% of patients after non-operative reduction.

Surgery is required when radiological reduction has failed or is contraindicated. After resuscitation, a transverse right-sided abdominal incision provides good access. Reduction is achieved by gently compressing the most distal part of the intussusception toward its origin (Fig. 66.15), making sure not to pull. The last part of the reduction is the most difficult (Fig. 66.16). After reduction, the terminal part of the small bowel and the appendix will be seen to be bruised and oedematous. The viability of the whole bowel should be checked carefully. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection and primary anastomosis.

Acute intestinal obstruction of the newborn

Neonatal intestinal obstruction has many potential causes. Congenital atresia and stenosis are the most common. Intestinal

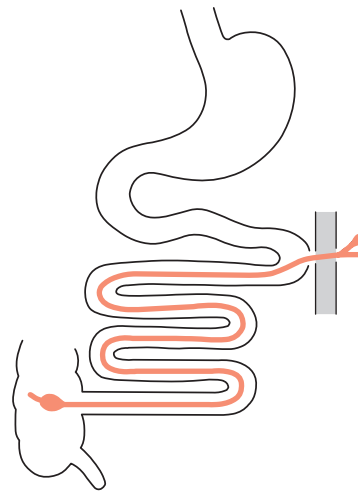

Figure 66.14 A Baker's tube inserted via a Witzel jejunostomy. A gastrostomy may also be used.

Friedrich Oskar Witzel, 1856–1925, a Surgeon at Bonn, Germany.

Figure 66.15 Diagram showing the method used to reduce an intussusception.

Figure 66.16 Reducing the terminal part of the intussusception (after R.E. Gross).

malrotation with midgut volvulus, meconium ileus, Hirschprung's disease, imperforate anus, necrotising enterocolitis and an incarcerated inguinal hernia may also be responsible. Many of these conditions are discussed in Chapter 6.

Intestinal atresia

Duodenal atresia and stenosis are the commonest forms of intestinal obstruction in the newborn (see Chapter 6). Jejunal or ileal atresias are next in frequency whereas colonic atresia is rare. The possibility of multiple atresias makes intraoperative assessment of the whole small and large bowel mandatory. As with all congenital anomalies, associated malformations are common and should be excluded.

There are four main types of jejunal/ileal atresia, ranging from an obstructing membrane with continuity of the bowel wall, through blind-ended segments of bowel separated by a fibrous cord or V-shaped mesenteric defect (including the so called apple-peel atresia) (Fig. 66.17), to multiple atresias ('string of sausages'). The obstructed proximal bowel is at risk of perforation, which may happen prenatally causing meconium peritonitis in the fetus.

Small bowel atresias present with intestinal obstruction soon after birth. Bilious vomiting is the dominant feature in jejunal atresia whereas abdominal distension is more prominent with ileal atresia. A small amount of pale meconium may be passed despite the atresia.

Plain abdominal radiographs show a variable number of dilated loops of bowel and fluid levels according to the level of obstruction.

Figure 66.17 Apple-peel jejunal bowel atresia with obstructed proximal jejunum and collapsed distal ileum coiled round a remnant ileocolic artery (courtesy of M.D. Stringer, Leeds, UK).

In a stable infant, a contrast enema may be required to clarify the cause of a distal bowel obstruction.

Surgery

Duodenal atresia is corrected by a duodenoduodenostomy. In most cases of jejunal/ileal atresia, the distal end of the dilated proximal small bowel is resected and a primary end-to-end anastomosis is possible. If the proximal bowel is extremely dilated it may need to be tapered to the distal bowel before anastomosis. Occasionally, a temporary stoma is required before definitive repair.

Meconium ileus

Cystic fibrosis is almost always the underlying cause of this condition. Meconium is normally kept fluid by the action of pancreatic enzymes. In meconium ileus the terminal ileum becomes filled with thick viscid meconium, resulting in progressive intestinal obstruction. A sterile meconium peritonitis may have occurred *in utero*.

Visibly dilated loops of bowel are often palpable in the newborn with meconium ileus. An abdominal radiograph may show a dilated small intestine with mottling. Fluid levels are generally not seen. Unlike ileal atresia there is no abrupt termination of the gas-filled intestine. A contrast enema shows an unused micro-colon. As the condition is caused by an autosomal recessive genetic defect, a family history may be present. Further assessment includes gene mutation analysis and, beyond the neonatal period, a sweat test, which shows elevated sodium and chloride levels ($> 70 \text{ mmol l}^{-1}$).

Uncomplicated meconium ileus may respond to treatment with a hyperosmolar gastrografin enema; this draws fluid into the gut lumen and also has detergent properties, which help to liquefy the meconium. Infants treated in this way need extra intravenous fluids to compensate for fluid shifts. Meconium ileus complicated by intestinal perforation, volvulus or atresia, or unresponsive to enemas, demands surgery. Various surgical procedures are used including intestinal resection and temporary stoma formation, resection and primary anastomosis, and, in uncomplicated cases, enterotomy and irrigation of the bowel. The

Bishop–Koop operation (Fig. 66.18) with its irrigating stoma is now only rarely used.

TREATMENT OF ACUTE LARGE BOWEL OBSTRUCTION

Large bowel obstruction is usually caused by an underlying carcinoma or occasionally diverticular disease, and presents in an acute or chronic form. The condition of pseudo-obstruction should always be considered and excluded by a limited contrast study or a CT air scan to confirm organic obstruction.

After full resuscitation, the abdomen should be opened through a midline incision. Distension of the caecum will confirm large bowel involvement. Identification of a collapsed distal segment of the large bowel and its sequential proximal assessment will readily lead to identification of the cause. When a removable lesion is found in the caecum, ascending colon, hepatic flexure or proximal transverse colon, an emergency right hemicolectomy should be performed. If the lesion is irremovable, a proximal stoma (colostomy or ileostomy if the ileocaecal valve is incompetent) or ileotransverse bypass should be considered. Obstructing lesions at the splenic flexure should be treated by an extended right hemicolectomy with ileodescending colonic anastomosis.

For obstructing lesions of the left colon or rectosigmoid junction, immediate resection should be considered unless there are clear contraindications (Summary box 66.15).

Summary box 66.15

Management of left-sided large bowel obstruction

Contraindications to immediate resection include:

- Inexperienced surgeon
- Moribund patient
- Advanced disease

Figure 66.18 Bishop–Koop operation. This shows the completed procedure after grossly distended ileum has been resected. Because intestinal continuity is preserved, early closure of the ileostomy is not essential.

In rare instances, or when caecal perforation is imminent, additional time to improve the patient's clinical condition can be bought by performing an emergency caecostomy (or ileostomy in the presence of an incompetent ileocaecal valve).

In the absence of senior clinical staff it is safest to bring the proximal colon to the surface as a colostomy. When possible the distal bowel should be brought out at the same time (Paul–Mikulicz procedure) to facilitate subsequent extraperitoneal closure. In the majority of cases, the distal bowel will not reach and is closed and returned to the abdomen (Hartmann's procedure). A second-stage colorectal anastomosis can be planned when the patient is fit.

If an anastomosis is to be considered using the proximal colon, in the presence of obstruction, it must be decompressed and cleaned by an on-table colonic lavage. Nevertheless, the subsequent anastomosis should still be protected with a covering stoma.

Treatment of caecal volvulus

At operation the volvulus should be reduced. Sometimes, this can only be achieved after decompression of the caecum using a needle. Further management consists of fixation of the caecum to the right iliac fossa (caecopexy) and/or a caecostomy. If the caecum is ischaemic or gangrenous, a right hemicolectomy should be performed.

Treatment of sigmoid volvulus

Flexible sigmoidoscopy or rigid sigmoidoscopy and insertion of a flatus tube should be carried out to allow deflation of the gut. Success, as long as ischaemic bowel is excluded, will provide temporary respite, allowing resuscitation and an elective procedure. Failure results in an early laparotomy, with untwisting of the loop and per anum decompression (Fig. 66.19). When the bowel is viable, fixation of the sigmoid colon to the posterior abdominal wall may be a safer manoeuvre in inexperienced hands. Resection is preferable if it can be achieved safely. A Paul–Mikulicz procedure is useful, particularly if there is suspicion of impending gangrene (Fig. 66.20); an alternative procedure is a sigmoid colectomy and, when anastomosis is considered unwise, a Hartmann's procedure with subsequent reanastomosis can be carried out.

CHRONIC LARGE BOWEL OBSTRUCTION

The symptoms of chronic intestinal obstruction may arise from two sources – the cause and the subsequent obstruction.

The causes of obstruction may be organic:

- intramural – faecal impaction;
- mural – colorectal cancer, diverticulitis, strictures (Crohn's disease, ischaemia), anastomotic stenosis;
- extramural – metastatic deposits, endometriosis;

or functional:

- Hirschsprung's disease, idiopathic megacolon, pseudo-obstruction.

Frank Thomas Paul, 1851–1941, Surgeon, The Royal Infirmary, Liverpool, England.
 Johann von Mikulicz-Radecki, 1850–1905, Professor of Surgery, Breslau, Germany, (now Wrocław, Poland).
 Harald Hirschsprung, 1830–1916, Physician, The Queen Louise Hospital for Children, Copenhagen, Denmark, described congenital megacolon in 1887.

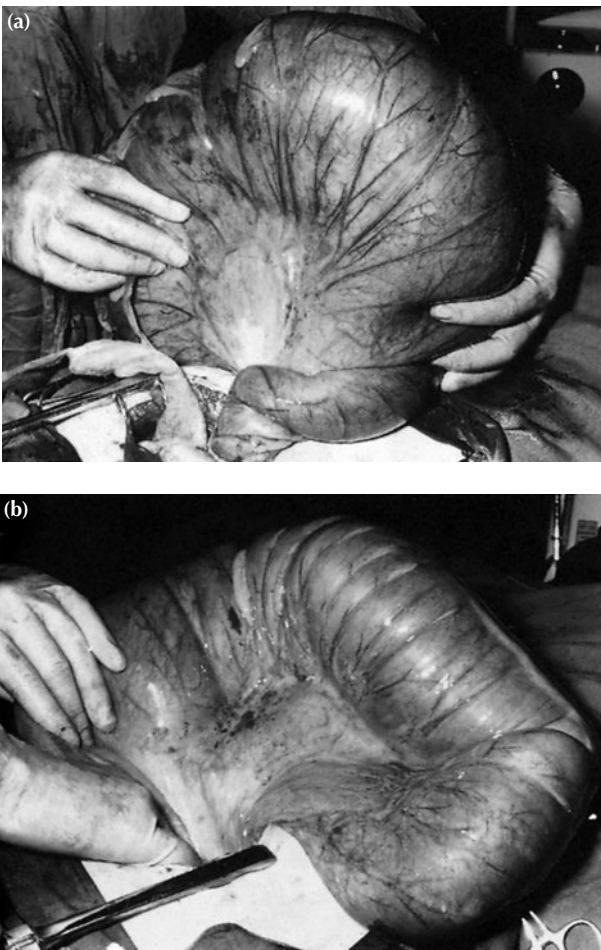

Figure 66.19 Volvulus of the sigmoid colon (a) before and (b) after untwisting (courtesy of S.U. Rahman, Manchester, England).

The symptoms of chronic obstruction differ in their predominance, timing and degree from acute obstruction. Constipation appears first. It is initially relative and then absolute, associated with distension. In the presence of large bowel disease, the point of greatest distension is in the caecum, and this is heralded by the onset of pain. Vomiting is a late feature and therefore dehydration is exceptional. Examination is unremarkable, save for confirmation of distension and the onset of peritonism in late cases. Rectal examination may confirm the presence of faecal impaction or a tumour.

Investigation

Plain abdominal radiography may confirm the presence of large bowel obstruction. All such cases should be confirmed by a subsequent single-contrast water-soluble enema study to rule out functional disease (Summary box 66.16).

Summary box 66.16

Principles of investigation of possible large bowel obstruction

- In the presence of large bowel obstruction, a single-contrast water-soluble enema or CT should be undertaken to exclude a functional cause

Figure 66.20 The Paul–Mikulicz operation applied to volvulus of the pelvic colon.

Organic disease requires a laparotomy, whereas functional disease requires colonoscopic decompression and conservative management. In the presence of organic obstruction, surgical management after resuscitation depends on the underlying cause and the relevant chapters in this book should be consulted.

ADYNAMIC OBSTRUCTION

Paralytic ileus

This may be defined as a state in which there is failure of transmission of peristaltic waves secondary to neuromuscular failure [i.e. in the myenteric (Auerbach's) and submucous (Meissner's) plexuses]. The resultant stasis leads to accumulation of fluid and gas within the bowel, with associated distension, vomiting, absence of bowel sounds and absolute constipation.

Varieties

The following varieties are recognised.

- *Postoperative*: a degree of ileus usually occurs after any abdominal procedure and is self-limiting, with a variable duration of 24–72 hours. Postoperative ileus may be prolonged in the presence of hypoproteinaemia or metabolic abnormality (see below).
- *Infection*: intra-abdominal sepsis may give rise to localised or generalised ileus. Resultant adhesions may contribute a mechanical element to the initial neurogenic aetiology.
- *Reflex ileus*: this may occur following fractures of the spine or ribs, retroperitoneal haemorrhage or even the application of a plaster jacket.
- *Metabolic*: uraemia and hypokalaemia are the most common contributory factors.

Clinical features

Paralytic ileus takes on a clinical significance if, 72 hours after laparotomy:

- there has been no return of bowel sounds on auscultation;
- there has been no passage of flatus.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany, (now Wrocław, Poland), described the myenteric plexus in 1862.
Georg Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany, described the submucous plexus of the alimentary tract in 1852.

Abdominal distension becomes more marked and tympanic. Pain is not a feature. In the absence of gastric aspiration, effortless vomiting may occur. Radiologically, the abdomen shows gas-filled loops of intestine with multiple fluid levels.

Management

The essence of treatment is prevention, with the use of nasogastric suction and restriction of oral intake until bowel sounds and the passage of flatus return. Electrolyte balance must be maintained. The use of an enhanced recovery programme with early introduction of fluids and solids is, however, becoming increasingly popular.

Specific treatment is directed towards the cause, but the following general principles apply:

- The primary cause must be removed.
- Gastrointestinal distension must be relieved by decompression.
- Close attention to fluid and electrolyte balance is essential.
- There is no place for the routine use of peristaltic stimulants. Rarely, in resistant cases, medical therapy with an adrenergic blocking agent in association with cholinergic stimulation, e.g. neostigmine (the Catchpole regimen), may be used, provided that an intraperitoneal cause has been excluded.
- If paralytic ileus is prolonged and threatens life, a laparotomy should be considered to exclude a hidden cause and facilitate bowel decompression.

Pseudo-obstruction

This condition describes an obstruction, usually of the colon, that occurs in the absence of a mechanical cause or acute intra-abdominal disease. It is associated with a variety of syndromes in which there is an underlying neuropathy and/or myopathy and a range of other factors (Summary box 66.17).

Summary box 66.17

Factors associated with pseudo-obstruction

Idiopathic

- Metabolic
 - Diabetes: intermittent porphyria
 - Acute hypokalaemia
 - Uraemia
 - Myxodoema
- Severe trauma (especially to the lumbar spine and pelvis)
- Shock
 - Burns
 - Myocardial infarction
 - Stroke

Septicaemia

- Retroperitoneal irritation
 - Blood
 - Urine
 - Enzymes (pancreatitis)
 - Tumour
- Drugs
 - Tricyclic antidepressants
 - Phenothiazines
 - Laxatives
- Secondary gastrointestinal involvement
 - Scleroderma
 - Chagas' disease

Carlos Justiniano Ribeiro Chagas, 1879–1934, Director of The Oswald Cruz Institute, and Professor of Tropical Medicine, The University of Rio de Janeiro, Brazil.

Small intestinal pseudo-obstruction

This condition may be primary (i.e. idiopathic or associated with familial visceral myopathy) or secondary. The clinical picture consists of recurrent subacute obstruction. The diagnosis is made by the exclusion of a mechanical cause. Treatment consists of initial correction of any underlying disorder. Metoclopramide and erythromycin may be of use.

Colonic pseudo-obstruction

This may occur in an acute or a chronic form. The former, also known as Ogilvie's syndrome, presents as acute large bowel obstruction. Abdominal radiographs show evidence of colonic obstruction, with marked caecal distension being a common feature. Indeed, caecal perforation is a well-recognised complication. The absence of a mechanical cause requires urgent confirmation by colonoscopy or a single-contrast water-soluble barium enema or CT. Once confirmed, pseudo-obstruction should be treated by colonoscopic decompression. It may recur in 25% of cases, necessitating further colonoscopy with simultaneous placement of a flatus tube. When colonoscopy fails or is unavailable, a tube caecostomy may be required. Continued symptoms may benefit from surgical intervention with subtotal colectomy and ileo-rectal anastomosis.

Acute mesenteric ischaemia

Mesenteric vascular disease may be classified as acute intestinal ischaemia – with or without occlusion – venous, chronic arterial, central or peripheral. The superior mesenteric vessels are the visceral vessels most likely to be affected by embolisation or thrombosis, with the former being most common. Occlusion at the origin of the superior mesenteric artery (SMA) is almost invariably the result of thrombosis, whereas emboli lodge at the origin of the middle colic artery. Inferior mesenteric involvement is usually clinically silent because of a better collateral circulation.

Possible sources for the embolisation of the SMA include a left atrium associated with fibrillation, a mural myocardial infarction, an atheromatous plaque from an aortic aneurysm and a mitral valve vegetation associated with endocarditis.

Primary thrombosis is associated with atherosclerosis and thromboangitis obliterans. Primary thrombosis of the superior mesenteric veins may occur in association with factor V Leiden, portal hypertension, portal pyaemia and sickle cell disease and in women taking the contraceptive pill.

Irrespective of whether the occlusion is arterial or venous, haemorrhagic infarction occurs. The mucosa is the only layer of the intestinal wall to have little resistance to ischaemic injury. The intestine and its mesentery become swollen and oedematous. Blood-stained fluid exudes into the peritoneal cavity and bowel lumen. If the main trunk of the SMA is involved, the infarction covers an area from just distal to the duodenojejunal flexure to the splenic flexure. Usually, a branch of the main trunk is implicated and the area of infarction is less.

Clinical features

The most important clue to an early diagnosis of acute mesenteric ischaemia is the sudden onset of severe abdominal pain in a patient with atrial fibrillation or atherosclerosis. The pain is typically central and out of all proportion to physical findings.

Sir William Heneage Ogilvie, 1887–1971, Surgeon, Guy's Hospital, London, England.

Persistent vomiting and defaecation occur early, with the subsequent passage of altered blood. Hypovolaemic shock rapidly ensues. Abdominal tenderness may be mild initially with rigidity being a late feature.

Investigation will usually reveal a profound neutrophil leucocytosis with an absence of gas in the thickened small intestine on abdominal radiographs. The presence of gas bubbles in the mesenteric veins is rare but pathognomonic.

Treatment needs to be tailored to the individual. In conjunction with full resuscitation, embolectomy via the ileocolic artery or revascularisation of the SMA may be considered in early embolic cases. The majority of cases, however, are diagnosed late. In the young, all affected bowel should be resected, whereas in the elderly or infirm the situation may be deemed incurable. Anti-coagulation should be implemented early in the postoperative period.

After extensive enterectomy it is usual for patients to require intravenous alimentation. The young, however, may sometimes develop sufficient intestinal digestive and absorptive function to lead relatively normal lives. In selected cases consideration may be given to small bowel transplantation.

Infarction of the large intestine alone is relatively rare. Involvement of the middle colic artery territory should be treated by transverse colectomy and exteriorisation of both ends, with an extended right hemicolectomy in selected cases.

Ischaemic colitis describes the structural changes that occur in the colon as a result of the deprivation of blood. They are most

common in the splenic flexure, whose blood supply is particularly tenuous. They have been classified by Marston into gangrenous, transient and stricturing forms; only stricturing forms cause obstruction and only a few such patients require resection.

The vermiform appendix

CHAPTER 67

LEARNING OBJECTIVES

To understand:

- The aetiology and surgical anatomy of acute appendicitis
- The clinical signs and differential diagnoses of appendicitis
- The management of postoperative problems
- Basic surgical techniques, both open and laparoscopic
- Less common conditions occasionally encountered

The vermiform appendix is considered by most to be a vestigial organ; its importance in surgery results only from its propensity for inflammation, which results in the clinical syndrome known as acute appendicitis. Acute appendicitis is the most common cause of an 'acute abdomen' in young adults and, as such, the associated symptoms and signs have become a paradigm for clinical teaching. Appendicitis is sufficiently common that appendicectomy (termed appendectomy in North America) is the most frequently performed urgent abdominal operation and is often the first major procedure performed by a surgeon in training. Notwithstanding advances in modern radiographic imaging and diagnostic laboratory investigations, the diagnosis of appendicitis remains essentially clinical, requiring a mixture of observation, clinical acumen and surgical science. In an age accustomed to early and accurate preoperative diagnosis, acute appendicitis remains an enigmatic challenge and a reminder of the art of surgical diagnosis.

ANATOMY

The vermiform appendix is present only in humans, certain anthropoid apes and the wombat. It is a blind muscular tube with mucosal, submucosal, muscular and serosal layers. Morphologically, it is the undeveloped distal end of the large caecum found in many lower animals. At birth, the appendix is short and broad at its junction with the caecum, but differential growth of the caecum produces the typical tubular structure by about the age of 2 years (Condon). During childhood, continued growth of the caecum commonly rotates the appendix into a retrocaecal but intraperitoneal position (Fig. 67.1). In approximately one-quarter of cases, rotation of the appendix does not occur, resulting in a pelvic, subcaecal or paracaecal position. Occasionally, the tip of the appendix becomes extraperitoneal, lying behind the caecum or ascending colon. Rarely, the caecum does not migrate

Figure 67.1 The various positions of the appendix (after Sir C. Wakeley, London, formerly PRCS).

during development to its normal position in the right lower quadrant of the abdomen. In these circumstances, the appendix can be found near the gall bladder or, in the case of intestinal malrotation, in the left iliac fossa, causing diagnostic difficulty if appendicitis develops (Fig. 67.2).

The position of the base of the appendix is constant, being found at the confluence of the three taeniae coli of the caecum, which fuse to form the outer longitudinal muscle coat of the appendix. At operation, use can be made of this to find an elusive appendix, as gentle traction on the taeniae coli, particularly the anterior taenia, will lead the operator to the base of the appendix.

The mesentery of the appendix or mesoappendix arises from the lower surface of the mesentery or the terminal ileum and is itself subject to great variation. Sometimes, as much as the distal one-third of the appendix is bereft of mesoappendix. Especially in childhood, the mesoappendix is so transparent that the contained blood vessels can be seen (Fig. 67.3). In many adults, it becomes laden with fat, which obscures these vessels. The appendicular artery, a branch of the lower division of the ileocolic artery, passes behind the terminal ileum to enter the mesoappendix a short distance from the base of the appendix. It then comes

A wombat is a nocturnal, burrowing Australian marsupial.
Robert E. Condon, Contemporary, Emeritus Professor of Surgery, The Medical College of Wisconsin, WI, USA.

Figure 67.2 Left-sided caecum and appendix due to intestinal malrotation (after Findley and Humphreys).

Figure 67.3 Mesoappendix displayed demonstrating the appendicular artery.

to lie in the free border of the mesoappendix. An accessory appendicular artery may be present but, in most people, the appendicular artery is an 'end-artery', thrombosis of which results in necrosis of the appendix (synonym: gangrenous appendicitis). Four, six or more lymphatic channels traverse the mesoappendix to empty into the ileocaecal lymph nodes.

Microscopic anatomy

The appendix varies considerably in length and circumference. The average length is between 7.5 and 10 cm. The lumen is irregular, being encroached upon by multiple longitudinal folds of mucous membrane lined by columnar cell intestinal mucosa of colonic type (Fig. 67.4). Crypts are present but are not numerous. In the base of the crypts lie argentaffin cells (Kulchitsky cells), which may give rise to carcinoid tumours (see below). The appendix is the most frequent site for carcinoid tumours, which may present with appendicitis due to occlusion of the appendiceal lumen. The submucosa contains numerous lymphatic aggregations or follicles. While no discernible change in immune

Nikolai Kulchitsky, 1856–1925, Professor of Histology, Kharkov, Ukraine, who left Russia after the Revolution of 1917, and later worked at University College, London. He described these cells in 1897.

Figure 67.4 Normal vermiform appendix. The narrow lumen is bounded by mucosa which may be arranged in folds. There is usually abundant lymphoid tissue in the mucosa, especially in younger individuals. This may encroach on and further narrow the lumen. The mucosa is bounded by a relatively thin muscularis mucosa (courtesy of Dr P. Kelly, FRCPath, Dublin, Ireland).

function results from appendicectomy, the prominence of lymphatic tissue in the appendix of young adults seems to be important in the aetiology of appendicitis (see below).

ACUTE APPENDICITIS

While there are isolated reports of perityphlitis (fatal inflammation of the caecal region) from the late 1500s, recognition of acute appendicitis as a clinical entity is attributed to Reginald Fitz, who presented a paper to the first meeting of the Association of American Physicians in 1886 entitled 'Perforating inflammation of the vermiform appendix'. Soon afterwards, Charles McBurney described the clinical manifestations of acute appendicitis including the point of maximum tenderness in the right iliac fossa that now bears his name.

The incidence of appendicitis seems to have risen greatly in the first half of this century, particularly in Europe, America and Australasia, with up to 16% of the population undergoing appendicectomy. In the past 30 years, the incidence has fallen dramatically in these countries, such that the individual lifetime risk of appendicectomy is 8.6% and 6.7% among males and females respectively.

Reginald Heber Fitz, 1843–1913, Professor of Medicine, Harvard University, Boston, MA, USA.

Charles McBurney, 1854–1913, Professor of Surgery, Columbia College of Physicians and Surgeons, New York, NY, USA. In 1889 McBurney published a paper on appendicitis in which he stated 'I believe that in every case the seat of greatest pain "determined by the pressure of one finger" has been very exactly between an inch and a half and two inches from the anterior spirous process of the ilium on a straight line drawn from that process to the umbilicus.'

Acute appendicitis is relatively rare in infants, and becomes increasingly common in childhood and early adult life, reaching a peak incidence in the teens and early 20s. After middle age, the risk of developing appendicitis is quite small. The incidence of appendicitis is equal among males and females before puberty. In teenagers and young adults, the male–female ratio increases to 3:2 at age 25; thereafter, the greater incidence in males declines.

Aetiology

There is no unifying hypothesis regarding the aetiology of acute appendicitis. Decreased dietary fibre and increased consumption of refined carbohydrates may be important. As with colonic diverticulitis, the incidence of appendicitis is lowest in societies with a high dietary fibre intake. In developing countries that are adopting a more refined western-type diet, the incidence continues to rise. This is in contrast to the dramatic decrease in the incidence of appendicitis in western countries observed in the past 30 years. No reason has been established for these paradoxical changes; however, improved hygiene and a change in the pattern of childhood gastrointestinal infection related to the increased use of antibiotics may be responsible.

While appendicitis is clearly associated with bacterial proliferation within the appendix, no single organism is responsible. A mixed growth of aerobic and anaerobic organisms is usual. The initiating event causing bacterial proliferation is controversial. Obstruction of the appendix lumen has been widely held to be important, and some form of luminal obstruction, either by a faecolith or a stricture, is found in the majority of cases.

A faecolith is composed of inspissated faecal material, calcium phosphates, bacteria and epithelial debris (Fig. 67.5). Rarely, a foreign body is incorporated into the mass. The incidental finding of a faecolith is a relative indication for prophylactic appendicectomy (Fig. 67.6). A fibrotic stricture of the appendix usually indicates

Figure 67.5 Colonoscopic view of the lumen of the appendix showing intraluminal debris (courtesy of Mr D. Winter, FRCSI, Dublin, Ireland).

Figure 67.6 Supine abdominal radiograph showing the presence of a large faecolith in the right iliac fossa (arrow).

previous appendicitis that resolved without surgical intervention (Fig. 67.7). Obstruction of the appendiceal orifice by tumour, particularly carcinoma of the caecum, is an occasional cause of acute appendicitis in middle-aged and elderly patients. Intestinal parasites, particularly *Oxyuris vermicularis* (pinworm), can proliferate in the appendix and occlude the lumen.

Pathology

Obstruction of the appendiceal lumen seems to be essential for the development of appendiceal gangrene and perforation. Yet, in many cases of early appendicitis, the appendix lumen is patent despite the presence of mucosal inflammation and lymphoid hyperplasia. Occasional clustering of cases among children and young adults suggests an infective agent, possibly viral, which initiates an inflammatory response. Seasonal variation in the incidence is also observed, with more cases occurring between May and August in northern Europe than at other times of the year.

Lymphoid hyperplasia narrows the lumen of the appendix, leading to luminal obstruction. Once obstruction occurs, continued mucus secretion and inflammatory exudation increase intraluminal pressure, obstructing lymphatic drainage. Oedema and mucosal ulceration develop with bacterial translocation to the submucosa. Resolution may occur at this point either spontaneously or in response to antibiotic therapy. If the condition

Figure 67.7 Barium enema radiograph demonstrating faecoliths of the appendix (arrow) with distal stricture of the appendix.

progresses, further distension of the appendix may cause venous obstruction and ischaemia of the appendix wall. With ischaemia, bacterial invasion occurs through the muscularis propria and submucosa, producing acute appendicitis (Fig. 67.8). Finally, ischaemic necrosis of the appendix wall produces gangrenous appendicitis, with free bacterial contamination of the peritoneal cavity. Alternatively, the greater omentum and loops of small bowel become adherent to the inflamed appendix, walling off the spread of peritoneal contamination, and resulting in a phlegmonous mass or paracaecal abscess. Rarely, appendiceal inflammation resolves, leaving a distended mucus-filled organ termed a mucocele of the appendix (Fig. 67.9).

It is the potential for peritonitis that is the great threat of acute appendicitis. Peritonitis occurs as a result of free migration of bacteria through an ischaemic appendicular wall, the frank perforation of a gangrenous appendix or the delayed perforation of an appendix abscess. Factors that promote this process include extremes of age, immunosuppression, diabetes mellitus and faecolith obstruction of the appendix lumen, a free-lying pelvic appendix and previous abdominal surgery that limits the ability of the greater omentum to wall off the spread of peritoneal contamination. In these situations, a rapidly deteriorating clinical course is accompanied by signs of diffuse peritonitis and systemic sepsis syndrome (Summary box 67.1).

Figure 67.8 Acute appendicitis. A heavy acute inflammatory infiltrate extends through the full thickness of the wall of the appendix, destroying the mucosa, of which only a small island (M) remains, and the smooth muscle. The inflammation extends to involve the serosa (S) (courtesy of Dr P. Kelly, FRCPath, Dublin, Ireland).

- Pelvic appendix
- Previous abdominal surgery

Clinical diagnosis

History

The classical features of acute appendicitis begin with poorly localised colicky abdominal pain. This is due to mid-gut visceral discomfort in response to appendiceal inflammation and obstruction. The pain is frequently first noticed in the peri-umbilical region and is similar to, but less intense than, the colic of small bowel obstruction. Central abdominal pain is associated with anorexia, nausea and usually one or two episodes of vomiting that follow the onset of pain (Murphy). Anorexia is a useful and

John Benjamin Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, IL, USA.

constant clinical feature, particularly in children. The patient often gives a history of similar discomfort that settled spontaneously. A family history is also useful as up to one-third of children with appendicitis have a first-degree relative with a similar history (Summary box 67.2).

Summary box 67.2

Symptoms of appendicitis

- Peri-umbilical colic
- Pain shifts to the right iliac fossa
- Anorexia
- Nausea

With progressive inflammation of the appendix, the parietal peritoneum in the right iliac fossa becomes irritated, producing more intense, constant and localised somatic pain that begins to predominate. Patients often report this as an abdominal pain that has shifted and changed in character. Typically, coughing or sudden movement exacerbates the right iliac fossa pain.

The classic visceral–somatic sequence of pain is present in only about half of those patients subsequently proven to have acute appendicitis. Atypical presentations include pain that is predominantly somatic or visceral and poorly localised. Atypical pain is more common in the elderly, in whom localisation to the right iliac fossa is unusual. An inflamed appendix in the pelvis may never produce somatic pain involving the anterior abdominal wall, but may instead cause suprapubic discomfort and tenesmus. In this circumstance, tenderness may be elicited only on rectal examination and is the basis for the recommendation that a rectal examination should be performed on every patient who presents with acute lower abdominal pain.

During the first 6 hours, there is rarely any alteration in temperature or pulse rate. After that time, slight pyrexia (37.2–37.7°C) with a corresponding increase in the pulse rate to 80 or 90 is usual. However, in 20% of patients, there is no pyrexia or tachycardia in the early stages. In children, a temperature greater than 38.5°C suggests other causes, e.g. mesenteric adenitis (see below).

Typically, two clinical syndromes of acute appendicitis can be discerned, *acute catarrhal (non-obstructive)* appendicitis and *acute obstructive* appendicitis. The latter is characterised by a much more acute course. The onset of symptoms is abrupt, and there may be generalised abdominal pain from the start. The temperature may be normal and vomiting is common, so that the clinical picture may mimic acute intestinal obstruction. Once recognised, urgent surgical intervention is required because of the more rapid progression to perforation.

Signs

The diagnosis of appendicitis rests more on thorough clinical examination of the abdomen than on any aspect of the history or laboratory investigation. The cardinal features are those of an unwell patient with low-grade pyrexia, localised abdominal tenderness, muscle guarding and rebound tenderness. Inspection of the abdomen may show limitation of respiratory movement in the lower abdomen. The patient is then asked to point to where the pain began and where it moved (the pointing sign). Gentle superficial palpation of the abdomen, beginning in the left iliac fossa moving anticlockwise to the right iliac fossa will detect muscle

guarding over the point of maximum tenderness, classically McBurney's point. Asking the patient to cough or gentle percussion over the site of maximum tenderness will elicit rebound tenderness (Summary box 67.3).

Summary box 67.3

Clinical signs in appendicitis

- Pyrexia
- Localised tenderness in the right iliac fossa
- Muscle guarding
- Rebound tenderness

Deep palpation of the left iliac fossa may cause pain in the right iliac fossa, Rovsing's sign, which is helpful in supporting a clinical diagnosis of appendicitis. Occasionally, an inflamed appendix lies on the psoas muscle, and the patient, often a young adult, will lie with the right hip flexed for pain relief (the psoas sign). Spasm of the obturator internus is sometimes demonstrable when the hip is flexed and internally rotated. If an inflamed appendix is in contact with the obturator internus, this manoeuvre will cause pain in the hypogastrium (the obturator test; Zachary Cope). Cutaneous hyperaesthesia may be demonstrable in the right iliac fossa, but is rarely of diagnostic value (Summary box 67.4).

Summary box 67.4

Signs to elicit in appendicitis

- Pointing sign
- Rovsing's sign
- Psoas sign
- Obturator sign

Special features, according to position of the appendix

Retrocaecal

Rigidity is often absent, and even application of deep pressure may fail to elicit tenderness (silent appendix), the reason being that the caecum, distended with gas, prevents the pressure exerted by the hand from reaching the inflamed structure. However, deep tenderness is often present in the loin, and rigidity of the quadratus lumborum may be in evidence. Psoas spasm, due to the inflamed appendix being in contact with that muscle, may be sufficient to cause flexion of the hip joint. Hyperextension of the hip joint may induce abdominal pain when the degree of psoas spasm is insufficient to cause flexion of the hip.

Pelvic

Occasionally, early diarrhoea results from an inflamed appendix being in contact with the rectum. When the appendix lies entirely within the pelvis, there is usually complete absence of abdominal rigidity, and often tenderness over McBurney's point is also lacking. In some instances, deep tenderness can be made out just above and to the right of the symphysis pubis. In either event,

Thorikild Rovsing, 1862–1937, Professor of Surgery, Copenhagen, Denmark.
Sir Vincent Zachary Cope, 1881–1975, Surgeon, St. Mary's Hospital, London, England.

a rectal examination reveals tenderness in the rectovesical pouch or the pouch of Douglas, especially on the right side. Spasm of the psoas and obturator internus muscles may be present when the appendix is in this position. An inflamed appendix in contact with the bladder may cause frequency of micturition. This is more common in children.

Postileal

In this case, the inflamed appendix lies behind the terminal ileum. It presents the greatest difficulty in diagnosis because the pain may not shift, diarrhoea is a feature and marked retching may occur. Tenderness, if any, is ill defined, although it may be present immediately to the right of the umbilicus.

Special features, according to age

Infants

Appendicitis is relatively rare in infants under 36 months of age and, for obvious reasons, the patient is unable to give a history. Because of this, diagnosis is often delayed, and thus the incidence of perforation and postoperative morbidity is considerably higher than in older children. Diffuse peritonitis can develop rapidly because of the underdeveloped greater omentum, which is unable to give much assistance in localising the infection.

Children

It is rare to find a child with appendicitis who has not vomited. Children with appendicitis usually have complete aversion to food.

The elderly

Gangrene and perforation occur much more frequently in elderly patients. Elderly patients with lax abdominal walls or obesity may harbour a gangrenous appendix with little evidence of it, and the clinical picture may simulate subacute intestinal obstruction. These features, coupled with coincident medical conditions, produce a much higher mortality for acute appendicitis in the elderly.

The obese

Obesity can obscure and diminish all the local signs of acute appendicitis. Delay in diagnosis, coupled with the technical difficulty of operating in the obese, makes it wiser to consider operating through a midline abdominal incision. Laparoscopy is particularly useful in the obese as it may obviate the need for a large abdominal incision.

Pregnancy

Appendicitis is the most common extrauterine acute abdominal condition in pregnancy, with a frequency of 1:1500–2000 pregnancies. Diagnosis is complicated by delay in presentation as early non-specific symptoms are often attributed to the pregnancy. Obstetric teaching has been that the caecum and appendix are progressively pushed to the right upper quadrant of the abdomen as pregnancy develops during the second and third trimesters. However, pain in the right lower quadrant of the abdomen remains the cardinal feature of appendicitis in pregnancy. Fetal loss occurs in 3–5% of cases, increasing to 20% if perforation is found at operation.

Differential diagnosis

Although acute appendicitis is the most common abdominal surgical emergency, the diagnosis can be extremely difficult at times. There are a number of common conditions that it is wise to consider carefully and, if possible, exclude. The differential diagnosis differs in patients of different ages; in women, additional differential diagnoses are diseases of the female genital tract (Table 67.1).

Children

The diseases most commonly mistaken for acute appendicitis are *acute gastroenteritis* and *mesenteric lymphadenitis*. In mesenteric lymphadenitis, the pain is colicky in nature and cervical lymph nodes may be enlarged. It may be impossible to clinically distinguish *Meckel's diverticulitis* from acute appendicitis. The pain is similar; however, signs may be central or left sided. Occasionally, there is a history of antecedent abdominal pain or intermittent lower gastrointestinal bleeding.

It is important to distinguish between acute appendicitis and *intussusception*. Appendicitis is uncommon before the age of 2 years, whereas the median age for intussusception is 18 months. A mass may be palpable in the right lower quadrant, and the preferred treatment of intussusception is reduction by careful barium enema.

Henoch–Schönlein purpura is often preceded by a sore throat or respiratory infection. Abdominal pain can be severe and can be confused with intussusception or appendicitis. There is nearly always an ecchymotic rash, typically affecting the extensor surfaces of the limbs and on the buttocks. The face is usually spared. The platelet count and bleeding time are within normal limits. Microscopic haematuria is common.

Lobar pneumonia and pleurisy, especially at the right base,

Table 67.1 Differential diagnosis of acute appendicitis

Children	Adult	Adult female	Elderly
Gastroenteritis	Regional enteritis	Mittelschmerz	Diverticulitis
Mesenteric adenitis	Ureteric colic	Pelvic inflammatory disease	Intestinal obstruction
Meckel's diverticulitis	Perforated peptic ulcer	Pyelonephritis	Colonic carcinoma
Intussusception	Torsion of testis	Ectopic pregnancy	Torsion appendix epiploicae
Henoch–Schönlein purpura	Pancreatitis	Torsion/rupture of ovarian cyst	Mesenteric infarction
Lobar pneumonia	Rectus sheath haematoma	Endometriosis	Leaking aortic aneurysm

James Douglas, 1675–1742, Anatomist and Man-midwife who practised in London, England, described this pouch in 1730.

Johann Friedrich Meckel, 1781–1883, Professor of Anatomy and Surgery, Halle, Germany.

Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.

Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, described this form of purpura in 1837.

may give rise to right-sided abdominal pain and mimic appendicitis. Abdominal tenderness is minimal, pyrexia is marked, and chest examination may reveal a pleural friction rub or altered breath sounds on auscultation. A chest radiograph is diagnostic.

Adults

Terminal ileitis in its acute form may be indistinguishable from acute appendicitis unless a doughy mass of inflamed ileum can be felt. An antecedent history of abdominal cramping, weight loss and diarrhoea suggests regional ileitis rather than appendicitis. The ileitis may be non-specific, due to Crohn's disease or *Yersinia* infection. *Yersinia enterocolitica* causes inflammation of the terminal ileum, appendix and caecum with mesenteric adenopathy. If suspected, serum antibody titres are diagnostic, and treatment with intravenous tetracycline is appropriate. If *Yersinia* infection is suspected at operation, a mesenteric lymph node should be excised and divided, with half submitted for microbiological culture (including tuberculosis) and half for histological examination.

Ureteric colic does not commonly cause diagnostic difficulty, as the character and radiation of pain differs from that of appendicitis. Urinalysis should always be performed, and the presence of red cells should prompt a supine abdominal radiograph. Renal ultrasound or intravenous urogram is diagnostic.

Right-sided acute pyelonephritis is accompanied and often preceded by increased frequency of micturition. It may cause difficulty in diagnosis, especially in women. The leading features are tenderness confined to the loin, fever (temperature 39°C) and possibly rigors and pyuria.

In perforated peptic ulcer, the duodenal contents pass along the paracolic gutter to the right iliac fossa. As a rule, there is a history of dyspepsia and a very sudden onset of pain that starts in the epigastrium and passes down the right paracolic gutter. In appendicitis, the pain starts classically in the umbilical region. Rigidity and tenderness in the right iliac fossa are present in both conditions but, in perforated duodenal ulcer, the rigidity is usually greater in the right hypochondrium. An erect chest radiograph will show gas under the diaphragm in 70% of patients. An abdominal computerised tomography (CT) examination is valuable when there is diagnostic difficulty.

Testicular torsion in a teenage or young adult male is easily missed. Pain can be referred to the right iliac fossa, and shyness on the part of the patient may lead the unwary to suspect appendicitis unless the scrotum is examined in all cases.

Acute pancreatitis should be considered in the differential diagnosis of all adults suspected of having acute appendicitis and, when appropriate, should be excluded by serum or urinary amylase measurement.

Rectus sheath haematoma is a relatively rare but easily missed differential diagnosis. It usually presents with acute pain and localised tenderness in the right iliac fossa, often after an episode of strenuous physical exercise. Localised pain without gastrointestinal upset is the rule. Occasionally, in an elderly patient, particularly one taking anticoagulant therapy, a rectus sheath haematoma may present as a mass and tenderness in the right iliac fossa after minor trauma.

Adult female (see also Chapter 76)

It is in women of childbearing age that pelvic disease most often mimics acute appendicitis. A careful gynaecological history should be taken in all women with suspected appendicitis, concentrating on menstrual cycle, vaginal discharge and possible pregnancy. The most common diagnostic mimics are pelvic inflammatory disease (PID), Mittelschmerz, torsion or haemorrhage of an ovarian cyst and ectopic pregnancy.

Pelvic inflammatory disease

PID comprises a spectrum of diseases that include salpingitis, endometritis and tubo-ovarian sepsis. The incidence of these conditions is increasing, and the diagnosis should be considered in every young adult female. Typically, the pain is lower than in appendicitis and is bilateral. A history of vaginal discharge, dysmenorrhoea and burning pain on micturition is a helpful differential diagnostic point. The physical findings include adenexal and cervical tenderness on vaginal examination. When suspected, a high vaginal swab should be taken for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* culture, and the opinion of a gynaecologist should be obtained. Treatment is usually a combination of ofloxacin and metronidazole. Transvaginal ultrasound can be particularly helpful in establishing the diagnosis. When serious diagnostic uncertainty persists, diagnostic laparoscopy should be undertaken.

Mittelschmerz

Midcycle rupture of a follicular cyst with bleeding produces lower abdominal and pelvic pain, typically midcycle. Systemic upset is rare, a pregnancy test is negative, and symptoms usually subside within hours. Occasionally, diagnostic laparoscopy is required. Retrograde menstruation may cause similar symptoms.

Torsion/haemorrhage of an ovarian cyst

This can prove a difficult differential diagnosis. When suspected, pelvic ultrasound and a gynaecological opinion should be sought. If encountered at operation, untwisting of the involved adnexa and ovarian cystectomy should be performed, if necessary, in women of childbearing years. Documented visualisation of the contralateral ovary is an essential medico-legal precaution prior to oophorectomy for any reason.

Ectopic pregnancy

It is unlikely that a ruptured ectopic pregnancy, with its well-defined signs of haemoperitoneum, will be mistaken for acute appendicitis, but the same cannot be said for a right-sided tubal abortion, or still more for a right-sided unruptured tubal pregnancy. In the latter, the signs are very similar to those of acute appendicitis, except that the pain commences on the right side and stays there. The pain is severe and continues unabated until operation. Usually, there is a history of a missed menstrual period, and a urinary pregnancy test may be positive. Severe pain is felt when the cervix is moved on vaginal examination. Signs of intraperitoneal bleeding usually become apparent, and the patient should be questioned specifically regarding referred pain in the shoulder. Pelvic ultrasonography should be carried out in all cases in which an ectopic pregnancy is a possible diagnosis.

Elderly

Sigmoid diverticulitis

In some patients with a long sigmoid loop, the colon lies to the right of the midline, and it may be impossible to differentiate between

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.
Alexandre Emile Yersin, 1863–1943, Bacteriologist, Paris, France.

diverticulitis and appendicitis. Abdominal CT scanning is particularly useful in this setting and should be considered in the management of all patients over the age of 60 years. A trial of conservative management with intravenous fluids and antibiotics is often appropriate, with a low threshold for exploratory laparotomy in the face of deterioration or lack of clinical response.

Intestinal obstruction

The diagnosis of intestinal obstruction is usually clear; the subtlety lies in recognising acute appendicitis as the occasional cause in the elderly. As with diverticulitis, intravenous fluids, antibiotics and nasogastric decompression should be instigated, with early resort to laparotomy.

Carcinoma of the caecum

When obstructed or locally perforated, carcinoma of the caecum may mimic or cause obstructive appendicitis in adults. A history of antecedent discomfort, altered bowel habit or unexplained anaemia should raise suspicion. A mass may be palpable (see below) and barium enema diagnostic.

Rare differential diagnoses

Preherpetic pain of the right 10th and 11th dorsal nerves is localised over the same area as that of appendicitis. It does not shift and is associated with marked hyperaesthesia. There is no intestinal upset or rigidity. The herpetic eruption may be delayed for 3–8 hours.

Tabetic crises are now rare. Severe abdominal pain and vomiting usher in the crisis. Other signs of tabes confirm the diagnosis.

Spinal conditions are sometimes associated with acute abdominal pain especially in children and the elderly. These may include tuberculosis of the spine, metastatic carcinoma, osteoporotic vertebral collapse and multiple myeloma. The pain is due to compression of nerve roots and may be aggravated by movement. There is rigidity of the lumbar spine and intestinal symptoms are absent.

The abdominal crises of *porphyria* and *diabetes mellitus* need to be remembered. A urinalysis should be undertaken in every abdominal emergency. In cyclical vomiting of infants or young children, there is a history of previous similar attacks and abdominal rigidity is absent. Acetone is found in the urine but is not diagnostic as it may accompany starvation.

Typhlitis or leukaemic ileocaecal syndrome is a rare but potentially fatal enterocolitis occurring in immunosuppressed patients. Gram-negative or *clostridial* (especially *Clostridium septicum*) *septicaemia* can be rapidly progressive. Treatment is with appropriate antibiotics and haematopoietic factors. Surgical intervention is rarely indicated.

Investigation

The diagnosis of acute appendicitis is essentially clinical; however, a decision to operate based on clinical suspicion alone can lead to the removal of a normal appendix in 15–30% of cases. The premise that it is better to remove a normal appendix than to delay diagnosis does not stand up to close scrutiny, particularly in the elderly. A number of clinical and laboratory-based scoring systems have been devised to assist diagnosis. The most widely used is the Alvarado score (Table 67.2). A score of 7 or more is strongly predictive of acute appendicitis.

Alfredo Alvarado, Contemporary, Surgeon, Plantation, FL, USA.

Table 67.2 The Alvarado (MANTRELS) score

Symptoms	Score

In patients with an equivocal score (5–6), abdominal ultrasound or contrast-enhanced CT examination further reduces the rate of negative appendectomy. Abdominal ultrasound examination is more useful in children and thin adults, particularly if gynaecological pathology is suspected, with a diagnostic accuracy in excess of 90% (Fig. 67.10). Contrast-enhanced CT scan (Fig. 67.11) is most useful in patients in whom there is diagnostic uncertainty, particularly older patients, in whom acute diverticulitis, intestinal obstruction and neoplasm are likely differential diagnoses. Selective use of CT scanning may be cost-effective by reducing both the negative appendectomy rate and the length of hospital stay (Summary box 67.5).

Summary box 67.5

Preoperative investigations in appendicitis

Routine

- Full blood count
- Urinalysis

Selective

- Pregnancy test
- Urea and electrolytes
- Supine abdominal radiograph
- Ultrasound of the abdomen/pelvis
- Contrast-enhanced CT scan of the abdomen

Treatment

The treatment for acute appendicitis is appendectomy. There is a perception that urgent operation is essential to prevent the increased morbidity and mortality of peritonitis. While there should be no unnecessary delay, all patients, particularly those most at risk of serious morbidity, benefit by a short period of intensive preoperative preparation. Intravenous fluids, sufficient to establish adequate urine output (catheterisation is needed only in the very ill), and appropriate antibiotics should be given. There is ample evidence that a single preoperative dose of antibiotics reduces the incidence of postoperative wound infection. When peritonitis is suspected, therapeutic intravenous antibiotics to cover Gram-negative bacilli as well as anaerobic cocci should be given. Hyperpyrexia in children should be treated with salicylates

Figure 67.10 Abdominal ultrasound examination showing features of acute appendicitis, distended oedematous appendix (open arrows), longitudinal scan (left) and transverse scan (right). A faecolith is seen (closed arrow) (courtesy of Dr M. Behan, FRCR, Dublin, Ireland).

Figure 67.11 Abdominal contrast-enhanced computerised tomography scan showing a faecolith (open arrow) at the base of a distended (> 0.6 cm) appendix with intramural gas (white arrows) (courtesy of Dr H. Fenlon, FRCR, Dublin, Ireland).

in addition to antibiotics and intravenous fluids. With appropriate use of intravenous fluids and parenteral antibiotics, a policy of deferring appendicectomy after midnight to the first case on the following morning does not increase morbidity. However, when acute obstructive appendicitis is recognised, operation should not be deferred longer than it takes to optimise the patient's condition.

Appendicectomy

Claudius Amyand successfully removed an acutely inflamed appendix from the hernial sac of a boy in 1736. The first surgeon to perform deliberate appendicectomy for acute appendicitis was Lawson Tait in May 1880. The patient recovered; however, the

Claudius Amyand, 1685–1740, Surgeon, St. George's Hospital, London, England.
Robert Lawson Tait, 1845–1899, Surgeon, The Hospital for Diseases of Women, Birmingham, England.

case was not reported until 1890. Meanwhile, Thomas Morton was the first to diagnose appendicitis, drain the abscess and remove the appendix with recovery, publishing his findings in 1887.

Appendicectomy should be performed under general anaesthetic with the patient supine on the operating table. When a laparoscopic technique is to be used, the bladder must be empty (ensure that the patient has voided before leaving the ward). Prior to preparing the entire abdomen with an appropriate antiseptic solution, the right iliac fossa should be palpated for a mass. If a mass is felt, it may, on occasion, be preferable to adopt a conservative approach (see below). Draping of the abdomen is in accordance with the planned operative technique, taking account of any requirement to extend the incision or convert a laparoscopic technique to an open operation.

Conventional appendicectomy

When the preoperative diagnosis is considered reasonably certain, the incision that is widely used for appendicectomy is the so called gridiron incision (gridiron: a frame of cross-beams to support a ship during repairs). The gridiron incision (described first by McArthur) is made at right angles to a line joining the anterior superior iliac spine to the umbilicus, its centre being along the line at McBurney's point (Fig. 67.12). If better access is required, it is possible to convert the gridiron to a Rutherford Morison incision (see below) by cutting the internal oblique and transversus muscles in the line of the incision.

In recent years, a transverse skin crease (Lanz) incision has become more popular, as the exposure is better and extension, when needed, is easier. The incision, appropriate in length to the size and obesity of the patient, is made approximately 2 cm below the umbilicus centred on the mid-clavicular–midinguinal line (Fig. 67.13). When necessary, the incision may be extended medially, with retraction or suitable division of the rectus abdominis muscle.

Figure 67.12 Gridiron incision for appendicitis, at right angles to a line joining the anterior superior iliac spine and umbilicus, centred on McBurney's point (courtesy of Mr M. Earley, FRSCI, Dublin, Ireland).

Thomas George Morton, 1835–1903, Surgeon, Philadelphia, PA, USA.
Lewis Linn McArthur, 1858–1934, Surgeon, St. Luke's Hospital, Chicago, IL, USA.
James Rutherford Morison, 1853–1939, Professor of Surgery, The University of Durham, Durham, England.
Otto Lanz, 1865–1935, Surgeon, Amsterdam, The Netherlands.

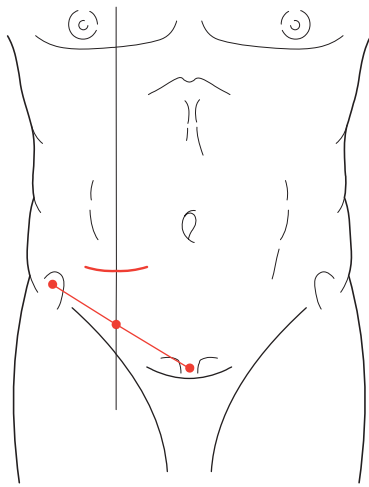

Figure 67.13 Transverse or skin crease (Lanz) incision for appendicitis, 2 cm below the umbilicus, centred on the mid-clavicular-midinguinal line (courtesy of Mr M. Earley, FRSCI, Dublin, Ireland).

When the diagnosis is in doubt, particularly in the presence of intestinal obstruction, a lower midline abdominal incision is to be preferred over a right lower paramedian incision. The latter, although widely practised in the past, is difficult to extend, more difficult to close and provides poorer access to the pelvis and peritoneal cavity.

Rutherford Morison's incision is useful if the appendix is para- or retrocaecal and fixed. It is essentially an oblique muscle-cutting incision with its lower end over McBurney's point and extending obliquely upwards and laterally as necessary. All layers are divided in the line of the incision.

Removal of the appendix

The caecum is identified by the presence of taeniae coli and, using a finger or a swab, the caecum is withdrawn. A turgid appendix may be felt at the base of the caecum. Inflammatory adhesions must be gently broken with a finger, which is then hooked around the appendix to deliver it into the wound. The appendix is conveniently controlled using a Babcock or Lane's forceps applied in such a way as to encircle the appendix and yet not damage it. The base of the mesoappendix is clamped in artery forceps, divided and ligated (Fig. 67.14a). When the mesoappendix is broad, the procedure must be repeated with a second or, rarely, a third artery forceps. The appendix, now completely freed, is crushed near its junction with the caecum in artery forceps, which is removed and reapplied just distal to the crushed portion. An absorbable 2/0 ligature is tied around the crushed portion close to the caecum. The appendix is amputated between the artery forceps and the ligature (Fig. 67.14b). An absorbable 2/0 or 3/0 purse-string or 'Z' suture may then be inserted into the caecum about 1.25 cm from the base (Fig. 67.14c). The stitch should pass through the muscle coat, picking up the taeniae coli. The stump of the appendix is invaginated (Fig. 67.14d) while the purse-string or 'Z' suture is tied, thus burying the appendix stump. Many surgeons believe invagination of the appendiceal stump is unnecessary.

William Wayne Babcock, 1872–1963, Surgeon, Philadelphia, PA, USA.
Sir William Arbuthnot Lane, 1856–1943, Surgeon, Guy's Hospital, London, England.

Methods to be adopted in special circumstances

When the caecal wall is oedematous, the purse-string suture is in danger of cutting out. If the oedema is of limited extent, this can be overcome by inserting the purse-string suture into more healthy caecal wall at a greater distance from the base of the appendix. Occasions may arise when, because of the extensive oedema of the caecal wall, it is better not to attempt invagination.

When the base of the appendix is inflamed, it should not be crushed, but ligated close to the caecal wall just tightly enough to occlude the lumen, after which the appendix is amputated and the stump invaginated. Should the base of the appendix be gangrenous, neither crushing nor ligation should be attempted. Two stitches are placed through the caecal wall close to the base of the gangrenous appendix, which is amputated flush with the caecal wall, after which these stitches are tied. Further closure is effected by means of a second layer of interrupted seromuscular sutures.

Retrograde appendicectomy

When the appendix is retrocaecal and adherent, it is an advantage to divide the base between artery forceps. The appendiceal vessels are then ligated, the stump ligated and invaginated, and gentle traction on the caecum will enable the surgeon to deliver the body of the appendix, which is then removed from base to tip. Occasionally, this manoeuvre requires division of the lateral peritoneal attachments of the caecum.

Drainage of the peritoneal cavity

This is usually unnecessary provided adequate peritoneal toilet has been done. If, however, there is considerable purulent fluid in the retrocaecal space or the pelvis, a soft silastic drain may be inserted through a separate stab incision. The wound should be closed using absorbable sutures to oppose muscles and aponeurosis.

Laparoscopic appendicectomy

The most valuable aspect of laparoscopy in the management of suspected appendicitis is as a diagnostic tool, particularly in women of child-bearing age. The placement of operating ports may vary according to operator preference and previous abdominal scars. The operator stands to the patient's left and faces a video monitor placed at the patient's right foot (Fig. 67.15). A moderate Trendelenburg tilt of the operating table assists delivery of loops of small bowel from the pelvis. The appendix is found in the conventional manner by identification of the caecal taeniae and is controlled using a laparoscopic tissue-holding forceps. By elevating the appendix, the mesoappendix is displayed (Fig. 67.16a). A dissecting forceps is used to create a window in the mesoappendix to allow the appendicular vessels to be coagulated or ligated using a clip applicator. The appendix, free of its mesentery, can be ligated at its base with an absorbable loop ligature (Fig. 67.16b), divided (Fig. 67.16c) and removed through one of the operating ports. It is not usual to invert the stump of the appendix (Fig. 67.16d). A single absorbable suture is used to close the linea alba at the umbilicus, and the small skin incisions may be closed with subcuticular sutures.

Patients who undergo laparoscopic appendicectomy are likely to have less postoperative pain and to be discharged from hospital and return to activities of daily living sooner than those who have undergone open appendicectomy. While the incidence of

Figure 67.14 (a) Mesoappendix divided between artery forceps and ligated. (b) Appendix crushed and ligated at its base and about to be divided. (c) 'Z' suture inserted prior to inversion of the appendiceal stump. (d) Appendiceal stump inverted, the 'Z' suture having been tied.

postoperative wound infection is lower after the laparoscopic technique, the incidence of postoperative intra-abdominal sepsis may be higher in patients operated on for gangrenous or perforated appendicitis. There may be an advantage for laparoscopic over open appendicectomy in obese patients.

Problems encountered during appendicectomy

A normal appendix is found

This demands careful exclusion of other possible diagnoses, particularly terminal ileitis, Meckel's diverticulitis and tubal or ovarian causes in women. It is usual to remove the appendix to avoid future diagnostic difficulties, even though the appendix is macroscopically normal, particularly if a skin crease or gridiron incision has been made. A case can be made for preserving the macroscopically normal appendix seen at diagnostic laparoscopy, although approximately one-quarter of seemingly normal appendices show microscopic evidence of inflammation.

The appendix cannot be found

The caecum should be mobilised, and the taenia coli should be traced to their confluence on the caecum before the diagnosis of 'absent appendix' is made.

An appendicular tumour is found

Small tumours (under 2.0 cm in diameter) can be removed by appendicectomy; larger tumours should be treated by a right hemicolectomy.

An appendix abscess is found and the appendix cannot be removed easily

This should be treated by local peritoneal toilet, drainage of any abscess and intravenous antibiotics. Very rarely, a caecectomy or

Figure 67.15 Position of surgeon, assistants and equipment for laparoscopic appendicectomy.

Figure 67.16 Laparoscopic appendectomy. (a) Mesoappendix displayed. (b) Ligation at the base of the appendix. (c) Division of base. (d) Appendectomy complete (courtesy of Mr O. McAnena, FRCSI, Galway, Ireland).

partial right hemicolectomy is required. (The first recorded operation for an appendix abscess was by Henry Hancock of Charing Cross Hospital, London, in 1848.)

Appendicitis complicating Crohn's disease

Occasionally, a patient undergoing surgery for acute appendicitis is found to have concomitant Crohn's disease of the ileocaecal region. Providing that the caecal wall is healthy at the base of the appendix, appendectomy can be performed without increasing the risk of an enterocutaneous fistula. Rarely, the appendix is involved with the Crohn's disease. In this situation, a conservative approach may be warranted, and a trial of intravenous corticosteroids and systemic antibiotics can be used to resolve the acute inflammatory process.

Appendix abscess

Failure of resolution of an appendix mass or continued spiking pyrexia usually indicates that there is pus within the phlegmonous appendix mass. Ultrasound or abdominal CT scan may identify an area suitable for the insertion of a percutaneous drain. Should this prove unsuccessful, laparotomy through a midline incision is indicated.

Pelvic abscess

Pelvic abscess formation is an occasional complication of appendicitis and can occur irrespective of the position of the appendix within the peritoneal cavity. The most common presentation is a spiking pyrexia several days after appendicitis; indeed, the patient may already have been discharged from hospital. Pelvic pressure or discomfort associated with loose stool or tenesmus is common. Rectal examination reveals a boggy mass in the pelvis, anterior to the rectum, at the level of the peritoneal reflection (Fig. 67.17). Pelvic ultrasound or CT scan will confirm. Treatment is transrectal drainage under general anaesthetic.

Management of an appendix mass

If an appendix mass is present and the condition of the patient is satisfactory, the standard treatment is the conservative Ochsner–Sherren regimen. This strategy is based on the premise that the inflammatory process is already localised and that

Albert John Ochsner, 1858–1925, Professor of Clinical Surgery, The University of Illinois College of Medicine, Chicago, IL, USA.
James Sherren, 1872–1945, Surgeon, The London Hospital, London, England.

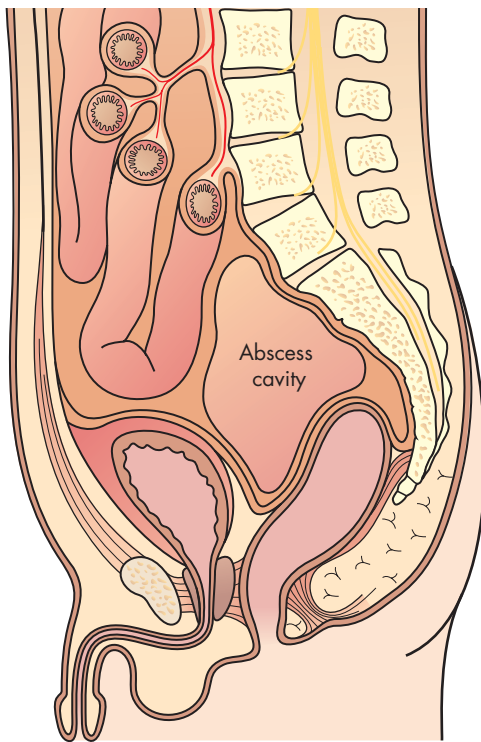

Figure 67.17 Appendix abscess involving the pelvis. Note the relationship to the rectum.

inadvertent surgery is difficult and may be dangerous. It may be impossible to find the appendix and, occasionally, a faecal fistula may form. For these reasons, it is wise to observe a non-operative programme but to be prepared to operate should clinical deterioration occur (Summary box 67.6).

Summary box 67.6

Criteria for stopping conservative treatment of an appendix mass

- A rising pulse rate
- Increasing or spreading abdominal pain
- Increasing size of the mass

Careful recording of the patient's condition and the extent of the mass should be made and the abdomen regularly re-examined. It is helpful to mark the limits of the mass on the abdominal wall using a skin pencil. A contrast-enhanced CT examination of the abdomen should be performed and antibiotic therapy instigated. An abscess, if present, should be drained radiologically. Temperature and pulse rate should be recorded 4-hourly and a fluid balance record maintained. Clinical deterioration or evidence of peritonitis is an indication for early laparotomy. Clinical improvement is usually evident within 24–48 hours. Failure of the mass to resolve should raise suspicion of a carcinoma or Crohn's disease. Using this regimen, approximately 90% of cases resolve without incident. The great majority of patients will not develop recurrence, and it is no longer considered advisable to remove the appendix after an interval of 6–8 weeks.

Postoperative complications

Postoperative complications following appendicectomy are relatively uncommon and reflect the degree of peritonitis that was present at the time of operation and intercurrent diseases that may predispose to complications (Summary box 67.7).

Summary box 67.7

Check-list for unwell patient following appendicectomy

- Examine the wound and abdomen for an abscess
- Consider a pelvic abscess and perform a rectal examination
- Examine the lungs – pneumonitis or collapse
- Examine the legs – consider venous thrombosis
- Examine the conjunctivae for an icteric tinge and the liver for enlargement, and enquire whether the patient has had rigors (pylephlebitis)
- Examine the urine for organisms (pyelonephritis)
- Suspect subphrenic abscess

Wound infection

Wound infection is the most common postoperative complication, occurring in 5–10% of all patients. This usually presents with pain and erythema of the wound on the fourth or fifth postoperative day, often soon after hospital discharge. Treatment is by wound drainage and antibiotics when required. The organisms responsible are usually a mixture of Gram-negative bacilli and anaerobic bacteria, predominantly *Bacteroides* species and anaerobic streptococci.

Intra-abdominal abscess

Intra-abdominal abscess has become a relatively rare complication after appendicectomy with the use of perioperative antibiotics. Postoperative spiking fever, malaise and anorexia developing 5–7 days after operation suggest an intraperitoneal collection. Interloop, paracolic, pelvic and subphrenic sites should be considered. Abdominal ultrasonography and CT scanning greatly facilitate diagnosis and allow percutaneous drainage. Laparotomy should be considered in patients suspected of having intra-abdominal sepsis but in whom imaging fails to show a collection, particularly those with continuing ileus.

Ileus

A period of adynamic ileus is to be expected after appendicectomy, and this may last a number of days following removal of a gangrenous appendix. Ileus persisting for more than 4 or 5 days, particularly in the presence of a fever, is indicative of continuing intra-abdominal sepsis and should prompt further investigation (see above). Rarely, early during postoperative recovery, a Richter's type of hernia may occur at the site of a laparoscopic port insertion and may be confused with a postoperative ileus. A CT scan is usually definitive.

Respiratory

In the absence of concurrent pulmonary disease, respiratory complications are rare following appendicectomy. Adequate

August Gottlieb Richter, 1742–1812, Lecturer in Surgery, Göttingen, Germany.

postoperative analgesia and physiotherapy, when appropriate, reduce the incidence.

Venous thrombosis and embolism

These conditions are rare after appendicectomy, except in the elderly and in women taking the oral contraceptive pill. Appropriate prophylactic measures should be taken in such cases.

Portal pyaemia (pylephlebitis)

This is a rare but very serious complication of gangrenous appendicitis associated with high fever, rigors and jaundice. It is caused by septicaemia in the portal venous system and leads to the development of intrahepatic abscesses (often multiple). Treatment is with systemic antibiotics and percutaneous drainage of hepatic abscesses as appropriate.

Faecal fistula

Leakage from the appendicular stump occurs rarely, but may follow if the encircling stitch has been put in too deeply or if the caecal wall was involved by oedema or inflammation. Occasionally, a fistula may result following appendicectomy in Crohn's disease. Conservative management with low-residue enteral nutrition will usually result in closure.

Adhesive intestinal obstruction

This is the most common late complication of appendicectomy. At operation, a single band adhesion is often found to be responsible. Occasionally, chronic pain in the right iliac fossa is attributed to adhesion formation after appendicectomy. In such cases, laparoscopy is of value in confirming the presence of adhesions and allowing division.

Recurrent acute appendicitis

Appendicitis is notoriously recurrent. It is not uncommon for patients to attribute such attacks to 'biliousness' or dyspepsia. The attacks vary in intensity and may occur every few months, and the majority of cases ultimately culminate in severe acute appendicitis. If a careful history is taken from patients with acute appendicitis, many remember having had milder but similar attacks of pain. The appendix in these cases shows fibrosis indicative of previous inflammation (Fig. 67.18). Chronic appendicitis, per se, does not exist; however, there is evidence of altered neuroimmune function in the myenteric nerves of patients with so called recurrent appendicitis (Büchler).

Neoplasms of the appendix

Carcinoid tumour (synonym: argentaffinoma)

Carcinoid tumours arise in argentaffin tissue (Kulchitsky cells of the crypts of Lieberkühn) and are most common in the vermiform appendix. Carcinoid tumour is found once in every 300–400 appendices subjected to histological examination and is 10 times more common than any other neoplasm of the appendix. In many instances, the appendix had been removed because of symptoms of subacute or recurrent appendicitis. The tumour can occur in any part of the appendix, but it is frequently found in the distal third. The neoplasm feels moderately hard and, on sectioning the

Figure 67.18 Excised appendix showing the point of luminal obstruction with distal fibrosis.

appendix, it can be seen as a yellow tumour between the intact mucosa and the peritoneum. Microscopically, the tumour cells are small, arranged in small nests within the muscle and have a characteristic pattern using immunohistochemical stain for chromogranin B (Fig. 67.19). Unlike carcinoid tumours arising in other parts of the intestinal tract, carcinoid tumour of the appendix rarely gives rise to metastases. Appendicectomy has been shown to be sufficient treatment, unless the caecal wall is involved, the tumour is 2 cm or more in size or involved lymph nodes are found, when right hemicolectomy is indicated.

Primary adenocarcinoma

Primary adenocarcinoma of the appendix is extremely rare. It is usually of the colonic type and should be treated by right

Figure 67.19 Carcinoid tumour. A small incidental carcinoid tumour of the appendix. The tumour cells infiltrate the muscle arranged in small nests and trabeculae (arrows). Tumour cells are small and have inconspicuous nuclei. Inset: higher magnification of an immunohistochemical stain for chromogranin B shows a strong positive reaction (brown) of tumour cells (courtesy of Dr P. Kelly, FRCPATH, Dublin, Ireland).

Marcus Büchler, Contemporary, Professor of Surgery, Heidelberg, Germany.
Johann Nathaniel Lieberkühn, 1711–1756, Physician and Anatomist, Berlin, Germany, described these glands in 1745.

hemicolectomy (as a second-stage procedure if the condition is not recognised at the first operation). A mucus-secreting adenocarcinoma of the appendix may rupture into the peritoneal cavity, seeding it with mucus-secreting malignant cells. Presentation is often delayed until the patient has gross abdominal distension as a result of pseudomyxoma peritonei, which may mimic ascites. Treatment consists of radical resection of all involved parietal peritoneal surfaces and aggressive intraperitoneal chemotherapy (Sugarbaker).

The rectum

LEARNING OBJECTIVES

To understand:

- The anatomy of the rectum and its relationship to surgical disease and its treatment
- The pathology, clinical presentation, investigation, differential diagnosis and treatment of diseases that affect the rectum

To appreciate that:

- Carcinoma of the rectum is common and its symptoms are similar to those of benign disease and, hence, patients with such symptoms must be carefully evaluated

ANATOMY

Surgical anatomy

The rectum begins where the taenia coli of the sigmoid colon join to form a continuous outer longitudinal muscle layer at the level of the sacral promontory. The rectum follows the curve of the sacrum, to end at the anorectal junction. The puborectalis muscle encircles the posterior and lateral aspects of the junction, creating the anorectal angle (normally 120°). The rectum has three lateral curvatures: the upper and lower are convex to the right, and the middle is convex to the left. On the luminal aspect, these three curves are marked by semicircular folds (Houston's valves) (Fig. 68.1). That part of the rectum that lies below the middle valve has a much wider diameter than the upper third and is known as the ampulla of the rectum.

The adult rectum is approximately 12–18 cm in length and is conveniently divided into three equal parts: the upper third, which is mobile and has a peritoneal coat; the middle third where the peritoneum covers only the anterior and part of the lateral surfaces; and the lowest third, which lies deep in the pelvis surrounded by fatty mesorectum and has important relations to fascial layers.

The lower third of the rectum is separated by a fascial condensation – Denonvilliers' fascia – from the prostate/vagina in front, and behind by another fascial layer – Waldeyer's fascia – from the coccyx and lower two sacral vertebrae (Table 68.1). These fascial layers are surgically important as they are a barrier to malignant invasion (Summary box 68.1).

Summary box 68.1

Anatomy of the rectum

- The rectum measures approximately 15 cm in length
- It is divided into lower, middle and upper thirds
- The blood supply consists of inferior, middle and superior rectal vessels
- Although the lymphatic drainage follows the blood supply, the principal route is upwards along the superior rectal vessels to the para-aortic nodes

Blood supply

The *superior rectal artery* is the direct continuation of the inferior mesenteric artery and is the main arterial supply of the rectum. The arteries and their accompanying lymphatics lie within the loose fatty tissue of the mesorectum, surrounded by a sheath of connective tissue (the mesorectal fascia).

The *middle rectal artery* arises on each side from the internal iliac artery (Fig. 68.2) and passes to the rectum in the lateral ligaments. It is usually small and breaks up into several terminal branches.

The *inferior rectal artery* arises on each side from the internal pudendal artery as it enters Alcock's canal. It hugs the inferior surface of the levator ani muscle as it crosses the roof of the ischioanal fossa to enter the anal muscles (Fig. 68.2).

Venous drainage

The superior haemorrhoidal veins draining the upper half of the anal canal above the dentate line pass upwards to become the rectal veins: these unite to form the *superior rectal vein*, which later becomes the *inferior mesenteric vein*. This forms part of the portal venous system and ultimately drains into the splenic vein. Middle rectal veins exist but are small, unimportant channels unless the normal paths are blocked.

Lymphatic drainage

The lymphatics of the mucosal lining of the rectum communicate freely with those of the muscular layers. The usual drainage flow is *upwards*, and only to a limited extent laterally and downwards. For this reason, surgical ablation of malignant disease concentrates mainly on achieving wide clearance of proximal lymph nodes. However, if the usual upwards routes are blocked (e.g. by

carcinoma), flow can reverse, and it is then possible to find metastatic lymph nodes on the side walls of the pelvis (along the middle rectal vessels) or even in the inguinal region (along the inferior rectal artery).

CLINICAL FEATURES OF RECTAL DISEASE

Symptoms

Rectal diseases are common and serious and can occur at any age. The symptoms of many of them overlap. In general, the inflammations affect younger age groups, while the tumours occur in the middle-aged and elderly. But no age is exempt from any of the diseases, however young: ulcerative colitis has been reported in the newborn and rectal cancer can occur in young people. The common symptoms of rectal disease are shown in Summary box 68.2.

Summary box 68.2

Main symptoms of rectal disease

- Bleeding per rectum
- Altered bowel habit
- Mucus discharge
- Tenesmus
- Prolapse

Bleeding

This is often bright red in colour but may be darker, and should be carefully investigated at any age.

Altered bowel habit

Early-morning stool frequency ('spurious diarrhoea') is a symptom of rectal carcinoma, while blood-stained frequent loose stools characterise the inflammatory diseases.

Discharge

Mucus and pus are associated with rectal pathology.

Tenesmus

Often described by the patient as 'I feel I want to go but nothing happens', this is normally an ominous symptom of rectal cancer but can occur with any rectal pathology.

Prolapse

This usually indicates either mucosal or full-thickness rectal wall descent.

Loss of weight

This usually indicates serious or advanced disease, e.g. hepatic metastases.

Signs

Because the rectum is accessible via the anus, these can be elicited by systematic examination. The patient is either positioned in the left lateral (Sims') position or examined in the knee-elbow position (Fig. 68.3).

James Marion Sims, 1813–1883, Gynaecological Surgeon, the State Hospital for Women, New York, NY, USA, introduced this position to give access to the anterior vaginal wall during operations for the closure of vagino-vesical fistulae.

Figure 68.2 The rectum lying in the pelvis (coronal view). Note the curvatures corresponding to Houston's valves.

Figure 68.3 Positions for digital rectal examination. (a) Left lateral (Sims). (b) Knee-elbow. [Redrawn with permission from Corman, M.L. (1992) *Colon and Rectal Surgery*, 3rd edn. J.B. Lippincott Co., London].

Inspection

Visual examination of the anus precedes rectal examination to exclude the presence of anal disease, e.g. fissure or fistula.

Digital examination

The index finger used with gentleness and precision remains a valuable test for rectal disease (Fig. 68.4). Tumours in the lower and middle thirds of the rectum can be felt and assessed; by asking the patient to strain, even some tumours in the upper third can be ‘tipped’ with the finger. After it is removed, the finger should be examined for tell-tale traces of mucus, pus or blood. It

Figure 68.4 Illustration showing how the various methods of examining the rectum reach different levels. Note that even cancers in the upper part of the rectum can be felt with the index finger, especially if the patient is asked to ‘strain down’ (courtesy of C.V. Mann).

is always useful to note the normal as well as the abnormal findings on digital examination, e.g. the prostate in the male. Digital findings can be recorded as intraluminal (e.g. blood, pus), intramural (e.g. tumours, granular areas, strictures) or extramural (e.g. enlarged prostate, uterine fibroids).

Proctoscopy

This procedure can be used to inspect the anus, anorectal junction and lower rectum (up to 10 cm) (Fig. 68.5). Biopsy can be performed of any suspicious areas.

Figure 68.5 (a) A metal proctoscope and two different-sized metal Lloyd-Davies rigid sigmoidoscopes – small (diameter 20 mm). Since the advent of greater awareness of transmitted infection, disposable proctoscopes and sigmoidoscopes (b) have replaced the re-usable metal types.

Sigmoidoscopy

The sigmoidoscope was in the past a rigid stainless steel instrument of variable diameter and normally 25 cm in length (Fig. 68.5). This has in the main been replaced by a disposable plastic instrument. The rectum must be empty for proper inspection with a sigmoidoscope. Gentleness and skill are required for its use, and perforations can occur if care is not exercised.

Flexible sigmoidoscope

The 'flexiscope' can be used to supplement or replace rigid sigmoidoscopy (Fig. 68.6). It requires special skill and experience, and the lower bowel should be cleaned out with preliminary enemas. In addition to the rectum, the whole sigmoid colon is within visual reach of this instrument. The instrument is expensive and requires careful maintenance (Summary box 68.3).

Summary box 68.3

Examination of the rectum

- Visual inspection of the perineum
- Digital examination
- Proctoscopy
- Sigmoidoscopy – rigid or flexible

INJURIES

The rectum or anal canal may be injured in a number of ways, all uncommon:

- by falling in a sitting posture onto pointed object: the upturned leg of a chair, handle of a broom, floor-mop, pitchfork or a broken shooting stick have all resulted in rectal impalement;
- by penetrating injury (including gunshots) to the buttocks;
- by sexual assault or sexual activity involving anal penetration;
- by the fetal head during childbirth, especially forceps-assisted.

Diagnosis

The anus should be inspected and the abdomen palpated. If rigidity or tenderness is present, early laparotomy is imperative. A water-soluble contrast enema or computerised tomography (CT) scan with rectal contrast is useful to identify perforation. Prior to the operation, a urethral catheter is passed, but if there is any

Figure 68.6 The flexible (60 cm) endoscope ('flexiscope').

possibility of urethral injury (suggested by difficulty passing urine or haematuria), a urethrogram should be performed (see Chapters 72 and 74).

Treatment

If perforation is suspected, the rectum is examined under general anaesthetic with a finger and a speculum, particular attention being directed to the anterior wall. If penetrating injury is confirmed, lower laparotomy is then performed. If an intraperitoneal rupture of the rectum is found, the perforation is closed with sutures. After closing the laparotomy wound, a defunctioning colostomy is usually required, constructed in the left iliac fossa. If the rectal injury is below the peritoneal reflection, wide drainage from below is indicated, with rectal washout and a defunctioning colostomy. If the defect in the rectum is very large, resection may have to be contemplated, usually in the form of a Hartmann's procedure. Care must be taken to preserve sphincter function during debridement of the perineal wounds. Antibiotic cover must be provided against both aerobic and anaerobic organisms.

FOREIGN BODIES IN THE RECTUM

The variety of foreign bodies that have found their way into the rectum is hardly less remarkable than the ingenuity displayed in their removal (Fig. 68.7). A turnip has been delivered per anum by the use of obstetric forceps. A large soft rubber sex toy has been withdrawn by inserting a myomectomy screw into its lower end. A tumbler, mouth looking downwards, has been extracted by filling the interior with a wet plaster of Paris bandage, leaving the end of the bandage protruding and allowing the plaster to set.

If insurmountable difficulty is experienced in grasping any foreign body in the rectum, a laparotomy is usually necessary, which allows that object to be pushed from above into the assistant's fingers in the rectum. If there is considerable laceration of the mucosa, a temporary colostomy is advisable (Summary box 68.4).

Summary box 68.4

Injuries to the rectum are serious and invariably require surgery

- A temporary colostomy is often necessary
- There is a serious risk of associated necrotising fasciitis, and broad-spectrum antibiotics are mandatory
- There may be associated bladder or urethral damage

PROLAPSE

Mucosal prolapse

The mucosal membrane and submucosa of the rectum protrude outside the anus for approximately 1–4 cm. When the prolapsed mucosa is palpated between the finger and thumb, it is evident that it is composed of no more than a double layer of mucous membrane (cf. full-thickness prolapse) (Summary box 68.5).

Henri Albert Charles Antoine Hartmann, 1860–1952. Professor of Clinical Surgery, Paris, France.

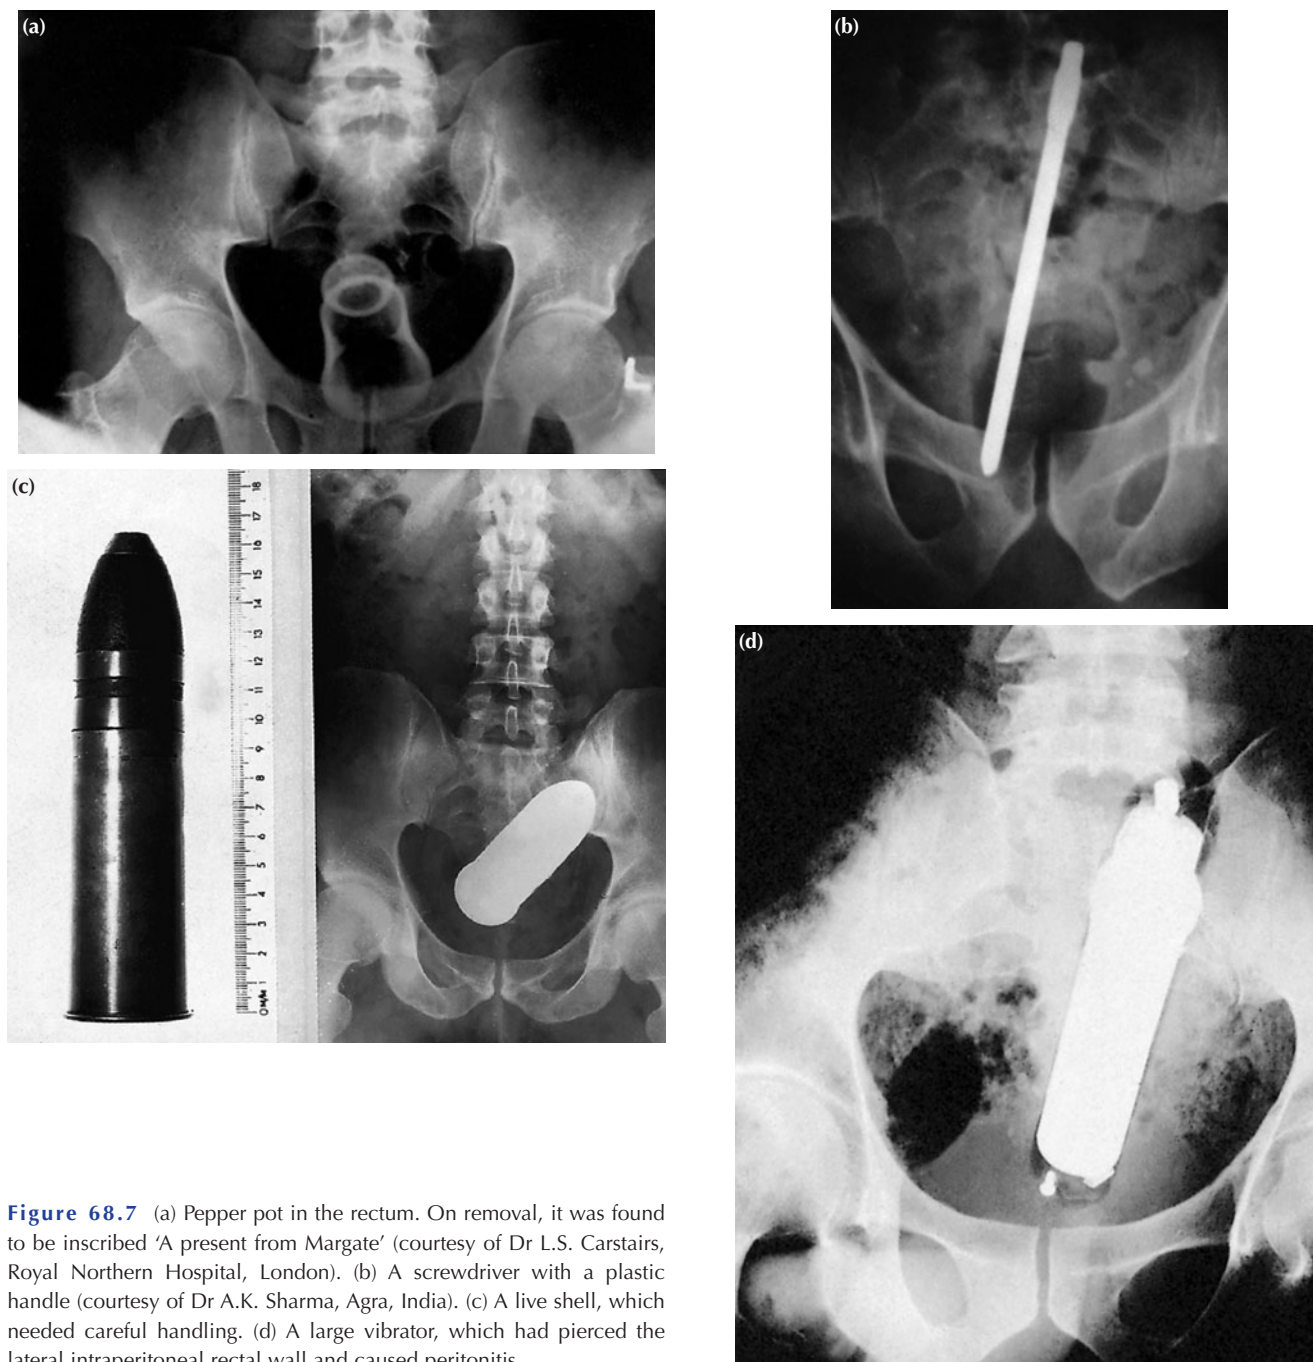

Figure 68.7 (a) Pepper pot in the rectum. On removal, it was found to be inscribed 'A present from Margate' (courtesy of Dr L.S. Carstairs, Royal Northern Hospital, London). (b) A screwdriver with a plastic handle (courtesy of Dr A.K. Sharma, Agra, India). (c) A live shell, which needed careful handling. (d) A large vibrator, which had pierced the lateral intraperitoneal rectal wall and caused peritonitis.

Summary box 68.5

Rectal prolapse

- It may be mucosal or full thickness
- If full thickness, the whole wall of the rectum is included
- It commences as a rectal intussusception
- In children, the prolapse is usually mucosal and should be treated conservatively
- In the adult, the prolapse is often full thickness and is frequently associated with incontinence
- Surgery is necessary for full-thickness rectal prolapse
- The operation is performed either via the perineum or via the abdomen

In infants

The direct downward course of the rectum, due to the as yet undeveloped sacral curve (Fig. 68.8), predisposes to this condition, as does the reduced resting anal tone, which offers diminished support to the mucosal lining of the anal canal (Mann).

In children

Mucosal prolapse often commences after an attack of diarrhoea, or from loss of weight and consequent loss of fat in the ischioanal

Charles Victor Mann, Formerly Surgeon, St Mark's Hospital and the Royal London Hospital, London, UK.

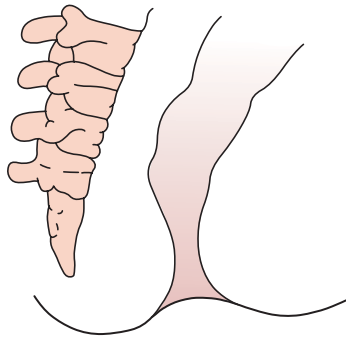

Figure 68.8 The absence of the normal sacral curve predisposes to rectal prolapse in an infant.

fossae. It may also be associated with fibrocystic disease, neurological causes and maldevelopment of the pelvis.

In adults

The condition in adults is often associated with third-degree haemorrhoids. In the female a torn perineum, and in the male straining from urethral obstruction, predisposes to mucosal prolapse. In old age, both mucosal and full-thickness prolapse are associated with atony of the sphincter mechanism, but whether this is the cause of the problem or secondary to it is unknown.

Partial prolapse may follow an operation for fistula *in ano* where a large portion of muscle has been divided. Here, the prolapse is usually localised to the damaged quadrant and is seldom progressive.

Prolapsed mucous membrane is pink; prolapsed internal haemorrhoids are plum coloured and more pedunculated.

Treatment

In infants and young children

Digital repositioning

The parents are taught to replace the protrusion, and any underlying causes are addressed.

Submucosal injections

If digital repositioning fails after 6 weeks' trial, injections of 5% phenol in almond oil are carried out under general anaesthetic. As a result of the aseptic inflammation following these injections, the mucous membrane becomes tethered to the muscle coat.

Surgery

Occasionally, surgery is required and, in such cases, the child is placed in the prone jack-knife position, the retrorectal space is entered, and the rectum is sutured to the sacrum.

In adults

Local treatments

Submucosal injections of phenol in almond oil or the application of rubber bands are sometimes successful in cases of mucosal prolapse.

Excision of the prolapsed mucosa

When the prolapse is unilateral, the redundant mucosa can be excised or, if circumferential, an endoluminal stapling technique can be used.

Full-thickness prolapse

Full-thickness prolapse (synonym: procidentia) is less common than the mucosal variety. The protrusion consists of all layers of the rectal wall and is usually associated with a weak pelvic floor. The prolapse is thought to commence as an intussusception of the rectum, which descends to protrude outside the anus. The process starts with the anterior wall of the rectum, where the supporting tissues are weakest, especially in women. It is more than 4 cm and commonly as much as 10–15 cm in length (Fig. 68.9). On palpation between the finger and thumb, the prolapse feels much thicker than a mucosal prolapse, and obviously consists of a double thickness of the entire wall of the rectum. Any prolapse over 5 cm in length contains anteriorly between its layers a pouch of peritoneum (Fig. 68.10). When large, the peritoneal pouch contains small intestine, which returns to the general peritoneal cavity with a characteristic gurgle when the prolapse is reduced. The anal sphincter is characteristically patulous and gapes widely on straining to allow the rectum to prolapse. Complete prolapse is uncommon in children. In adults, it can occur at any age, but it is more common in the elderly. Women are affected six times more often than men, and it is commonly associated with prolapse of the uterus. In the Middle East and Asia, complete rectal prolapse is not uncommon in young males. In approximately 50% of adults, faecal incontinence is also a feature.

Differential diagnosis

In the case of a child with abdominal pain, prolapse of the rectum must be distinguished from *ileocaecal intussusception* protruding from the anus. Figures 68.11 and 68.12 make the differential

Figure 68.9 Full-thickness rectal prolapse (courtesy of G.D. Adhia, Bombay, India).

Figure 68.10 Rectal prolapse containing a pouch of peritoneum.

Figure 68.11 Intussusception protruding from the anus.

Figure 68.12 Partial prolapse of the rectum.

diagnosis clear. In *rectosigmoid intussusception* in the adult, there is a deep groove (5 cm or more) between the emerging protruding mass and the margin of the anus, into which the finger can be placed.

Treatment

Surgery is required, and the operation can be performed via the perineal or the abdominal approaches. An abdominal rectopexy has a lower rate of recurrence but, when the patient is elderly and very frail, a perineal operation is indicated. As an abdominal procedure risks damage to the pelvic autonomic nerves, resulting in possible sexual dysfunction, a perineal approach is also usually preferred in young men.

Perineal approach

These procedures have been used most commonly.

Thiersch operation

This procedure, which aimed to place a steel wire or, more commonly, a silastic or nylon suture around the anal canal, has become obsolete. The reasons for its lack of popularity were that the suture would often break or cause chronic perineal sepsis, or both, or the anal stenosis so created would produce severe functional problems. Delorme's operation is now the preferred perineal operation.

Delorme's operation (Fig. 68.13)

In this procedure, the rectal mucosa is removed circumferentially from the prolapsed rectum over its length. The underlying muscle is then plicated with a series of sutures, such that, when these are tied, the rectal muscle is concertinaed towards the anal canal. The anal canal mucosa is then sutured circumferentially to the rectal mucosa remaining at the tip of the prolapse. The prolapse is reduced, and a ring of muscle is created above the anal canal, which prevents recurrence.

Altemeier's procedure

This consists of excision of the prolapsed rectum and associated sigmoid colon from below, and construction of a coloanal anastomosis.

Figure 68.13 Delorme's operation for rectal prolapse. (a) The mucosa has been removed from the prolapse. (b) Interrupted sutures have been placed in the underlying muscle so that, when tied, the muscle is plicated. [Redrawn with permission from Keighley, M.R.B. and Williams, N.S. (1999) *Surgery of the Anus, Rectum and Colon*. W.B. Saunders, London].

Abdominal approach

The principle of all abdominal operations for rectal prolapse is to replace and hold the rectum in its proper position. They are recommended in patients with complete prolapse who are otherwise in good health. Many variations have been described: in *Wells' operation*, the rectum is fixed firmly to the sacrum by inserting a sheet of polypropylene mesh between them; *Ripstein's operation* involves hitching up the rectosigmoid junction by a Teflon sling to the front of the sacrum (Fig. 68.14); many surgeons simply suture the mobilised rectum to the sacrum using four to six interrupted non-absorbable sutures – so called sutured rectopexy. Recently, the technique has been performed laparoscopically, thus reducing the operative trauma and limiting the time in hospital.

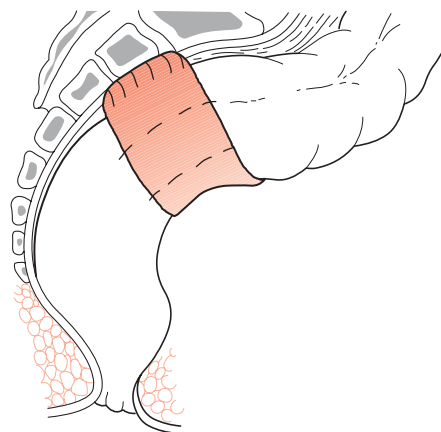

Figure 68.14 Abdominal rectopexy for rectal prolapse. The rectum is mobilised and fixed to the sacrum with a sheet of polypropylene mesh. [Redrawn with permission from Corman, M.L. (1992) *Colon and Rectal Surgery*, 3rd edn. J.B. Lippincott Co., London].

Karl Thiersch, 1822–1895. Professor of Surgery, Leipzig, Germany.

Charles Alexander Wells, 1898–1989. Professor of Surgery, University of Liverpool, Liverpool, UK.

As an abdominal rectopexy may lead to severe constipation, some surgeons recommend combining this procedure with resection of the sigmoid colon (Goldberg), so called resection rectopexy. Approximately 50% of adult patients with a complete rectal prolapse are incontinent, and rectopexy cures only about one-third.

PROCTITIS

Inflammation is sometimes limited to the rectal mucosa; in other cases, it is associated with a similar condition in the colon (proctocolitis). The inflammation can be acute or chronic. The symptoms are tenesmus and the passage of blood and mucus and, in severe cases, of pus also. Although the patient has a frequent intense desire to defaecate, the amount of faeces passed at a time is small. Acute proctitis is usually accompanied by malaise and pyrexia. On rectal examination, the mucosa feels swollen and is often tender. Proctoscopy is seldom sufficient, and sigmoidoscopy is the more valuable method of examination. If the diagnosis is confirmed, colonoscopy with multiple biopsies is mandatory, to determine the extent of the inflammatory process. Skilled pathological assessment is required to establish or exclude the diagnosis of specific infection by bacteriological examination and culture of the stools, examination of scrapings or swabs from ulcers and serological tests.

Non-specific proctitis is an inflammatory condition affecting the mucosa and, to a lesser extent, the submucosa, confined to the distal rectum. In 10% of cases, the condition extends to involve the whole colon (total ulcerative colitis) (Summary box 68.6).

Summary box 68.6

Proctitis

- May be non-specific or related to a specific infective agent
- Non-specific proctitis usually remains confined to the distal bowel, but can spread to the proximal colon
- Causes bleeding, diarrhoea and tenesmus
- Treatment is usually conservative

Aetiology

This is unknown. The concept that the condition is a mild and limited form of ulcerative colitis (although actual ulceration is often not present) is the most acceptable hypothesis.

Clinical features

The patient is usually middle-aged and complains of slight loss of blood in the motions. Often, the complaint is one of diarrhoea but, on closer questioning, it transpires that usually one relatively normal action of the bowels occurs each day, although it is accompanied by some blood. During the day, the patient attempts to defaecate, with the passage of flatus and a little blood-stained faecal matter, which is interpreted as diarrhoea. On rectal examination, the mucosa feels warm and smooth. Often, there is some blood on the examining finger. Proctoscopic and sigmoidoscopic examination shows inflamed mucosa of the rectum, but usually no ulceration. The inflammation usually extends for only 5–15 cm from the anus, with the mucosa above this level being normal.

Treatment

The condition is usually self-limiting, but treatment with topical 5-aminosalicylic acid compounds (5-ASA) (Asacol, Penasa) in the form of suppositories or foam enemas is effective. Topical steroids are a less effective alternative. In very severe resistant cases, oral steroids may have to be used to obtain remission. Rarely, surgical treatment is required as a last resort when the patient is desperate for relief of symptoms.

Ulcerative proctocolitis

Proctitis is present in a high percentage of cases of ulcerative colitis, and the degree of severity of the rectal involvement may influence the type of operative procedure (see Chapter 65).

Proctitis due to Crohn's disease

Crohn's disease can occasionally affect the rectum, although classically it is spared. Sigmoidoscopic characteristics differ from those in non-specific proctitis. The inflammatory process tends to be patchy rather than confluent, and there may be fissuring, ulceration and even a cobblestone appearance. Rectal Crohn's disease is often associated with severe perineal disease characterised by fistulation. Skip lesions are also often present in the rest of the colon or small bowel, or both.

Proctitis due to specific infections

Clostridium difficile

An acute form of proctocolitis caused by infection with *Clostridium difficile* can follow broad-spectrum antibiotic administration. A 'membrane' can sometimes be seen on proctoscopy ('pseudomembranous' colitis).

Bacillary dysentery

The appearance is that of an acute purulent proctitis with multiple small, shallow ulcers. The examination of a swab taken from the ulcerated mucous membrane is more certainly diagnostic than stool microscopy.

Amoebic dysentery

The infection is more liable to be chronic, and exacerbations after a long period of freedom from symptoms often occur. Proctoscopy and sigmoidoscopy are not painful. The appearance of an amoebic ulcer is described in Chapter 65. Scrapings from the ulcer should be immersed in warm isotonic saline solution and sent to the laboratory for immediate microscopic examination.

Amoebic granuloma

This presents as a soft mass, usually in the rectosigmoid region. This lesion is frequently mistaken for a carcinoma. Sigmoidoscopy shows an ulcerated surface, but the mass is less friable than a carcinoma. A scraping should be taken, preferably with a small, sharp spoon on a long handle, and the material sent for immediate microscopic examination, as detailed above. A biopsy can also help. Treatment is as described in Chapter 65. Amoebic granuloma of the rectum is encountered from time to time in a patient who has never visited a country in which the disease is endemic.

Burrill Bernard Crohn, 1884–1956, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Tuberculous proctitis

This is nearly always associated with active pulmonary tuberculosis or tuberculous ulceration of the anus. Submucous rectal abscesses burst and leave ulcers with an undermined edge. A hypertrophic type of tuberculous proctitis occurs in association with tuberculous peritonitis, or tuberculous proctitis occurs in association with tuberculous peritonitis or tuberculous salpingitis. This type of tuberculous proctitis requires biopsy for confirmation of the diagnosis.

Gonococcal proctitis

Gonococcal proctitis occurs in both sexes as the result of rectal coitus and, in the female, from direct spread from the vulva. In the acute stage, the mucous membrane is hyperaemic, and thick pus can be expressed as the proctoscope is withdrawn. In the early stages, the diagnosis can be readily established by bacteriological examination but, later, when the infection is mixed, it is more difficult to recognise. Systemic treatment is so effective that local treatment is unnecessary.

Lymphogranuloma venereum

The modes of infection are similar to those of gonococcal proctitis but, in the female, chlamydial infection spreading from the cervix uteri via lymphatics to the pararectal lymph nodes is common. The proctological findings are similar to those of gonococcal proctitis. The diagnosis of lymphogranuloma venereum should be suspected when the inguinal lymph nodes are greatly enlarged, although the enlargement may be subsiding by the time proctitis commences.

Acquired immunodeficiency syndrome

Acquired immunodeficiency syndrome (AIDS) may present with a particularly florid type of proctitis. In such patients, unusual organisms such as cytomegalovirus (CMV), herpes simplex virus and organisms such as *Cryptosporidium* are often found.

'Strawberry' lesion of the rectosigmoid

This results from an infection by *Spirochaeta vincenti* and *Bacillus fusiformis*. The leading symptom is diarrhoea, often scantily blood-stained. Occasionally, the diagnosis can be made by the demonstration of the specific organisms in the stools. More often, sigmoidoscopy is required. The characteristic lesion is thickened, somewhat raised mucosa with superficial ulceration in the region of the rectosigmoid. The inflamed mucous membrane oozes blood at numerous pinpoints, giving the appearance of an over-ripe strawberry. A swab should be taken from the lesion and examined for Vincent's and fusiform organisms. Swabs from the gums and the throat are also advisable.

Rectal bilharziasis

Rectal bilharziasis is caused by *Schistosoma mansoni*, which is endemic in many tropical and subtropical countries, and particularly in the delta of the Nile.

In stage 1, a cutaneous lesion develops at the site of entrance of the cercariae (parasites of freshwater snails). Stage 2 is characterised by pyrexia, urticaria and a high eosinophilia. Both these

stages are frequently overlooked. Stage 3 results from deposition of the ova in the rectum (much more rarely in the bladder; Chapter 72) and is manifested by bilharzial dysentery. On examination in the later stages, papillomas are frequently present. The papillomas, which are sessile or pedunculated, contain the ova of the trematode, the life cycle of which resembles that of *Schistosoma haematobium*.

Untreated, the rectum becomes festooned, and prolapse of the diseased mucous membrane is usual. Multiple fistulae *in ano* are prone to develop.

Treatment

The primary treatment is systemic and should be undertaken by a specialist in tropical medicine. When the papillomas persist in spite of general treatment, they should be treated by local destruction.

Proctitis due to herbal enemas

This is a well-known clinical entity to those practising in tropical Africa. Following an enema consisting of a concoction of ginger, pepper and bark, administered by a witch doctor, a virulent proctitis sets in. Pelvic peritonitis frequently supervenes. Not infrequently, a complete gelatinous cast of the mucous membrane of the rectum is extruded. Very large doses of morphine, together with streptomycin, often prevent a fatal outcome if commenced early (Bowesman). Temporary colostomy is often advisable.

Treatment

General treatments should include bed rest in extreme cases. The stools should be kept soft. Suppositories of 5-ASA are often beneficial. Infective causes require specific treatment.

SOLITARY RECTAL ULCER

This is becoming a more commonly diagnosed problem. Classically, it takes the form of an ulcer on the anterior wall of the rectum. In this form, it must be differentiated from a rectal carcinoma or inflammatory bowel disease, particularly Crohn's disease. In recent years, it has been appreciated that the ulceration may heal, leaving a polypoid appearance. A variety of explanations as to its cause has been suggested, including persistent trauma by anal digitation. However, recent proctographic studies indicate that it may be due to a combination of internal intussusception or anterior rectal wall prolapse and an increase in intrarectal pressure. This combination of factors is usually caused by chronic straining as a result of constipation. The histological appearances confirm the diagnosis (Morson) and are similar to the appearances of biopsies from a full-thickness overt rectal prolapse. The condition, although benign, is difficult to treat. Symptomatic relief from bleeding and discharge may sometimes be achieved by preventing the internal prolapse by biofeedback, an intrarectal stapling procedure or an abdominal rectopexy. In rare cases, rectal excision may be required.

BENIGN TUMOURS

The rectum, along with the sigmoid colon, is the most frequent site of polyps (and cancers) in the gastrointestinal tract. Adenomatous polyps of the colon and rectum have the potential to become malignant. The chance of developing invasive cancer is enhanced if the polyp is more than 1 cm in diameter. Removal of all polyps is recommended to give complete histological examination and exclude (or confirm) carcinoma, and also to prevent local recurrence. This is best done using endoscopic hot biopsy or snare polypectomy techniques. If one or more rectal polyps are discovered on sigmoidoscopic examination, a colonoscopy must be performed, as further polyps are frequently found in the colon and treatment may be influenced. *No rectal polyp should be removed until the possibility of a proximal carcinoma has been ruled out, otherwise local implantation of cancer cells may occur in the distally situated rectal wound.*

The rectum shares substantially the same spectrum of polyps as the colon. Polyps are described chiefly in terms of their tissue organisation. Certain polyps that have features relevant to the rectum are now described.

Polyps relevant to the rectum

Juvenile polyp

This is a bright-red glistening pedunculated sphere ('cherry tumour'), which is found in infants and children. Occasionally, it persists into adult life. It can cause bleeding, or pain if it prolapses during defaecation. It often separates itself, but can be removed easily with forceps or a snare. A solitary juvenile polyp has virtually no tendency to malignant change, but should be treated if it is causing symptoms. It has a unique histological structure of large mucus-filled spaces covered by a smooth surface of thin rectal cuboidal epithelium (Fig. 68.15). The rare autosomal dominantly inherited syndrome juvenile polyposis does confer an increased risk of gastrointestinal cancers. It is characterised by multiple juvenile polyps and a positive family history (Summary box 68.7).

Summary box 68.7

Polyps in the rectum

- Are either single or multiple
- Adenomas are the most frequent histological type
- Villous adenomas may be extensive and undergo malignant change more commonly than tubular adenomas
- All adenomas must be removed to avoid carcinomatous change
- All patients must undergo colonoscopy to determine whether further polyps are present
- Most polyps can be removed by endoscopic techniques, but sometimes major surgery is required

Hyperplastic polyps

These are small, pinkish, sessile polyps, 2–4 mm in diameter and frequently multiple. They are harmless.

Inflammatory pseudopolyps

These are oedematous islands of mucosa. They are usually associated with colitis in the UK, but most inflammatory diseases

Figure 68.15 Microscopic appearance of a juvenile polyp.

(including tropical diseases) can cause them. They are more likely to cause radiological difficulty as the sigmoidoscopic appearances are usually associated with obvious signs of the inflammatory cause.

Villous adenomas

These have a characteristic frond-like appearance. They may be very large, and occasionally fill the entire rectum. These tumours have an enhanced tendency to become malignant – a change that can sometimes be detected by palpation with the finger; any hard area should be assumed to be malignant and should be biopsied.

Rarely, the profuse mucous discharge from these tumours, which is rich in potassium, causes dangerous electrolyte and fluid losses (Fig. 68.16).

Provided cancerous change has been excluded, these tumours can be removed by submucosal resection endoscopically, surgically per anum or by sleeve resection from above. Only very occasionally is rectal excision required. A recent technique known as transanal endoscopic microsurgery (TEM) has been developed (Buess), which has improved the endoanal approach for the local removal of villous adenomas. The method requires the insertion of a large operating sigmoidoscope. The rectum is distended by carbon dioxide insufflation, the operative field is magnified by a camera inserted via the sigmoidoscope, and the image is displayed on a monitor (Fig. 68.17). The lesion is excised using specially designed instruments. The technique is highly specialised and takes a considerable amount of time to master.

Familial adenomatous polyposis

This autosomal dominantly inherited condition is characterised by the development of multiple rectal and colonic polyps around

Figure 68.16 Huge villous adenoma which occupied the lower half of the rectum and caused hypokalaemia.

puberty. A colonoscopy and biopsy will confirm the diagnosis. Recently, the adenomatous polyposis coli (APC) gene responsible for the disease has been isolated on chromosome 5 (Bodmer), and its sequence has been determined. This discovery makes the screening of affected families far more straightforward. As this condition is pre-malignant, a total colectomy must be performed; often, the rectum can be preserved, but regular flexible endoscopy and removal of polyps before they develop carcinoma are required. The operation of restorative proctocolectomy with pouch–anus anastomosis is an alternative if proctectomy is required: the rectum is replaced by a ‘pouch’ of folded ileum (Chapter 65). A pan-proctocolectomy with permanent ileostomy is necessary in some instances, especially when patient follow-up may be impractical.

Treatment

Colonoscopic polypectomy is satisfactory in the case of most adenomas. For large lesions, especially the sessile variety, transanal excision or even excision of the rectum may be the only curative treatment. Follow-up is required, the frequency depending on the number, size and histological type of adenomas.

Benign lymphoma

This occurs as a circumscribed movable nodule, firm but not hard, greyish-white to pink in colour and essentially submucosal. This rare neoplasm, which occurs at all ages and in both sexes, has no definite capsule. Complete local excision is curative.

Endometrioma

Endometrioma is rare and may be misdiagnosed as a carcinoma. The focus of ectopic endometrial tissue produces either a constricting lesion of the rectosigmoid or a tumour invading the

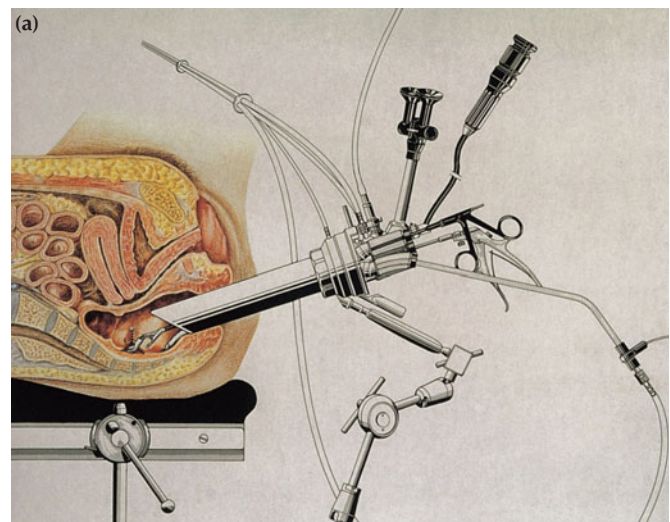

Figure 68.17 (a–c) Transanal endoscopic microsurgery technique (see text).

rectum from the rectovaginal septum. The latter variety gives rise to a very tender submucous elevation of the rectal wall. Endometrioma occurs usually between 20 and 40 years of age, less often at the menopause. Dysmenorrhoea and rectal bleeding

Sir Walter Fred Bodmer, Geneticist, Director of Research, Imperial Cancer Research Fund, London, UK.

(particularly coinciding with the menses) are the main symptoms. On sigmoidoscopy, endometriosis involving the rectosigmoid junction usually presents as a stricture, with the mucous membrane intact. Hormonal manipulation is the first line of therapy, but sometimes total abdominal hysterectomy and bilateral salpingophorectomy is required.

Haemangioma

Haemangioma of the rectum is an uncommon cause of serious haemorrhage. When localised in the lower part of the rectum or anal canal, a haemangioma can be excised. When the lesion is diffuse, or lying in the upper part of the rectum, the symptoms simulate ulcerative colitis, and the diagnosis is often missed for a long period, or it is mistakenly thought to be a carcinoma. Selective angiography and embolisation may be helpful, but excision of the rectum is sometimes required.

Gastrointestinal stromal tumour

Smooth muscle tumours of the rectum are rare. If the mitotic rate is high, and if there is variation in nuclear number, size and shape, hyperchromasia and frequent bizarre cells, these tumours are likely to metastasise. In these circumstances, they should be classified as malignant gastrointestinal stromal tumours (formerly leiomyosarcomas). The uncertainty in their behaviour means that treatment should, whenever possible, be by radical excision.

CARCINOMAS

Overall, colorectal cancer is the second most common malignancy in western countries, with approximately 18 000 patients dying per annum in the UK. The rectum is the most frequent site involved.

Origin

It is now accepted that colorectal cancer arises from adenomas in a stepwise progression in which increasing dysplasia in the adenoma is due to an accumulation of genetic abnormalities (the adenoma–carcinoma sequence; Vogelstein). In approximately 5% of cases, there is more than one carcinoma present. Usually, these carcinomas present as an ulcer, but polypoid and infiltrating types are also common.

Types of carcinoma spread

Local spread

Local spread occurs circumferentially rather than in a longitudinal direction. It is thought that a period of 6 months is required for involvement of a quarter of the circumference, and 18 months to 2 years for complete encirclement. After the muscular coat has been penetrated, the growth spreads into the surrounding mesorectum, but is initially limited by the mesorectal fascia. If penetration occurs anteriorly, the prostate, seminal vesicles or bladder become involved in the male; in the female, the vagina or the uterus is invaded. In either sex, if the penetration is lateral, a ureter may become involved, while posterior penetration may reach the sacrum and the sacral plexus. Downward spread for more than a few centimetres is rare.

Lymphatic spread

Lymphatic spread from a carcinoma of the rectum above the peritoneal reflection occurs almost exclusively in an upward direction; below that level, the lymphatic spread is still upwards, but when the neoplasm lies within the field of the middle rectal artery, primary lateral spread along the lymphatics that accompany it is not infrequent.

Downward spread is exceptional, with drainage along the subcutaneous lymphatics to the groins being confined, for practical purposes, to the lymph nodes draining the perianal rosette and the epithelium lining the distal 1–2 cm of the anal canal.

Metastasis at a higher level than the main trunk of the superior rectal artery occurs only late in the disease. A radical operation should ensure that the high-lying lymph nodes are removed by ligating the inferior mesenteric artery at a high level.

Atypical and widespread lymphatic permeation can occur in highly undifferentiated neoplasms.

Venous spread

The principal sites for blood-borne metastases are liver (34%), lungs (22%) and adrenals (11%). The remaining 33% are divided among the many other locations where secondary carcinomatous deposits tend to lodge, including the brain.

Peritoneal dissemination

This may follow penetration of the peritoneal coat by a high-lying rectal carcinoma.

Stages of progression

Dukes classified carcinoma of the rectum into three stages (Fig. 68.18).

Dukes' staging

- A The growth is limited to the rectal wall (15%): prognosis excellent.
- B The growth is extended to the extrarectal tissues, but no metastasis to the regional lymph nodes (35%): prognosis reasonable.
- C There are secondary deposits in the regional lymph nodes (50%). These are subdivided into C1, in which the local pararectal lymph nodes alone are involved, and C2, in which the nodes accompanying the supplying blood vessels are implicated up to the point of division. This does not take into account cases that have metastasised beyond the regional lymph nodes or by way of the venous system: prognosis is poor.

Figure 68.18 The three cardinal stages of progression of the neoplasm (after C. Dukes, FRCS).

A stage D is often included, which was not described by Dukes. This stage signifies the presence of widespread metastases, usually hepatic.

Other staging systems have been developed (e.g. Astler–Coller, TNM) to improve prognostic accuracy, but the tumour–node–metastasis (TNM) classification is now recognised internationally as the optimum classification for staging.

TNM staging

T represents the extent of local spread and there are four grades:

- T1 tumour invasion through the muscularis mucosae, but not into the muscularis propria;
- T2 tumour invasion into but not through the muscularis propria;
- T3 tumour invasion through the muscularis propria, but not through the serosa (on surfaces covered by peritoneum) or mesorectal fascia;
- T4 tumour invasion through the serosa or mesorectal fascia.

N describes nodal involvement:

- N0 no lymph node involvement;
- N1 1–3 involved lymph nodes;
- N2 4 or more involved lymph nodes.

M indicates the presence of distant metastases:

- M0 no distant metastases;
- M1 distant metastases.

The prefix ‘p’ indicates that the staging is based on histopathological analysis, and ‘y’ that it is the stage after neoadjuvant treatment, which may have resulted in downstaging.

Histological grading

In the great majority of cases, carcinoma of the rectum is a columnar-celled adenocarcinoma. The more nearly the tumour cells approach normal shape and arrangement, the less malignant the tumour is. Conversely, the greater the percentage of cells of an undifferentiated type, the more malignant the tumour is:

- Low grade = well-differentiated 11% prognosis good;
- Average grade 64% prognosis fair;
- High grade = anaplastic tumours 25% prognosis poor.

Vascular and perineural invasion are poor prognostic features, as is the presence of an infiltrating (rather than pushing) margin. In a small number of cases, the tumour is a primary mucoid carcinoma. The mucus lies within the cells, displacing the nucleus to the periphery, like the seal of a signet ring. Primary mucoid carcinoma gives rise to a rapidly growing bulky growth that metastasises very early and the prognosis of which is very poor (Summary box 68.8).

Cuthbert Esquire Dukes, 1890–1977, Pathologist, St Mark’s Hospital, London, UK.

Summary box 68.8

Pathology and staging of rectal cancer

- Tumours are adenocarcinomas and are well, moderately or poorly differentiated
- They spread by local, lymphatic, venous and transperitoneal routes
- Circumferential local spread is the most important as this profoundly affects surgical treatment
- Although lymphatic spread follows the blood supply of the rectum, most occurs in an upwards direction via the superior rectal vessels to the para-aortic nodes
- The TNM classification is the internationally recognised staging system

Clinical features

Carcinoma of the rectum can occur early in life, but the age of presentation is usually above 55 years, when the incidence rises rapidly. Often, the early symptoms are so insignificant that the patient does not seek advice for 6 months or more (Summary box 68.9), and the diagnosis is often delayed in younger patients as these symptoms are attributed to benign causes. Initial rectal examination and a low threshold for investigating persistent symptoms are essential to prevent this.

Summary box 68.9

Early symptoms of rectal cancer

- Bleeding per rectum
- Tenesmus
- Early morning diarrhoea

Bleeding

Bleeding is the earliest and most common symptom. There is nothing characteristic about the time at which it occurs, nor is the colour or the amount of blood distinctive; often, the bleeding is slight in amount and occurs at the end of defaecation, or is noticed because it has stained underclothing. Indeed, more often than not, the bleeding in every respect simulates that of internal haemorrhoids (haemorrhoids and carcinoma sometimes coexist).

Sense of incomplete defaecation

The patient’s bowels open, but there is the sensation that there are more faeces to be passed (*tenesmus*, a distressing straining to empty the bowels without resultant evacuation). This is a very important early symptom and is almost invariably present in tumours of the lower half of the rectum. The patient may endeavour to empty the rectum several times a day (spurious diarrhoea), often with the passage of flatus and a little blood-stained mucus (‘bloody slime’).

Alteration in bowel habit

This is the next most frequent symptom. The patient may find it necessary to start taking an aperient or to supplement the usual dose. A patient who has to get up early in order to defaecate, or one who passes blood and mucus in addition to faeces (‘early-morning bloody diarrhoea’), is usually found to be suffering from carcinoma of the rectum. Often, it is the patient with an annular carcinoma at the rectosigmoid junction who

suffers with increasing constipation, and the one with a growth in the ampulla of the rectum who has early-morning diarrhoea (Bruce).

Pain

Pain is a late symptom, but pain of a colicky character may accompany advanced tumours of the rectosigmoid, and is caused by some degree of intestinal obstruction. When a deep carcinomatous ulcer of the rectum erodes the prostate or bladder, there may be severe pain. Pain in the back, or sciatica, occurs when the cancer invades the sacral plexus.

Weight loss is suggestive of hepatic metastases.

Investigation

Abdominal examination

Abdominal examination is normal in early cases. Occasionally, when an advanced annular tumour is situated at the rectosigmoid junction, signs of obstruction of the large intestine are present. By the time the patient seeks advice, metastases in the liver may be palpable. When the peritoneum has become studded with secondary deposits, ascites results.

Rectal examination

In many cases, the neoplasm can be felt digitally: in early cases as a nodule with an indurated base. When the centre ulcerates, a shallow depression will be found, the edges of which are raised and everted. On bimanual examination, it may be possible to feel the lower extremity of a carcinoma situated in the rectosigmoid junction. After the finger has been withdrawn, if it has been in direct contact with a carcinoma, it is smeared with blood or mucopurulent material tinged with blood. When a carcinomatous ulcer is situated in the lower third of the rectum, involved lymph nodes can sometimes be felt as one or more hard, oval swellings in the mesorectum posteriorly or posterolaterally above the tumour. In females, a vaginal examination should be performed and, when the neoplasm is situated on the anterior wall of the rectum, with one finger in the vagina and another in the rectum, very accurate palpation can be carried out.

Proctosigmoidoscopy

Proctosigmoidoscopy will always show a carcinoma, if present, provided that the rectum is emptied of faeces beforehand.

Biopsy

Using biopsy forceps (Fig. 68.19) via a sigmoidoscope, a portion of the edge of the tumour can be removed. If possible, another

Figure 68.19 Yeoman's biopsy forceps.

Sir John Bruce, 1905–1975, Professor of Surgery, Edinburgh, UK.

specimen from the more central part of the growth should also be obtained.

Colonoscopy

A colonoscopy is required if possible in all patients to exclude a synchronous tumour, be it an adenoma or a carcinoma. If a proximal adenoma is found, it can be conveniently snared and removed via the colonoscope. If a synchronous carcinoma is present, the operative strategy will need changing. If a full colonoscopy is not possible, a CT colonography or barium enema can be performed.

When a stenosing carcinoma is present, it may not be possible using these investigations, especially colonoscopy, to visualise the proximal colon. However, in view of the high incidence of synchronous tumours, it is imperative that a colonoscopy is always performed either before or within a few months of surgical resection.

Differential diagnosis

When an adenoma shows evidence of induration or unusual friability, it is almost certain that malignancy has occurred, even in spite of biopsy findings to the contrary. On the other hand, biopsy is invaluable in distinguishing carcinoma from an inflammatory stricture or an amoebic granuloma. The possibility of a neoplasm being an endometrioma should always be considered in patients with dysmenorrhoea. The possibility of a carcinoid tumour in atypical cases must be remembered. In the last four instances, biopsy should establish the correct diagnosis. The solitary ulcer syndrome has already been alluded to above (Summary box 68.10).

Summary box 68.10

Diagnosis and assessment of rectal cancer

All patients with suspected rectal cancer should undergo:

- Digital rectal examination
- Sigmoidoscopy and biopsy
- Colonoscopy if possible (or CT colonography or barium enema)

All patients with proven rectal cancer require staging by:

- Imaging of the liver and chest, preferably by CT
- Local pelvic imaging by magnetic resonance imaging and/or endoluminal ultrasound

Treatment

Some form of excision of the rectum is essential, if at all possible, because of the extreme suffering entailed if the neoplasm remains. However, before surgery is embarked upon, it is necessary to assess:

- the fitness of the patient for operation;
- the extent of spread of the tumour.

The findings will affect the surgical approach.

Assessment of spread should include CT of the chest and abdomen to exclude distant metastases (Fig. 68.20). Ultrasonography of the liver and a chest radiograph are decreasingly used alternatives. Positron emission tomography (PET) scanning can be helpful in identifying metastases if imaging is otherwise equivocal.

Figure 68.20 Computerised tomography scan of the liver in a patient with a rectal cancer showing multiple liver metastases.

Endoluminal ultrasound, whereby a probe is placed in the rectal lumen, can be used to assess the local spread of the tumour (Fig. 68.21), and is particularly accurate in staging the degree of penetration through the rectal wall in early tumours. CT is not particularly accurate in local staging, which is usually performed using magnetic resonance imaging (MRI), which allows assessment of the proposed circumferential resection margin and adjacent structures (Fig. 68.22).

Principles of surgical treatment

Radical excision of the rectum, together with the mesorectum and associated lymph nodes, should be the aim. Even in the presence of widespread metastases, a rectal excision should be considered, as this is often the best means of palliation. The presence of liver metastases does not necessarily rule out the feasibility of a radical excision. The results of surgery for liver metastases have

Figure 68.21 Endoluminal ultrasound. The probe is in the rectal lumen and shows a rectal tumour invading through the rectal wall.

Figure 68.22 Magnetic resonance imaging scan of pelvis showing extensive T3 rectal carcinoma invading the left side of the mesorectum.

greatly improved, with long-term survival being achieved in over a third of patients.

When a tumour appears to be locally advanced (i.e. invading a neighbouring structure or threatening to breach the circumferential resection margin), the administration of a course of preoperative chemoradiotherapy may reduce its size and make curative surgery possible. Recent evidence suggests that the administration of preoperative 'short-course' neoadjuvant radiotherapy in resectable rectal cancer cases significantly reduces the incidence of local recurrence (Pahlman).

For patients who are unfit for radical surgery or who have widespread metastases, a local procedure such as transanal excision, laser destruction or interstitial radiation should be considered.

When a rectal excision is possible, whenever feasible, the aim should be to restore gastrointestinal continuity and continence by preserving the anal sphincter. A sphincter-saving operation (anterior resection) is usually possible for tumours whose lower margin is two or more centimetres above the anal canal. Although removal of the rectum with a permanent colostomy (abdominoperineal excision) was often required for tumours of the lower third of the rectum in the past, the introduction of the stapling gun has enabled many more of these patients to be treated by a sphincter-saving procedure. Provided a minimum distal margin of clearance of 2 cm can be secured, it is safe to restore gastrointestinal continuity (Williams).

The principles of the operation involve radical excision of the neoplasm, removal of the mesorectum and high proximal ligation of the inferior mesenteric lymphovascular pedicle. Once the rectum has been adequately mobilised, it is removed, and the rectal stump is washed out. Restoration of continuity by direct end-to-end anastomosis (manually or by stapling) must be carried out by a meticulous technique to reduce the risks of suture line breakdown.

Rectosigmoid tumours and those in the upper third of the rectum are removed by 'high anterior resection', in which the rectum and mesorectum are taken to a margin 5 cm distal to

Norman Stanley Williams, Contemporary, Professor of Surgery, Barts and The London School of Medicine and Dentistry, London, UK.

the tumour, and a colorectal anastomosis is performed. This does not usually require defunctioning. The retention of at least a part of the rectum results in good postoperative function.

For tumours in the middle and lower thirds of the rectum, complete removal of the rectum and mesorectum is required, i.e. total mesorectal excision (TME) (Heald). A temporary protecting stoma is usually formed after TME (see later).

Preoperative preparation

The bowel is prepared by mechanical cleansing using a combination of diet, purgatives and enemas (e.g. senna, PicoLax). Prophylactic systemic antibiotics are given preoperatively. The antibiotic regimen must be active against both aerobic and anaerobic organisms. At present, a suitable prescription would be cefuroxime 750 mg plus metronidazole 500 mg given on induction of anaesthesia. If a patient comes to surgery with a loaded colon, on-table intraoperative irrigation can be performed.

All patients should see a stoma care nurse preoperatively and be sited for a temporary or permanent ileostomy or colostomy. They must also be counselled as to the complications of the procedure, and particularly about the risks of pelvic autonomic nerve damage causing bladder and sexual disturbance, especially impotence.

Blood and electrolyte deficiencies are corrected. Before commencing the operation, an indwelling catheter is inserted into the bladder (Summary box 68.11).

Summary box 68.11

Preoperative preparation

- Mechanical bowel preparation
- Counselling and siting of stomas
- Correction of anaemia and electrolyte disturbance
- Cross-matching of blood
- Prophylactic antibiotics
- Deep vein thrombosis prophylaxis
- Insertion of urethral catheter

Combined (abdominal and perineal) excision of the rectum

This operation is still required for some tumours of the lower third of the rectum, which are unsuitable for a sphincter-saving procedure. It has the advantage for difficult tumours of the lower rectum of two surgeons operating from the abdominal and perineal approaches simultaneously. A large catheter is passed to allow easy identification of the urethra and, with the patient in the Trendelenburg lithotomy position, the legs being supported in special supports (Lloyd-Davies–Allen), access is afforded to the abdomen and the perineum at the same time.

The abdominal surgeon makes a midline incision. The liver and the peritoneum are examined for metastases. The small intestine is packed away from the pelvis. A self-retaining retractor is placed in the wound, and the sigmoid colon is freed by dividing the peritoneal reflection on the left side. The sigmoid colon is mobilised to the midline on its mesentery, and the left

ureter and testicular or ovarian vessels are identified. The mesocolon is now divided at the site of the proposed division of the colon and the trunk of the inferior mesenteric artery (Fig. 68.23), ligated and divided distal to the first branch. (Some surgeons emphasise ‘flush ligation’ of the artery at its origin from the aorta.) Most surgeons prefer to divide the sigmoid colon at this point, and this is usually done with a linear stapling cutting instrument. The rectosigmoid mesentery is further divided and separated from the sacrum by sharp dissection with scissors or, more usually, diathermy. Great care is exercised to ensure that the hypogastric nerves are identified and preserved. It is essential that, as the distal dissection proceeds, the surgeon remains outside the posterior margin of the mesorectum and stays within the bloodless plane between the mesorectum and the sacrum, i.e. ‘the holy plane’ (Heald). In this way, the sacrum is cleared almost down to the coccyx.

The peritoneal incision is carried anteriorly around the rectum and deepened, and the seminal vesicles or the vaginal wall are identified so that Denonvilliers’ fascia behind them is cleared by a dissection leading down to the prostate or perineal body. The condensations of fascia that attach the rectum to the pelvic side walls and are known as the lateral ligaments are dissected by diathermy. This tissue contains the middle rectal vessels, which sometimes require separate ligation and division.

When the abdominal surgeon has made certain that the condition is operable, the perineal surgeon closes the anus with purse-string sutures of stout silk or nylon. An elliptical incision between the tip of the coccyx and the central perineal point is

Figure 68.23 Exposure and division of the inferior mesenteric vessels flush with the aorta (high tie) in the course of an abdominoperineal excision of the rectum. Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock, Bonn and Leipzig, Germany.
Oswald Vaughan Lloyd-Davies, 1905–1987, Surgeon, St. Mark's Hospital and The Middlesex Hospital, London, UK.

made around the anus and deepened. The left forefinger is insinuated into the levator ani, which is divided lateral to the finger, first on one side and then on the other (Fig. 68.24). The dissection is deepened posteriorly by incising Waldeyer's fascia, which is a thick condensation of pelvic fascia lying between the rectum and the sacrum. Contact is made with the abdominal surgeon. The apex of skin anterior to the anus is grasped in artery forceps, which serves as a retractor, and by scissors or diathermy and gauze dissection, the wound is deepened, when the catheter within the membranous urethra will be felt. A plane of cleavage will be found between the rectum and the prostate in the male or between the rectum and the vagina in the female. This plane having been carefully determined, Denonvilliers' fascia is divided, after which the rectum can be stripped from the prostate or the vagina. The posterior wall of the vagina is frequently excised with the rectum. When the abdominal surgeon has cleared the rectum laterally, the whole of the anus and rectum can be drawn downwards and removed through the perineal wound.

Haemostasis must be secured and the perineal wound closed in layers. It is usual to use laterally situated suction drains brought out through each ischio-rectal fossa to keep the large perineal cavity from filling up with blood and serous exudate. These drains can be removed after several days.

The site for the colostomy in the left iliac fossa should have been marked preoperatively by the stoma care nurse in consultation with the patient. If this has not been possible, it should be sited equidistant from the umbilicus and the left anterior superior iliac spine at the linea semilunaris, about 2.5 cm above the spin-umbilical line. A circular piece of skin and fascia, about 3 cm in diameter, is excised and this trephine deepened. The rectus sheath and muscle layers are split, and the peritoneum divided. The stapled end of the colon is now passed through this incision

and the colostomy formed (usually after closure of the abdominal wound) by suturing the colon directly to the skin. The paracolic gutter may be closed with sutures – this will close the 'lateral space'. An adherent plastic colostomy bag is then fitted in position, and the dressings are placed on the abdominal wound.

Care of the colostomy

This is much the same as care of an ileostomy (Chapter 65). Within a very short time, the colostomy acts once or twice a day. The patient soon learns which foods cause diarrhoea and therefore avoids them. Many patients are now taught to empty their lower colon by irrigation through the colostomy: this has many advantages for the patient who requires an inactive colostomy while at work. Occlusive caps are also available, which fit in the end of the stoma and allow some degree of continence.

Stenosis of the colostomy is usually avoided by the removal of a circle of skin and subcutaneous tissues at the colostomy site. Dilators may be necessary if there is any tendency for stenosis to occur.

Laparoscopic abdominoperineal excision

Recently, it has been demonstrated that the operation can be carried out laparoscopically. The rectum is mobilised completely from above, using the laparoscope. The perineal part of the procedure is unchanged. After transecting the midsigmoid colon with an endoscopic stapler–cutter instrument, the specimen containing the carcinoma is delivered through the perineal wound. A trephine incision is made in the left iliac fossa, and the sigmoid colon is brought out as an end-colostomy. Although the operative technique has been shown to be quite feasible and reduces post-operative pain and time in hospital, there is concern that it may not be as curative as the standard 'open' technique. The concern

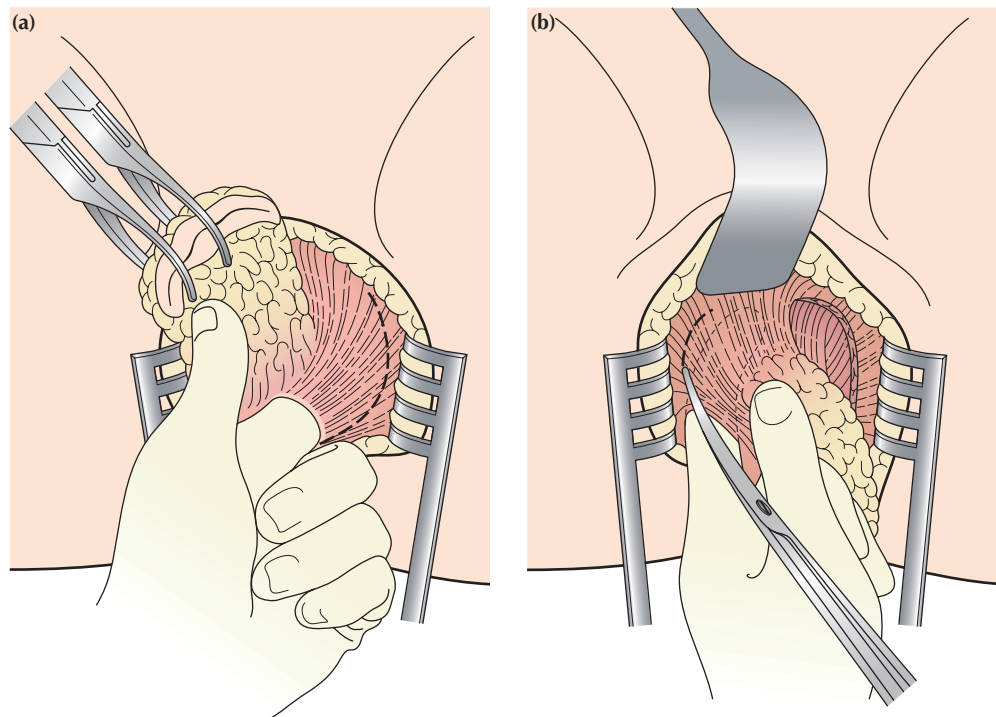

Figure 68.24 (a and b) Separation and division of the pubococcygeus and puborectalis muscles in the course of the perineal phase of an abdominoperineal excision of the rectum. [Redrawn with permission from Keighley, M.R.B. and Williams, N.S. (1999) *Surgery of the Anus, Rectum and Colon*. W.B. Saunders, London.]

surrounds the degree of clearance that can be achieved via the laparoscope, and the risk of free cancer cells being disseminated around the peritoneal cavity and implanting, particularly at the 'port' sites. Controlled trials will be needed to determine whether the laparoscopic approach is safe and as effective as the open technique, and these are in progress.

Anterior resection

As discussed previously, in the last two decades, there has been a move to extend sphincter-saving operations to treat most tumours of the middle third of the rectum, and indeed many in the lower third. The introduction of the circular stapling instruments, with their detachable heads, has made such procedures far more feasible.

The operation of low anterior resection proceeds in the same manner as the abdominal part of abdominoperineal excision. The rectum is mobilised to the pelvic floor, and a right-angled clamp is placed at least 2 cm below the tumour. The rectal stump can then be stapled transversely, using an appropriate instrument. After the rectum and sigmoid colon have been excised, continuity is re-established by the method depicted in Figure 68.25. Although a single loop of colon is often used for the anastomosis, a short J-shaped colonic pouch may be constructed with the aim of increasing neorectal capacity and thus reducing postoperative bowel frequency and urgency (Parc). Some surgeons are concerned that the anastomotic leakage rate will be increased if the technique of cross-stapling of the rectal stump is used. They prefer to place a purse-string suture in the rectal stump lumen, as well as in the proximal colon. After the stapling gun is fired and removed, it is essential that the head of the instrument is

detached and the 'doughnuts' are examined. A break in the circumference of one or both 'doughnuts' signifies a defect in the anastomosis, and the latter should be sought and repaired with interrupted sutures. In these circumstances, a covering stoma will also be required to allow safe healing of the anastomosis. Some surgeons believe that such a stoma is required for all colorectal and coloanal anastomoses that are constructed below the peritoneal reflection.

Occasionally, although the rectum, together with its tumour, can be removed adequately, continuity cannot be restored by a stapling technique. In such cases, it may still be possible to restore continuity by bringing the colon down to the anal canal and constructing a coloanal anastomosis via the transanal route (Fig. 68.26) (the so called abdominotransanal–coloanal operation first described by Parks).

In each of the procedures, it is essential to ensure that any free tumour cells released by mobilisation of the rectum are destroyed by irrigation of the rectal lumen with a cancericidal solution such as 1% cetrimide. By so doing, the implantation of such cells and subsequent local recurrence is prevented. However, it should be realised that, although a small percentage of local recurrences are due to implantation of shed cells, the majority result from inadequate removal of the tumour at the time of the initial operation. Although it is usual for the surgeon to remove all macroscopic tumour, he or she is often unable to remove all microscopic tumour. Particular interest has recently focused on local microscopic spread. It is now known that micrometastases are present in the mesorectum, and these are the most likely cause of local recurrence after rectal excision (Quirke). Heald has emphasised

Figure 68.25 Low anterior resection by the double stapling method. The rectum has been excised, and the distal anorectal stump has been transected with a transverse stapling device. A circular stapling gun is used to construct (a) a straight low coloanal anastomosis or (b) a colonic pouch–anus anastomosis.

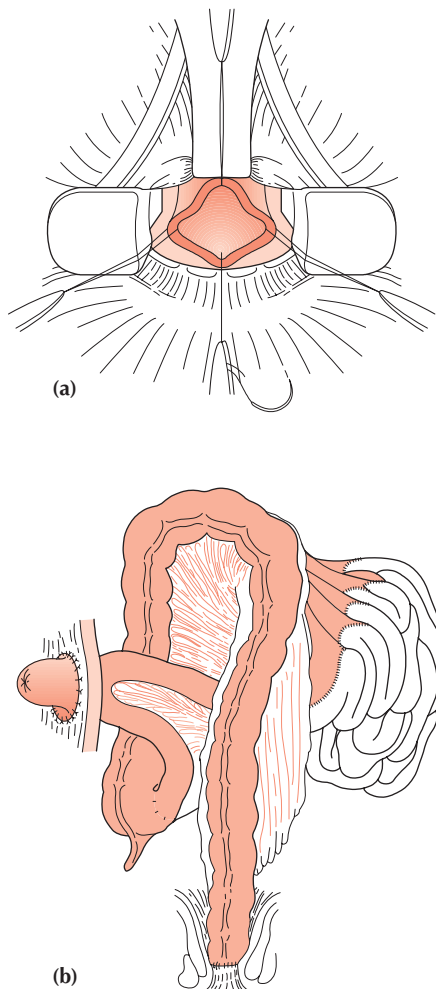

Figure 68.26 Abdominotransanal–coloanal anastomosis. (a) The rectum has been excised, and the mucosa from the distal anorectal stump has been removed, leaving the rectal muscle intact. The proximal colon has been brought down through the rectal muscular cuff to be anastomosed to the anal mucosa via the transanal route. (b) The completed coloanal anastomosis. A covering ileostomy has been performed, to allow the anastomosis to heal.

how important it is to remove all the mesorectum during anterior resection or abdominoperineal excision, the procedure known as TME. TME is now being practised worldwide and appears to reduce the risks of local recurrence substantially (Fig. 68.27). However, it is unlikely that surgery alone will deal adequately with all the micrometastases in the pelvis. Consequently, neoadjuvant radiotherapy may have added benefit (see below).

Laparoscopic anterior resection

It is now possible to perform anterior resection using the laparoscope, the anastomosis being performed using a circular stapling gun. Considerable skill and experience is required but, with improvements in technology, such procedures may become more commonplace. Nevertheless, like laparoscopic abdominoperineal excision, there is concern that these operations may be less curative than the standard operations.

Figure 68.27 Plane of dissection for total mesorectal excision.

Hartmann's operation

This is an excellent procedure in an old and frail patient who would not stand a lengthy anterior resection, or in whom there is concern about anal sphincter function or the viability of an anastomosis. Through an abdominal incision, the rectum is excised, the anorectal stump is transected, usually with a stapler, a colostomy is performed and the peritoneum is oversewn to cover the pelvic defect in the usual way.

Palliative colostomy

This is indicated only in cases giving rise to intestinal obstruction, or where there is gross infection of the neoplasm. It is sometimes possible to resect the growth later (e.g. after chemoradiotherapy) and, in some cases, cure, rather than palliation, is achieved.

Other palliative procedures

Occasionally, a neodymium:yttrium–aluminium–garnet (Nd:YAG) laser can be used to deal with an obstructing or bleeding lesion. Intraluminal stents can also be inserted endoscopically in high, stenosing rectal cancers to palliate a tumour that is causing obstruction.

Local operations

For small, low-grade mobile lesions, which are often Dukes' A (T1) tumours, local removal should be curative. For these tumours, especially in the unfit or in patients who will not accept a colostomy, local removal has been used. Such operations are only suitable for lesions within 10 cm of the anal verge. Turnbull advocated local diathermy removal, while York-Mason developed a trans-sphincteric approach, but a perianal approach is usually possible, with full-thickness excision of the lesion. More recently, the TEM technique has been used for these tumours. This involves inserting a large-calibre operating sigmoidoscope transanally, through which carbon dioxide is infused to produce rectal distension. Using specially designed instruments and an

Rupert B. Turnbull, Jr, 1913–1981, Surgeon, the Cleveland Clinic, Cleveland, OH, USA.
Aubrey York-Mason, 1910–1993, Surgeon, St Helier Hospital, Carshalton, Surrey, UK.

endoluminal camera inserted through the sigmoidoscope, the rectal carcinoma can be excised and the defect closed under direct vision by magnification of the image on a video monitor.

There is considerable doubt, however, as to whether such local techniques should be used for potentially curable lesions as they do not allow full histopathological staging or deal with the mesorectal or lymphatic spread of the tumour. Combined local excision with chemotherapy and radiotherapy has been suggested as a curative treatment for T1 and T2 tumours, but is not widely accepted.

More extensive operations

When the carcinoma of the rectum has spread to contiguous organs, the radical operation can often be extended to remove these structures. Thus, in the male, in whom spread is usually to the bladder, a cystectomy and resection of the rectum can be effected. In the female, the uterus acts as a barrier, preventing spread from the rectum to the bladder. Accordingly, a hysterectomy should be undertaken in addition to excision of the rectum. Should the bladder base be involved, then pelvic exenteration must include that structure. Pelvic exenteration for carcinoma of the rectum is justifiable only when the surgeon is reasonably confident that the growth can be completely removed.

Pelvic exenteration (Brunschwig's operation)

The aim is to remove all the pelvic organs, together with the internal iliac and the obturator groups of lymph nodes (Fig. 68.28). The Trendelenburg lithotomy position facilitates the procedure, and ligation of both internal iliac arteries diminishes the blood loss. A rectus abdominis flap can be used to fill the empty pelvis. Special care must therefore be taken to suture the perineal skin accurately, and to avoid pressure necrosis of the perineal incision by nursing the patient on alternate sides. Some form of urinary diversion is necessary, usually an ileal conduit.

Liver resection

Single or several well-localised liver metastases can now be resected with relatively low mortality and morbidity. Provided the patients are carefully selected, a reasonable long-term survival rate can be achieved (approximately 40% in some series). Such surgery is usually carried out in a specialised liver unit, and it is generally advised that it takes place after the primary lesion has been dealt with (Summary box 68.12).

Summary box 68.12

Surgery for rectal cancer

- Surgery is the mainstay of curative therapy
- The primary resection consists of rectal excision with TME
- Most cases can be treated by anterior resection with the colorectal anastomosis being achieved with a circular stapling gun
- A smaller group of low, extensive tumours require an abdominoperineal excision with a permanent colostomy
- Preoperative radiotherapy can reduce local recurrence
- Adjuvant chemotherapy can improve survival in node-positive disease
- Liver resection in carefully selected patients offers the best chance of cure for single or well-localised liver metastases

Radiotherapy

With modern techniques, some adenocarcinomas now respond to radiotherapy. Various controlled trials have been performed to investigate the effect of adjuvant radiotherapy given either pre- or postoperatively. The overall results of these trials suggest that, provided an adequate dose is given, neoadjuvant radiotherapy can reduce the incidence of local recurrence; however, long-term survival is not affected. Recent studies have combined radiotherapy with chemotherapy in an attempt to shrink an extensive tumour prior to surgical excision. In some cases using this combined therapy, the results can be spectacular, and it has become the standard initial treatment for locally advanced tumours, allowing potentially curative resection in cases that would otherwise be inoperable.

Palliative irradiation can be given for inoperable primary tumours or local recurrence, especially when painful. Papillon refined a technique of intracavity radiation that applies the treatment direct to the tumour from the rectal lumen. In a selected series of early cases, the results were good (5-year survival rates of more than 70%). Intraoperative irradiation is also being evaluated as an adjuvant therapy.

Chemotherapy

A variety of drugs has been tried both as an adjuvant therapy and for the treatment of disseminated disease. The most frequently used drug is 5-fluorouracil (5-FU). Up until recently, the results of various trials using 5-FU, either alone or in combination, were disappointing. However, there is now good evidence that the combination of systemic 5-FU and folinic acid (leucovorin) has a small, yet significant effect on survival when combined with surgery in node-positive disease. Similarly, studies in which 5-FU has been infused into the portal vein during and immediately after the primary operation (Taylor) have shown a small benefit. Such intraportal adjuvant therapy is thought to kill malignant cells,

which are released into the circulation during operative manipulation of tumour, and thus prevent the formation of metastases.

Some exciting new drugs have become available recently, the most notable being irinotecan and oxaliplatin. Both agents have been shown to have a moderate but beneficial effect in disseminated disease, but it remains to be seen whether they will be effective in an adjuvant setting.

Results of surgery for rectal cancer

In specialised centres, the resectability rate may be as high as 95%, with an operative mortality of less than 5%. Overall, 5-year survival rate is about 50%, but it may be a little higher in these centres. The most likely reason for this difference is the higher proportion of advanced and emergency cases treated in non-specialised hospitals. However, another contributing reason is that, in specialised centres, there is a concentration of expertise that is not readily available in district hospitals. Survival rates are influenced by Dukes' stage, with stage C patients doing worse than those with A and B lesions (Fig. 68.29). The degree of mobility also influences survival, with fixed lesions having a worse prognosis than mobile lesions. The lower the tumour is in the rectum, the worse the outlook. Histological grade also influences outcome, with anaplastic lesions having the worse prognosis. Interestingly, despite the more frequent use of sphincter-saving resection compared with abdominoperineal excision, survival has not been affected.

Local recurrence

Local recurrence after rectal excision is a major problem. The patient often presents with persistent pelvic pain, which radiates down the legs if the sacral roots are involved. Bladder problems may occur. If recurrence develops after abdominoperineal excision, a swelling or induration may be present in the perineum,

or an abscess or discharging sinus may develop. Occasionally, the presence of a large recurrence in the pelvis may lead to bilateral leg oedema caused by pressure or invasion of lymphatics or veins. After sphincter-saving resection, local recurrence may produce a change in bowel habit or the passage of blood per rectum. Sigmoidoscopic examination after sphincter-saving resection may reveal friable tissue at the anastomosis which, when biopsied, confirms the diagnosis. However, the recurrence is usually situated extrarectally, and is detected either as induration on digital examination or by endoluminal ultrasonography, CT or MRI. These investigations can also detect recurrence before it causes symptoms. Local recurrence rates vary between 2% and 25% and are higher after abdominoperineal excision than after sphincter-saving resection. The most common cause is inadequate removal of all the tumour at the initial operation. This is due to the presence of microscopic tumour deposits in the tissues surrounding the rectum. Heald has shown that, if the mesorectum is removed in its entirety, the local recurrence rate can be reduced to less than 5%.

Other possible causes of local recurrence include implantation of viable cells on the suture line and the development of a new primary tumour. Although both mechanisms may occur, inadequate removal of the tumour is far and away the most important reason for recurrence. Eighty per cent of all local recurrences develop within 2 years following surgery, and they are very difficult to treat. The best prospect of salvage is by surgical resection. However, it is possible to achieve apparently complete removal in only a minority of cases. It was hoped that serial measurements of carcinoembryonic antigen might identify those patients who might benefit from early radical surgery, but this has been found not to be the case (Northover). The mainstay of therapy for local recurrence is radiotherapy, which is invariably palliative. Surgery is occasionally indicated and will usually involve hysterectomy, bladder resection and even partial sacrectomy.

Carcinoid tumour

Like benign lymphoma, carcinoid tumour originates in the submucosa, with the mucous membrane over it being intact. Consequently, it seldom produces evidence of its presence in the early stages, when it presents as a small plaque-like elevation. The incidence of clinical malignancy, i.e. the occurrence of metastases, is 10%. This is much less than that for carcinoid tumour of the small intestine, but it is greater than that for carcinoid tumour of the appendix. Multiple primary carcinoid tumours of the rectum are not infrequent. The neoplasm is of slow progression, and usually metastasises late. Large carcinoids (over 2 cm) are almost always malignant.

Treatment

Local excision is sufficient treatment for small carcinoids. Resection of the rectum is advisable if the growth is more than 2.5 cm in diameter, if recurrence follows local excision or if the growth is fixed to the perirectal tissues. Even when metastases are present, resection may prolong life.

The anus and anal canal

CHAPTER 69

LEARNING OBJECTIVES

To understand

- The anatomy of the anus and anal canal and their relationship to surgical disease and its treatment
- The pathology, clinical presentation, investigation, differential diagnosis and treatment of diseases that affect the anus and anal canal
- That anal disease is common and its treatment tends to be conservative, although surgery may be required
- That too aggressive or inappropriate surgery may render the patient permanently disabled

ANATOMY AND PHYSIOLOGY

Surgical anatomy

The anal canal commences at the level where the rectum passes through the pelvic diaphragm and ends at the anal verge. The muscular junction between the rectum and anal canal can be felt with the finger as a thickened ridge – the anorectal ‘bundle’ or ‘ring’.

Anal canal anatomy (Fig. 69.1)

The anorectal ring

The anorectal ring marks the junction between the rectum and the anal canal. It is formed by the joining of the puborectalis muscle (Fig. 69.2), the deep external sphincter, conjoined longitudinal muscle and the highest part of the internal sphincter. The anorectal ring can be clearly felt digitally, especially on its posterior and lateral aspects.

The puborectalis muscle

Puborectalis, part of the funnel-shaped muscular pelvic diaphragm, maintains the angle between the anal canal and rectum and hence is an important component in the continence mechanism (Fig. 69.2). The muscle derives its nerve supply from the sacral somatic nerves, and is functionally indistinct from the external anal sphincter. The position and length of the anal canal, as well as the angle of the anorectal junction, depend to a major extent on the integrity and strength of the puborectalis muscle sling. It gives off fibres that contribute to the longitudinal muscle layer.

The external sphincter

The external sphincter forms the bulk of the anal sphincter complex and, although traditionally it has been subdivided into deep, superficial and subcutaneous portions, it is a single muscle

Figure 69.1 Relevant anatomy of the anus. [Redrawn with permission from Mann, C.V. (2002) *Surgical Treatment of Haemorrhoids*. Springer, London.]

(Goligher), which is variably divided by lateral extensions from the longitudinal muscle layer. Some of its fibres are attached posteriorly to the coccyx, whereas anteriorly they fuse with the perineal muscles. Being a somatic voluntary muscle, the external sphincter is red in colour and is innervated by the pudendal nerve.

John Cedric Goligher, 1912–1998, Professor of Surgery, University of Leeds, Leeds, UK.

Figure 69.2 The disposition of the puborectalis muscle. Note how it maintains the rectoanal angle.

The intersphincteric plane

Between the external sphincter muscle laterally and the longitudinal muscle medially exists a potential space, the intersphincteric plane. This plane is important as it contains intersphincteric anal glands (see below) and is also a route for the spread of pus, which occurs along the extensions from the longitudinal muscle layer. The plane can be opened up surgically to provide access for operations on the sphincter muscles.

The longitudinal muscle

The longitudinal muscle is a direct continuation of the smooth muscle of the outer muscle coat of the rectum, augmented in its upper part by striated muscle fibres originating from the medial components of the pelvic floor. Most of the muscle continues caudally before splitting into multiple terminal septa that surround the muscle bundles of the subcutaneous portion of the external sphincter to insert into the skin of the lowermost part of the anal canal and adjacent perianal skin. Milligan and Morgan named the most medial of these septa, passing around the inferior border of the internal sphincter, the ‘anal intermuscular septum’. As it descends, however, it gives off fibres that pass medially across the internal sphincter to reach the submucosal space, and laterally across the external sphincter and ischioanal space to reach the fascia of the pelvic side walls. As well as providing a supportive mesh for the anal canal and other muscular components, its ramifications provide potential pathways for the spread of infection. During defaecation, its contraction widens the anal lumen, flattens the anal cushions, shortens the anal canal and everts the anal margin; subsequent relaxation allows the anal cushions to distend and thus contribute to an airtight seal.

The internal sphincter

The internal sphincter is the thickened (2–5 mm) distal continuation of the circular muscle coat of the rectum, which has

developed special properties and which is in a tonic state of contraction. This involuntary muscle commences where the rectum passes through the pelvic diaphragm and ends above the anal orifice, its lower border palpable at the intersphincteric groove, below which lie the most medial fibres of the subcutaneous external sphincter, and separated from it by the anal intermuscular septum. When exposed during life, it is pearly-white in colour and its circumferentially placed fibres can be seen clearly. Although innervated by the autonomic nervous system, it receives intrinsic non-adrenergic and non-cholinergic (NANC) fibres, stimulation of which causes release of the neurotransmitter nitric oxide, which induces internal sphincter relaxation.

The epithelium and sub-epithelial structures

The pink columnar epithelium lining the rectum extends through the anorectal ring into the surgical anal canal. Passing downwards the mucous membrane becomes cuboidal and redder in colour (Fig. 69.3) whereas above the anal valves it is plum coloured. Just below the level of the anal valves there is an abrupt, albeit wavy, transition to stratified squamous epithelium, which is parchment coloured. This wavy junction constitutes the dentate line. The dentate line is a most important landmark both morphologically and surgically, representing the site of fusion of the proctodaeum and post-allantoic gut, and being the site of the crypts of Morgagni (synonym: anal crypts, sinuses). The latter are small pockets between the inferior extremities of the columns of Morgagni through which anal ducts that communicate with deeper placed anal glands open into the anal lumen. The squamous epithelium lining the lower anal canal is thin and shiny and is known as the anoderm; it differs from the true skin in that it has no epidermal appendages, i.e. hair and sweat glands. At the dentate line, the anoderm is attached more firmly to deeper structures. The mucosa and submucosa above the dentate line is uneven and thrown into folds, the so called anal cushions. There are variations in the numbers and positions of these cushions but there are usually three, corresponding to those seen in later life. These are described classically as occupying the left lateral, right posterior and right anterior positions, and they continue proximally as the primary rectal foldings. Secondary foldings (the rectal columns of Morgagni) lie both over and between the primary folds. This area is the caudal limit of the so called epithelial

Giovanni Battista Morgagni, Professor of Anatomy, Padua, Italy, for 59 years. He is regarded as the founder of morbid anatomy.

transitional zone, below which the stratified squamous epithelium is richly innervated by sensory nerve endings serving several modalities including touch, pain and temperature. The bulk of the anal cushions themselves, situated in the upper part of the anal canal, receive only visceral afferent innervation and, although there is perception of stretching, sensitivity to noxious stimuli is much more blunted than distally.

Between the epithelial layer and the internal sphincter lies the submucosa, consisting of vascular, muscular and connective tissue supportive elements. From the longitudinal muscle, medial extensions cross the internal anal sphincter and form part of the supporting meshwork of the submucosa, blending with the true submucosal smooth muscle layer and thereby supporting the mucosa itself. Parks described the increased density of fibres that insert into the mucosa of the anal crypts at the level of the dentate line, termed the 'mucosal suspensory ligament'. One feature of this structure is that it separates the superior (portal) and inferior (systemic) haemorrhoidal plexuses, another is that the mucosa is more firmly tethered to underlying tissues at this level than above. It is important to appreciate that the meshwork of supporting tissues (muscle fibres and connective tissue) within the subepithelial space is intimately linked to deeper structures within the anal sphincter complex, including the internal sphincter, longitudinal muscle layer and external anal sphincter, and indeed structures beyond the sphincter complex. With age, the smooth muscle component of this mesh is reduced and muscle fibres are gradually replaced with fibroelastic connective tissue, which in turn becomes fragmented.

Blood supply

In addition to the meshwork support of the lining of the anal canal, the subepithelial space contains venous dilatations supported by the same fibroelastic connective tissue and smooth muscle scaffolding. Debate has centred on the nature of the vascular component of haemorrhoids, but the seminal anatomical studies of Thomson have clarified this issue. Venous dilatations are seen in the submucosa both above and below the level of the dentate line; they are much more numerous above although tend to be larger below. The historical description of the blood supply to the upper anal canal as constant, with bifurcation of the main trunk of the superior rectal artery into right and left branches and with subsequent division of the former into anterior and posterior divisions thereby determining the sites of haemorrhoids around the anal circumference, was questioned by Thomson. He demonstrated that the divisions of the superior rectal artery were not constant and that, furthermore, the anal submucosa in a proportion of his specimens received a blood supply from the middle and inferior rectal arteries. He was also able to show the presence of free communications between tributaries of the superior, middle and inferior rectal veins, as well as tiny direct arteriovenous communications with the submucosal venous dilatations. These communications have been shown both histologically and radiologically, and the oxygen tension of the blood contained within the venous dilatations (as well as the colour) is more arterial than venous.

Sir Alan Guyatt Parks, 1920–1962, Surgeon, St Mark's Hospital and the London Hospital, London, UK.
William Hamish Fearon Thomson, Surgeon, The Gloucestershire Royal Infirmary, Gloucester, England.

Venous drainage

The anal veins are distributed in a similar fashion to the arterial supply. The upper half of the anal canal is drained by the superior rectal veins, tributaries of the inferior mesenteric vein and thus the portomesenteric venous system, and the middle rectal veins, which drain into the internal iliac veins. The inferior rectal veins drain the lower half of the anal canal and the subcutaneous perianal plexus of veins: they eventually join the internal iliac vein on each side.

Lymphatic drainage

Lymph from the upper half of the anal canal flows upwards to drain into the postrectal lymph nodes and from there goes to the para-aortic nodes via the inferior mesenteric chain. Lymph from the lower half of the anal canal drains on each side first into the superficial and then into the deep inguinal group of lymph glands. However, if the normal flow is blocked, e.g. by tumour, the lymph can be diverted into the alternative route (Summary box 69.1).

Summary box 69.1

Anal canal anatomy

- The internal sphincter is composed of circular, non-striated involuntary muscle supplied by autonomic nerves
- The external sphincter is composed of striated voluntary muscle supplied by the pudendal nerve
- Extensions from the longitudinal muscle layer support the sphincter complex
- The space between sphincters is known as the intersphincteric plane
- The superior part of the external sphincter fuses with the puborectalis muscle, which is essential for maintaining the anorectal angle, necessary for continence
- The lower part of the anal canal is lined by sensitive squamous epithelium
- Blood supply to the anal canal is via superior, middle and inferior rectal vessels
- Lymphatic drainage of the lower half of the anal canal goes to inguinal lymph nodes

The anal glands

Anal glands (which are not vestigial remnants of sexual scent glands) may be found in the submucosa and intersphincteric space (Fig. 69.4), and normally number between 0 and 10 in an individual. They drain via ducts into the anal sinuses at the level of the dentate line. Not all sinuses have a duct draining into them and, occasionally, more than one gland can discharge into the same sinus. Their function is unknown although they secrete mucin (distinct from that secreted by the rectal epithelium), which perhaps lubricates the anal canal to ease defaecation. The importance of intersphincteric anal glands is that they are widely considered to be the potential source of anal sepsis, either acute, presenting as perianal, ischiorectal or even pelvic sepsis, or chronic, presenting as a cryptoglandular (non-specific) anal fistula.

EXAMINATION OF THE ANUS

Careful clinical examination will be diagnostic in the vast majority of patients complaining of anal symptoms but it requires a

Figure 69.4 Intersphincteric anal gland lying between the voluntary muscle of the external sphincter and the longitudinal muscle. The internal sphincter is also seen. [Reproduced with permission from Nicholls, R.J. and Dozois, R.R. (1997) *Surgery of the Colon and Rectum*. Churchill Livingstone, Edinburgh.]

relaxed patient who is informed of what the examination will entail, a private environment, a chaperone (for the security of both parties) and good light. Most commonly, the patient is examined in the left lateral (Sims) position with the buttocks overlying the edge of the examination couch and with the axis of the torso crossing, rather than parallel with, the edge of the couch. Alternatively, in younger patients, the prone jack-knife or knee–elbow positions may be used (Fig. 69.5). The examining couch should be of sufficient height to allow easy inspection and access for any necessary manoeuvres. A protective glove should be worn.

Inspection

The buttocks are gently parted to allow inspection of the anus and perineum: the presence of any skin lesions and whether they

are confined to the perineum or evident elsewhere on general examination, e.g. psoriasis, lichen planus, or on genital examination, e.g. warts, candidiasis, lichen sclerosus et atrophicus, the vesicles of herpes simplex virus (HSV); evidence of anal leakage; whether the anus is closed or patulous; and the position of the anus and perineum at rest and on bearing down (the latter may reveal prolapse of haemorrhoids or even the rectum). Pain on parting the buttocks, perhaps together with the presence of a sentinel tag, may indicate the presence of an underlying fissure, but may also prompt the need for examination under anaesthesia to exclude more suspicious pathology, for example squamous cell carcinoma of the anal canal.

Digital examination with the index finger

With an adequately lubricated index finger, the soft tissues around the anus are palpated for induration, tenderness and subcutaneous lesions. The index finger is then introduced gently into the anal canal along its posterior aspect. At the apex of the canal, the sling of puborectalis is felt posteriorly; supralelevator induration feels bony hard and is more easily appreciated if unilateral. The posterior surface of the prostate gland with its median sulcus can be palpated anteriorly in male patients; in female patients, the uterine cervix can be palpated. The presence of any distal intrarectal, intra-anal or extraluminal mass is recorded. Sphincter length, resting tone and voluntary squeeze are assessed. On withdrawal the examining finger is inspected for the presence of mucus, blood or pus and to identify stool colour.

Proctoscopy (Fig. 69.6)

Proctoscopy, performed with the patient in the same position, allows a detailed inspection of the distal rectum and anal canal. Minor procedures can also be carried out through this instrument, e.g. treatment of haemorrhoids by injection or banding (see below) and biopsy. Asking the patient to bear down on slow withdrawal of the proctoscope may reveal a descending intussusception.

James Marion Sims, 1813–1883, Gynaecological Surgeon, the State Hospital for Women, New York, USA. Introduced this position to give access to the anterior vaginal wall during operations for the closure of vesico-vaginal fistulae.

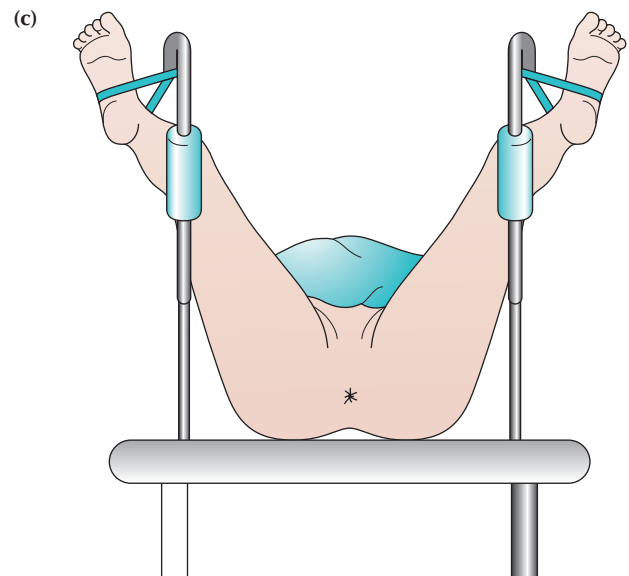

Figure 69.5 The left lateral, knee–elbow and lithotomy positions for examination. [Redrawn with permission from Mann, C.V. (2002) *Surgical Treatment of Haemorrhoids*. Springer, London.]

Figure 69.6 Various types of proctoscope. [Redrawn with permission from Mann, C.V. (2002) *Surgical Treatment of Haemorrhoids*. Springer, London.]

Sigmoidoscopy (see Chapter 68)

Although this is strictly an examination of the rectum, it should always be carried out even when an anal lesion has been confirmed. Rectal pathology, e.g. colitis or carcinoma, is frequently associated with an anal lesion, e.g. fissure or haemorrhoids. Not infrequently, rectal pathology is found that is independent of the anal lesion and which requires treatment (Summary box 69.2).

Summary box 69.2

Examination of anal canal

- A rectal examination is essential for any patient with anorectal and/or bowel symptoms – ‘If you don’t put your finger in, you might put your foot in it’
- A proctosigmoidoscopy is essential in any patient with bowel symptoms, and particularly if there is rectal bleeding

PHYSIOLOGICAL ASPECTS OF THE ANAL SPHINCTERS AND PELVIC FLOOR, AND SPECIAL INVESTIGATIONS

Anal continence and defaecation are highly complex processes that necessitate the structural and functional integrity of the cerebral, autonomic and enteric nervous systems, the gastrointestinal tract (especially the rectum) and the pelvic floor and anal sphincter complex, any of which may be compromised and lead to disturbances of function of varying severity. The sphincter

mechanism provides the ultimate barrier to leakage and its integrity can be assessed fairly simply and objectively in the physiology laboratory (Swash and Henry). Perineal position and degree of descent on straining (markers of pelvic floor and pudendal nerve function) can be quantified, and functional anal canal length, resting tone (reflective predominantly of internal sphincter activity) and squeeze increment (reflective of external sphincter function) can be measured by a variety of simple manometric techniques (Fig. 69.7). The structural integrity of the sphincters can be visualised with endoluminal ultrasound (Fig. 69.8), and neuromuscular function can be measured by assessment of conduction velocity along the pudendal nerve on each side, or, more painfully, by needle electromyogram (EMG) studies (Figs 69.9 and 69.10). In the elderly especially, but also in younger patients, disorders relating to rectal sensorimotor dysfunction can lead to ‘overflow’ of rectal contents through what may be an otherwise normal sphincter. The dynamics of defaecation can also be assessed radiologically by evacuation proctography, in which radio-opaque pseudo-stool is inserted into the rectum and the patient asked to rest, squeeze and then bear down to evacuate the rectal contents under real-time imaging. Proctography can be combined with synchronous EMG and pressure studies (Williams) (Fig. 69.11) to yield more information about possible reasons [mechanical (rectocele, intussusception) or functional (anismus, lack of effort)] for disordered defaecation in an individual. Results of all physiological tests have to be compared with a normal range and within the context of the patient’s symptoms, and are used to guide rational rather than empirical treatment strategies.

CONGENITAL ABNORMALITIES

Early in embryonic life there is a common chamber – the cloaca – into which the hind gut and the allantois open. This endoderm-lined chamber is separated from the surface ectoderm of the embryo by the cloacal membrane. The cloaca becomes divided into two parts, dorsal (rectum) and ventral (urogenital sinus), by the downgrowth of a septum. The dorsal part of the cloacal

Figure 69.9 A typical, normal electromyographic study of the external sphincter during various activities.

Figure 69.10 An electromyographic study of the external sphincter showing prolonged inhibition on straining and absent cough reflex. This is typical of a denervated patulous sphincter.

Figure 69.11 Integrated dynamic proctography. (a) At rest; (b) during evacuation. Visualisation of the rectum is achieved using barium-impregnated 'synthetic stool'. The effects of straining and evacuation on the electromyographic activity of the sphincter muscles and intrarectal pressure can be simultaneously recorded (Williams).

membrane, known as the anal membrane, is thus composed of an outer layer of ectoderm and an inner layer of endoderm. Resorption of this anal membrane by the eighth week of embryonic life creates the anal canal.

Imperforate anus (see Chapter 6)

Imperforate anus (strictly, it should be anal 'agenesis' or 'atresia') has historically been divided into two main groups – high and low – depending on the level of termination of the rectum in relation to the pelvic floor. Treatment and prognosis are influenced by any associated abnormalities of the sacrum and genitourinary systems. In both sexes, low defects embrace rectoperineal fistula (Fig. 69.12), covered anus and anal membrane. The most frequent defect in boys with imperforate anus is one in which the distal rectum is sited within the puborectalis sling but

Figure 69.12 Low anorectal malformations. (a) Rectoperineal fistula in a boy; (b) rectoperineal fistula in a girl (anterior anus); (c) rectovestibular fistula (courtesy of Alberto Pena and Springer-Verlag. From 'Atlas of Surgical Management of Anorectal Malformations' by Alberto Pena, 1990. Copyright Springer-Verlag.

terminates as a fistula into the bulbar urethra (Fig. 69.13) (see also Chapter 6, Fig. 6.22) or prostatic urethra above the main anal sphincter complex. Boys with a fistula into the bladder neck (a high defect) have the poorest prognosis because of the underdevelopment of the sacrum and pelvic and anal musculature. The most common defect in girls is a rectovestibular fistula, in which the fistula opens into the posterior vestibule (not the vagina) (Fig. 69.12). The finding of a single perineal orifice indicates a persistent cloaca in which the rectum, vagina and urinary tract form a confluence (Fig. 69.13); the longer the common channel, the greater the likelihood of more complex defects, including vaginal and uterine septation, duplication or atresia. An anterior anus, although not imperforate, is not fully located within the sphincter mechanism and is regarded as part of the spectrum of anorectal malformations (Fig. 69.12).

Clinical management

Careful perineal examination will usually provide the most important clues about the neonate's type of malformation. The presence of meconium on the perineum indicates a low defect and meconium in the urine is evidence of a urinary tract fistula. During the first 24 hours the baby should receive intravenous fluids and antibiotics, and should be evaluated for associated congenital anomalies. By 24 hours, the distal limit of air within the rectum, seen on a lateral prone radiograph, indicates the distance between the rectal stump and perineum (Fig. 69.14).

Figure 69.13 More complex anorectal malformations. (a) Rectobulbar fistula; (b) cloacal malformation (courtesy of Alberto Pena and Springer-Verlag. From 'Atlas of Surgical Management of Anorectal Malformations' by Alberto Pena, 1990. Copyright Springer-Verlag.

Figure 69.14 Lateral prone shoot-through radiograph of a neonate with (a) low and (b) high anorectal malformation. A radio-opaque marker has been placed on the anal dimple (courtesy of Mark D. Stringer, Leeds, UK).

Treatment

Low anomalies with a perineal fistula can be treated by an anoplasty. More complex malformations require early colostomy, with definitive repair performed several months later. This may involve posterior sagittal anorectoplasty (PSARP, Pena, with or without transabdominal mobilisation of the left colon and division of any communication with the urinary tract. In girls with a cloaca and long common channel, urinary and vaginal reconstruction is also required. Postoperatively, a programme of anal dilatation is instituted, and any residual colostomy is closed at a later date. Ultimate bowel function (voluntary bowel movements, continence, constipation) is related to the type of anorectal abnormality and the presence of associated defects, especially sacral (Summary box 69.3).

Alberto Pena, Contemporary, Professor of Pediatric Surgery, Schneider Children's Hospital, New York, NY, USA.

Summary box 69.3

Imperforate anus

- A rare congenital disorder
- Classified as being high or low depending on the site of the rectal termination in relation to the pelvic floor
- Low defects: relatively easy to correct but prone to constipation
- High defects: more difficult to correct and prone to faecal incontinence

Post-anal dermoid

The space in front of the lower part of the sacrum and coccyx may be occupied by a soft, cystic swelling – a post-anal dermoid cyst. Hidden in the hollow of the sacrum it is unlikely to be discovered unless a sinus communicating with the exterior is present or it develops as a result of inflammation. Such a cyst usually remains asymptomatic until adult life, when it is prone to becoming infected. Exceptionally, because of its size, it gives rise to difficulty in defaecation. The cyst is easily palpable on rectal examination.

Differential diagnosis

Especially in a child, an anterior sacral meningocele must be excluded. This enlarges when the child cries and is frequently associated with paralysis of the lower limbs and incontinence. When a discharging sinus is present, a post-anal dermoid will probably be mistaken for a pilonidal sinus or even an anal fistula. Pressure over the sacrococcygeal region with a finger in the rectum may cause a flow of sebaceous material, and injection of contrast media followed by radiography reveals a bottle-necked cyst in front of the coccyx.

Treatment

Treatment involves complete excision of the cyst and, if present, the sinus. In the case of large cysts it is necessary to remove the coccyx to gain access. The coccyx should also be removed *en bloc* in any child with a presacral dermoid because of the risk of sacrococcygeal teratoma.

Post-anal dimple (synonym: fovea coccygea)

A dimple in the skin beneath the tip of the coccyx, sometimes amounting to a short blind pit, is noticed from time to time in the course of a clinical examination and is of no consequence.

Pilonidal sinus

The term pilonidal sinus describes a condition found in the natal cleft overlying the coccyx, consisting of one or more, usually non-infected, midline openings, which communicate with a fibrous track lined by granulation tissue and containing hair lying loosely within the lumen. A common affliction amongst the military, it has been referred to as 'jeep disease'.

Aetiology and pathology

Although acquired theories of development are better accepted than the more historical congenital theories, exact mechanisms

A jeep is a small military, general purpose, vehicle with hard springing, which gives its occupants a very bouncy ride when driven over rough terrain.

of development are speculative. Evidence that supports the acquired theory of origin of pilonidal sinuses can be summarised as follows:

- Interdigital pilonidal sinus is an occupational disease of hair-dressers, the hair within the interdigital cleft or clefts being the customers'. Pilonidal sinuses of the axilla and umbilicus have also been reported.
- The age incidence of the appearance of pilonidal sinus (82% occur between the ages of 20 and 29 years) is at variance with the age of onset of congenital lesions.
- Hair follicles have almost never been demonstrated in the walls of the sinus.
- The hairs projecting from the sinus are dead hairs, with their pointed ends directed towards the blind end of the sinus.
- The disease mostly affects men, in particular hairy men.
- Recurrence is common, even though adequate excision of the track is carried out.

It is thought that the combination of buttock friction and shearing forces in that area allows shed hair or broken hairs which have collected there to drill through the midline skin, or that infection in relation to a hair follicle allows hair to enter the skin by the suction created by movement of the buttocks, so creating a subcutaneous, chronically infected, midline track. From this primary sinus, secondary tracks may spread laterally, which may emerge at the skin as granulation tissue-lined, discharging openings. Usually, but not invariably (when diagnosis may be confused with anal fistula or hidradenitis suppurativa), the sinus runs cephalad. Carcinoma arising in chronic pilonidal disease has been described but is exceedingly rare.

Clinical features

The condition is seen much more frequently in men than women, usually after puberty and before the fourth decade of life, and is characteristically seen in dark-haired individuals rather than those with softer blond hair (Oldham). Patients complain of intermittent pain, swelling and discharge at the base of the spine but little in the way of constitutional symptoms. There is often a history of repeated abscesses that have burst spontaneously or which have been incised, usually away from the midline. The primary sinus may have one or many openings, all of which are strictly in the midline between the level of the sacrococcygeal joint and the tip of the coccyx.

Conservative treatment

As the natural history of the condition is usually one of regression, in those whose symptoms are relatively minor, simple cleaning out of the tracks and removal of all hair, with regular shaving of the area and strict hygiene, may be recommended.

Treatment of an acute exacerbation (abscess)

If rest, baths, local antiseptic dressings and the administration of a broad-spectrum antibiotic fail to bring about resolution, the abscess should be drained through a small longitudinal incision made over the abscess and off the midline, with thorough curettage of granulation tissue and hair. This procedure may or may not be associated with complete resolution.

Surgical treatment of chronic pilonidal disease

The multitude of surgical procedures advocated to eradicate pilonidal disease, combined with the lack of prospective trials, attests to the lack of overall superiority of one method over the others. Time spent off work and perceived recurrence rates, but more usually surgeon preference, influence the choice of method, which includes the laying open of all tracks with or without marsupialisation, the excision of all tracks with or without primary closure, and the excision of all tracks and then closure by some other means designed to avoid a midline wound [Z-plasty, Karydakis procedure (Fig 69.15)]. Bascom's procedure involves an incision lateral to the midline to gain access to the sinus cavity, which is rid of hair and granulation tissue (Fig. 69.16), and excision and closure of the midline pits (Fig. 69.17). The lateral wound is left open (Fig. 69.18). Irrespective of procedure, postoperative wound care is important and centres around elimination of hair (ingrown, local or other) from the wound.

Figure 69.15 Karydakis's operation for pilonidal sinus. A semilateral incision is made around the sinus complex, the diseased component excised and the flap mobilised to allow tension-free closure of the wound off the midline. J. Bascom, American Surgeon.

Figure 69.16 Bascom's technique for pilonidal sinus: 1.

Figure 69.17 Bascom's technique for pilonidal sinus: 2.

Recurrent pilonidal sinus

Three possibilities account for this disappointment:

- part of the sinus complex has been overlooked at the primary operation;
- new hairs enter the skin or the scar;
- there is persistence of a midline wound caused by shearing forces and scarring; in this situation, revisional surgery may include re-excision followed by wound closure and obliteration of the natal cleft either by myocutaneous rotational buttock flap or cleft closure (Bascom).

ANAL INCONTINENCE

Aetiology

As continence is dependent upon the structural and functional integrity of both the neurological pathways and the gastrointestinal tract, the risk factors for anal incontinence are many (Summary box 69.4). Patients complaining of the involuntary loss of rectal contents require a comprehensive assessment of the nature and severity of symptoms; past history, especially of gastrointestinal disease, neurological conditions, obstetric events and anal surgery; and careful clinical examination (in the elderly, incontinence is often one of overflow secondary to rectal impaction, and proctitis may lead to such an irritable rectum that even the strongest sphincter is occasionally overwhelmed). A

combination of history and examination will usually be diagnostic, but special investigations are then usually required to clarify the exact cause, including exclusion of an underlying malignancy, and to direct management.

Summary box 69.4

Causes of anal incontinence

Congenital/childhood

- Anorectal anomalies
- Spina bifida
- Hirschsprung's disease
- Behavioural

Acquired/adulthood

- Diabetes mellitus
 - Cerebrovascular accident
 - Parkinson's disease
 - Multiple sclerosis
 - Spinal cord injury
 - Other neurological conditions:
 - Myotonic dystrophy
 - Shy-Drager syndrome
 - Amyloid neuropathy
 - Gastrointestinal infection
 - Irritable bowel syndrome
 - Metabolic bowel disease
 - Inflammatory bowel disease
 - Megacolon/megarectum
 - Anal trauma
 - Abdominal surgery:
 - Small bowel resection
 - Colonic resection
 - Pelvic surgery:
 - Hysterectomy
 - Rectal excision
 - Pelvic malignancy
 - Pelvic radiotherapy
 - Rectal prolapse
 - Rectal evacuatory disorder:
 - Mechanical, e.g. rectocele, intussusception
 - Functional, i.e. pelvic floor dyssynergia
 - Anal surgery:
 - Haemorrhoidectomy
 - Surgery for fistula
 - Surgery for fissure
 - Rectal disimpaction
 - Obstetric events
- ###### *General*
- Ageing
 - Dependence of nursing care
 - Obesity
 - Psycho-behavioural factors
 - Intellectual incapacity
 - Drugs:
 - Primary constipating and laxative agents
 - Secondary effects

Sphincteric causes of incontinence may be classified as structural, in which there is disruption (or atrophy) of part of the sphincter muscles, neuropathic (previously termed idiopathic), in which the nerve supply to the sphincters is damaged, usually by chronic straining or complicated vaginal delivery (prolonged second stage), or a combination of the two. The commonest causes of

Figure 69.18 Bascom's technique for pilonidal sinus: 3.

sphincteric disruption are obstetric damage, anal surgery (following haemorrhoidectomy, dilatation or sphincterotomy for anal fissure, and fistulotomy for anal fistula) and trauma (including anal intercourse, forced or otherwise).

In general, conservative measures to reduce symptoms are employed initially. These may be in the form of stool bulking or constipating agents, nurse-led bowel retraining including specific biofeedback programmes, or anal plugs, which expand within and thus seal the anal canal. Failure of such measures and severity of symptoms may result in selection for surgery.

Operations to reunite divided sphincter muscles

In situations in which there is a discrete disruption of the sphincters, the ends of the divided muscle are found and reunited by a double overlap repair (Fig. 69.19).

Operations to reef the external sphincter and puborectalis muscle

If the sphincter muscles are stretched and patulous (as they often are in old age and in cases of rectal prolapse) they may be tightened by a post-anal repair, which, through the use of darns of absorbable material to narrow down and plicate the external sphincter and the puborectalis sling (Fig. 69.20), aims to recreate the anorectal angle and to restore length to the anal canal and strength to the anal sphincter. The approach is usually through the intersphincteric plane. The operation is now much less popular because long-term outcomes have been reported as poor.

Operations to augment the anal sphincters

If the degree of sphincter disruption or weakness is such that restoration of function cannot be achieved by direct means, the sphincter can be augmented by using muscle transposed from nearby (gluteus maximus or gracilis) or by using an artificial sphincter. Transposition of the gracilis muscle around the anal canal is followed by electrical stimulation, with conversion from a fast-twitch to a less fatiguable slow-twitch muscle by an implanted pacemaker (Williams) (Fig. 69.21). Because of its magnitude this technique is performed only in highly selected and motivated patients, most of whom have had more conventional treatment that has failed to cure their incontinence; it is effective in approximately 60% of patients in the long term. A simpler means of augmenting the sphincter, developed initially for urinary incontinence, is the placement of an inflatable silastic cuff around

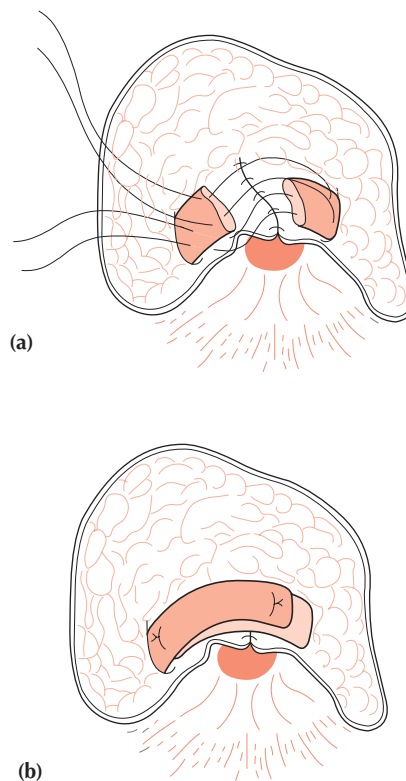

Figure 69.19 Direct sphincter repair in which (a) the sphincter defect is excised and (b) the remaining muscle is overlapped. [Redrawn with permission from Mann, C.V. and Glass, R.E. (1991) *Surgical Treatment of Anal Incontinence*. Springer, New York.]

the anal canal. When evacuation is required the cuff is deflated by squeezing a small balloon positioned in the scrotum or labia, the balloon being attached to a subcutaneous reservoir (Fig. 69.22). However, because this device is a foreign body that exerts pressure on the bowel wall, erosion and infection have been found to be common problems. To reduce the risk of septic complications the operation should be covered by antibiotics active against both aerobic and anaerobic organisms. Paradoxically, all of these methods used to treat incontinence may be associated with difficulties in rectal evacuation.

More recently, again as a result of its use in urinary incontinence, sacral nerve stimulation has been used to treat faecal incontinence, with encouraging short-term results. Rather than any direct action on sphincter strength, this technique appears to work by sensorimotor neurophysiological modulation of the hindgut through electrical stimulation of the sacral nerve roots via a needle positioned through one of the posterior sacral foramina (Fig. 69.23). A potential advantage of this technique is its relatively non-invasive nature, as well as the fact that its effects can be tested by temporary stimulation using an external stimulator before the expensive permanent pacemaker is implanted.

For some patients, and in those in whom quality of life remains poor despite attempts at restoring continence, a colostomy can provide relief from a condition which is both disabling and socially isolating.

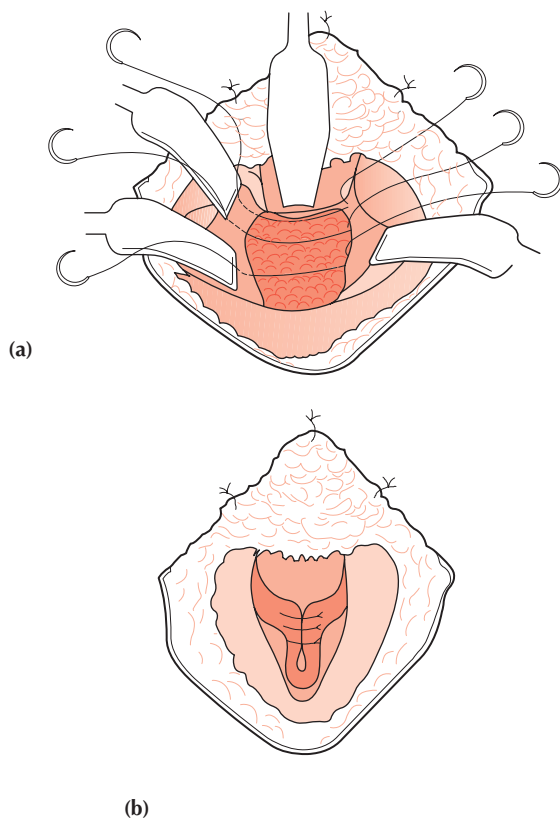

Figure 69.20 Post-anal repair in which (a) the sphincter muscle is plicated posterior to the anal canal, thus restoring the anorectal angle. (b) The completed repair. [Redrawn with permission from Mann, C.V. and Glass, R.E. (1991) *Surgical Treatment of Anal Incontinence*. Springer, New York.]

ANAL FISSURE

Definition

An anal fissure (synonym: fissure-in-ano) is a longitudinal split in the anoderm of the distal anal canal (Fig. 69.24), which extends from the anal verge proximally towards, but not beyond, the dentate line.

Aetiology

The cause of an anal fissure, and particularly the reason why the posterior midline is so frequently affected, is not completely understood. Classically, acute anal fissures arise from the trauma caused by the strained evacuation of a hard stool or, less commonly, from the repeated passage of diarrhoea. The location in the posterior midline perhaps relates to the exaggerated shearing forces acting at that site at defaecation, combined with a less elastic anoderm endowed with an increased density of longitudinal muscle extensions in that region of the anal circumference. Anterior anal fissure is much more common in women and may arise following vaginal delivery. Perpetuation and chronicity may result from repeated trauma, anal hypertonicity and vascular insufficiency, either secondary to increased sphincter tone or because the posterior commissure is less well perfused than the remainder of the anal circumference.

Figure 69.22 Artificial bowel sphincter. A cuff is placed around the anal canal. An inflatable pump control assembly is placed in the scrotum and the balloon reservoir is placed under the symphysis pubis.

Figure 69.23 Diagram showing the placement of the electrode through a sacral foramen in sacral nerve stimulation.

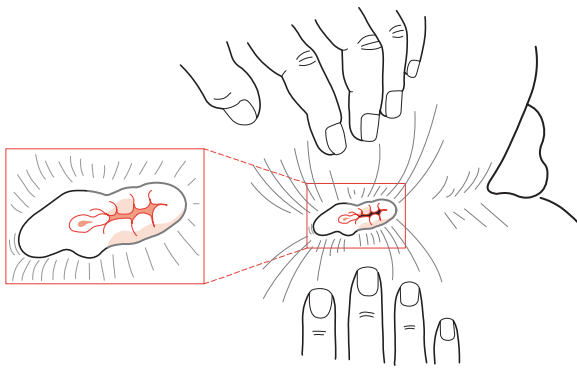

Figure 69.24 The appearance of an anal fissure. If the buttocks are gently parted, the presence of an anal fissure can usually be detected as an ulcer of variable depth with the skin tag and an anal papilla. [Redrawn with permission from Keighley, M.R.B. and Williams, N.S. (1999) *Surgery of the Anus, Colon and Rectum*, 2nd edn. W.B. Saunders, Philadelphia, PA.]

Clinical features

Although simple epithelial splits, acute anal fissures are, because of their location involving the exquisitely sensitive anoderm, characterised by severe anal pain associated with defaecation, which usually resolves spontaneously after a variable time only to recur at the next evacuation, as well as the passage of fresh blood, normally noticed on the tissue after wiping. Chronic fissures are characterised by a hypertrophied anal papilla internally and a sentinel tag externally (both consequent upon attempts at healing and breakdown), between which lies the slightly indurated anal ulcer overlying the fibres of the internal sphincter. When chronic, patients may also complain of itching secondary to irritation from the sentinel tag, discharge from the ulcer or discharge from an associated intersphincteric fistula, which has arisen through infection penetrating via the fissure base. Although most sufferers are young adults, the condition can affect any age, from infants to the elderly. Men and women are affected equally. Anterior fissures account for about 10% of those encountered in women but only 1% in men. A fissure sited

elsewhere around the anal circumference or with atypical features should raise the suspicion of a specific aetiology, and failure of adequate examination in the clinic should prompt early examination under anaesthesia, with biopsy and culture to exclude Crohn's disease, tuberculosis, sexually transmitted or human immunodeficiency virus (HIV)-related ulcers (syphilis, *Chlamydia*, chancroid, lymphogranuloma venereum, HSV, cytomegalovirus, Kaposi's sarcoma, B-cell lymphoma) and squamous cell carcinoma (Summary box 69.5).

Summary box 69.5

Anal fissure

- Acute or chronic
- Ischaemic ulcer in the midline of the anal canal
- Ectopic site suggests a more sinister cause

Symptoms:

- Pain on defaecation
- Bright-red bleeding
- Mucous discharge
- Constipation

Treatment

After confirmation of the diagnosis in the clinic or under anaesthesia, with exclusion of secondary causes of anal ulceration, conservative management should result in the healing of almost all acute and the majority of chronic fissures. Emphasis must be placed on normalisation of bowel habits such that the passage of stool is less traumatic. The addition of fibre to the diet to bulk up the stool, stool softeners and adequate water intake are simple and helpful measures. Warm baths and topical local anaesthetic agents relieve pain; however, providing patients with anal dilators is usually associated with low compliance and consequently little effect. The mainstay of current conservative management is the topical application of pharmacological agents that relax the internal sphincter, most commonly nitric oxide donors (Scholefield); by reducing spasm, pain is relieved, and increased vascular perfusion promotes healing. Such agents include glyceryl trinitrate (GTN) 0.2% applied four times per day to the anal margin (although this may cause headaches) and diltiazem 2% applied twice daily.

Operative measures

Historically, under regional or general anaesthesia, forceful manual (four- or eight-digit) sphincter dilatation was used to reduce sphincter tone; however, this was achieved in an uncontrolled fashion with potential disruption at multiple sites of the internal (and even external) sphincter. The risk of incontinence following this procedure has now made it unpopular, although more conservative controlled stretching is still practised in young men with very high sphincter tone.

Fissure healing can also be achieved by a posterior division of the exposed fibres of the internal sphincter in the fissure base, but this is associated with prolonged healing, as well as passive anal

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

John Howard Scholefield, Contemporary, Professor of Surgery, The University of Nottingham, Nottingham, England.

leakage thought mainly to be due to the resulting keyhole gutter deformity; however, it may be indicated if there is an associated intersphincteric fistula.

Lateral anal sphincterotomy (Notaras)

In this operation, the internal sphincter is divided away from the fissure itself – usually either in the right or the left lateral positions. The procedure can be carried out using an open or a closed method, under local, regional or general anaesthesia, and with the patient in the lithotomy or prone jack-knife position. The distal internal sphincter is palpated with a bivalved speculum at the intersphincteric groove. In the closed method a small longitudinal incision is made over this, and the submucosal and intersphincteric planes are carefully developed to allow precise division of the internal sphincter with a knife or scissors to the level of the apex of the fissure; the wound is then closed with absorbable sutures. Alternatively, either plane can be entered using a scalpel (no. 11 blade), with the blade advanced parallel to the sphincter and then rotated such that the sharp edge faces the internal sphincter, which can then be divided along its distal third. Pressure should be applied to the wound for a few minutes to prevent haematoma formation. In the open technique, the anoderm overlying the distal internal sphincter is divided longitudinally to expose the sphincter, which is divided, and the wound is closed with absorbable sutures. Although the fissure needs no specific attention, problematic papillae and external tags can be excised concomitantly.

Early complications of sphincterotomy include haemorrhage, haematoma, bruising, perianal abscess and fistula. Despite low recurrence rates the most important complication is incontinence of a variable nature and severity, which may affect up to 30% of patients, particularly women, who have weaker, shorter sphincter complexes and in whom there may already have been covert sphincter compromise incurred by childbirth.

Anal advancement flap

The recognition of the risk to continence following internal sphincterotomy has led some to advocate a different approach, especially in women and those with normal or low resting anal pressures, developed from the treatment of anal stenosis. After excision of the edges of the fissure and, if necessary, its base overlying the internal sphincter, an inverted house-shaped flap of perianal skin is carefully mobilised on its blood supply and advanced without tension to cover the fissure, and then sutured with interrupted absorbable sutures. The patient is maintained on stool softeners and bulking agents postoperatively, and usually also on topical sphincter relaxants; minor breakdown of one anastomotic edge does not herald ultimate failure (Summary box 69.6).

Summary box 69.6

Treatment of an anal fissure

- Conservative initially, consisting of stool-bulking agents and softeners, and chemical agents in the form of ointments designed to relax the anal sphincter and improve blood flow
- Surgery if above fails, consisting of lateral internal sphincterotomy or anal advancement flap

Mitchell James Notaras, Surgeon, Barnet General Hospital, Barnet, England.

Hypertrophied anal papilla

Anal papillae occur at the dentate line and are remnants of the ectodermal membrane that separated the hindgut from the proctodaeum. As these papillae are present in 60% of patients examined proctologically they should be regarded as normal structures. Anal papillae can become elongated, as they frequently do in the presence of an anal fissure. Occasionally, an elongated anal papilla may be the cause of pruritus. An elongated anal papilla associated with pain and/or bleeding at defaecation is sometimes encountered in infancy. Haemorrhage into a hypertrophied anal papilla can cause sudden rectal pain. A prolapsed papilla may become nipped by contraction of the sphincter mechanism after defaecation. Occasionally, a red oedematous papilla is encountered, with local pain and a purulent discharge from the associated crypt. This condition of ‘cryptitis’ may be cured by laying open the mouth of the infected anal gland and excising the papilla. Troublesome papillae may be simply excised.

Proctalgia fugax

This problem is characterised by attacks of severe pain arising in the rectum, recurring at irregular intervals and apparently unrelated to organic disease. The pain is described as cramp-like, often occurs when the patient is in bed at night, usually lasts only for a few minutes and disappears spontaneously. It may follow straining at stool, sudden explosive bowel action or ejaculation. It seems to occur more commonly in patients suffering from anxiety or undue stress, and it is also said to afflict young doctors. The pain may be unbearable – it is possibly caused by segmental cramp in the pubococcygeus muscle. It is unpleasant and incurable but is fortunately harmless and gradually subsides. A more chronic form of the disease has been termed the ‘levator syndrome’ and can be associated with severe constipation. Biofeedback techniques have been used to help such patients; in the past some surgeons tried severing the puborectalis muscle, but this can cause incontinence and should never be carried out.

HAEMORRHOIDS

The prevalence of haemorrhoids when patients are assessed proctoscopically far outweighs the prevalence of symptoms, and the term should only be used when patients have symptoms referable to them. Occasionally, patients with portal hypertension develop rectal varices, but these should not be confused with haemorrhoids as the consequences may be disastrous. Internal haemorrhoids (Greek: *haima* = blood, *rhoos* = flowing; synonym: piles, Latin: *pila* = a ball) are symptomatic anal cushions and characteristically lie in the 3, 7 and 11 o’clock positions (with the patient in the lithotomy position). In addition, haemorrhoids may be observed between the main pile masses, in which case they are internal haemorrhoids at the secondary position. External haemorrhoids relate to venous channels of the inferior haemorrhoidal plexus deep in the skin surrounding the anal verge and are not true haemorrhoids; they are usually only recognised as a result of a complication, which is most typically a painful solitary acute thrombosis. External haemorrhoids associated with internal haemorrhoids (‘intero-external piles’) result from progression of the latter to involve both haemorrhoidal plexuses and are best thought of as being external extensions of internal haemorrhoids. Secondary internal haemorrhoids arise as a result of a specific condition, although

the mechanisms involved may be the same as those involved in the formation of primary internal haemorrhoids. The most important cause, albeit relatively uncommon, is carcinoma of the anorectum (Fig. 69.25) but there are many other causes, which may be categorised as follows:

- local, e.g. anorectal deformity, hypotonic anal sphincter;
- abdominal, e.g. ascites;
- pelvic, e.g. gravid uterus, uterine neoplasm (fibroid, carcinoma of the uterus or cervix), ovarian neoplasm, bladder carcinoma;
- neurological, e.g. paraplegia, multiple sclerosis.

Primary internal haemorrhoids

Theories of development

Portal hypertension and varicose veins

Misconceptions concerning the vascular anatomy of the anal canal (specifically the lack of appreciation of communications between portal and systemic systems and the 'normality' of venous dilatations) led to theories of development of primary internal haemorrhoids that lasted for several centuries. Man's upright posture (we know little about haemorrhoidal problems in animals), lack of valves in the portal venous system and raised abdominal pressure were thought to contribute to the development of anal varicosities. If raised portal venous pressure were indeed the cause, one would expect a high incidence in subjects suffering from portal hypertension; however, although such patients have a higher incidence of anorectal varices, these are a separate anatomical and clinical entity from haemorrhoids, which are seen no more frequently than in those without cirrhosis, portal hypertension and oesophageal varices.

Other vascular causes

Historically, some considered haemorrhoids to be haemangiomas or to result from changes in the erectile tissue that forms part

of the continence mechanism, such as hyperplasia of the 'corpus cavernosum recti'.

Infection

Repeated infection of the anal lining, secondary to trauma at defaecation, has been postulated as a cause of weakening and erosion of the walls of the veins of the submucosa. This hypothesis is difficult to accept, as one of the truly incredible properties of the anal canal is its resistance to infection, as well as the ability of its mucosa to heal after surgical intervention despite the torrent of micro-organisms passing over it.

Diet and stool consistency

Much emphasis has been placed on the role of constipation in the development of haemorrhoids and, indeed, much of the management of sufferers involves attempts to 'normalise' bowel habits. A fibre-deficient diet results in a prolonged gut transit time, which is associated with the passage of smaller, harder stools that require more straining to expel. The presence of a hard faecal mass in the rectum could obstruct venous return, resulting in engorgement of the anal veins with the act of straining at stool or sitting for prolonged periods on the lavatory with a relaxed perineum, causing a disturbance of vascular flow. However, the epidemiological pattern of constipation is different from that of haemorrhoidal disease and, indeed, an association has been demonstrated between haemorrhoids and diarrhoeal disorders.

Anal hypertonia

The association between raised anal canal resting pressure and haemorrhoids is well known, but whether anal hypertonia causes symptoms attributable to haemorrhoids or whether anal cushion hypertrophy causes anal hypertonia is a subject of debate. The fact that surgical haemorrhoidectomy restores resting pressures to the normal range is not absolute evidence that the pile masses themselves are the cause of the hypertonia. It should be remembered, however, that there are a significant proportion of patients who suffer haemorrhoidal symptoms in whom the anal canal is relatively patulous, and there is mucosal prolapse, which is associated with perineal descent and pudendal neuropathy.

Ageing

In contrast to the anal cushion of early life, with age, the supporting structures show a higher proportion of collagen than muscle fibres and are fragmented and disorganised. Presumably, these changes arise over time with continued use of the anal canal for defaecation; however, similar changes are noted histologically in surgically excised haemorrhoids in younger patients.

Current view

Shearing forces acting on the anus (for a variety of reasons) lead to caudal displacement of the anal cushions and mucosal trauma. With time, fragmentation of the supporting structures (a normal consequence of ageing but perhaps accelerated in those with haemorrhoids) leads to loss of elasticity of the cushions such that they no longer retract following defaecation.

Clinical features

Bleeding, as the name haemorrhoid implies, is the principal and earliest symptom. The nature of the bleeding is characteristically separate from the motion and is seen either on the paper on wiping or as a fresh splash in the pan. Very rarely,

Figure 69.25 Carcinoma of the rectum associated with haemorrhoids, a not infrequent diagnostic pitfall.

the bleeding may be sufficient to cause anaemia. Pain is not commonly associated with the bleeding and its presence should make the clinician alert to the possibility of another diagnosis; however, pain may result from congestion of pile masses below a hypertonic sphincter. Piles associated with bleeding alone are called first-degree haemorrhoids (Summary box 69.7).

Summary box 69.7

Haemorrhoids: clinical features

- Haemorrhoids or piles are symptomatic anal cushions
- They are more common when intra-abdominal pressure is raised, e.g. in obesity, constipation and pregnancy
- Classically, they occur in the 3, 7 and 11 o'clock positions with the patient in the lithotomy position
- Symptoms of haemorrhoids:
 - bright-red, painless bleeding
 - mucus discharge
 - prolapse
 - pain only on prolapse

Patients may complain of true 'piles', lumps that appear at the anal orifice during defaecation and which return spontaneously afterwards (second-degree haemorrhoids), piles that have to be replaced manually (third-degree haemorrhoids) (Fig. 69.26) or piles that lie permanently outside (fourth-degree haemorrhoids). By this stage there is often a significant cutaneous component to the pile masses, which arise through repeated congestion and oedema. In addition to the main symptoms of pain and prolapse, patients may complain of anal irritation, which may occur as a result of mucus secretion from the caudally displaced rectal mucosa, minor leakage through a now imperfect anal seal or difficulties in cleaning after defaecation because of the irregularity of the anal verge (Summary box 69.8).

Figure 69.26 Third-degree haemorrhoids (courtesy of C.V. Mann, The Royal London Hospital, London).

Summary box 69.8

Four degrees of haemorrhoids

- First degree – bleed only, no prolapse
- Second degree – prolapse but reduce spontaneously
- Third degree – prolapse and have to be manually reduced
- Fourth degree – permanently prolapsed

Complications

Profuse haemorrhage is not rare. The bleeding mainly occurs externally but it may continue internally after the bleeding haemorrhoid has retracted or has been returned. In these circumstances the rectum is found to contain blood (Summary box 69.9).

Summary box 69.9

Complications of haemorrhoids

- Strangulation and thrombosis (Fig. 69.27)
- Ulceration
- Gangrene
- Portal pyaemia
- Fibrosis

Treatment of complications

Strangulation, thrombosis and gangrene In these cases it was formerly believed that surgery would promote portal pyaemia. However, if adequate antibiotic cover is given from the start, this is not found to be so, and immediate surgery can be justified in many patients. The other risk if surgery is performed at this stage, that of postoperative stenosis, results in some surgeons reviewing the situation much later and carrying out haemorrhoidectomy only if necessary. Besides adequate pain relief, bed rest with frequent hot baths and warm or cold saline compresses with firm pressure usually cause the pile mass to shrink considerably in 3–4 days. An anal dilatation technique has in the past been used as an alternative treatment to surgery for painful 'strangulated' haemorrhoids. However, because of the risk of incontinence this is no longer advised.

Figure 69.27 An attack of piles. Prolapsed strangulated piles, as commonly seen, on the left. A less common mass on the right with fibrofatty covering.

Severe haemorrhage The cause usually lies in a bleeding diathesis or the use of anticoagulants. If such causes are excluded, a local compress containing adrenaline solution, with an injection of morphine and blood transfusion if necessary, will usually suffice. However, after adequate blood replacement, ligation and excision of the piles may be required.

Management

Exclusion of other causes of rectal bleeding, especially colorectal malignancy, is the first priority. In the absence of a specific predisposing cause, important measures include attempts at normalising bowel and defaecatory habits: only evacuating when the natural desire to do so arises, adopting a defaecatory position to minimise straining, and the addition of stool softeners and bulking agents to ease the defaecatory act. Various proprietary creams can be inserted into the rectum from a collapsible tube fitted with a nozzle, at night and before defaecation. Suppositories are also useful.

In those with first- or second-degree piles whose symptoms are not improved by conservative measures, injection sclerotherapy (Mitchell), the submucosal injection of 5% phenol in arachis oil or almond oil, may be advised. Any invasive treatment, however, must be with full agreement of the patient, who should be informed of the potential risks of such interventions. The aim is to create fibrosis, cause obliteration of the vascular channels and hitch up the anorectal mucosa. With the awake patient in the left lateral position and under direct vision with a proctoscope, about 5 ml of sclerosant is injected into the apex of the pile pedicle (Fig. 69.28) using a (now) disposable needle and syringe (Fig. 69.29). The procedure is repeated for each pile and the patient reassessed after 8 weeks; if necessary, the injections are repeated. Pain upon injection means that the needle is in the wrong place and should be withdrawn. Injections that are too superficial are heralded by the rapid bulging of the musosa, which turns white; this leads to superficial ulceration but rarely serious septic sequelae. However, injections placed too deeply can have disastrous consequences, including pelvic sepsis, prostatitis, impotence and rectovaginal fistula.

For more bulky piles, banding has been shown to be efficacious, but it is associated with more discomfort. The Barron's bander is a commonly available device used to slip tight elastic bands

Figure 69.28 Correct site (cross) for injecting a haemorrhoid (after W.B. Gabriel, London).

Clinton Mitchell of Illinois, IL, USA was the first to use carbolic acid for injecting haemorrhoids. Itinerant irregular practitioners exploited the method.
John Baron, Surgeon, Chicago, IL., USA.

Figure 69.29 Gabriel's syringe (a) has now been replaced by disposable syringes (b).

onto the base of the pedicle of each haemorrhoid (Fig. 69.30). The bands cause ischaemic necrosis of the piles, which slough off within 10 days; this may be associated with bleeding, about which the patient must be warned. As with sclerotherapy, three piles may be treated at one session, and the process may be repeated after several weeks if necessary. The techniques of cryotherapy (Lloyd Williams) and infrared photocoagulation (Leicester) are not often used nowadays.

Operation

Indications

The indications for haemorrhoidectomy include:

- third- and fourth-degree haemorrhoids;
- second-degree haemorrhoids that have not been cured by non-operative treatments;
- fibrosed haemorrhoids;
- intero-external haemorrhoids when the external haemorrhoid is well defined.

If there is any doubt about the diagnosis of haemorrhoids, examination under anaesthesia and, if indicated, biopsy are necessary.

William Bashall Gabriel, 1893–1975, Surgeon, St Mark's Hospital and the Royal Northern Hospital, London, UK.
Kenneth Lloyd Williams, Dcd, Surgeon, The Royal United Hospitals, Bath, England.
Roger James Leicester, Formerly Surgeon, St George's Hospital, London, England.

Figure 69.30 Barron's banding apparatus, with the appearance of a typical 'banded' haemorrhoid.

The other strong indication for surgery is haemorrhoidal bleeding sufficient to cause anaemia. Beyond these, the indications summarised above are more relative than absolute, because in these situations surgery aims simply to improve symptoms and, of course, is not without risk. For instance, elderly multiparous women with hypotonic sphincters who are just continent before haemorrhoidectomy may find that the procedure results in frank incontinence, a far worse condition than that for which they originally sought help.

Technique

It is usual for the patient to have been taking stool softeners in the days before surgery and a preoperative enema to empty the rectum is administered. The procedure is usually performed under general or regional anaesthesia with the patient in the lithotomy or prone jack-knife position. The perianal skin is shaved and a formal examination performed. Haemorrhoidectomy can be performed using an open or a closed technique. The open technique is most commonly used in the UK and is known as the Milligan–Morgan operation – named after the surgeons who described it. The closed technique is the popular technique in the USA. Both involve ligation and excision of the haemorrhoid but in the open technique the anal mucosa and skin are left open to heal by secondary intention, and in the closed technique the wound is sutured.

Open technique The anoderm and subcutaneous tissues between the pile masses may be injected with dilute adrenaline (epinephrine; 1:300 000 dilution) to reduce bleeding and aid preservation of the skin bridges left following excision. Artery forceps are applied to the skin-covered external components of the piles and traction exerted to reveal the internal components, which are also grasped by artery forceps. When held out by the assistant these pairs of artery forceps form a triangle (Fig. 69.31a). The operator takes the left lateral pair of artery forceps in the palm of the hand and places the extended forefinger in the anal canal to support the internal haemorrhoid. In this way traction is applied to the skin of the anal margin. With scissors or cutting diathermy, a V-shaped cut is made through the skin and those fibres inserting into it around the skin-holding artery forceps. Traction by both operator and assistant, combined with careful dissection,

will expose the lower border of the internal sphincter. The dissection proceeds up the anal canal, with the sides of the mucosal dissection converging towards the pile apex and with the internal sphincter visible and separate from the dissected pile (Fig. 69.31b). A transfixion ligature of strong Vicryl is applied to the pedicle at this level (Fig. 69.31c), the pile is excised well distal to the ligature and, after ensuring haemostasis, the ligature is cut long. Each haemorrhoid is dealt with in this manner, taking care to leave mucocutaneous bridges. If there are significant secondary haemorrhoids under these bridges they can be filleted out by scissor dissection. Haemostasis must be absolute at the end of the procedure, when a soft absorbable anal dressing is inserted. The margins of the skin wounds are trimmed so as not to leave overhanging edges (Fig. 69.32). Bleeding subcutaneous arteries having been secured, the areas denuded of skin are dressed with three pieces of petroleum jelly gauze. A pad of gauze and wool and a firmly applied T-bandage complete the operation.

Closed technique The haemorrhoid is excised, together with the overlying mucosa, as illustrated in Fig. 69.33a. The haemorrhoid is dissected carefully from the underlying sphincter and artery forceps is achieved. The pedicle is transfixed and ligated with 3/0 Vicryl or Dexon. Any residual small haemorrhoids should be removed by filleting them out after undermining the edges of the cut mucosa. The mucosal defect is then closed completely with a continuous suture using the same stitch that was employed to ligate the haemorrhoid pedicle. The remaining haemorrhoids are excised and ligated in a similar fashion, ensuring that there are adequate mucosal and skin bridges between each area of excision to avoid a subsequent stenosis.

With the aim of symptom relief but preservation of the anal cushions, the technique of stapled haemorrhoidopexy (Longo), which utilises a purpose-designed stapling gun (PPH, Ethicon Inc.), has recently been described. This procedure excises a strip of mucosa and submucosa (together with the vessels travelling within them) circumferentially, well above the dentate line. Activation of the gun also simultaneously repairs the cut mucosa and submucosa by stapling the edges together (Fig. 69.34). This procedure is quick to perform, and controlled trials suggest that it is less painful and less traumatic than conventional haemorrhoidectomy and, at least in the short term, it seems to be equally efficacious. However, its efficacy in the long term is unknown (Summary box 69.10).

Summary box 69.10

Treatment of haemorrhoids

- Symptomatic – advice about defaecatory habits, stool softeners and bulking agents
- Injection of sclerosant
- Banding
- Haemorrhoidectomy

Postoperative care

In these days of economic stringencies, the patient is discharged from hospital within a day or two of the operation. In the USA,

A. Longo, Surgeon, Sicily, Italy.

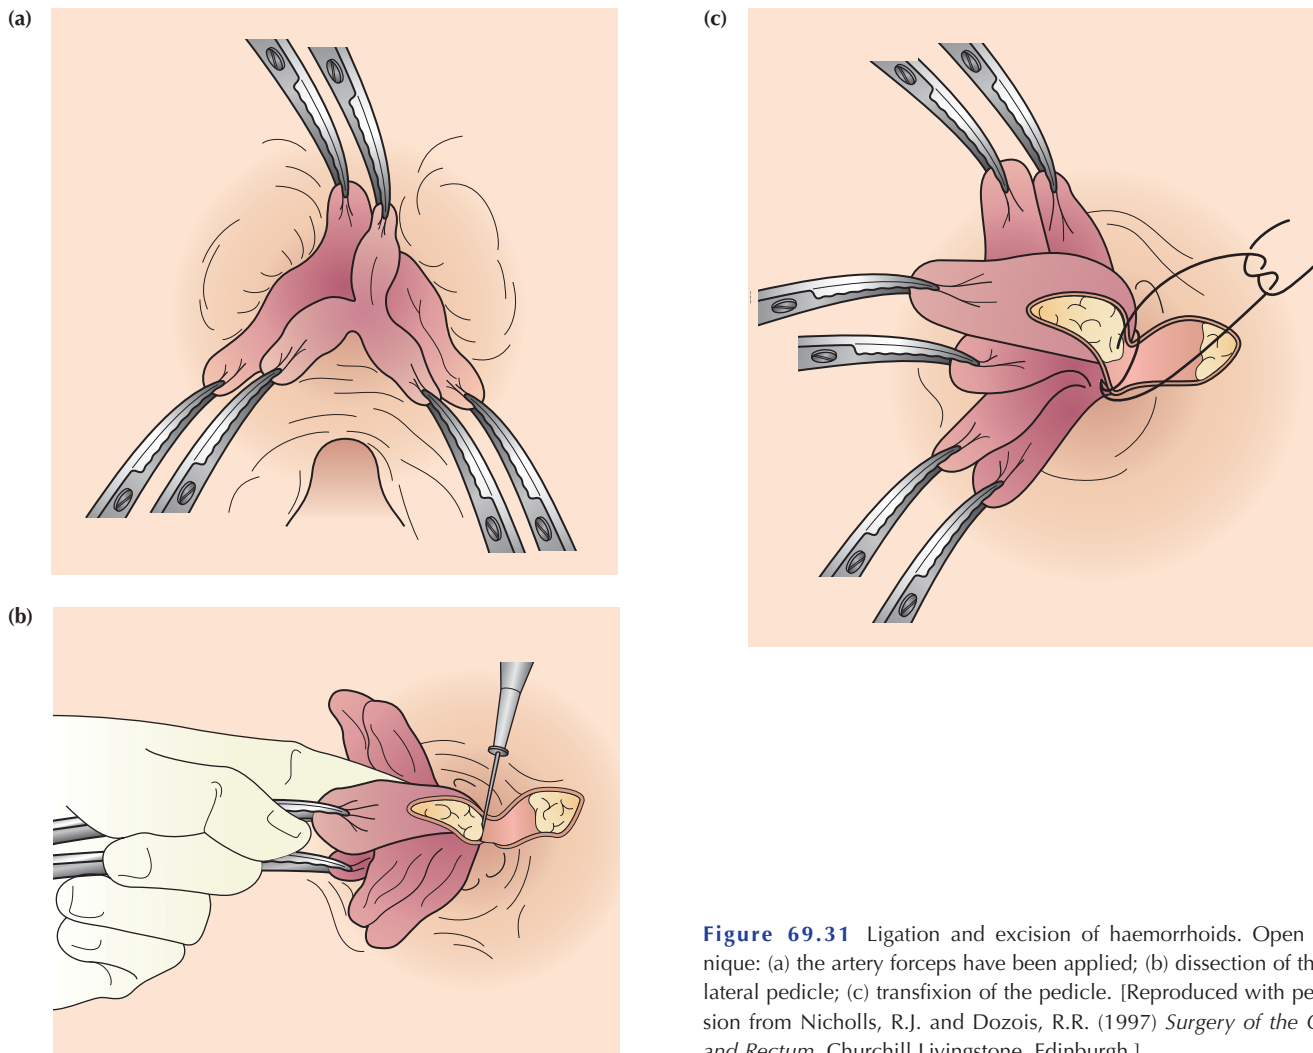

Figure 69.31 Ligation and excision of haemorrhoids. Open technique: (a) the artery forceps have been applied; (b) dissection of the left lateral pedicle; (c) transfixion of the pedicle. [Reproduced with permission from Nicholls, R.J. and Dozois, R.R. (1997) *Surgery of the Colon and Rectum*. Churchill Livingstone, Edinburgh.]

the procedure is often performed on a day-care basis. The patient is instructed to take two warm baths each day and is given a bulk laxative to take twice daily together with appropriate analgesia. Dry dressings are applied as necessary, a sterile sanitary towel usually being ideal. The patient is seen again 3–4 weeks after discharge and a rectal examination is performed. If there is evidence of stenosis, the patient is encouraged to use a dilator.

Postoperative complications

Postoperative complications may be early or late. Early complications include pain, which may require opiate analgesia; retention of urine, especially in men, which rarely may need relief by catheterisation; and reactionary haemorrhage, which is much more common than secondary haemorrhage. The haemorrhage may be mainly or entirely concealed but will become evident on examining the rectum. If persistent following adequate analgesia, the patient must be taken to the operating theatre and the bleeding point secured by careful diathermy or under-running with a

ligature on a needle, care being taken to avoid damage to the internal sphincter. Should a definite bleeding point not be found, the anal canal and rectum are packed.

Late postoperative complications include:

- *Secondary haemorrhage*. This is uncommon, occurring about the seventh or eighth day after operation. It is usually controlled by morphine but, if the haemorrhage is severe, an anaesthetic should be given and the bleeding controlled.
- *Anal stricture*, which must be prevented at all costs. A rectal examination at the postoperative review will indicate whether stricturing is to be expected. It may then be necessary to give a general anaesthetic and dilate the anus. After that, daily use of the dilator should give a satisfactory result.
- *Anal fissures and submucous abscesses*.
- *Incontinence*, especially if there has been inadvertent damage to the underlying internal sphincter. Although uncommon, this is obviously a very serious problem that is difficult to treat (Summary box 69.11).

Figure 69.32 The appearance of the anus at the conclusion of the operation. (Note that to avoid stricture formation it is necessary to ensure that a bridge of skin and mucous membrane remains between each wound.) 'If it looks like a clover the trouble is over, if it looks like a dahlia, it is surely a failure.' [Reproduced with permission from Nicholls, R.J. and Dozois, R.R. (1997) *Surgery of the Colon and Rectum*. Churchill Livingstone, Edinburgh.]

Summary box 69.11

Complications of haemorrhoidectomy

Early

- Pain
- Acute retention of urine
- Reactionary haemorrhage

Late

- Secondary haemorrhage
- Anal stricture
- Anal fissure
- Incontinence

External haemorrhoids

A thrombosed external haemorrhoid relates anatomically to the veins of the superficial or external haemorrhoidal plexus and is commonly termed a perianal haematoma. It presents as a sudden-onset, olive-shaped, painful blue subcutaneous swelling at the anal margin and is usually consequent upon straining at stool, coughing or lifting a heavy weight (Fig. 69.35). The thrombosis is usually situated in a lateral region of the anal margin. If the patient presents within the first 48 hours the clot may be evacuated under local anaesthesia. Untreated it may resolve, suppurate, fibrose and give rise to a cutaneous tag, burst and the clot extrude, or continue bleeding. In the majority of cases, resolution or fibrosis occurs. Indeed, this condition has been called 'a 5-day, painful, self-curing lesion' (Milligan).

Figure 69.33 Closed technique of haemorrhoidectomy. (a) The haemorrhoidal tissue is excised. (b) Bleeding is controlled by diathermy. (c) The defect is closed with a continuous suture after first undermining the anoderm on each side. [Redrawn with permission from Keighley, M.R.B. and Williams, N.S. (1999) *Surgery of the Anus, Colon and Rectum*, 2nd edn. W.B. Saunders, Philadelphia, PA.]

PRURITUS ANI

This is intractable itching around the anus, a common and embarrassing condition. Usually, the skin is reddened and hyperkeratotic and it may become cracked and moist.

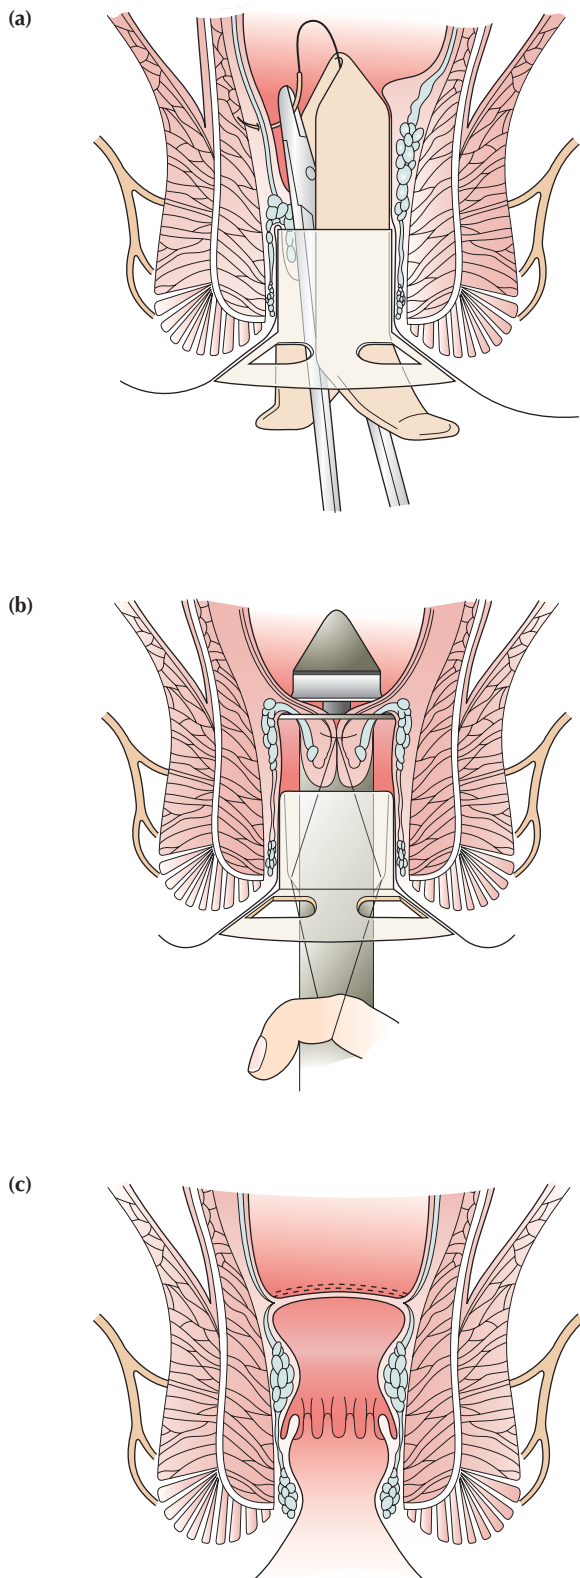

Figure 69.34 Staped haemorrhoidectomy. (a) The purse-string suture is placed several centimetres above the dentate line. (b) The anvil of the fully opened stapling gun is inserted endoanally so that it is above the purse-string suture, which is then tied around the shaft of the gun. The gun is closed and fired. (c) After firing, a 3–4 cm strip of mucosa and submucosa containing the haemorrhoids is excised and the mucosal edges are simultaneously stapled together.

Figure 69.35 A thrombosed external haemorrhoid that has burst. There is also a mucosal prolapse, which is separate from the cutaneous lesion.

Causes

The causes are numerous. A useful mnemonic is ‘pus, polypus, parasites, piles, psyche’:

- *Lack of cleanliness*, excessive sweating and wearing rough or woollen underclothing.
- *An anal or perianal discharge* that renders the anus moist. The causative lesions include an anal fissure, fistula-in-ano, prolapsed internal or external haemorrhoids, genital warts and excessive ingestion of liquid paraffin. A mucous discharge is an intense pruritic agent and a polyp can be the cause.
- *A vaginal discharge*, especially caused by *Trichomonas vaginalis* infection.
- *Parasitic causes*. Threadworms should be excluded, especially in young subjects. Children suffering from threadworms should wear gloves at night, lest they scratch the perianal region and are reinfested with ova by nail biting – ‘parasites lost, parasites regained’. Scabies and pediculosis pubis may infest the anal region.
- *Epidermophytosis* is a common cause, especially if the skin between the toes is also infected; microscopic and cultural examinations are essential. Half-strength Whitfield’s ointment quickly gives relief and is the sheet anchor of treatment.
- *Allergy* is sometimes the cause, in which case there is likely to be a history of other allergic manifestations, such as urticaria, asthma or hay fever. Antibiotic therapy may be the precipitating factor.
- *Skin diseases* localised to the perianal skin: psoriasis, lichen planus and contact dermatitis.

Arthur Whitfield, 1867–1967, Professor of Dermatology, Kings College Hospital, London, UK. Whitfield’s ointment is ‘compound ointment of benzoic acid’.

- *Bacterial infection*, such as intertrigo resulting from a mixed bacterial infection. Erythrasma caused by *Corynebacterium minutissimum* is responsible for some cases and its presence is detected by ultraviolet light, which induces a pink fluorescence.
- A *psychoneurosis*. It is alleged that in a few instances neurotic individuals become so immersed in their complaint that a pain–pleasure complex develops, the pleasure being the scratching. Possibly this is true, but such a syndrome should not be assumed without firm grounds for coming to this conclusion.
- *Diabetes* can sometimes present with pruritus ani, and the urine should be tested in all patients.

Treatment

The cause is treated. Symptomatic treatment includes the following:

- *Hygiene measures*. Cotton wool should be substituted for toilet paper. Soap is avoided and replaced by water alone, and the area pat-dried rather than rubbed. These measures alone, combined with wearing cotton underwear and the application of calamine lotion or zinc and castor oil, are all that is necessary to cure some cases. If there is much anal hair trapping the moisture and discharge, shaving can be very helpful.
- *Hydrocortisone*. In patients with dermatitis, and only in patients with dermatitis, the topical application of 0.5% or 1% prednisolone cream is often beneficial; sometimes after discontinuation of the therapy, the pruritus is liable to return, in which case 5% lidocaine hydrochloride (Xylocaine) ointment can be substituted for a time.
- *Strapping the buttocks* keeps moist opposing surfaces apart but is not well tolerated. If the moistness originates from anal discharge, a cotton wool anal plug will seal the anal orifice.

Operative treatment

This may be necessary for a concomitant lesion of the anorectum that is thought to initiate or contribute to the pruritus. Otherwise, surgery is not indicated (Summary box 69.12).

Summary box 69.12

Pruritus ani

- Common
- Numerous causes including skin diseases, parasites (threadworm), anal discharge, allergies, diabetes
- Treat the cause if possible
- Symptomatic treatment is the mainstay

ANORECTAL ABSCESSSES

Acute sepsis in the region of the anus is common. A fundamental distinction that has to be made is whether the sepsis is in that area by chance (simple boil, skin appendage infection) or whether it has arisen as a consequence of the presence of the anorectum, specifically the anal glands. Overall, anorectal sepsis is more common in men than women, although infections with skin-type organisms (and thus unrelated to fistula) are evenly distributed. The cryptoglandular theory of intersphincteric anal gland infection (Parks) holds that, upon infection of a gland, pus, which

travels along the path of least resistance, may spread caudally to present as a perianal abscess, laterally across the external sphincter to form an ischioanal abscess or, rarely, superiorly above the anorectal junction to form a supralelevator intermuscular or pararectal abscess (depending on its relation to the longitudinal muscle), as well as circumferentially in any of the three planes: intersphincteric/intermuscular, ischioanal or pararectal supralevator (Fig. 69.36). Sepsis unrelated to anal gland infection may occur at the same or at other sites (Fig. 69.37), including

Figure 69.36 Axial magnetic resonance imaging (MRI) scan (STIR sequence) showing posterior horseshoe spread of sepsis within the intersphincteric space.

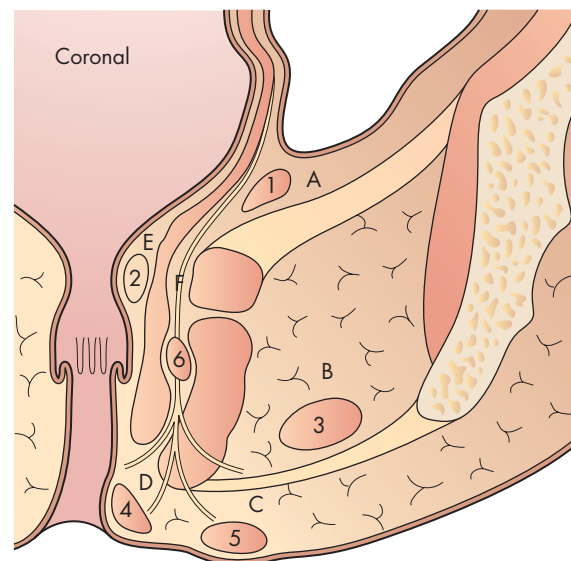

Figure 69.37 Diagram showing the spaces in relation to the anus and types of anorectal abscess in coronal section: A, pelvirectal supralevator space; B, ischioanal space; C, perianal or superficial ischioanal space; D, marginal or mucocutaneous space; E, submucous space; F, anorectal intermuscular (intersphincteric) space; 1, pelvirectal supralevator abscess; 2, submucous abscess; 3, ischioanal abscess; 4, marginal abscess; 5, perianal abscess; 6, intersphincteric abscess. [Reproduced with permission from Nicholls, R.J. and Dozois, R.R. (1997) *Surgery of the Colon and Rectum*. Churchill Livingstone, Edinburgh.]

submucosal abscess (following haemorrhoidal sclerotherapy, which usually resolve spontaneously), mucocutaneous or marginal abscess (infected haematoma), ischioirectal abscess (foreign body, trauma, deep skin-related infection) and pelvirectal supralelevator sepsis originating in pelvic disease. Underlying rectal disease, such as neoplasm and particularly Crohn's disease, may be the cause. Similarly, patients with generalised disorders, such as diabetes and acquired immunodeficiency syndrome (AIDS), may present with an anoirectal abscess; in these patients, abscesses may run an aggressive course.

Presentation

A perianal abscess, confined by the terminal extensions of the longitudinal muscle, is usually associated with a short (2–3 day) history of increasingly severe, well-localised pain and a palpable tender lump at the anal margin. Examination reveals an indurated hot tender perianal swelling. Patients with infection in the larger fatty-filled ischioirectal space, in which tissue tension is much lower, usually present later, with less well localised symptoms but more constitutional upset and fever. On examination, the affected buttock is diffusely swollen with widespread induration and deep tenderness. If sepsis is higher, deep rectal pain, fever and sometimes disturbed micturition may be the only features, with nothing evident on external examination but tender supralelevator induration palpable on digital examination above the anoirectal junction.

Differential diagnosis

The only conditions with which an anoirectal abscess is likely to be confused are abscesses connected with a pilonidal sinus, Bartholin's gland or Cowper's gland.

Management

Management of acute anoirectal sepsis is primarily surgical, including careful examination under anaesthesia, sigmoidoscopy and proctoscopy, and adequate drainage of the pus. For perianal and ischioirectal sepsis (with an incidence of 60% and 30% respectively), drainage is through the perineal skin, usually through a cruciate incision over the most fluctuant point, with excision of the skin edges to de-roof the abscess (Fig. 69.38). Pus is sent for microbiological culture (Grace) and tissue from the wall is sent for histological appraisal to exclude specific causes. With a finger in the anoirectum to avoid creation of a false opening, the cavity is carefully curetted. A gentle search may be made for an underlying fistula if the surgeon is experienced, and, if obvious, a loose draining seton may be passed; injudicious probing in the acute stage is, however, potentially dangerous and may lead to a much more difficult situation. Unless by highly experienced hands, immediate fistulotomy should not be performed. After irrigation of the cavity, the wound is lightly tucked; antibiotics are prescribed if there is surrounding cellulitis and especially in those less resistant to infection, such as diabetics. If the pus subsequently cultures skin-type organisms there will be no underlying fistula and the patient can be reassured. If gut flora are cultured, it is likely, but not inevitable, that there is an underlying fistula.

Figure 69.38 Incision of an ischioirectal abscess. The cavity is explored and, if septa exist, they should be broken down gently with a finger and the necrotic tissue lining the walls of the abscess removed by the finger wrapped in gauze. It is wise to biopsy the wall and send the pus for culture. Nothing further is done at this stage.

The management of supralelevator sepsis is dependent upon its exact anatomy (within or outside the rectal wall) and its origin. Sepsis originating in pelvic disease necessitates appropriate management of the underlying cause (appendiceal, gynaecological, diverticular, Crohn's disease, malignancy), although intrarectal drainage may be apt to avoid creation of an extrasphincteric fistula. Cephalad extension of an intersphincteric fistula can be safely drained into the rectum, whereas supralelevator extension of a trans-sphincteric fistula should be drained via the skin of the buttock. Rarely, a colostomy may be necessary to control severe sepsis, especially in the immunocompromised individual (Summary box 69.13).

Summary box 69.13

Anoirectal abscess

- Usually produces a painful, throbbing swelling in the anal region. The patient often has swinging pyrexia
- Subdivided according to anatomical site into perianal, ischioirectal, submucous and pelvirectal
- Underlying conditions include fistula-in-ano (most common), Crohn's disease, diabetes, immunosuppression
- Treatment is drainage of pus in first instance, together with appropriate antibiotics
- Always look for a potential underlying problem

FISTULA-IN-ANO

A fistula-in-ano, or anal fistula, is a chronic abnormal communication, usually lined to some degree by granulation tissue, which runs outwards from the anoirectal lumen (the internal opening) to an external opening on the skin of the perineum or buttock (or rarely, in women, to the vagina). Anal fistulae may be found in association with specific conditions, such as Crohn's disease, tuberculosis, lymphogranuloma venereum, actinomycosis, rectal duplication, foreign body and malignancy (which may also very rarely arise within a longstanding fistula), and suspicion of these should be aroused if clinical findings are unusual. However, the majority are termed non-specific, idiopathic or cryptoglandular,

Caspar Bartholin, Secundus, 1655–1709, Professor of Medicine, Anatomy and Physics, Copenhagen, Denmark, described these glands in 1677.

William Cowper, 1666–1709, London surgeon, described these glands in 1697.

Roger Hew Grace, Formerly Professor of Colorectal Surgery, The Royal Wolverhampton Hospital, Wolverhampton, England.

and intersphincteric anal gland infection is deemed central to them.

Presentation

For reasons that are unknown, non-specific anal fistulae are more common in men than women. The overall incidence is about 9 cases per 100 000 population per year in western Europe, and those in their third, fourth and fifth decades of life are most commonly affected. Patients usually complain of intermittent purulent discharge (which may be bloody) and pain (which increases until temporary relief occurs when the pus discharges). There is often, but not invariably, a previous episode of acute anorectal sepsis that settled (incompletely) spontaneously or with antibiotics, or which was surgically drained. The passage of flatus or faeces through the external opening is suggestive of a rectal rather than an anal internal opening.

Classification

The most widespread and useful classification of anal fistulae is that proposed by Parks, based on the centrality of intersphincteric anal gland sepsis (the internal opening is usually at the dentate line), which results in a primary track whose relation to the external sphincter defines the type of fistula and which influences management (Fig. 69.39). Classifications based simply on level are less practical because they mean different things to different people, although the description of a fistula as high, indicating a high risk of incontinence if laid open, or low, with a lower but still some risk to function, is often used. Similarly, 'simple' and 'complex' are commonly used adjectives – complexity may be endowed by the level at which the primary track crosses the sphincters, the presence of secondary extensions or the difficulties faced in treatment. The vast majority of fistulae are intersphincteric or trans-sphincteric.

Intersphincteric fistulae (45%) do not cross the external sphincter (bar, for the purist, the most medial subcutaneous fibres running below the distal border of the internal sphincter); most commonly they run directly from the internal to the external openings across the distal internal sphincter, but may extend proximally in the intersphincteric plane to end blindly with or without an abscess, or enter the rectum at a second internal opening.

Trans-sphincteric fistulae (40%) have a primary track that crosses both internal and external sphincters (the latter at a variable level) and which then passes through the ischioanal fossa

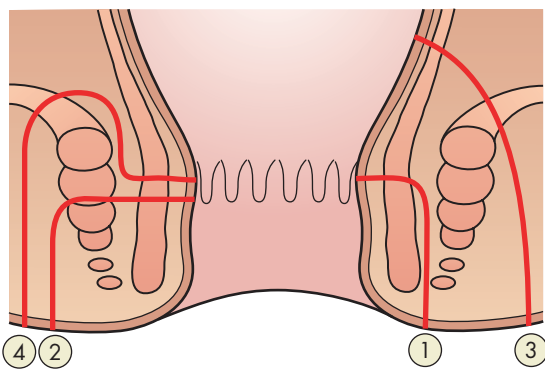

Figure 69.39 Types of anal fistula (Parks' classification): 1, intersphincteric; 2, trans-sphincteric; 3, suprasphincteric; and 4, extrasphincteric primary tracks.

to reach the skin of the buttock. The primary track may have secondary tracks arising from it, which often reach the roof of the ischioanal fossa, which may rarely pass through the levators to reach the pelvis and which may spread circumferentially (horseshoe). Circumferential spread of sepsis may occur in the intersphincteric and pararectal planes, as well as in the ischioanal plane.

Suprasphincteric fistulae are very rare, are thought by some to be iatrogenic and are difficult to distinguish from high-level trans-sphincteric tracks (for which, fortunately, management strategies are similar). Extrasphincteric fistulae run without specific relation to the sphincters and usually result from pelvic disease or trauma.

Clinical assessment

A full medical (including obstetric, gastrointestinal, anal surgical and continence) history and proctosigmoidoscopy are necessary to gain information about sphincter strength and to exclude associated conditions. The key points to determine are the site of the internal opening; the site of the external opening(s); the course of the primary track; the presence of secondary extensions; and the presence of other conditions complicating the fistula. Palpable induration between external opening and anal margin suggests a relatively superficial track, whereas supralevator induration suggests a primary track above the levators or high in the roof of the ischioanal fossa, or a high secondary extension. Intersphincteric fistulae usually have an external opening close to the anal verge. Goodsall's rule (Fig. 69.40), used to indicate the likely position of the internal opening according to the position of the external opening(s), is helpful but not infallible. The site of the internal opening may be felt as a point of induration or seen as an enlarged papilla. Probing in an awake patient is painful, unhelpful and can be dangerous. Full examination under anaesthesia should be repeated before surgical intervention. Dilute hydrogen peroxide, instilled via the external opening, is a very useful way of demonstrating the site of the internal opening; gentle use of probes (Fig. 69.41) and a finger in the anorectum usually delineates primary and secondary tracks and their relations to the sphincters. Any concerns about fistula topography at clinical examination or examination under anaesthesia (more common after previous unsuccessful surgery) should prompt further investigations before surgical intervention.

Special investigations

A successful outcome after fistula surgery requires an accurate assessment of the fistula itself, the sphincter through which it passes and patient expectations (especially in terms of risk to continence). Clinical examination will give some indication of functional anal sphincter length, resting tone and voluntary squeeze;

Figure 69.40 Goodsall's rule.

David Henry Goodsall, 1843–1906, Surgeon, St Mark's Hospital, London, UK.

Figure 69.41 Retrograde probing of an anal canal sometimes reveals the internal orifice of the fistula.

these may be more objectively assessed by manometry whereas endoanal ultrasound gives useful information about sphincter integrity – the knowledge so gained may well influence surgical strategy. Endoanal ultrasound, especially with hydrogen peroxide, can also be used to delineate fistulae, although definition of sepsis outside or above the sphincters is limited by the probe's focal range and scarring makes interpretation difficult. Nonetheless, ultrasound, which is more accurate than clinical examination, is useful to determine whether a fistula is relatively straightforward or not. Magnetic resonance imaging (MRI) is acknowledged to be the 'gold standard' for fistula imaging but it is limited by availability and cost and is usually reserved for difficult recurrent cases. The great advantage of MRI is its ability to demonstrate secondary extensions, which may be missed at surgery and which are the cause of persistence (Fig. 69.42). Fistulography and computerised tomography (CT) both have limitations but are useful techniques if an extrasphincteric fistula is suspected.

Surgical management

Patients with minimal symptoms, especially if they have compromised sphincters, may be managed expectantly. Eradication of sepsis requires surgery, the aim of which must be balanced with

Figure 69.42 Coronal magnetic resonance imaging (MRI) scan (STIR sequence) demonstrating a primary track running up the right ischioanal space (short white arrow), which then crosses the sphincters to open into the anal canal just below the puborectalis. However, there is a blind secondary extension (long white arrow) passing to the contralateral side in the roof of the left ischioanal fossa (and involving the levators), which was missed at surgery and which was the cause of fistula persistence.

the preservation of continence. Most fistulae are relatively straightforward to deal with; however, a minority are extremely problematic and are not the realm of the 'occasional proctologist'. The multitude of strategies advocated attests to these difficult situations; comparisons between techniques are difficult to make because of the heterogeneity of patient groups, the variability in classification, the inapplicability of certain techniques in some situations, inadequate reporting of functional outcomes, inadequate follow-up and surgeon preference over-riding entry into prospective randomised trials.

Fistulotomy

That the fistulous track must be laid open from its termination to its source was a rule promulgated by John of Arderne more than 600 years ago. Fistulotomy, or laying open, is the surest way of getting rid of a fistula, but, by definition, it involves division of all those structures lying between the external and internal openings. It is therefore applied mainly to intersphincteric fistulae and trans-sphincteric fistulae involving less than 30% of the voluntary musculature (but not anteriorly placed fistulae in women); however, even then, it is not immune to postoperative defects in continence. After full examination under anaesthesia in the lithotomy or prone jackknife position, during which the internal opening should have been identified, a grooved fistula probe is passed from the external to the internal opening (Fig. 69.43), the amount of sphincter below and above the probe is noted and, if indicated, the track is laid open over the probe. Granulation tissue is curetted and sent for histological appraisal and the wound edges are trimmed. Secondary tracks, often identified as granulation tissue that persists despite curettage, should be laid open or drained. Marsupialisation reduces wound size and speeds up healing. Primary tracks crossing the external sphincter more deeply have been managed with good outcomes by fistulotomy and immediate reconstitution of the divided muscle – failure to eradicate all sepsis and subsequent breakdown of the repair, however, are very problematic. Alternatively, a staged fistulotomy may be carried out in which secondary tracks are laid open and only part of the sphincter enclosed by the primary track is divided, with the remainder encircled by a loose seton. After sufficient time for healing of the wound and fibrosis, the seton-enclosed track is divided at a second stage.

Fistulectomy

This technique involves coring out of the fistula, usually by diathermy cautery; it allows better definition of fistula anatomy than fistulotomy, especially the level at which the track crosses the sphincters and the presence of secondary extensions. If the sphincteric component of the fistula is deemed low enough to allow safe fistulotomy, then this may proceed (at the expense of longer healing times than conventional fistulotomy). If laying open is not advisable, then the sphincteric component can be managed by another method.

Setons

Setons (Latin: *seta* = bristle) have been used in a variety of ways in fistula surgery and it is important for surgeons to be clear about

John of Arderne, 1307–1390, was the first English surgeon of note. He practised at Newark-upon-Trent, Nottinghamshire and, from 1370, in London, UK. He described his operation for the treatment of fistula in about 1376.

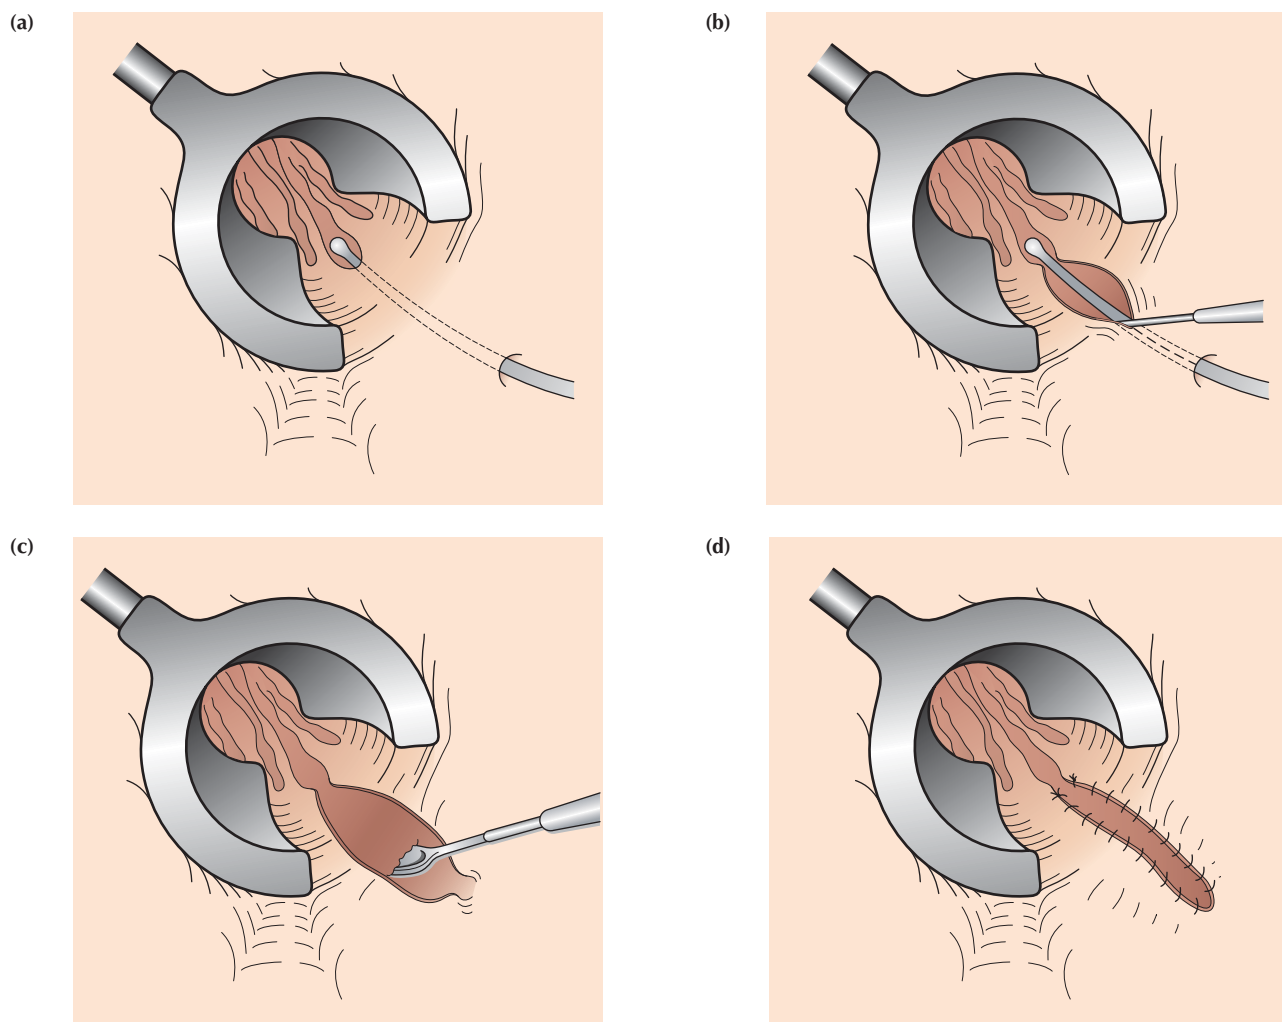

Figure 69.43 Fistulotomy. A grooved probe is passed from the external to internal openings and the track laid open over the probe. The track is curetted to remove granulation tissue, the edges of the wound are trimmed and the wound may then be marsupialised. [Reproduced with permission from Nicholls, R.J. and Dozois, R.R. (1997) *Surgery of the Colon and Rectum*. Churchill Livingstone, Edinburgh.]

what they are trying to achieve in a particular situation. *Loose* setons are tied such that there is no tension upon the encircled tissue; there is no intent to cut the tissue. A variety of materials have been used but the seton should be non-absorbable, non-degenerative and comfortable. *Tight* or *cutting* setons are placed with the intention of cutting through the enclosed muscle.

Uses of loose setons

1. For *long-term palliation* to avoid septic and painful exacerbations by establishing effective drainage; most often in Crohn's disease and in those with problematic fistulae not wishing to countenance the possibility of incontinence.
2. Used *before 'advanced' techniques* (fistulectomy, advancement flap, cutting seton); acute sepsis and secondary extensions are eradicated and a loose seton is passed across the sphincteric component of the primary track to simplify the fistula and allow fibrosis.
3. As part of a *staged fistulotomy*.
4. As part of a therapeutic strategy to *preserve the external sphincter* in trans-sphincteric fistulae. Secondary tracks in the ischioanal fossa are laid open. Access to the site where the

primary track crosses the external sphincter may sometimes necessitate division of the anococcygeal ligaments to reach the deep post-anal space. The internal sphincter is laid open to the level of the internal opening (or higher if there is a cephalad intersphincteric extension) to eradicate the presumed source and the sepsis in the intersphincteric space. A seton is then passed along the residual track around the denuded external sphincter and tied loosely, and the wounds are dressed. Initial postoperative management includes daily wound irrigation and light wound redressing. The seton is left in place for 3 months and, if there is evidence of good healing, simply removed. Such a strategy certainly protects against the consequences of external sphincter division, with an incidence of healing in the short term of 50–60%.

Uses of cutting setons

Cutting setons aim to achieve the high fistula eradication rates associated with fistulotomy but without the degree of functional impairment endowed by division of the sphincters at a single stage. The enclosed muscle is gradually severed ('cheese wiring through ice') such that the divided muscles do not spring apart,

and the site of the fistula track is replaced by a thin line of fibrosis as it is brought down. Some recommend prior internal sphincter division, others incorporation of the internal sphincter within the cutting seton. A variety of seton material has been used, either elastic and 'self-cutting' or non-elastic and tightened at intervals, with the sphincter being divided at varying speeds. In eastern parts of the world the same aim has been achieved by chemical cautery using an Ayurvedic method, known in India as Kshara sutra, in which a specially prepared seton thread burns through the enclosed tissue. This out-patient method has been shown to be equivalent to one-stage fistulotomy in patients with intersphincteric and distal trans-sphincteric fistulae.

Advancement flaps

When the sphincter complex is not too indurated and adequate intra-anal access can be obtained, the advancement flap technique can be employed, which aims to preserve both anatomy and function. The principles are prior elimination of acute sepsis and secondary tracks, with ideally a direct track from internal to external openings; coring out of the entire track; and closure of the communication with the anal lumen with an adequately vascularised flap consisting of mucosa and internal sphincter, sutured without tension to the anoderm, well distant from the site of the (excised) internal opening. Modifications include flap orientation (proximally or distally based) and thickness (mucosal, partial or full-thickness internal sphincter), and treatment of the external wound.

Glues

The functional consequences of fistulotomy and the poorer eradication rates of sphincter-preserving techniques has led to a search for agents that, once the fistula has been adequately rid of lining granulation tissue and epithelium, essentially plug and seal the track and allow ingrowth of healthy tissue to replace it. Results with fibrin glue have shown short-term promise but there is currently insufficient evidence concerning indications for use, technique and long-term outcomes. Nevertheless, research into biological agents must continue if outcomes for the patient with an anal fistula are to be improved (Summary box 69.14).

Summary box 69.14

Anorectal fistulae

- Are common and may be simple or complex
- Are classified according to their relationship to the anal sphincters
- May be associated with underlying disease such as tuberculosis or Crohn's disease
- Laying open is the surest method of eradication, but sphincter division may result in incontinence

HIDRADENITIS SUPPURATIVA

This is a chronic suppurative condition of apocrine gland-bearing skin, which is found in the axillae, submammary regions, nape of the neck, groin, mons pubis, inner thighs and sides of the

The Ayurvedic method is derived from the Ayurveda, the most ancient system of Hindu medicine whose origin is ascribed to Brahma and dates from circa 1400 to 1200 BC.

scrotum, as well as the perineum and buttocks, and is a source of considerable physical and psychological morbidity. There is no confirmatory test or specific characteristic for diagnosis, which makes definition difficult. Acne, pilonidal sinus and chronic scalp folliculitis may co-exist with hidradenitis suppurativa in the condition 'follicular occlusion tetrad'.

Pathology

Occlusion of gland ducts leads to bacterial proliferation, gland rupture and spread of infection and epithelial components into the surrounding soft tissue and to adjacent glands. Secondary infection (with *Staphylococcus aureus*, *Streptococcus milleri* and anaerobes) causes further local extension, skin damage and deformity, with multiple communicating subcutaneous fistulae. There is some evidence that the disease may be related to a relative androgen excess.

Presentation

The condition is not seen before puberty and rarely presents after the fourth decade of life. Overall, it is three times more common in women than men, although anogenital disease is more common in men, and obesity is a common association. When affecting the perineum, lesions begin as multiple raised boils, with recurrent lesions within the same vicinity leading to sinus tract formation, bridged scarring and multiple points of discharge. Rarely, it may involve the anal canal anoderm but it does not extend above the dentate line or involve the sphincter muscles themselves.

Differential diagnosis

In the early stages distinction from furunculosis can be difficult. Crohn's disease, cryptoglandular fistula, pilonidal sinus, tuberculosis, actinomycosis, lymphogranuloma venereum and granuloma inguinale must be considered when later stages present.

Treatment

In the early stages, general measures, including weight reduction and antiseptic soaps, may be helpful. Antibiotics may induce remission but often the disease relapses and progresses, at which point surgery is indicated. Inadequate treatment may lead to prolonged morbidity but any surgery should be less debilitating than the condition. Surgical intervention ranges from simple incision and drainage of acute sepsis to radical excision of all apocrine gland-bearing skin. Careful laying open of all tracts, possibly as a staged procedure according to anatomical location, is an option that appeals to many patients. Radical excision requires closure by skin graft or rotation flap and, occasionally, a defunctioning colostomy to allow healing.

CONDYLOMATA ACCUMINATA (ANAL WARTS)

There is increasing evidence that sexually transmitted infection with human papillomavirus (HPV) forms the aetiological basis of anal and perianal warts, anal intraepithelial neoplasia (AIN) and squamous cell carcinoma of the anus. In those areas of the world where sexual promiscuity (especially anal intercourse) is more common, and in immunocompromised individuals (HIV-infected individuals and transplant recipients), there have been dramatic increases in the incidence of these conditions over the last 30

years, most importantly of AIN and anal cancers. Similar virally induced changes have been noted in the genital tracts of women [vulval intraepithelial neoplasia (VIN), cervical intraepithelial neoplasia (CIN) and cancers]. There are over 80 subtypes of HPV but certain subtypes (16, 18, 31, 33) are associated with a greater risk of progression to dysplasia and malignancy.

Condylomata accuminata is the most common sexually transmitted disease encountered by colorectal surgeons and is most frequently observed in homosexual men. Associated warts on the penis and along the female genital tract are common.

Presentation

Many are asymptomatic but pruritus, discharge, bleeding and pain are usual presenting complaints. In the early stages, examination reveals separate pinkish-white warts close to the anal margin and also often on the anoderm within the distal anal canal. Later, the warts enlarge, coalesce and carpet the skin. Rarely, relentless growth results in giant condylomata (Buschke–Löwenstein tumour), which may obliterate the anal orifice. The diagnosis is aided by aceto-whitening upon application of acetic acid but confirmed by biopsy, which will also indicate the presence or absence of dysplasia.

Treatment

Because of the field effect endowed by viral skin infection, long-term resolution can be problematic. Careful serial application of 25% podophyllin to discrete warts on the perianal skin is often used; however, it cannot be used intra-anally. Surgical excision under local, regional or general anaesthesia involves raising and separating the lesions with local infiltration of dilute adrenaline, which allows more accurate scissor or electrocautery excision to maximise the preservation of normal skin.

ANAL INTRAEPITHELIAL NEOPLASIA

AIN (Fig. 69.44) is virally induced dysplasia of the perianal or intra-anal epidermis. The incidence is unknown but it is being detected with increasing frequency in those areas where anoreceptive intercourse and HIV are prevalent. Patients are often asymptomatic and the diagnosis is often a histological surprise, although increasing numbers in high-risk groups are picked up on anal cytology. It is classified according to the degree of dysplasia on biopsy into AIN I, AIN II and AIN III, according to the lack of keratocyte maturation and extension of the proliferative zone from the lower third (AIN I) to the full thickness of the epithelium (AIN III), in the same manner as cervical or vulval dysplasia. The natural history is uncertain but progression from AIN II to AIN III to invasive carcinoma has been observed, notably in the immunocompromised. The term Bowen's disease should probably be avoided.

Presentation

AIN is often subclinical but is found in up to 30% of patients with anal warts. Suspicious areas are raised, scaly, white, erythematous, pigmented or fissured.

Abraham Buschke, 1868–1943, a German Dermatologist.

L. W. Löwenstein described this condition in 1939.

John Templeton Bowen, 1857–1941, Professor of Dermatology, Harvard University Medical School. Boston, MA, USA, described this intradermal precancerous skin lesion in 1912.

Figure 69.44 Extensive anal intraepithelial neoplasia (AIN), which extends intra-anally.

Diagnosis and management

A high index of suspicion and targeted biopsy yields the diagnosis, whereas multiple (mapping) biopsies give an indication of the extent and overall severity of the disease. AIN II and III should be regularly monitored clinically and, if necessary, by repeat biopsy to exclude invasive disease. Focal disease may be excised. More widespread disease can be dealt with surgically by wide local excision and closure of the resultant defect by flap or skin graft, with or without covering colostomy (especially if there is intra-anal disease). Topical imiquimod or oral retinoids have some effect on the progression of dysplasia.

NON-MALIGNANT STRICTURES

Spasmodic

An anal fissure causes spasm of the internal sphincter. Rarely, a spasmodic stricture accompanies secondary megacolon, possibly as a result of the chronic use of laxatives.

Organic

Postoperative stricture

This sometimes follows a haemorrhoidectomy performed incorrectly. Low coloanal anastomoses, especially if a stapling gun is used, can narrow down postoperatively.

Irradiation stricture

This is an aftermath of irradiation.

Senile anal stenosis

A condition of chronic internal sphincter contraction is sometimes seen in the elderly. Increasing constipation is present, with pronounced straining at stool. Faecal impaction is liable to occur. The muscle is rigid and feels like a tight rubber ring. There is no evidence of a fissure-*in-ano*. The treatment is dilatation at frequent intervals.

Lymphogranuloma inguinale (see Chapter 68)

This is by far the most frequent cause of a tubular inflammatory stricture of the rectum and 80% of the sufferers are women. Frei's

Wilhelm Sigmund Frei, 1885–1943, Professor of Dermatology, the State Hospital, Spandau, Berlin, who later settled in New York, NY, USA, described his test for lymphogranuloma inguinale in 1925.

reaction is usually positive. This variety of rectal stricture is particularly common in black populations and may be accompanied by elephantiasis of the labia majora. In the early stages, antibiotic treatment may lead to cure. In advanced cases, excision of the rectum is required.

Inflammatory bowel disease

Stricture of the anorectum may complicate Crohn's disease and, in this instance, the stricture is annular and often more than one is present. Occasionally, an anal stricture may occur in ulcerative colitis. Until a biopsy is obtained, a carcinoma should be suspected if a stricture is found.

Endometriosis

Endometriosis of the rectovaginal septum may present as a stricture. There is usually a history of frequent menstrual periods with severe pain during the first 2 days of the menstrual flow.

Neoplastic

When free bleeding occurs after dilatation of a supposed inflammatory stricture, carcinoma should be suspected (Grey Turner) and a portion of the stricture should be removed for biopsy. Sometimes in these cases, repeated biopsies show inflammatory tissue only. If, however, the symptoms show a marked progression, malignancy should be strongly suspected.

Clinical features

Increasing difficulty in defaecation is the leading symptom. The patient finds that increasingly large doses of aperients are required and, if the stools are formed, they are 'pipe-stem' in shape. In cases of inflammatory stricture, tenesmus, bleeding and the passage of mucus are superadded. Sometimes the patient comes under observation only when subacute or acute intestinal obstruction has supervened.

Rectal examination

The finger encounters a sharply defined shelf-like interruption of the lumen. If the calibre is large enough to admit the finger, it should be noted whether the stricture is annular or tubular. Sometimes this point can be determined only after dilatation. A biopsy of the stricture must be taken.

Treatment

Prophylactic

The passage of an anal dilator during convalescence after haemorrhoidectomy greatly reduces the incidence of postoperative

stricture. Efficient treatment of lymphogranuloma inguinale in its early stages should lessen the frequency of stricture from that cause.

Dilatation by bougies

For anal and many rectal strictures, dilatation by bougies at regular intervals is all that is required.

Anoplasty

The stricture is incised and a rotation or advancement flap of skin and subcutaneous tissue replaces the defect and enlarges the anal orifice (Fig. 69.45). This technique is particularly useful for post-operative strictures.

Colostomy

Colostomy must be undertaken when a stricture is causing intestinal obstruction and in advanced cases of stricture complicated by fistulae-in-ano. In selected cases, this can be followed by restorative resection of the stricture-bearing area. If this step is anticipated, a loop ileostomy is constructed.

Rectal excision and coloanal anastomosis

When the strictures are at or just above the anorectal junction and are associated with a normal anal canal, but irreversible changes necessitate removal of the area, excision can be followed by a coloanal anastomosis with good functional results (Summary box 69.15).

Summary box 69.15

Benign anal stricture

- May be spasmodic or organic
- May be iatrogenic, e.g. after haemorrhoidectomy or repair of imperforate anus
- Biopsy must be taken to rule out malignancy
- Can usually be managed by regular dilatation

MALIGNANT TUMOURS

Malignant lesions of the anus and anal canal

Anal malignancy is rare and accounts for less than 2% of all large bowel cancers. Those arising below the dentate line are usually squamous, whereas those above are variously termed basaloid,

Figure 69.45 (a-c) Y-V advancement flap for anal stenosis.

cloacogenic or transitional. Collectively they are known as epidermoid carcinomas, to distinguish them from those of non-squamous cell origin (adenocarcinoma, melanoma, lymphoma, sarcoma).

Squamous cell carcinoma

Although rare, the incidence of anal squamous cell carcinoma (SCC) is rising, with a direct association with HPV infection, AIN and immunosuppression. Thus, high-risk groups are those infected with HPV (especially subtypes 16, 18, 31 or 33) (Fig. 69.46), those with HIV infection, recipients of organ transplants (renal transplant patients have a 100-fold increased risk) and those with a past history of cancers at 'sexually accessible' sites (usually genital). Pain and bleeding are the most common symptoms and the disease is thus often initially misdiagnosed as a benign condition, highlighting the need for a level of suspicion and adequate examination. A mass, pruritus or discharge is less common. Advanced tumours may cause faecal incontinence by invasion of the sphincters and, in women, anterior extension may result in anovaginal fistulation. On examination, anal margin tumours look like malignant ulcers. There may be associated HPV lesions. Anal canal tumours are palpable as irregular indurated tender ulceration. Sphincter involvement may be evident.

Management

Historically, early anal margin tumours were treated by local excision and anal canal tumours by abdominoperineal excision of the rectum. Nowadays, primary treatment is by chemoradiotherapy [combined modality therapy (CMT); Nigro], the chemotherapy usually including a combination of 5-fluorouracil (5-FU) with mitomycin C or cisplatin. The surgeon, however, has an important role in management: initial diagnosis is surgical; small marginal tumours are still best treated by local excision; radical surgery is indicated in those with persistent or recurrent disease following

CMT; and a defunctioning stoma may be indicated for those in whom treatment and disease regression is associated with radionecrosis, incontinence or fistula.

Other anal malignancies

Adenocarcinoma within the anal canal are usually extensions of distal rectal cancers. Rarely, adenocarcinoma may arise from anal glandular epithelium or develop within a longstanding (usually complex) anal fistula; treatment is as for low rectal cancers [i.e. abdominoperineal excision of the rectum (APER) with or without previous radiotherapy or chemoradiotherapy] but prognosis is less good.

Melanocytes can be found in the transitional zone of the anal canal. Malignant melanoma of the anus is very rare and usually presents as a bluish-black soft mass that may mimic a thrombosed external pile, although it may be amelanotic (Fig. 69.47). The prognosis, irrespective of treatment, is extremely poor. Perianal Paget's disease is exceedingly rare (Summary box 69.16).

Summary box 69.16

Anal cancer

- Uncommon tumour, which is usually a squamous cell carcinoma
- Associated with HPV
- More prevalent in patients with HIV infection
- May affect the anal verge or anal canal
- Lymphatic spread is to the inguinal lymph nodes
- Treatment is by chemoradiotherapy in the first instance
- Major ablative surgery is required if the above fails

Figure 69.46 Neglected papillomas of the anus that have become malignant.

Urinary symptoms and investigations

CHAPTER 70

LEARNING OBJECTIVES

To recognise and understand:

- The major symptoms of urological disease

- The most commonly used investigations for urological conditions

URINARY SYMPTOMS

Haematuria

The presence of blood in the urine (haematuria) may be the only indication of pathology in the urinary tract (Fig. 70.1). Tiny amounts of blood that are insufficient to stain the urine (microscopic haematuria) may be detected by dipstick testing as part of a routine health check. A substantial haemorrhage into the urinary tract will give the urine a red or brownish tinge

(macroscopic haematuria) and the patient may pass blood clots. False-positive stick tests and the discoloured urine caused by beetroot and some drugs [e.g. Dindevan (phenindione), Pyridium (phenazopyridine) and Furadantin (nitrofurantoin)] can be distinguished from haematuria by the absence of red blood cells on urinary microscopy.

Haematuria may be intermittent or persistent. Blood appearing at the beginning of the urinary stream indicates a lower urinary tract cause, whereas uniform staining throughout the stream points to a cause higher up. Terminal haematuria is typical of severe bladder irritation caused stone or infection. If the patient experiences pain with haematuria, the characteristics of the pain may help to identify the source of the bleeding. If there is a malignant cause for the haematuria there is usually no pain.

None of these variations in the presentation of haematuria is sufficient in itself to diagnose the cause of bleeding, and all patients with haematuria should be investigated even if they are taking anti-coagulant drugs. In a significant proportion, all tests will be negative: the chance of finding a urological cause in patients under 40 years of age with microscopic haematuria is particularly small. However, bleeding into the urinary tract may be caused by an occult nephropathy so it is important to check for significant proteinuria and hypertension in these patients (Summary box 70.1).

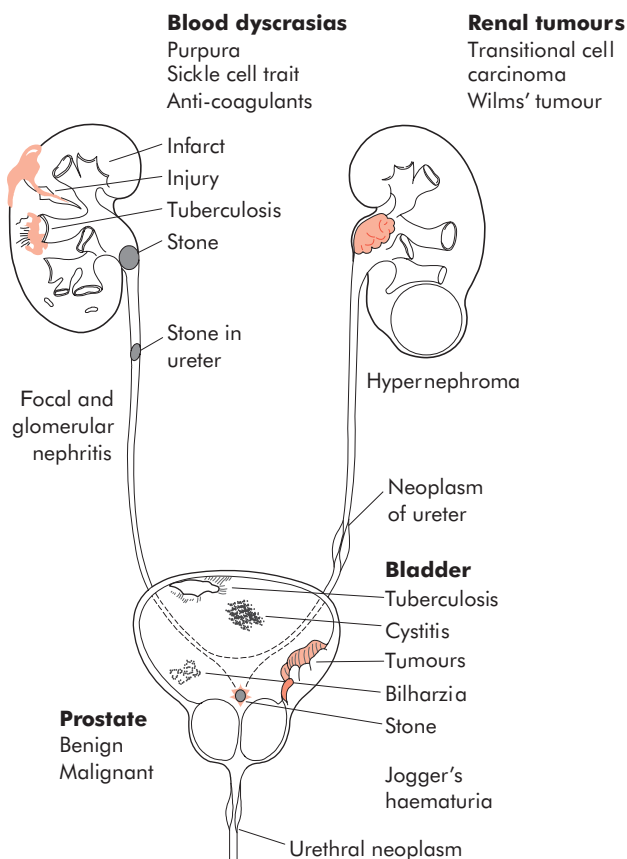

Figure 70.1 The more common causes of haematuria.

Summary box 70.1

Haematuria

- Is always abnormal whether microscopic or macroscopic
- May be caused by a lesion anywhere in the urinary tract
- Is investigated by:
 - examination of midstream specimen for infection
 - cytological examination of a urine specimen
 - intravenous urogram and/or urinary tract ultrasound scan
 - flexible or rigid cystoscopy
- Is commonly caused by urinary infection, especially in young women

Pain (Summary boxes 70.2 and 70.3)

Renal pain

Inflammation and acute obstruction to the flow of urine from the renal pelvis are liable to cause pain that is typically felt as a

deep-seated, sickening ache in the loin. It is probably the result of stretching of the capsule of the kidney. However, calculi in the kidney can also be painful in the absence of infection, although they may be too small or peripherally placed to cause obstruction. Slow-growing masses such as tumours or cysts are not usually painful unless they are very large. When the cause is inflammatory, there may be local deep tenderness and occasionally reflex spasm of the psoas muscle, leading to involuntary flexion of the hip joint.

Ureteric colic

This is an acute pain felt in the loin and radiating to the ipsilateral iliac fossa and genitalia. The patient often rolls around in agony as waves of excruciating sharp pain are imposed upon a continuing background of discomfort. Contrast this with the patient suffering from peritoneal pain, who lies still to avoid exacerbating the pain by movement.

Ureteric colic is usually caused by the passage of a stone, but blood clot or sloughed renal papilla may give identical pain. The site of the pain is a partial guide to the progress of a stone: the more the pain radiates into the groin, the more distal the stone. Local tenderness is much less than would be expected from the severity of the pain.

Summary box 70.2

Pain from the upper urinary tract

- When caused by acute obstruction of the renal pelvis, is typically fixed deep in the loin and 'bursting' in character
- When caused by acute ureteric obstruction (usually by a stone), is colicky with sharp exacerbations against a constant background
- Is liable to be referred to the groin, scrotum or labium as calculus obstruction moves distally in the ureter

Bladder pain

Bladder pain is felt as a suprapubic discomfort made worse by bladder filling. In men, a sharp pain misleadingly referred to the tip of the penis may be the result of irritation of the trigone of the bladder. Severe inflammation of the bladder can cause an extreme wrenching discomfort at the end of micturition. This symptom of bladder stone was recognised by the old lithotomists, who called it strangury.

Perineal pain

This is experienced as a penetrating ache in the perineum and rectum, sometimes with associated inguinal discomfort. The patient is characteristically exasperated and depressed by pain that has a peculiarly relentless nature. Pelvic pain is often blamed on 'chronic prostatitis', 'prostadynia' or 'chronic prostate pain syndrome', but it occurs in both men and women. It is notoriously difficult to treat successfully, a characteristic shared with various chronic scrotal pain syndromes.

Urethral pain

Urethral pain is a scalding or burning felt in the vulva or penis, especially during voiding.

Summary box 70.3

Pain from the lower urinary tract

- Is commonly felt as subrapubic discomfort, worsening as the bladder fills
- When caused by cystitis, typically has a burning or scalding character felt in the urethra on micturition
- May be referred to the tip of the penis in men, even when lesion is in the bladder

Altered bladder function

The normal bladder has two distinct phases of function. During the *filling phase* the bladder acts as a reservoir to collect urine until it is emptied in the *voiding phase*. Inappropriate contraction of the bladder detrusor muscle during filling (instability) is perceived as a sensation of urgency to pass urine. The patient may have frequency of micturition and a tendency to urge incontinence. Sleep may be disturbed by nocturia. Instability may be idiopathic in both sexes or part of the bladder response to outflow obstruction, notably in men with enlargement of the prostate. When detrusor instability has a demonstrable neurological cause, it is known as hyperreflexia.

Symptoms of impaired emptying are most commonly the result of bladder outflow obstruction, but detrusor failure presents a similar picture. The patient has difficulty initiating voiding (hesitancy) and the stream is variable or slow. Abdominal straining improves the weak flow. When the act of micturition is completed, there may be a feeling that urine remains in the bladder so the patient tries again (*pis-en-deux*). With time, the bladder becomes chronically overfilled. Urine spills out, typically at night when sleep halts constant trips to the lavatory (chronic retention with overflow) (Summary box 70.4).

Summary box 70.4

Altered bladder function

- Failure of the storage function of the bladder leads to urgency and frequency of micturition, often by day and by night
- Failure of the emptying function of the bladder is most commonly caused by obstruction to the bladder outflow (e.g. by prostatic enlargement) but can also be caused by weakness of the detrusor muscle
- Chronic retention of urine may present as nocturnal bedwetting

INVESTIGATION OF THE URINARY TRACT

With the exception of renal and scrotal masses or tenderness, a palpable bladder or an abnormal prostate on digital rectal examination, urological conditions are most likely to be diagnosed from the history or by investigations.

Urine

Dipsticks impregnated with chemicals that change colour in the presence of blood, protein or nitrites (Multistix, Labstix) are a

pis-en-deux is French for to urinate twice.

convenient way to screen urine for the presence of abnormalities. They can be read mechanically so that the clinician is provided with a paper readout of the results. When the urine is macroscopically clear and negative on dipstick testing, the chances of finding an abnormality on microscopy and culture of a midstream clean-catch specimen are small. Indeed, some bacteriological laboratories decline further examination of the urine in these circumstances on the grounds that it is not cost-effective. The presence of protein and nitrites (which are a product of the activity of organisms in the urine) indicates the likelihood of infection. The significance of microscopic haematuria is discussed above. Some dipsticks also give an indication of the pH and specific gravity of the urine.

Microscopy is essential to confirm the presence of white and red blood cells in the urine, and bacteria may also be visible under light microscopy. The presence of protein casts suggests disease affecting the renal parenchyma, as does red cell dysmorphism seen on phase contrast microscopy. Schistosoma ova have a typical appearance (Fig. 70.2), and vegetable or meat fibres may be present if there is a fistula connecting the bowel with the urinary tract.

Cytological examination of the urinary sediment is sensitive and specific for poorly differentiated transitional cell tumours anywhere in the urinary tract. However, false negatives are common in the 50% of these cancers that are well differentiated. A new chemical test (BTA-Bard) detects a bladder tumour antigen in the urine, and its findings can complement cytological examination of the urine.

Bacteriological culture of a clean-catch midstream specimen of the urine is the standard means of identifying urinary pathogens. The presence of organisms at a level of $> 10^5 \text{ ml}^{-1}$ is deemed to indicate the presence of infection rather than contamination of the urine by bacteria. If there are pus cells in the urine but there is no growth on the routine culture media (sterile pyuria), it is worth testing for more fastidious organisms. The centrifuged sediment of multiple early-morning urine specimens must be cultured on Löwenstein–Jensen medium to detect urinary tract tuberculosis. *Chlamydia* is another common urinary pathogen that will not be detected on routine culture.

Biochemical examination for electrolytes, glucose, bilirubin, haemoglobin and myoglobin is essential to detect abnormal amounts of these substances in the urine. Analysis of a 24-hour

Figure 70.2 Schistosoma ovum (courtesy of Dr Nawal Derius).

Ernst Lowenstein, b. 1878, Pathologist, Vienna, Austria.
Carl Oluf Jensen, 1864–1934, Veterinary Surgeon and Pathologist, Copenhagen, Denmark.

specimen of urine will quantify the rate of loss, and is especially useful in the investigation of calculus disease caused by abnormal excretion of calcium, oxalate, uric acid and other products of metabolism (Summary box 70.5).

Summary box 70.5

Microscopic, cytological, bacteriological and biochemical examination of urine

- Abnormalities found on Multistix testing of the urine should be confirmed by microscopy and culture
- The presence of greater than 10^5 organisms per ml of urine is deemed to indicate the presence of a significant urinary infection
- Cytological examination of the urine is likely to be abnormal when there is a poorly differentiated transitional cell tumour in the bladder

Tests of renal function

More than 70% of kidney function must be lost before renal failure becomes evident: there is a large functional reserve. It follows that renal damage must be extensive before changes occur in blood constituents whose level is controlled by renal excretion. Such damage is of three main types: reduction of renal plasma flow, destruction of glomeruli and impairment of tubular function. In severe hypertension or renal artery stenosis, the plasma flow is impaired. In glomerulonephritis or acute cortical necrosis, there is a loss of glomeruli, whereas in pyelonephritis, tubular function is most severely affected. In obstructive nephropathy, back pressure on the renal parenchyma causes all three types of damage.

Levels of blood urea and serum creatinine can be affected by various factors but, in practice, when taken together they serve as a useful clinical guide to overall renal function. A creatinine clearance test will give an approximate value for glomerular filtration rate but is prone to error. A more accurate assessment of glomerular function can be obtained from an estimate of the clearance of chromium-51-labelled ethylenediaminetetraacetic acid. Surgeons will usually call on their nephrological colleagues for more detailed investigations of tubular function and renal blood flow.

The specific gravity of the urine is fixed at a low level when the kidney loses the power to concentrate because of renal tubular dysfunction. Estimation of the urinary loss of sodium, β_2 -microglobulin or the tubular enzyme *N*-acetylglucosamine (NAG) will further define the nature of any functional impairment (Summary box 70.6).

Summary box 70.6

Tests of renal function

- Elevated blood urea and serum creatinine levels usually indicate a significant impairment of renal function
- More sophisticated renal assessment is required to quantify the functional deficit

Imaging

A plain abdominal radiograph showing the kidneys, ureters and bladder (the KUB) can disclose a wealth of useful information.

With the film properly orientated (with the liver on the right and gastric air bubble on the left unless there is situs invertus!) a glance at the spine and bony structures may reveal the presence of scoliosis, spina bifida, degenerative disease of the spine, metastases, fractures and arthritis. All of these may have relevance to the urological diagnosis. The soft-tissue shadows of the kidneys, outlined to a greater or lesser extent by their more radiolucent fatty coverings, overlie the upper attachments of the psoas muscles. A full bladder often presents a hazy outline arising from the pelvis.

Most urinary calculi absorb X-rays and should be sought in the region of the renal shadows and along the course of each ureter. These normally follow the tips of the transverse processes of the vertebrae, cross the sacroiliac joints and head for the ischial spine before hooking medially towards the bladder base. Stones with a low calcium content and those overlying bony structures may be difficult to see on the plain film. Pelvic phleboliths are very common and can look like lower ureteric calculi. Uric acid stones are the most common radiolucent calculi (Summary box 70.7).

Summary box 70.7

Straight abdominal radiograph

- Most urinary calculi are radiodense
- Uric acid calculi are typically radiolucent

Intravenous urography (urography) (Fig. 70.3)

Excretion renography has been a mainstay of urological investigation since the introduction of intravenous contrast media in the 1930s. These are organic chemicals to which iodine atoms are attached to absorb X-rays. When such a chemical is injected, usually into a vein in the antecubital fossa, it is filtered from the blood by the glomeruli and does not undergo tubular absorption. As a result, it rapidly passes through the renal parenchyma into the urine, which it renders radio-opaque.

Although intravenous urography (IVU) gives excellent images of the urinary tract, its use should be restricted because in a few patients the iodine in the contrast medium may provoke a

Figure 70.3 Normal intravenous urogram showing the outline of both kidneys with the collecting system and upper ureters highlighted by the contrast medium.

potentially life-threatening anaphylactic reaction. Patients with a history of allergy, atopy and eczema are particularly vulnerable, but severe reactions may occur without warning. Less invasive and dangerous imaging techniques are clearly to be preferred if they are able to give comparable diagnostic information (Summary box 70.8).

Summary box 70.8

Intravenous urography

- IVU can cause a dangerous hypersensitivity reaction in a small number of patients

Preparation

It is usual to give a laxative to clear faeces that might otherwise obscure details of urinary tract anatomy. Modest fluid restriction is permissible, but dehydration is dangerous because it may precipitate acute renal failure.

Technique

The patient is observed carefully while the first few drops of contrast medium (Urografin or Niopam 370) are injected. The earliest films, taken within minutes of the injection, show the renal parenchyma opacified by contrast medium – the nephrogram phase. A delayed nephrogram on one side indicates unilateral functional impairment. Distortion of the renal outline or failure of part of the kidney to function suggests a space-occupying lesion.

After a few minutes, the contrast is excreted into the collecting system, opacifying the calyces and the renal pelvis. Later films show the ureters and, at the end of the study, the patient is asked to pass urine and a final film is taken to show detail of the bladder area. It is important to bear in mind that the static images of IVU provide only snapshots of dynamic events in the urinary tract. The appearance of a normal ureter changes as peristaltic waves of contraction pass along it.

IVU is particularly valuable to demonstrate tumours and calculi within the urinary tract, which are sometimes difficult to see on ultrasonography. It may also be useful to show details of abnormal anatomy that are difficult to interpret on an ultrasonogram.

As ultrasonography and other forms of scanning have become more sophisticated, the indications for the urogram are fewer. Obstruction to the upper urinary tract interferes with transport of contrast medium into the urine, which will show up as a non-functioning kidney on the standard urogram films. In these circumstances, a further radiograph taken many hours after injection of the contrast medium may show hazy opacification of a dilated system. Distortion of the calyces or the renal outline can equally be caused by a tumour or by harmless simple cysts. In each of these cases, more information can be obtained from ultrasonography or computerised tomography (CT).

Retrograde ureteropyelography (synonym: retrograde ureterogram)

A fine ureteric catheter can be passed into the ureteric orifice through a cystoscope (Fig. 70.4). Contrast medium injected through the catheter will demonstrate the anatomy of the upper urinary tract. The procedure is particularly useful if there is doubt

Figure 70.4 A ureteric catheter about to enter the left ureteric orifice. Cystoscopic view.

about an intraluminal lesion (Fig. 70.5) or if renal function is deficient (before surgery for pelviureteric junction obstruction, for instance). When a transitional tumour is found, it can be sampled by aspiration of urine from the upper tract or by brush biopsy. Retrograde ureteropyelography is possible under topical urethral anaesthesia using a flexible cystoscope. Introducing infection into a poorly draining part of the system carries a serious risk of septicaemia. If there is to be any delay in correcting the blockage surgically, facilities must be available to decompress the kidney by retrograde stenting or percutaneous nephrostomy.

Figure 70.5 Retrograde ureterogram demonstrating the collecting system. The radiolucent filling defect in the renal pelvis is caused by a uric acid calculus.

Antegrade pyelography

Percutaneous puncture of a dilated renal collecting system is a reasonably simple procedure for the experienced interventional radiologist. The most common indication is the placement of a nephrostomy tube to drain an obstructed infected kidney or to provide access for percutaneous nephrolithotomy. Antegrade pyelography – in which contrast medium is introduced through the nephrostomy – can be helpful when retrograde studies are prevented by obstruction at the extreme lower end of the ureter.

Digital subtraction arteriography

Refinements in radiological imaging have now almost eliminated the need for translumbar aortography. Satisfactory imaging of the renal vessels can even be achieved by digital subtraction angiography after intravenous injection of contrast medium. More precise information can be obtained by intra-arterial injection through a fine catheter inserted into the femoral artery using the Seldinger technique. Arteriography is now rarely used to demonstrate tumour vasculature in a hypernephroma (Fig. 70.6), but a flush venogram is useful when CT suggests tumour invasion of the renal vein and vena cava.

Cystography

Cystography is now most commonly a component of video-urodynamic assessment (see Chapter 72). Its role in assessing ureteric reflux in children has been largely superseded by radioisotope scanning and dynamic ultrasonography.

Urethrography

Ascending urethrography is valuable to demonstrate the extent of a urethral stricture (Fig. 70.7) and the presence of false

Figure 70.6 A selective renal arteriogram showing abnormal vessels in a renal cell carcinoma.

Sven Ivar Seldinger, b. 1921, Radiologist, Karolinska Sjukhuset, Stockholm, Sweden.

Figure 70.7 Ascending urethrogram demonstrating a tight stricture in the bulbular urethra. Above the stricture the contrast outlines the prostatic urethra and bladder.

passages and diverticula associated with it. A urethrogram can be used to assess the extent of urethral trauma, but there is a serious danger that contrast medium may pass into the circulation. Lipiodol carries the danger of fat embolus and should never be used, and death has followed the use of barium emulsion. Umbradil viscous V is a radio-opaque water-soluble gel that contains the local anaesthetic lignocaine. It can be injected gently and safely using Knutsson's apparatus even if the urothelium is breached.

Venography

Because extension of a renal carcinoma from the renal vein into the vena cava can usually be demonstrated by ultrasound, venography is now infrequently used for this purpose.

Ultrasonography

High-resolution ultrasonography is perhaps the imaging technique most widely used in urology. The size of the kidney, the thickness of its cortex and the presence and degree of hydronephrosis can be measured with great accuracy. Intrarenal masses can be diagnosed as smooth walled and fluid filled (simple cysts) or solid and complex (possible tumours). Stones produce a bright ultrasonic reflection and cast an acoustic shadow (Fig. 70.8). The volume of urine in the bladder before and after micturition can be calculated, and even tiny filling defects within it detected. Scrotal contents can be displayed in great detail. Only the lower ureter resists effective investigation by trans-abdominal ultrasonography because of its small calibre and its proximity to the large bones of the pelvis and spine (Summary box 70.9).

Folke Knutsson, Director, The Roentgen Department, The University Hospital, Uppsala, Sweden.

Figure 70.8 A calculus in the kidney casts an acoustic shadow (courtesy of Dr Matthew Matson).

Summary box 70.9

Ultrasonography

- Ultrasound scanning provides broadly similar anatomical information to an intravenous urogram but without the risks

Transrectal ultrasonography

This has become a routine component of the investigation of suspected carcinoma of the prostate. Most commonly, suspicion has arisen because the level of prostate-specific antigen is raised or there is an abnormality of the texture or outline of the prostate on digital rectal examination. The features of carcinoma or benign enlargement of the prostate, although not absolutely specific, are sufficiently well recognised to allow an experienced ultrasonographer to identify promising sites for transrectal fine-needle biopsy.

Figure 70.9 Computerised tomography showing renal cell carcinoma of the right kidney.

Computerised tomography

CT is particularly useful to assess structures in the retroperitoneum (Fig. 70.9). In renal carcinoma it will show:

- the size and site of the tumour and the degree of invasion of adjacent tissue;
- the presence of enlarged lymph nodes at the renal hilum;
- invasion of the renal vein and vena cava.

CT is of crucial importance in the initial staging and follow-up of men with testicular cancer, in whom the presence of retroperitoneal lymph node masses is a feature of advanced disease. It has also been used to stage bladder and prostate cancer, but its value is less clear-cut in these diseases. Non-contrast CT is also used routinely in the diagnosis of urinary calculi (Figs 70.10 and 70.11).

Magnetic resonance imaging and positron emission tomography

These technologies give information about the function of organs as well as detailed structural images. It is likely that as they become more widely available, they will replace many of the routine imaging techniques.

Radioisotope scanning

Radioisotope scanning is used in particular to obtain information about function in individual renal units. Diethyltriaminepentaacetic acid (DTPA) behaves in the kidney like inulin: it is filtered by the glomeruli and not absorbed by the tubules. Using a gamma camera, DTPA labelled with technetium-99m can be followed during its transit through individual kidneys to give a dynamic representation of renal function. A ^{99m}Tc-DTPA scan is particularly useful to prove that collecting system dilatation is caused by obstruction. In obstruction, radioactivity will remain in the kidney even if urine flow is stimulated by administration of a diuretic like frusemide (furosemide). Other substances [dimercaptosuccinic acid (DMSA), mercaptoacetyl-glycine (MAG-3) and sodium orthoiodohippurate (Hippuran)] labelled with suitable radioactive isotopes have similarly been used to investigate renal function (Fig. 70.12).

Figure 70.10 A non-contrast CT clearly shows a calculus in the left upper ureter (courtesy of Dr Matthew Matson).

Isotope bone scanning is fundamental to the staging of kidney and prostate cancers, which typically metastasise to the skeleton.

Endoscopy

Effective visual inspection of the lower urinary tract has been possible since 1877, when Nitze invented his cystoscope. A second leap forward in urological endoscopy came with the introduction by Hopkins of the rod lens telescope and fibreoptic illumination. This permitted the development of a family of endoscopes, which allow the urologist to visualise the upper and lower urinary tracts for diagnosis and therapy. Finally, in the early 1980s, the small-calibre flexible fibroscopic cystoscope was introduced. This allows simple diagnostic cystourethroscopy, bladder biopsy and retrograde ureterography to be performed under topical urethral anaesthesia with minimal discomfort to the patient (Summary box 70.10).

Summary box 70.10

Diagnostic examination

- Diagnostic examination of the bladder is performed painlessly under local anaesthesia using a flexible cystoscope

ANURIA

Anuria is defined as the complete absence of urine production. Oliguria is present when less than 300 ml of urine is excreted in a day (Summary box 70.11).

Summary box 70.11

Diagnosing anuria

- Check that the bladder is empty before diagnosing anuria
- Ultrasound the bladder

The maintenance of renal function and urine production depends upon perfusion of the kidneys with oxygenated blood. Reduced renal blood flow or hypoxia impairs renal function. When both are present, the danger of acute renal failure is even greater.

Renal failure is traditionally divided into:

- prerenal;
- renal;
- postrenal (obstructive).

Prerenal

Prerenal causes of acute renal failure include:

- hypovolaemia;
- blood loss;
- sepsis;
- cardiogenic shock;
- anaesthesia;
- hypoxia.

Max Nitze, 1848–1906, Urological Surgeon, Vienna, Austria.

Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, The University of Reading, Reading, England.

Figure 70.11 Reconstructed spiral computerised tomography scan showing calculi in the right kidney (courtesy of Professor R. Resnek).

Hypovolaemia

This may result from inadequate fluid intake or from excessive loss of body water. Dehydration, prolonged vomiting, diarrhoea and other abnormal gastrointestinal fluid losses, burns and excessive sweating are all common causes of hypovolaemia.

Blood loss

This is usually caused by trauma or surgery, but acute blood loss from the gastrointestinal tract or haemorrhage associated with childbirth may be sufficient to cause hypovolaemic renal impairment.

Sepsis

Gram-negative septicaemia from a urinary tract source is a particularly potent cause of bacteraemic shock. Sepsis from the biliary tract and overwhelming infection from other sites, especially in the immunocompromised individual, are also associated with acute renal failure.

Cardiogenic shock

Acute dysrhythmia secondary to myocardial infarction, cardiac tamponade and pulmonary embolus may all result in reduced cardiac output of often poorly oxygenated blood.

Figure 70.12 Radioisotope renogram.

Anaesthesia

Hypotension is a hazard of epidural and spinal anaesthesia.

Hypoxia

Prolonged hypoxia from any cause may occasionally be responsible.

Renal

Renal causes of acute renal failure include:

- drugs;
- poisons;
- contrast media;
- eclampsia;
- myoglobinuria;
- incompatible blood transfusion;
- disseminated intravascular coagulation.

It is uncommon for patients with established glomerulonephritis to develop acute oliguria; however, such patients are more prone to rapid deterioration of remaining function should any renal insult occur.

Drugs

Aminoglycosides, cephalosporins and diuretics can be nephrotoxic, particularly if used in combination. They are quite commonly used in patients whose renal function is already compromised by sepsis or circulatory abnormalities. Prolonged use of non-steroidal anti-inflammatory drugs (NSAIDs) can cause a chronic interstitial nephritis and papillary necrosis; they also reduce renal plasma flow and therefore have nephrotoxic properties. Angiotensin-converting enzyme inhibitors used for the control of hypertension can cause a rapid reduction in the glomerular filtration rate; this is particularly liable to occur in patients who have a reduced renal blood flow.

Poisons

Some of these are nephrotoxic.

Contrast media

Even modern contrast media may cause renal failure when injected into a dehydrated patient with compromised renal function.

Eclampsia

The early recognition of pre-eclampsia is vital to avoid the nephrotoxic consequences of toxæmia and uncontrolled hypertension.

Myoglobinuria

The presence of myoglobin in the urine is associated with the 'crush' syndrome after major trauma. Less severe injuries can also cause the syndrome, especially if a compartment syndrome is unrecognised or pressure areas break down.

Incompatible blood transfusion

This may lead to renal failure with myoglobinuria.

Disseminated intravascular coagulation

Disseminated intravascular coagulation usually follows major sepsis or massive blood transfusion and may occur post-partum.

Obstructive

Obstructive causes of acute renal failure include:

- calculi;
- pelvic malignancy;
- surgery;
- retroperitoneal fibrosis;
- bilharzia;
- crystalluria.

Calculi

Renal calculus disease is probably the most common cause of acute obstruction leading to anuria. The patient is likely to have unilateral renal colic against a background of non-function of the contralateral kidney, often due to previous surgery or pre-existing obstruction by calculus.

Pelvic malignancy

Carcinomas arising from the bladder, prostate, cervix, ovary or rectum can all lead to obstruction of one or both ureters. A history of haematuria and vaginal or rectal bleeding signpost the diagnosis. A large pelvic mass is commonly palpable on bimanual examination.

Surgery

The ureters are vulnerable to damage during pelvic and retroperitoneal surgery, but injury should be avoided if proper care is taken. It is unusual, but not impossible, to damage both ureters.

Retroperitoneal fibrosis

For details of retroperitoneal fibrosis see Chapter 71.

Bilharzia (see Chapter 5)

Schistosomiasis may lead to ureteric fibrosis and stenosis, and may be responsible for the development of squamous cell carcinoma of the bladder.

Crystalluria

Crystalluria causing urinary tract obstruction used to be associated with sulphonamide medications but this is now rare. However, uric acid crystalluria can develop in patients receiving chemotherapy for leukaemia or lymphoma unless they are given prophylactic treatment with allopurinol.

Clinical aspects

Answers to the following questions should indicate the probable cause of reduced urine output.

- *Is urine being produced?* Catheterisation of the bladder is essential if a voided sample cannot be obtained. If urine is available, check the specific gravity, look for the presence of casts (implying a renal cause), test for myoglobinuria and send a sample for culture and microscopy.
- *Is there an obvious prerenal cause?* This can usually be answered by clinical examination, assessment of the patient's vital signs, examination of the fluid balance chart and measurement of the arterial oxygen concentration.
- *Is there ureteric obstruction?* Hydronephrosis may not be marked in acute obstruction, but ultrasonography will usually show some degree of ureteric dilatation. A plain abdominal radiograph should be checked for calculi.
- *What drugs have been given recently?* If a drug is thought to be responsible for renal impairment, it should obviously be withdrawn unless its use is vital.
- *Is this a progression to chronic renal failure?* The presence of shrunken kidneys on ultrasound, normochromic anaemia and hypertension suggest progression to a chronic state even if a previous history of renal failure is not available.

Management and treatment

Renal failure caused by acute tubular necrosis may progress through three recognisable phases:

- oliguria;
- the diuretic phase;
- recovery.

The initial management is aimed at prompt restoration of the circulating volume deficit and correction of tissue hypoxia. Most patients will require a level of care that is available only in a specialised unit. As a minimum, monitoring with a pulse oximeter and central venous pressure measurements will supplement basic observations. For patients with hypovolaemia or sepsis, inotropic support with dopamine may improve cardiac efficiency and increase renal blood flow. If urine production is not promptly restored, frusemide (furosemide) can be given but this is not always successful and the drug itself may be nephrotoxic. Mannitol may be used as a plasma expander and osmotic diuretic, but care must be taken not to overload the circulation. The aim is to achieve the best possible blood pressure, with a central venous pressure of 7–9 cmH₂O. It may be that 100% oxygen is needed to maintain the oxygen tension (PO₂).

If these measures fail, acute tubular necrosis has supervened. Excess fluid loads must be avoided and fluid input restricted to match the reduced output plus insensible losses (500–800 ml per 24 hours depending on ambient conditions). Abnormal losses due to vomiting, nasogastric aspiration, diarrhoea or fistulae will be monitored and replaced.

A hyperkalaemic acidosis is the characteristic metabolic abnormality of the oliguric phase of renal failure. Correction of the metabolic acidosis with intravenous bicarbonate is tempting but not always advisable. Rising serum potassium is life-threatening and requires effective intervention. A calcium resonium enema is the simplest remedy. The ion-exchange resin can also be administered orally but is unpalatable. Cautious use of intravenous dextrose and insulin should be considered if ion

exchange fails. The help of a renal physician is highly desirable because urgent dialysis may become necessary to save life (Summary box 70.12).

Summary box 70.12

Shared management with nephrologist

- Enlist the help of a nephrologist at an early stage in the management of renal failure

The diuretic phase traditionally occurs between the eighth and 10th day but may be delayed as long as 6 weeks. Glomerular filtration recommences but tubular function takes longer to recover. A heavy loss of sodium and potassium can be expected, and fluid and electrolyte requirements must be carefully judged. In most patients the diuretic phase is followed by the recovery phase, but some never recover and will need renal replacement therapy if they are to survive.

Factors that influence the outcome of acute renal failure include the need for artificial ventilation, the need for inotropic support and the presence of jaundice. There is a significant mortality rate.

Nutritional support

Many patients are unable to eat. If enteral feeding is impossible, parenteral nutrition must be administered, with extreme care to avoid circulatory overload.

Infection

These patients are at increased risk of generalised infection. Swabs taken from the nose and throat, sputum specimens and urine, if available, should be sent for culture. If antibiotics are required, they should be non-nephrotoxic.

General nursing care

Meticulous recording of fluid balance is obviously central to the successful management of these patients. Patients who are seriously ill or comatose need regular turning and care of pressure areas if they are to avoid pressure sores. Physiotherapy to the chest and extremities will aid recovery.

Renal support

Renal replacement is needed for those patients in whom the oliguric or anuric phase is associated with significant uraemic symptoms (vomiting, muscular twitching, itching and altered states of consciousness) or uncontrollable hyperkalaemia (Summary box 70.13).

Summary box 70.13

Life-threatening hyperkalaemia

- In acute renal failure, significant hyperkalaemia is life-threatening and should be corrected at an early stage

Peritoneal dialysis

Provided that the patient has not had recent abdominal surgery, peritoneal dialysis can be performed by insertion of a fenestrated catheter under local anaesthetic. This is placed just inferior to the

umbilicus in the midline. Sterile dialysis fluid is then run into the peritoneal cavity, where it equilibrates with the extracellular fluid using the peritoneum as a dialysis membrane. After a variable time, the fluid is drained into a closed drainage system. The process is repeated in cycles. Occasionally, when anuria is prolonged, a cuffed catheter needs to be inserted, as used in chronic ambulatory peritoneal dialysis. The disadvantages of acute peritoneal dialysis are the potential for introducing infection into the peritoneum and the rather slow rate of correcting metabolic imbalance, particularly hyperkalaemia.

Haemodialysis

A few sessions of haemodialysis may be life saving. A double-lumen catheter is placed over a guidewire into one of the great veins (jugular, subclavian or femoral). Between sessions of dialysis the lines are kept patent by filling them with heparin solution. Haemodialysis can result in a rapid correction of metabolic abnormalities but also tends to result in considerable fluctuations of the overall fluid balance. The other disadvantage is that heparinisation is necessary, and this may be undesirable after a recent surgical procedure.

Haemofiltration

This, like haemodialysis, requires the use of an extracorporeal machine but causes much less haemodynamic upset. This may be of critical importance for the acutely ill patient.

Obstructive renal failure

When the patient is too ill for surgery to remove the cause of obstruction to the upper urinary tract, the treatment of obstructive renal impairment is drainage, either externally using a nephrostomy or internally using an indwelling stent (Summary box 70.14).

Summary box 70.14

Catheterisation and stents

- Urethral or suprapubic catheterisation will relieve obstruction distal to the bladder
- Indwelling stents to relieve ureteric obstruction can be inserted cystoscopically or percutaneously

Percutaneous nephrostomy

Under ultrasonographic guidance and local anaesthetic, a fine-bore hollow needle is introduced via the flank through the parenchyma and into the expanded collecting system of the obstructed kidney. Once it penetrates the system, contrast medium can be injected through the needle to define its exact position. A wire passed through the lumen of the needle is used to guide the insertion of a series of dilators, which enlarge the track until it will accept a suitably sized nephrostomy tube (Fig. 70.13). This will drain urine and pus, provided that the latter is not too viscous. The tube is anchored firmly in place to allow continued drainage as renal function recovers.

Insertion of a J-stent

The ureter can be drained into the bladder by the insertion of a pigtail- or J-stent (see Fig. 70.13). The procedure begins with a retrograde ureterogram under fluoroscopic control to provide an image of the ureter. This will often give an indication of the cause

Figure 70.13 Radiograph showing a left-sided, pigtail nephrostomy tube draining a kidney obstruction by a ureteric calculus, seen at the level of L3–4. A J-stent is in the right ureter, which has been cleared of stones.

of the obstruction. A guidewire is introduced through the ureteric orifice and guided up the ureter into the renal pelvis. The stent is rail-roaded over the guidewire until its distal end also lies within the renal pelvis above the obstruction. When the guidewire is removed, the ends of the stent curl to form a J-shape or a pigtail to secure the device against migration. Stents can be placed under topical urethral anaesthesia using the flexible cystoscope and may be safely left in position for several months. They are a foreign body in the urinary tract and are prone to infection and encrustation if neglected. It is vital to keep careful records to account for all stents inserted.

If the J-stent cannot be inserted cystoscopically, it may be placed from above through a nephrostomy.

Open surgery

This is a rarity when the minimally invasive methods described above are available. Retrograde insertion of a nephrostomy through an incision in the renal pelvis is the preferred method because it can be surprisingly difficult to locate even dilated calyces by blind puncture of the renal parenchyma.

The kidneys and ureters

LEARNING OBJECTIVES

To recognise and understand:

- The major types of congenital abnormality of the upper urinary tract
- The major types of cystic disease of the kidney
- The presentation and management of open and closed trauma to the kidney and ureter
- The aetiology, presentation and surgical management of obstruction to the upper urinary tract
- The main types of renal calculi and the pathophysiology of their formation
- The modern management of urinary tract calculi
- The aetiology, presentation and management of sepsis in the upper urinary tract
- The major types of renal neoplasm and the clinical signs and symptoms associated with them
- The surgical management of tumours of the upper urinary tract

EMBRYOLOGY

A bud from the lower end of the mesonephric (wolffian) duct grows backwards behind the peritoneum to the sacral region. The stalk of the bud forms the ureter and its dilated upper extremity, the renal pelvis. From 6 weeks to 8 months of gestation, the primitive pelvis bifurcates repeatedly to form first the calyces and, after several subsequent divisions, the collecting ducts.

The renal parenchyma is derived from the metanephros, which is the most caudal of a series of embryonic renal masses: the primitive pronephros regresses as its function is supplanted by the mesonephros, which in turn is succeeded by the metanephros. The continuity of the glomerular apparatus and nephric tubules formed within the metanephros is established through connection with the collecting ducts. Between weeks 5 and 8 of embryonic development, each kidney ascends the posterior abdominal wall to reach its normal position in the loin. At the same time it rotates so that its hilum faces medially instead of forwards as it previously did.

In humans, the lobulation of the fetal kidney is usually lost as the lobules become bonded together by the growth of new cortex and the renal capsule. In some mammals, e.g. oxen and bears, fetal lobulation is retained.

SURGICAL ANATOMY

The parenchyma of each kidney usually drains into seven calyces, three upper, two middle and two lower calyces (Fig. 71.1). Each

Figure 71.1 The arrangement of renal calyces.

of the three segments represents an anatomical and physiologically distinct unit with its own blood supply.

CONGENITAL ABNORMALITIES OF THE KIDNEY (TABLE 71.1)

Absence of one kidney

The prevalence of unilateral renal agenesis is about 1:1400 and it is usually discovered incidentally. If the mesonephric duct has failed to bud, the ureter will be absent. Alternatively, the ureter and renal pelvis are present but the kidney is absent. In either

Kaspar Friedrich Wolff, 1733–1794, Professor of Anatomy and Physiology, St Petersburg, Russia, described the mesonephric duct and body in 1759.

Table 71.1 Congenital abnormalities of the kidney and ureter

Renal agenesis	
Renal ectopia	Pelvic kidney Horseshoe kidney Crossed dystopia Infantile polycystic disease Unilateral multicystic dysplastic kidney
Aberrant renal vessels	Multiple renal arteries and veins
Duplication	Duplex kidney Duplex renal pelvis Duplex kidney and ureter
Others	Congenital hydronephrosis Retrocaval ureter Congenital megaureter

case, the solitary contralateral kidney is likely to be hypertrophied (Summary box 71.1).

Summary box 71.1**Absence of one kidney**

- About 1:1400 people has an absent kidney
- It is usually symptomless and often discovered by accident
- When planning a nephrectomy the surgeon should consider the possibility that the other kidney is congenitally absent

Renal ectopia

In approximately 1:1000 people the kidney does not ascend. Ectopic kidneys are usually found near the pelvic brim and are usually left sided. The contralateral kidney is generally in its normal position. Disease in an ectopic kidney may present diagnostic problems and an unwary surgeon may be tempted to remove it as an unexplained pelvic mass.

Horseshoe kidney

When the medial subdivisions of the mesonephric bud meet and fuse, the normal ascent of the kidneys is impeded by midline structures. The result is a pair of ectopic kidneys, usually fused at their lower poles, lying in front of the fourth lumbar vertebra and great vessels. Horseshoe kidney is found in 1:1000 necropsies and is commoner in men. Upper pole fusion is rare.

Clinical features

Horseshoe kidneys are liable to disease, possibly because the ureters angulate as they pass over the fused isthmus (Fig. 71.2).

Figure 71.2 Horseshoe kidney. Note the ureters passing in front of the fused lower poles.

This may lead to urinary stasis with consequent infection and nephrolithiasis. Sometimes there is a true pelviureteric junction obstruction (see below), which has the same consequences. Horseshoe kidney is usually a radiological diagnosis. The most frequent appearance on the urogram shows the lower pole calyces on both sides being directed towards the midline. More rarely, all or most of the calyces are reversed (Fig. 71.3). Horseshoe kidney is not a contraindication to pregnancy but urinary complications are more frequent.

Division of the isthmus between the kidneys is usually only indicated in the course of surgery for abdominal aortic aneurysm. Although the tissue is often less vascular than normal renal parenchyma, the vascular supply of the horseshoe is typically eccentric, springing unpredictably from adjacent major vessels (Summary box 71.2).

Summary box 71.2**Horseshoe kidneys**

- Horseshoe kidneys are liable to pelviureteric obstruction, infection and stone formation
- If not recognised, a pelvic kidney may cause diagnostic confusion during surgery

Unilateral fusion

Unilateral fusion (synonyms: crossed dystopia, cross fused renal ectopia) is rare but the urogram appearance is striking. Both kidneys are in one loin and are usually fused. The ureter of the lower kidney crosses the midline to enter the bladder on the contralateral side. Both renal pelves can lie one above each other medial to the renal parenchyma (unilateral long kidney) or the pelvis of the crossed kidney faces laterally (unilateral S-shaped kidney; Fig. 71.4).

Congenital cystic kidneys

Congenital cystic kidneys (synonym: polycystic kidneys) are hereditary and potentially lethal, and can be transmitted by either parent as an autosomal dominant trait. Thus, the risk of an offspring inheriting the condition can be as high as one in two depending upon the penetrance of the gene. The disease is not usually detectable on standard imaging until the second and third

Figure 71.3 Urogram of a horseshoe kidney. Only rarely are all the calyces directed towards the spinal column.

Figure 71.4 Unilateral S-fusion of the kidneys.

decades of life and does not usually manifest itself clinically before the age of 30 years.

Pathology

The kidneys are huge: the cysts distort the renal capsule. The renal parenchyma is riddled with cysts of varying size containing clear fluid, thick brown material or coagulated blood. There may be a congenital cystic disease of the liver. The aetiology of all renal cysts is uncertain although theories abound.

Clinical features in the adult

The condition is slightly more common in women than men. There are six clinical features:

- an irregular upper quadrant abdominal mass;
- loin pain;
- haematuria;
- infection;
- hypertension;
- uraemia.

Renal enlargement

The bilateral knobbly enlargement is unmistakable. Less florid examples may be revealed unexpectedly at laparotomy or on abdominal imaging. Unilateral renal swelling, in which one kidney contains larger cysts than the other, may be confused clinically with a cystic renal tumour.

Pain

Pain, felt as dull loin ache, is thought to be caused by the weight of the organ dragging upon its pedicle or by stretching of the renal capsule by the cysts. Haemorrhage into a cyst may cause more severe pain, as may the passage of a calculus from the diseased kidney.

Haematuria

Rupture of a cyst into the renal pelvis may cause recurrent haematuria. Profuse haematuria is uncommon.

Infection

Pyelonephritis is common in patients with congenital cystic kidney, presumably because of urinary stasis.

Hypertension

Hypertension is present in up to 75% of patients with polycystic kidneys over the age of 20 years.

Uraemia

Patients with congenital cystic kidneys pass large volumes of urine of low specific gravity containing a trace of albumin but no casts or cells. The non-specific symptoms of chronic renal failure develop as functioning renal tissue is replaced progressively by cysts. Severe anaemia is common. Signs of end-stage renal failure often begin suddenly during middle life and the patient is unlikely to survive without renal replacement therapy.

Imaging

Renal imaging shows multiple cysts in both kidneys and sometimes cysts in the liver and other organs. Blood and debris in the cysts may mimic the heterogeneity of a cystic adenocarcinoma. Simple cysts are usually solitary and have smooth thin walls and homogeneous contents (Fig. 71.5). Doubt about the diagnosis can be resolved by cytological examination of cyst fluid obtained by fine-needle aspiration.

Polycystic kidneys have a typical appearance on urography: the renal shadows are enlarged in all directions; the renal pelvis is compressed and elongated; and the calyces are stretched over the cysts ('big, bizarre and bilateral') (Fig. 71.6).

Treatment

As kidney failure develops, a low-protein diet will help to postpone the inevitability of renal replacement therapy. Infection, anaemia, hypertension and disturbances of calcium metabolism also need appropriate treatment by a nephrologist.

Surgery to uncap the cysts (Rovsing's operation) is rarely indicated because few now accept that this can preserve renal function by relieving pressure on the parenchyma (Summary box 71.3).

Summary box 71.3

Polycystic kidney disease

- Inherited as an autosomal dominant trait
- An important cause of end-stage renal failure in adults
- Pain, haematuria, infection and hypertension are common
- Liable to be fatal in early middle age

Figure 71.5 Simple cyst (C) of the lower pole shown on a longitudinal ultrasound scan of the kidney.

Nils Thorkild Rovsing, 1862–1927, Professor of Surgery, Copenhagen, Denmark.

Figure 71.6 Polycystic kidney: urographic appearance. Note the length of the kidney and the bell-like calyces stretched over the cysts.

Infantile polycystic disease

Infantile polycystic disease is a rare autosomal recessive condition. The kidneys are large and may obstruct birth. Many patients are stillborn or die from renal failure early in life. In some children, associated congenital hepatic fibrosis is a major problem.

Unilateral multicystic disease

Multicystic dysplastic kidney is much more common. It presents as a mass in the flank. Excision is the treatment of choice. Wilms' tumour (see below), neuroblastoma and congenital hydronephrosis are all rarer causes of flank masses in childhood.

Simple cyst of the kidney (Fig. 71.5)

Simple cysts in one or both kidneys are often discovered incidentally on imaging of the upper abdomen: they rarely give symptoms and are often multiple. A palpable mass, pain from haemorrhage into the cyst and infection are uncommon presentations. Occasionally, a cyst in the hilum of the kidney (a parapelvic cyst) presses on the pelviureteric junction and causes obstruction.

The true nature of a cyst will be apparent by its characteristic appearance on ultrasound or computerised tomography (CT). Percutaneous cyst puncture for cytology is rarely necessary with modern imaging (Summary box 71.4).

Summary box 71.4

Simple renal cysts

- Common
- Often multiple
- Diagnosed on ultrasound
- Rarely require treatment
- Treat only if causing obstruction

Max Wilms, 1867–1918, Professor of Surgery, Heidelberg, Germany, described the embryoma of the kidney in 1899.

Differential diagnosis

In sheep-rearing districts, hydatid cysts of the kidney are common. On the right side they are liable to be mistaken for a hydatid cyst of the liver. Occasionally, the patient complains of passing 'grape skins' (ruptured daughter cysts) in the urine. Removal of the cyst must follow the principles used in excision of hydatid cyst of the liver, i.e. the scolices must be killed by injection of a scolicide (e.g. formalin solution) before the cyst is handled. If the cyst is large, nephrectomy may be the safest course.

Aberrant renal vessels

Two or more renal arteries are most common on the left. The main importance of the abnormality is as a source of potential error during operations in the retroperitoneum, especially those on the kidney. The renal arteries are functional end-arteries, so division of an aberrant lower pole artery leads to infarction of the section of parenchyma that it supplies. Renal veins, by contrast, have extensive collaterals and an aberrant vein can be divided with impunity. Aberrant vessels probably do not cause hydronephrosis, although a hydronephrotic renal pelvis may bulge between renal vessels, making them particularly noticeable (Fig. 71.7).

CONGENITAL ABNORMALITIES OF THE RENAL PELVIS AND URETER

Duplication of a renal pelvis

Duplication of a renal pelvis (Fig. 71.8) is found in about 4% of patients. It is usually unilateral and left sided. The small upper renal pelvis drains the upper group of calyces; the larger lower renal pelvis drains the middle and lower groups of calyces.

Duplication of a ureter

Duplication of a ureter is found in about 3% of urograms. The ureters often join in the lower third of their course (Fig. 71.9) and have a common ureteric orifice. When the ureters open independently into the bladder the ureter from the upper pelvis opens distal and medial to its fellow (Fig. 71.10).

Clinical features

Duplication of the renal pelvis or ureter is often a chance finding on renal imaging, but infection, calculus formation and pelviureteric

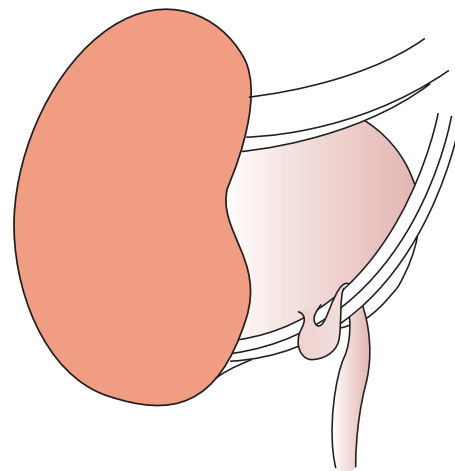

Figure 71.7 Aberrant accessory renal artery with hydronephrosis. The dilated renal pelvis bulges over the vessel.

Figure 71.8 Urogram showing a left kidney with double pelvis.

Figure 71.9 Retrograde ureterogram showing a double ureter on the left.

junction obstruction are more common than in normal kidneys. One of the moieties may be dysplastic and non-functioning. When the two ureters open separately, both may be abnormal in function, position or both. In children, this may result in a refluxing lower pole ureter and an upper pole ureter terminating in a ureterocele. In such cases, the duplex kidney is at risk of infection and/or obstruction.

An ectopic second ureteric opening is a rarity but it may cause puzzling symptoms. In the female, an ectopic ureter opens either into the urethra below the sphincter (Fig. 71.11) or into the vagina. The diagnosis can often be made from the history alone and is confirmed by urography. A girl or woman who voids normally but who has dribbled urine for as long as she can remember probably has an ectopic ureteric orifice. The orifice is difficult to see because it is guarded by a valve: it may help to give an intravenous injection of a dye such as indigocarmine to colour the urine leaking from it.

In the male patient, the aberrant opening is above the external urethral sphincter so the patient is continent. The ureteric orifice at the apex of the trigone, the posterior urethra, in

Figure 71.10 Complete ureteric duplication. Two ureteric orifices are seen on cystoscopy: the lower and more medial drains the upper renal pelvis.

a seminal vesicle or in an ejaculatory duct is likely to be functionally abnormal, and infection is common.

Treatment

Asymptomatic duplication of the kidney is harmless and does not require treatment. If one moiety is severely diseased or atrophic, partial nephrectomy is usually simple and effective. A refluxing ureter may need reimplanting. An ectopic ureter in the female frequently drains hydronephrotic and chronically infected renal tissue, which is best excised. Rarely, the incontinence can be cured and renal function preserved by implanting the ectopic ureter into the bladder or contralateral ureter (Summary box 71.5).

Summary box 71.5

Duplication of the kidneys and ureters

- Is relatively common and often asymptomatic and harmless
- One or both moieties of the duplex may be dysplastic
- Abnormalities of the insertion of the ureter into the bladder may cause urinary reflux, incontinence or obstruction

Figure 71.11 In women, one ureteric orifice may open below the sphincter, causing intractable incontinence of urine.

Congenital megaureter

Congenital megaureter is a rare oddity that may be bilateral and associated with other congenital anomalies. Functional obstruction at the lower end of the ureter may lead to progressive dilatation and infection. The ureteric orifice appears normal and a ureteric catheter passes easily. Reflux is not a feature of the untreated condition but is almost inevitable if the ureteric orifice is opened endoscopically. Spontaneous improvement can occur but infection or deteriorating function will require refashioning and reimplantation of the affected ureter.

Post-caval ureter

The right ureter passes behind the vena cava instead of lying to the right of it. If this causes obstructive symptoms, the ureter can be divided and rejoined in front of the cava using a long oblique anastomosis without tension. Unusually, the retrocaval portion of the ureter is fibrotic and must be excised.

Ureterocele

Ureterocele is a cystic enlargement of the intramural ureter, which is thought to result from congenital atresia of the ureteric orifice. Although present from childhood, the condition is often unrecognised until adult life. The 'adder head' on excretory urography (Fig. 71.12) is typical. Usually the cyst wall is composed of urothelium only and the diagnosis is confirmed by the cystoscopic appearance of a translucent cyst enlarging and collapsing as urine flows in from above (Fig. 71.13). Treatment should be

Figure 71.12 Adder-head appearance of a ureterocele.

Adder head. An adder is a venomous snake of the family Viperidae which is found in the UK and other parts of the world. It has a triangular shaped head.

Figure 71.13 Ureterocele on cystoscopy.

avoided unless there are symptoms arising from infection and/or stone formation. Ureterocele is most common in women; occasionally, the cyst may cause obstruction to the bladder outflow by prolapsing into the internal urethral opening.

Endoscopic diathermy incision is usually all that is required for treatment of a symptomatic ureterocele, although a micturating cystogram is advisable to detect postoperative urinary reflux. In advanced unilateral cases with hydronephrosis or pyonephrosis, nephrectomy may be appropriate.

INJURIES TO THE KIDNEY

In civilian life, injuries to the kidney result most often from either blows or falls on the loin or crushing injury to the abdomen, typically in a road traffic accident. Haematuria after trivial injury to the kidney should suggest the possibility of a pre-existing disease, e.g. calculus, hydronephrosis or tuberculosis.

The degree of injury varies considerably from a small subcapsular haematoma to a complete tear through the kidney (Fig. 71.14). The kidney may be partially or wholly avulsed from its vascular pedicle; one pole may be completely detached.

Closed renal injury is usually extraperitoneal. In young children who have very little extraperitoneal fat, the peritoneum, which is closely applied to the kidney, can tear with the renal capsule, leaking blood and urine into the peritoneum (Summary box 71.6).

Summary box 71.6

Haemorrhage

- Life-threatening haemorrhage is a serious risk in closed or open trauma to the kidney

Clinical features of closed renal trauma

Superficial soft-tissue bruising can be absent but there is local pain and tenderness.

Haematuria

Haematuria is the sign of a damaged kidney but it may not appear until some time after the injury. Profuse bleeding may cause clot colic.

Figure 71.14 Types of closed renal trauma: (a) subscapular haematoma; (b) laceration; (c) avulsion of one pole; (d) avulsion of the renal pedicle.

Severe delayed haematuria

Sudden profuse haematuria between the third day and the third week after the accident in a patient who appears to be progressing well is caused by a clot becoming dislodged.

Meteorism

Abdominal distension 24–48 hours after renal injury is probably a result of retroperitoneal haematoma implicating splanchnic nerves (Summary box 71.7).

Summary box 71.7

Clinical features of closed renal trauma

- There may be no external bruising
- Haematuria indicates that the kidney has been damaged and should prompt careful monitoring of vital signs and urgent investigation
- Delayed haemorrhage may occur days after injury

Management and treatment

Conservative watchful treatment of closed renal trauma is usually successful. The possibility of injury to other organs must be considered at an early stage.

- Blood should be cross-matched for transfusion if there is evidence of hypovolaemic shock or continuing haemorrhage. Intravenous access should be established.
- The patient should stay in bed while there is macroscopic haematuria and activity must be curtailed for a week after the urine clears.
- Morphine analgesia may be appropriate.
- Hourly pulse and blood pressure charts must be kept.

- Antibiotics should be given to prevent infection of the haematoma.
- Each sample of urine passed should be checked for haematuria and the result charted.
- Intravenous urography (IVU) or contrast-enhanced CT should be performed urgently to assess the damage to the kidney and to show that the other kidney is normal.
- Blood should be sent for grouping and serum saved for cross-matching.

Surgical exploration

Surgical exploration is necessary in less than 10% of closed injuries; it is indicated if there are signs of progressive blood loss or there is an expanding mass in the loin. The aim is to stop bleeding while conserving as much renal tissue as possible; a renal arteriogram performed preoperatively can be helpful in framing a strategy for doing this. A radiologist may be able to stop the haemorrhage by embolisation if a bleeding vessel can be identified.

The possibility of damage to other abdominal organs is checked during a transperitoneal approach. Release of the tamponading effect of the perirenal haematoma can result in massive haemorrhage and the surgeon must be fully prepared for this. When the kidney is irretrievably ruptured or avulsed from its pedicle, nephrectomy is the only course. Small tears can be sutured over a haemostatic sponge or a piece of detached muscle. Large single rents in the kidney are best dealt with by passing a tube nephrostomy through the defect and suturing the renal tissue around it. If the laceration is confined to one pole of the kidney, partial nephrectomy may be practicable.

When a solitary kidney is sufficiently damaged to need exploration, it must be repaired. Failing this, the wound is packed firmly with gauze to stop the bleeding in the hope that some renal function may be retained when the ruptured kidney heals (Summary box 71.8).

Summary box 71.8

Surgical treatment in closed renal trauma

- Exploration of the kidney may be associated with massive blood loss as the haematoma is opened
- Nephrectomy is a possibility so it is important to establish that the contralateral kidney is functioning

Complications

Heavy haematuria may lead to clot retention requiring bladder washout through a catheter or a cystoscope.

Pararenal pseudohydronephrosis may occur over the course of a few weeks after injury as a result of a combination of complete cortical tear and ureteric obstruction caused by scarring.

Hypertension resulting from renal fibrosis may occur long after injury. It is often refractory to medical treatment and nephrectomy may be necessary.

Post-traumatic aneurysm of the renal artery (Fig. 71.15) is rare. There is pain in the loin and a non-tender swelling may be felt if the aneurysm is large. Congestion of the parenchyma leads to intermittent haematuria. Aortography is diagnostic. Excision or nephrectomy is urgently indicated to prevent fatal rupture of the aneurysm.

Figure 71.15 Aneurysm of the renal artery containing lamellated thrombus.

INJURIES TO THE URETER

Rupture of the ureter

This is an uncommon result of a hyperextension injury of the spine. The diagnosis is rarely made until there is swelling in the loin or iliac fossa associated with a reduction of urine output. An excretion urogram or contrast-enhanced CT shows extravasation of contrast from the injured ureter.

Injury to one or both ureters during pelvic surgery

This occurs most often during vaginal or abdominal hysterectomy when the ureter is divided, ligated, crushed or excised, usually inadvertently. Pre-emptive ureteric catheterisation prevents such accidents as the catheters make it easier to identify the ureters.

Injury recognised at the time of operation

Ureterovesical continuity should be restored by one of the methods described below unless the patient's condition is poor. Deliberate ligation of the proximal ureter and temporary percutaneous nephrostomy is then the best course until the patient is well enough for a repair (Summary box 71.9).

Summary box 71.9

Ureteric injury during operation

- The most common cause of injury to the ureters is surgical trauma during hysterectomy or other pelvic surgery
- Preoperative catheterisation of the ureters makes them easier to protect during surgery
- Injuries discovered at the time of surgery should be repaired immediately

Injury not recognised at the time of operation

Unilateral injuries

There are three possibilities:

- *No symptoms.* Secure ligation of a ureter may simply lead to silent atrophy of the kidney. The injury may be unsuspected until the patient undergoes urological imaging some time later.
- *Loin pain and fever,* possibly with pyonephrosis, occur with infection of the obstructed system. Urography shows no function, which will be permanent unless steps are taken quickly to relieve the obstruction by inserting a percutaneous nephrostomy.
- A *urinary fistula* develops through the abdominal or vaginal wound. The urogram or contrast-enhanced CT shows extravasation with or without obstruction of one or both ureters. Nephrostomies may be inserted and repair postponed until oedema and inflammation have subsided. The traditional delayed repair leaves the patient incontinent and demoralised. Early repair is safe provided that the patient is fit for surgery.

Bilateral injury

Ligation of both ureters leads to anuria. Ureteric catheters will not pass and urgent relief of obstruction by nephrostomy or immediate surgery is essential.

Repair of the injured ureter (Table 71.2)

If the cut ends of the ureter can be apposed without tension, they should be joined by a spatulated anastomosis over a double-pigtail catheter. If it is possible to insert a stent endoscopically past a partial ureteric obstruction, an open repair may be avoidable.

If the division is very low down, the bladder may be hitched up so that the ureter can be reimplanted into it. Extra length may be obtained by mobilising the kidney.

In the Boari operation (Fig. 71.16), a flap of bladder wall is fashioned into a tube to replace the lower ureter. The disadvantage of implanting the ureter end to side into the contralateral ureter (a transureteroureterostomy) is that it risks converting a unilateral injury into a bilateral one.

Figure 71.16 Boari operation: a strip of bladder wall is fashioned into a tube to bridge the gap between the cut ureter and the bladder.

Achille Boari, nineteenth century Italian Surgeon.

Table 71.2 Methods for repairing a damaged ureter

If there is no loss of length	Spatulation and end-to-end anastomosis without tension
If there is little loss of length	Mobilise kidney Psoas hitch of bladder Boari operation
If there is marked loss of length	Transureteroureterostomy Interposition of isolated bowel loop or mobilised appendix Nephrectomy

Nephrectomy may be the best course when the patient's outlook is poor and the other kidney is normal. When conservation of all renal tissue is vital, replacement of the damaged ureter by a segment of ileum is necessary (Summary box 71.10).

Summary box 71.10**Repair of the injured ureter**

When surgical damage to a ureter is discovered postoperatively:

- Repair need not be delayed if the patient is fit
- A variety of techniques may be needed to ensure successful repair, and surgery should be performed by a urologist

HYDRONEPHROSIS

Hydronephrosis is an aseptic dilatation of the kidney caused by obstruction to the outflow of urine.

Unilateral hydronephrosis

See Summary box 71.11.

Summary box 71.11**Causes of unilateral ureteric obstruction****Extramural obstruction**

- Tumour from adjacent structures, e.g. carcinoma of the cervix, prostate, rectum, colon or caecum
- Idiopathic retroperitoneal fibrosis
- Retrocaval ureter

Intramural obstruction

- Congenital stenosis, physiological narrowing of the pelviureteric junction leading to pelviureteric junction obstruction
- Ureterocele and congenital small ureteric orifice
- Inflammatory stricture following removal of ureteric calculus, repair of a damaged ureter or tuberculous infection
- Neoplasm of the ureter or bladder cancer involving the ureteric orifice

Intraluminal obstruction

- Calculus in the pelvis or ureter
- Sloughed papilla in papillary necrosis (especially in diabetics, analgesic abusers and those with sickle cell disease) may obstruct the ureter

Bilateral hydronephrosis

Bilateral hydronephrosis is usually the result of urethral obstruction, but the lesions described above may occur on both sides.

When due to lower urinary obstruction, the cause may be:

- congenital:
 - posterior urethral valves;
 - urethral atresia;
- acquired:
 - benign prostatic enlargement or carcinoma of the prostate;
 - postoperative bladder neck scarring;
 - urethral stricture;
 - phimosis.

Urethral obstruction tends to lead to detrusor hypertrophy, which can lead to obstruction of the ureters in their intramural course.

Pathology

There is calyceal dilatation and the renal parenchyma is destroyed by pressure atrophy. A kidney destroyed by long-standing hydronephrosis is a thin-walled, lobulated, fluid-filled sac.

Clinical features**Unilateral hydronephrosis**

Unilateral hydronephrosis (commonly caused by idiopathic pelviureteric junction obstruction or calculus) is more common in women and on the right.

Presenting features include the following:

- *Mild pain or dull aching* in the loin, often with a sensation of dragging heaviness made worse by excessive fluid intake. The kidney may be palpable.
- Attacks of *acute renal colic* may occur with no palpable swelling.
- *Intermittent hydronephrosis* (Dietl's crisis). A swelling in the loin is associated with acute renal pain. Some hours later the pain is relieved and the swelling disappears when a large volume of urine is passed.
- *Antenatal detection* in the fetus by ultrasound scan. Many of these cases are benign but postnatal investigation is required to detect those with significant pelviureteric junction obstruction (Summary box 71.12).

Summary box 71.12**Idiopathic pelviureteric obstruction**

- May be asymptomatic
- May be present as intermittent loin pain exacerbated by a fluid load

Bilateral hydronephrosis**From lower urinary obstruction**

Symptoms of bladder outflow obstruction predominate. The kidneys are unlikely to be palpable because renal failure intervenes before the kidneys become sufficiently large.

Joseph Dietl, 1804–1878, Professor of Pathology and Therapeutics, Krakau, Poland.

From bilateral upper urinary tract obstruction

This is rare compared with unilateral lesions although idiopathic retroperitoneal fibrosis affects both ureters and idiopathic pelviureteric junction obstruction can be bilateral. Although both systems are obstructed, symptoms may be referred to one side.

From pregnancy

Dilatation of the ureters and renal pelves occurs early in pregnancy and becomes more marked until the 20th week. It results from the effects on the ureteric smooth muscle of high levels of circulating progesterone and it may be considered as part of normal pregnancy. The ureters return to their normal size within 12 weeks of delivery. This physiological condition is associated with an increased liability to infection and there is a possibility that abdominal pain during pregnancy may be erroneously ascribed to ureteric obstruction (Summary box 71.13).

Summary box 71.13

Ureteric dilatation in pregnancy

- Physiological dilatation of the ureter is common in pregnancy

Imaging

Ultrasound scanning (Fig. 71.17) is the least invasive means of detecting hydronephrosis and is regularly used to diagnose pelviureteric junction obstruction *in utero*.

Excretion urography is only helpful if there is significant function in the obstructed kidney. The extrarenal pelvis is dilated and the minor calyces lose their normal cupping and become 'clubbed'. If the level of obstruction is in doubt, it can help to take follow-up films up to 36 hours after the contrast has been injected. The radio-opaque medium slowly diffuses to fill the obstructed system down to the blockage.

Isotope renography is the best test to establish that dilatation

Figure 71.17 Ultrasound of a hydronephrotic kidney. A, artery; C, calyces; P, pelvis.

of the renal collecting system is caused by obstruction. A substance [usually diethylenetriaminepenta-acetic acid (DTPA) or MAG-3] that is filtered by the glomeruli and not absorbed is injected intravenously. The DTPA is labelled with technetium-99m, a gamma-ray emitter, so that the passage of ^{99m}Tc-labelled DTPA through the kidneys can be tracked using a gamma camera. ^{99m}Tc-DTPA is quickly cleared from a normal kidney but is trapped in the renal pelvis on the obstructed side and will not be washed out even if the flow of urine is increased by administering furosemide (frusemide) (Fig. 71.18).

Very occasionally, a Whitaker test is indicated. A percutaneous puncture of the kidney is made through the loin and fluid is infused at a constant rate with monitoring of intrapelvic pressure. An abnormal rise in pressure confirms obstruction. Retrograde pyelography (Fig. 71.19) is rarely indicated but will confirm the site of obstruction immediately before corrective surgery (Summary box 71.14).

Summary box 71.14

Imaging

- Obstruction of the ureter is diagnosed by a combination of ultrasound scanning and isotope renography
- An obstructed kidney is worth preserving if the isotope renogram shows that it is contributing more than 20% of total renal function

Treatment

The indications for operation are bouts of renal pain, increasing hydronephrosis, evidence of parenchymal damage and infection. Conservation of renal tissue is the aim; nephrectomy should be considered only when the renal parenchyma has been largely destroyed. Mild cases should be followed by serial ultrasound scans and operated upon if dilatation is increasing.

Pyeloplasty

The Anderson–Hynes operation (Fig. 71.20) is appropriate when a reasonable thickness of functioning parenchyma

Figure 71.18 Isotope renogram series shows a late accumulation and persistence of radioactivity in the left kidney (the image is a posterior view).

Robert Whitaker, Urologist, Addenbrooke's Hospital, Cambridge, England.
James Christie Anderson, 1899–1984, Urologist, the Royal Hallamshire Hospital, Sheffield, England.
Wilfred Hynes, 1903–1991, Plastic Surgeon, the Plastic and Jaw Department, the Royal Sheffield Hospital, Sheffield, England.

Figure 71.19 Retrograde ureteropyelogram showing hydronephrosis with greatly enlarged pelvis and dilated 'clubbed' calyces.

Figure 71.20 (a–e) Anderson–Hynes disjunction pyeloplasty.

remains. The upper third of the ureter and the renal pelvis are carefully mobilised. A renal vein overlying the distended pelvis can be divided, but an artery in this situation should be preserved to avoid infarction of the territory that it supplies. The anastomosis is made in front of such an artery using absorbable stitches to avoid calculus formation on the suture line. It is usual to protect the anastomosis with a nephrostomy tube or a ureteric stent.

Endoscopic pyelolysis

Disruption of the pelviureteric junction by a balloon passed up the ureter and distended under radiographic control has been used to treat idiopathic pelviureteric junction obstruction. The long-term efficacy of this and various forms of endoscopic pyelotomy has still to be proved.

RENAL CALCULI

Aetiology

This subject is complex and the following represents a brief summary of current opinion.

Dietetic

Deficiency of vitamin A causes desquamation of epithelium. The cells form a nidus on which a stone is deposited. It is uncertain whether this mechanism is of importance other than in the formation of bladder calculi.

Altered urinary solutes and colloids

Dehydration increases the concentration of urinary solutes until they are liable to precipitate. Reduction of urinary colloids, which adsorb solutes, or mucoproteins, which chelate calcium, might also result in a tendency for crystal and stone formation.

Decreased urinary citrate

The presence of citrate in urine, 300–900 mg 24 h⁻¹ (1.6–4.7 mmol 24 h⁻¹) as citric acid, tends to keep otherwise relatively insoluble calcium phosphate and citrate in solution. The urinary excretion of citrate is under hormonal control and decreases during menstruation.

Renal infection

Infection favours the formation of urinary calculi. Clinical and experimental stone formation are common when urine is infected with urea-splitting streptococci, staphylococci and especially *Proteus* spp. The predominant bacteria found in the nuclei of urinary stones are staphylococci and *Escherichia coli*.

Inadequate urinary drainage and urinary stasis

Stones are liable to form when urine does not pass freely.

Prolonged immobilisation

Immobilisation from any cause, e.g. paraplegia, is liable to result in skeletal decalcification and an increase in urinary calcium favouring the formation of calcium phosphate calculi.

Hyperparathyroidism

Hyperparathyroidism leading to hypercalcaemia and hypercalciuria is found in 5% or less of those who present with radio-opaque calculi. In cases of recurrent or multiple stones, this cause should be eliminated by appropriate investigations (see Chapter 48). Hyperparathyroidism results in a great increase in the elimination of calcium in the urine. These patients 'pass their skeletons in their urine'. A parathyroid adenoma should be removed before definitive treatment for the urinary calculi.

Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the bacterium *coli commune* in 1886.

Types of renal calculus

Oxalate calculus (calcium oxalate) (Fig. 71.21)

Oxalate stones are irregular in shape and covered with sharp projections, which tend to cause bleeding. The surface of the calculus is discoloured by altered blood. A calcium oxalate monohydrate stone is hard and radiodense.

Phosphate calculus

A phosphate calculus [calcium phosphate often with ammonium magnesium phosphate (struvite)] is smooth and dirty white. It tends to grow in alkaline urine, especially when urea-splitting *Proteus* organisms are present. As a result, the calculus may enlarge to fill most of the collecting system, forming a staghorn calculus (Fig. 71.22). Even a very large staghorn calculus may be clinically silent for years until it signals its presence by haematuria, urinary infection or renal failure. Because they are large, phosphate calculi are usually easy to see on radiographic films.

Uric acid and urate calculi

These are hard, smooth and often multiple. They vary from yellow to reddish brown and sometimes have an attractive, multi-faceted appearance. Pure uric acid stones are radiolucent and appear on an excretion urogram as a filling defect, which can be mistaken for a transitional tumour of the upper urinary tract. The presence of uric acid stones is confirmed by CT. Most uric acid

Figure 71.21 Oxalate calculi. The larger one removed from the right kidney is blackened by the deposition of altered blood.

Figure 71.22 Staghorn calculus.

stones contain some calcium, so they cast a faint radiological shadow. In children, mixed stones of ammonium and sodium urate are sometimes found. They are yellow, soft and friable. They are radiolucent unless they are contaminated with calcium salts.

Cystine calculus

These uncommon stones appear in the urinary tract of patients with a congenital error of metabolism that leads to cystinuria. Hexagonal, translucent, white crystals of cystine appear only in acid urine. They are often multiple and may grow to form a cast of the collecting system. Pink or yellow when first removed, they change to a greenish colour when exposed to air. Cystine stones are radio-opaque because they contain sulphur, and they are very hard.

Xanthine calculus

These are extremely rare. They are smooth and round, brick-red in colour, and show lamellation on cross-section.

Clinical features

Renal calculi are common. Approximately 50% of patients present between the ages of 30 and 50 years. The male–female ratio is 4:3.

Symptoms are variable and the diagnosis sometimes remains obscure until the stone is discovered on a radiograph (Summary box 71.15).

Summary box 71.15

Renal stones

- Are common
- May be clinically silent even when large
- Are usually visible on a plain abdominal radiograph
- May be radiolucent when composed of uric acid

Silent calculus

Even large staghorn calculi may cause no symptoms for long periods, during which time there is progressive destruction of the renal parenchyma. Uraemia may be the first indication of bilateral calculi, although secondary infection usually produces symptoms first.

Pain

Pain is the leading symptom in 75% of people with urinary stones. Fixed renal pain is located posteriorly in the renal angle (Fig. 71.23), anteriorly in the hypochondrium, or in both. It may be worse on movement, particularly on climbing stairs.

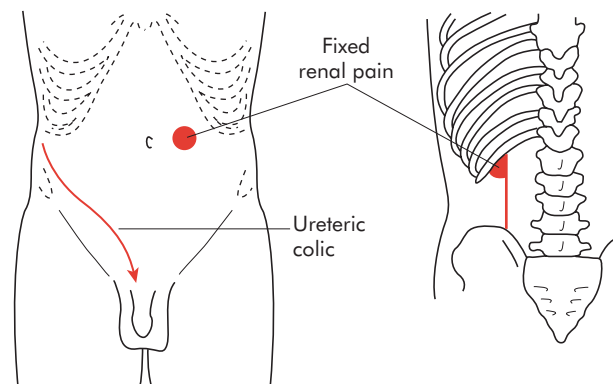

Figure 71.23 The usual distribution of renal pain.

Ureteric colic is an agonising pain passing from the loin to the groin. Typically, it starts suddenly causing the patient to writhe to find comfort. Pain resulting from renal stones rarely lasts more than 8 hours in the absence of infection. There is no pyrexia, although the pulse rate rises because of the severe pain. Ureteric colic is often caused by a stone entering the ureter but it may also occur when a stone becomes lodged in the pelviureteric junction. The severity of the colic is not related to the size of the stone (Summary box 71.16).

Summary box 71.16

Ureteric colic

- There is a pattern of severe exacerbation on a background of continuing pain
- Radiates to the groin, penis, scrotum or labium as the stone progresses down the ureter
- The severity of pain is not related to the size of the stone
- The pain is almost invariably associated with haematuria
- There may be few physical signs

Abdominal examination

During an attack of ureteric colic there is rigidity of the lateral abdominal muscles but not, as a rule, of the rectus abdominis. Percussion over the kidney produces a stab of pain and there may be tenderness on gentle deep palpation. Hydronephrosis or pyonephrosis leading to a palpable swelling in the loin is rare.

Haematuria

Haematuria is sometimes a leading symptom of stone disease and occasionally the only one. As a rule, the amount of bleeding is small.

Pyuria

Infection is likely in the presence of stones and is particularly dangerous when the kidney is obstructed. As pressure builds in the dilated collecting system, organisms are injected into the circulation and a life-threatening septicaemia can quickly develop.

The mechanical effect of stones irritating the urothelium may cause pyuria even in the absence of infection.

Investigation of suspected urinary stone disease

Radiography

The 'KUB' film shows the kidney, ureters and bladder. When a renal calculus is branched, there is no doubt about the diagnosis (Fig. 71.24). An opacity that maintains its position

Figure 71.24 Plain abdominal radiograph showing complete staghorn calculi.

relative to the urinary tract during respiration is likely to be a calculus.

Calcified mesenteric nodes and opacities within the alimentary tract can sometimes be shown to be anterior to the vertebral bodies on a lateral radiograph and hence outside the urinary tract (Summary box 71.17).

Summary box 71.17

Opacities on a plain abdominal radiograph that may be confused with renal calculus

- Calcified mesenteric lymph node
- Gallstones or concretion in the appendix
- Tablets or foreign bodies in the alimentary canal [e.g. cyclopenthiiazide (Navidrex-K)]
- Phleboliths – calcification in the walls of veins, especially in the pelvis
- Ossified tip of the 12th rib
- Calcified tuberculous lesion in the kidney
- Calcified adrenal gland

Contrast-enhanced computerised tomography

CT, preferably spiral, has become the mainstay of investigation for acute ureteric colic.

Excretion urography

Urography will establish the presence and anatomical site of a calculus. It also gives some important information about the function of the other kidney.

Ultrasound scanning

Ultrasound scanning is of most value in locating stones for treatment by extracorporeal shock wave lithotripsy (ESWL) (see below).

Surgical treatment of urinary calculi

Conservative management

Calculi smaller than 0.5 cm pass spontaneously unless they are impacted. Any surgical intervention carries the risk of complications and needless intervention should be avoided. Small renal calculi may cause symptoms by obstructing a calyx or acting as a focus for secondary infection. However, most can be safely observed until they pass (Summary box 71.18).

Summary box 71.18

Management of small stones

- Most small urinary calculi will pass spontaneously and can be treated conservatively
- The presence of infection in an upper urinary tract obstructed by stone is dangerous and is an indication for urgent surgical intervention

Preoperative treatment

If urinary infection is present, appropriate antibiotic treatment is started and continued during and after surgery as necessary.

Operation for stone

In developed countries, most stones are treated by urologists

using minimal access and minimally invasive techniques. Open operations are still needed when appropriate expertise is not available or newer techniques have failed to clear the calculus (Summary box 71.19).

Summary box 71.19

Kidney stone removal

- Most urinary calculi can be treated by minimal access techniques

Modern methods of stone removal

Kidney stones

Percutaneous nephrolithotomy (Fig. 71.25) This involves the placement of a hollow needle into the renal collecting system through the soft tissue of the loin and the renal parenchyma. A wire inserted through the needle is used to guide the passage of a series of dilators, which expand the track into the kidney until it is large enough to take the nephroscope used to visualise the stone. Small stones may be grasped under vision and extracted whole. Larger stones must be fragmented by an ultrasound, laser or electrohydraulic probe and removed in pieces.

The aim is to remove all fragments if possible, and this may take some time if the calculus is large. When the operation is over, a nephrostomy drain is left in the system. This decompresses the

kidney and allows repeated access if stone particles remain. Percutaneous nephrolithotomy is sometimes combined with ESWL in the treatment of complex (stag-horn) calculi. The surgeon removes the central part of the stone percutaneously and the more peripheral fragments are treated by ESWL.

Complications of percutaneous nephrolithotomy include (1) haemorrhage from the punctured renal parenchyma – this may be profuse and difficult to control; (2) perforation of the collecting system with extravasation of saline irrigant; (3) perforation of the colon or pleural cavity during placement of the percutaneous track.

Extracorporeal shock wave lithotripsy A urinary calculus has a crystalline structure. Bombarded with shock waves of sufficient energy it disintegrates into fragments. The principle is seen at its simplest in the original Dornier machine, in which shock waves were generated by an electrical discharge placed at one focus of an ellipsoid mirror. The patient was positioned under radiographic control so that the calculus was subjected to the full force of the shock waves concentrated at the second focus of the mirror. As shock waves are poorly transmitted through air, both the patient and the shock-wave generators were immersed in a bath of water.

Modern ESWL machines do not have a water bath; the fluid is confined to the path that the shock waves must follow to reach the kidney. The shocks may be generated by the discharge of an array of piezoelectric cells, and they may be aimed by ultrasound

Figure 71.25 Percutaneous renal stone removal. (a) The stone is in the right renal pelvis. (b) Placement of a cannula under radiological control into the renal pelvis and through it a balloon catheter to stop fragments migrating into the upper ureter. (c) The stone is disrupted by contact lithotripsy and the fragments have been successfully removed by irrigation. (d) A nephrostogram confirms that the renal pelvis is intact.

rather than radiographic imaging (Fig. 71.26). The devices also differ in the strength of the disruptive force that they can develop. Less powerful machines are less effective in breaking stones, and several treatments may be necessary to clear a stone. Weaker shocks hurt less and treatment can be given without general anaesthesia.

When ESWL is successful, the stone fragments must pass down the ureter. Ureteric colic is common after ESWL, and the patient needs analgesia, usually in the form of a non-steroidal anti-inflammatory drug such as diclofenac. The bulky fragments of a large stone may impact in the ureter, causing obstruction. To avoid this, a stent should be placed in the ureter so that the kidney can drain while the pieces of stone pass. Occasionally, impacted fragments have to be removed ureteroscopically (see below).

The principal complication of ESWL is infection. Many calculi contain bacteria, which are released from the broken stone. It is wise to give prophylactic antibiotics before ESWL, and an obstructed system should be decompressed by the insertion of a ureteric stent or percutaneous nephrostomy before treatment.

The clearance of stone from the kidney will depend upon the consistency of the stone and its site. Most oxalate and phosphate stones fragment well and, if lying in the renal pelvis, will clear within days. The results with harder stones, especially cystine stones, are less satisfactory. When treating calyceal stones, the patients should be warned that the clearance of fragments may take months.

There is currently great interest in the long-term outcome of patients treated by ESWL. Certainly, some stones recur, especially if small fragments remain after treatment.

Open surgery for renal calculi (Fig. 71.27)

Operations for kidney stone are usually performed via a loin or lumbar approach. All of the procedures are difficult unless the

kidney is fully mobilised and its vascular pedicle controlled. A sling should be placed around the upper ureter to stop stones migrating downwards.

Pyelolithotomy Pyelolithotomy is indicated for stones in the renal pelvis. When the wall of the renal pelvis has been dissected free from its surrounding fat, an incision is made in its long axis directly on to the stone. The stone is removed with gallstone forceps, taking care not to break it because fragments may be difficult to retrieve. Stone fragments in peripheral calyces may be detected by direct palpation or by intraoperative radiography or nephroscopy. If there is no infection, the pelvic incision is closed with interrupted absorbable sutures. If there is gross sepsis, a nephrostomy is essential to drain the system.

Extended pyelolithotomy The plane between the renal sinus and the wall of the collecting system is developed on the posterior surface of the kidney. This avoids major vessels and allows incisions to be made into the calyces so that even large staghorn stones can be removed intact.

Nephrolithotomy If there is a complex calculus branching into the most peripheral calyces, it may be necessary to make incisions into the renal parenchyma to clear the kidney. Nephrolithotomy may also be necessary when the adhesions resulting from previous surgery make access to the renal pelvis difficult. The renal pedicle must be temporarily cross-clamped to reduce bleeding from the highly vascular renal tissue. Incisions are made just posterior and parallel to the most prominent part of the convex renal border, where the territories of the anterior and posterior branches of the renal artery meet (Brödel's line). Cooling the kidney with ice packs or cooling coils extends the time that the kidney can remain ischaemic without permanent damage. All the incisions must be carefully closed with haemostatic sutures

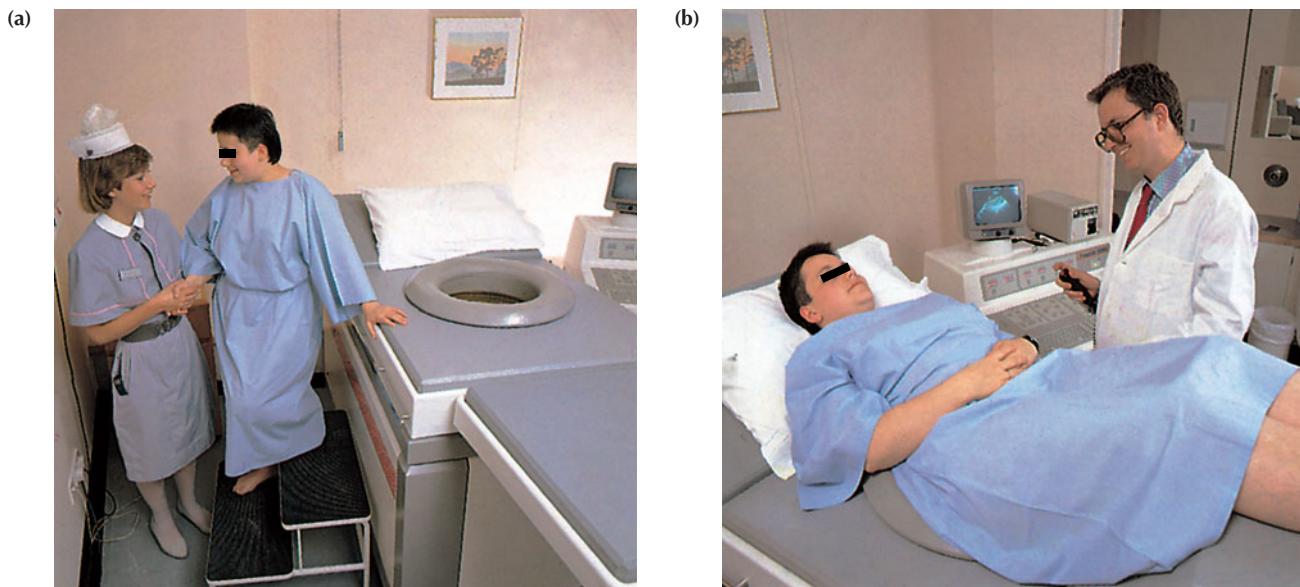

Figure 71.26 Extracorporeal shock wave lithotripsy. (a) The patient being placed on the ultrasound lithotripter. (b) Positioning of the patient being checked by ultrasound.

Max Brödel, 1870–1941, Medical artist who founded 'The Department of Art as Applied to Medicine' at the Johns Hopkins Hospital, Baltimore, MD, USA.

Figure 71.27 Open operations for renal calculus.

and the patient observed after the operation for signs of reactionary haemorrhage.

Partial nephrectomy is sometimes preferable when the stone is present in the lowermost calyx and there is associated infective damage to the adjacent parenchyma.

A kidney destroyed by obstruction and infection associated with stone disease should be removed, particularly when there is xanthogranulomatous pyelonephritis. This stone-related inflammatory mass must be removed with particular care because it is liable to be attached to adjacent structures such as the colon.

Treatment of bilateral renal stones Usually the kidney with better function is treated first unless the other kidney is more painful or there is pyonephrosis, which needs urgent decompression.

Silent bilateral staghorn calculi in the elderly and infirm may be treated conservatively. The patient should be encouraged to maintain a high fluid intake.

Prevention of recurrence

Ideally, all stone formers should be investigated to exclude metabolic factors, although the diagnostic yield is low in patients with a single small stone. The urine of all patients with stones should be screened for infection. The following investigations are appropriate in bilateral and recurrent stone formers:

- serum calcium, measured fasting on three occasions to exclude hyperparathyroidism;
- serum uric acid;
- urinary urate, calcium and phosphate in a 24-hour collection; the urine should also be screened for cystine;
- analysis of any stone passed.

Dietary advice is not usually helpful in avoiding stone recurrence in people who have a balanced diet. The enthusiast for excessive amounts of milk products (calcium stones), rhubarb, strawberries, plums, spinach and asparagus (calcium oxalate stones) should be advised to be more moderate.

Patients with hyperuricaemia should avoid red meats, offal and fish, which are rich in purines, and should be treated with allopurinol. Eggs, meat and fish are high in sulphur-containing proteins and should be restricted in cystinuria.

Stone sufferers should take the advice of Hippocrates and drink plenty to keep their urine dilute. Fluid intake should be increased appropriately to take account of increased losses.

Drug treatment is largely ineffective except in those few patients who are shown to have idiopathic hypercalciuria. Bendroflumethiazide (5 mg) and a calcium-restricted diet reduce urinary calcium (Summary box 71.20).

Summary box 71.20

Recurrent stone formation

- Calculus formation is more common in those who have had a previous urinary stone
- Unless calculi are caused by a specific biochemical abnormality, high fluid intake is the best way to discourage recurrent stone formation

URETERIC CALCULUS

A stone in the ureter usually comes from the kidney. Most are single small stones that are passed spontaneously.

Clinical features

The presence of a stone passing down the ureter often causes intermittent attacks of ureteric colic.

Ureteric colic

As the stone progresses to the lower ureter, the waves of agonising loin pain are typically referred more to the groin, external genitalia and the anterior surface of the thigh. The testis may be retracted by cremasteric spasm. When the stone is in the intramural ureter, the pain can be referred to the tip of the penis. Strangury, the painful passage of a few drops of urine, typically occurs with the stone in the intramural part of the ureter.

Impaction

Most stones pass spontaneously from the ureter but there are five sites of narrowing where the stone may be arrested (Fig. 71.28). When the stone becomes impacted, the attacks of colic give way to a more consistent dull pain, often felt in the iliac fossa. The pain may be increased by exercise and lessened by rest. Distension of the renal pelvis because of obstruction may cause pain and discomfort in the loin. The stone may become embedded as the adjacent ureteric wall becomes eroded and oedematous as a result of pressure ischaemia. Perforation of the ureter and extravasation of urine is a rare complication.

Severe renal pain subsiding after a day or so suggests complete ureteric obstruction. If obstruction persists after 1–2 weeks, the calculus should be removed because prolonged distension of the kidney will eventually lead to atrophy of the renal parenchyma.

Haematuria

Almost every attack of ureteric colic is associated with microscopic haematuria, which lasts for a day or so. More profuse

Hippocrates, c460–375 BC. A Greek Physician and Surgeon, who is regarded as 'The Father of Medicine'. He was born on the Greek island of Cos off the Turkish coast about 460 BC, and probably died in 375 BC.

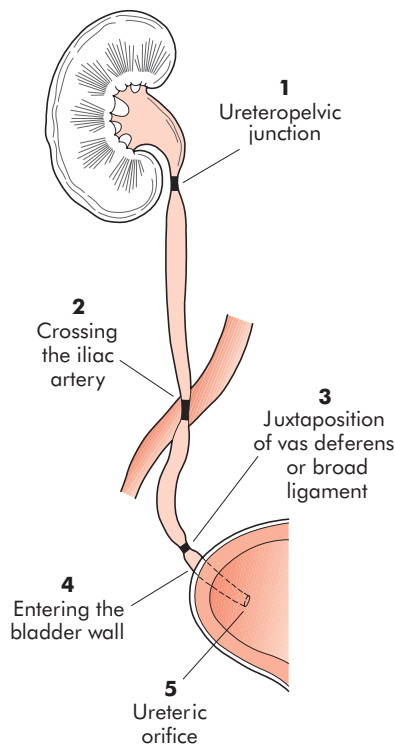

Figure 71.28 Normal anatomical narrowings (1–5) of the ureter.

bleeding is uncommon and should raise the suspicion that the colic is due to passage of a clot.

Abdominal examination

There is tenderness and some rigidity over some part of the course of the ureter. The principal difficulty on the right side is to distinguish symptoms and signs of ureteric colic from those of acute appendicitis or acute cholecystitis. The presence of haematuria does not rule out appendicitis, because an inflamed appendix can give rise to a local ureteritis leaking some red cells into the urine. The patient with acute ureteric colic is usually in greater pain and less systemically ill.

Imaging

Most urinary calculi are visible on a plain abdominal radiograph. The stone may not be seen along the line of the ureter if it is small or if it is obscured by bowel contents or the shadows cast by nearby bones. Intravenous urography performed while the patient has pain can confirm the diagnosis, although spiral CT is increasingly used for this purpose. In ureteric colic there will probably be little or no excretion on the affected side. Occasionally, there is an extravasation of contrast from the dilated system. Late radiographs, taken up to 36 hours after the injection of contrast, may show dilatation of the ureter down to an obstructing calculus. A radiolucent uric acid stone may be demonstrated as a filling defect in the contrast-filled system.

Analgesic abusers occasionally fake symptoms to obtain drugs, and emergency imaging is useful in excluding renal colic. If the CT or urogram is normal during an attack, the patient does not have renal colic. The absence of blood in the urine makes colic less likely but its presence can be simulated by those desperate for drugs.

Cystoscopy is not indicated routinely but may reveal oedema and petechiae of the urothelium around the ureteric orifice when

the stone is nearby. The stone may be visible in the orifice as it passes into the bladder.

Retrograde ureterography is performed as an immediate preliminary to an endoscopic operation to remove a calculus.

Treatment

Pain

Non-steroidal anti-inflammatory drugs such as diclofenac and indomethacin have replaced opiates as the first line of treatment for renal colic. The value of smooth muscle relaxants such as propantheline (Pro-Banthine) is debatable.

Removal of the stone (Summary box 71.21)

Expectant treatment is appropriate for small stones that are likely to pass naturally. This may take many months and, as long as the patient is not disabled by recurrent attacks of colic, progress can be followed by radiographs every 6–8 weeks.

Summary box 71.21

Indications for surgical removal of a ureteric calculus

- Repeated attacks of pain and the stone is not moving
- Stone is enlarging
- Complete obstruction of the kidney
- Urine is infected
- Stone is too large to pass
- Stone is obstructing solitary kidney or there is bilateral obstruction

Endoscopic stone removal

Dormia basket The use of wire baskets under image intensifier control has been replaced by ureteroscopic techniques but they may be useful when the necessary instruments and expertise are not available (Fig. 71.29). There is a significant danger of ureteric injury near the ureteric orifice, even with small stones.

Ureteric meatotomy Stones often lodge in the intramural part of the ureter. Endoscopic incision using a diathermy knife can

Figure 71.29 Dormia stone-catching basket in use: (a) basket introduced past stone; (b) opened; and (c) enclosing stone, ready for withdrawal.

Dormia, formerly Assistant Professor of Urology, The University of Milan, Milan, Italy.

enlarge the opening and free the stone. The procedure may lead to urinary reflux but this rarely causes problems.

Ureteroscopic stone removal

A ureteroscope is a long thin endoscope passed transurethraly across the bladder into the ureter (Fig. 71.30). The ureteroscope is used to remove stones that are impacted in the ureter. Stones that cannot be caught in baskets or endoscopic forceps under direct vision are fragmented using an electrohydraulic, percussive or laser lithotripter.

Push bang A stone in the middle or upper part of the ureter can often be flushed back into the kidney using a ureteric catheter. A J-stent secures the repositioned calculus in the kidney for subsequent treatment with ESWL.

A flexible fiberoptic ureteroscope can be used for laser destruction of calculi in the renal collecting system or ureter and to retrieve small stones from the kidney.

Lithotripsy *in situ*

A stone in a part of the ureter that can be identified by the imaging system of the lithotripter can be fragmented *in situ*. This form of treatment is not appropriate if there is complete obstruction or if the stone has been impacted for a long time.

Open surgery

Ureterolithotomy

A radiograph confirms the position of the stone immediately before surgery.

Figure 71.30 Ureteroscopy. Radiograph showing a ureteroscope and guidewire in the lower ureter.

The incision must be appropriate for the position of the stone. Calculi in the upper third of the ureter are approached through a loin or upper quadrant transverse incision as used for a stone in the renal pelvis. Access to midureteric stones is through a muscle-cutting iliac fossa incision; lower ureteric stones are best reached through a Pfannenstiel incision. For stones close to the bladder, exposure is improved by ligating and dividing the superior vesical vascular pedicle. The ureter is exposed in the retroperitoneum and slings are applied above and below the calculus to stop it from escaping. The ureter is incised longitudinally, directly on to the stone, which is freed from adhesions by blunt dissection and removed with stone forceps. Soft catheters are passed upwards and downwards to ensure that the ureter is clear. The ureterotomy is closed with interrupted absorbable sutures and a drain left in place for a day or so to drain urine leakage.

IDIOPATHIC RETROPERITONEAL FIBROSIS

In this rare condition one or both ureters are bound up in a progressive fibrosis of the retroperitoneal tissues. Most cases are idiopathic but some may be drug related. A similar clinical picture occurs in patients with leaking aortic aneurysm and infiltrating retroperitoneal malignancy.

The patient complains of backache, which is unremitting for several months. The onset of anuria and renal failure prompts investigation of the renal tract, which reveals hydronephrosis, usually on both sides. The excretion urogram typically shows medial displacement of the obstructed ureters and the appearances on CT are diagnostic. The sedimentation rate is markedly raised.

Treatment

It may be possible to insert ureteric stents as a temporary measure while renal function recovers. If not, percutaneous nephrostomies will allow the obstructed kidneys to drain. Some patients need renal replacement by dialysis. Some advocate conservative treatment with high-dose steroids. Surgical treatment involves dissection of the ureters from their fibrous jacket (ureterolysis). Wrapping omentum around the freed ureters discourages recurrent obstruction.

KIDNEY INFECTIONS (SUMMARY BOX 71.22)

Aetiology

Renal infections arise in the following ways:

- *Haematogenous infection* from a primary site in the tonsils or carious teeth or from cutaneous infections, particularly boils or a carbuncle. Renal tuberculosis occurs by blood-borne spread from lymph nodes in the neck, chest or abdomen.
- *Ascending infection* in the urinary tract is the most common route, and it is most likely to occur when there is vesicoureteric reflux. Urinary stasis and the presence of calculi are common contributory factors.

Herman Johann Pfannenstiel, 1862–1909, Gynaecologist, Breslau, Germany, (now Wrocław, Poland) described this incision in 1900.

Summary box 71.22

Kidney infection

- Acute pyelonephritis:
 - In childhood
 - In pregnancy
 - With urinary obstruction
- Chronic pyelonephritis:
 - Reflux nephropathy
- Pyonephrosis
- Renal abscess
- Perinephric abscess

Bacteriology

Escherichia coli and other Gram-negative organisms are commonly responsible. When *Streptococcus faecalis* is present it is usually accompanied by other organisms. In *E. coli* and streptococcal infections the urine is acidic. *Proteus* spp. and staphylococci split urea to form ammonia, which makes the urine alkaline and promotes the formation of calculi.

Acute pyelonephritis

Acute pyelonephritis is more common in females, especially during childhood, at puberty, after intercourse (as a complication of 'honeymoon cystitis'), during pregnancy and during menopause. It occurs more on the right and is frequently bilateral.

Clinical features

There may be prodromal symptoms of headache, lassitude and nausea, but the onset of pain is usually sudden, often with a rigor and vomiting. There is acute pain in the flank and hypochondrium. In a few cases the pain resembles renal colic. The remitting temperature rises to 39.0°C or more. The symptoms of cystitis commonly set in, with urgency, frequency and scalding dysuria. There is tenderness in the hypochondrium and in the loin. Rarely, in cases of severe bilateral pyelonephritis, especially when there is an associated obstruction, renal dysfunction may be sufficient to cause uraemia. The risk of life-threatening septicaemia is ever present (Summary box 71.23).

Summary box 71.23

Clinical features of kidney infections

- More common in women
- Often associated with septicaemia leading to pyrexia and rigors
- Associated with pyuria and occasionally haematuria
- Should be initially treated with broad-spectrum parenteral antibiotics
- Extremely dangerous if the kidney is obstructed

Bacteriological examination of the urine

A midstream urine specimen should be collected into a sterile container; the urine is centrifuged and the sediment examined microscopically. In early acute pyelonephritis, there are usually

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900), and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

pus cells and many bacteria. The urine may be misleadingly clear to the eye until the infection becomes established, when the urine is cloudy and full of pus. Culture and sensitivity testing of the causative organisms allows a rational choice of antibiotic, but parenteral treatment with a broad-spectrum antibiotic should be started before the results are available.

Severe cases

There are repeated rigors and a temperature of 40°C or more, often without a corresponding rise in pulse rate. There is vomiting, sweating and thirst; the patient feels awful. The blood culture is usually positive, especially if the specimen has been taken during a rigor.

Differential diagnosis

When the symptoms and signs are typical the diagnosis is straightforward. In other circumstances it may be difficult to be sure that the patient does not have pneumonia, acute appendicitis or acute cholecystitis. The urgent need is to distinguish acute pyelonephritis from appendicitis, and the site of pain and the presence of marked peritonism are usually helpful in identifying the latter. A plain abdominal radiograph may show the outline of a swollen kidney and, if the infection is severe, a skilled ultrasonographer may be able to detect the typical appearances of pyelonephritis.

Special cases

Pyelonephritis of pregnancy

Pyelonephritis of pregnancy usually occurs between the fourth and sixth months of gestation in women who have a past history of recurrent urinary infection. In about 10% of cases the disease runs a severe and protracted course and occasionally leads to abortion or premature birth.

Urinary infection in childhood

Urinary infection in childhood is important to recognise because it may damage the growing kidney. In young children, symptoms are often non-specific but the child may pass cloudy or offensive urine. The possibility of urinary sepsis should always be considered if a child fails to thrive or suffers unexplained pyrexia. Pain or screaming on micturition may occur. The older child may complain of loin pain and may develop urinary frequency and secondary enuresis.

Up to 50% of children with urinary infection have an underlying anatomical abnormality (e.g. reflux or obstruction). The diagnosis of infection is confirmed by examination of a clean-catch specimen or a specimen obtained by suprapubic needle puncture. On culture, a pure growth of more than 10⁵ organisms/ml with a significant pyuria is evidence of infection. Such children should be investigated by ultrasound scan and other modalities to identify underlying urinary tract abnormalities and to assess renal function and scarring.

Vesicoureteric reflux of urine is detectable in about 35% of children with recurrent urinary infection. In some patients the reflux is caused by high pressure in a neuropathic bladder. It may be intermittent and is often more marked when there is active infection. Renal damage results from the combination of reflux and urinary infection early in life, and reflux nephropathy is the most common cause of end-stage renal failure in the UK. Long-term prophylactic antibiotic treatment has become the favoured treatment for recurrent urinary infections resulting from reflux. Surgical reimplantation of the ureters is reserved for those in

whom conservative measures fail. However, reimplantation in these patients may fail to cure reflux (Summary box 71.24).

Summary box 71.24

Urinary infection in childhood

- A single proven urinary infection in a child should prompt referral to a paediatric urologist

Acute pyelonephritis associated with urinary retention

Acute pyelonephritis is a relatively uncommon complication of chronic urinary retention. Often the organisms are introduced during instrumentation. Patients who have a significant post-micturition urinary residue should be given prophylactic antibiotics to cover transurethral procedures.

Treatment

The treatment of acute pyelonephritis should be prompt, appropriate and prolonged. A full investigation to exclude underlying abnormalities in the urinary tract should be undertaken when the acute illness subsides.

The patient will usually feel like lying in bed. While awaiting the bacteriological report and the results of sensitivity tests, an antimicrobial with a wide range of activity, such as amoxicillin or gentamicin, should be administered, parenterally if necessary. If the urine is acidic, as it is in the common coliform infections, alkalinisation of the urine by potassium citrate may help by inhibiting the growth of these organisms and relieving dysuria. When pain is severe, a morphine-like analgesic drug may be necessary if non-steroidal anti-inflammatory agents are ineffective. The patient should drink copiously; if this is not possible because of nausea and vomiting, an intravenous infusion should be set up.

Most urinary infections acquired outside hospital are sensitive to relatively cheap agents such as trimethoprim and amoxicillin. Hospital-acquired infections are much more likely to be resistant and more expensive second-line antibiotics may be needed. Gentamicin and carbenicillin are suitable for combating infections with more resistant strains of *Pseudomonas pyocyanea*, *Proteus* spp. and *Klebsiella* spp. Ciprofloxacin is particularly useful against *Pseudomonas* spp. in patients who do not have septicæmia. Despite the efficacy of modern antibacterial drugs, recurrent infection is likely if there is an untreated underlying abnormality of the urinary tract such as a stone, vesicoureteric reflux, fistula to the gastrointestinal tract or retention of urine.

Chronic pyelonephritis

Chronic pyelonephritis is so often associated with vesicoureteric reflux that some feel that it is better named 'reflux nephropathy'. It is an important cause of renal damage and death from end-stage renal failure.

Pathology

There is interstitial inflammation and scarring of the renal parenchyma with a patchy distribution. The renal tubules are atrophic and dilated. The glomeruli retain their normal structure until the final stages of the disease.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, The Czech Republic; Zurich, Switzerland; and the Rush Medical College, Chicago, IL, USA.

Clinical features

The condition is almost three times as common in women as it is in men. Two-thirds of female patients are under 40 years of age, whereas 60% of male patients are over 40.

It is possible, but unusual, for chronic pyelonephritis to remain clinically silent until the symptoms of advanced renal insufficiency appear.

Lumbar pain, dull and non-specific in character, is present in 60% of cases. Increased urinary frequency and dysuria are common. Hypertension, present in 40% of cases, may be of the accelerated ('malignant') type. Constitutional symptoms of lassitude, malaise, anorexia, nausea and headache constitute the main complaint in 30% of cases. The true cause of these non-specific symptoms may elude diagnosis for years.

Attacks of low-grade fever often prompt the urinary tract investigations that bring the condition to light.

Normochromic anaemia due to unsuspected renal impairment is an occasional presenting feature (Summary box 71.25).

Summary box 71.25

Chronic pyelonephritis

- A common cause of end-stage renal failure
- Often associated with ureteric reflux
- May be symptomatically silent
- Leads to progressive renal scarring

Investigations

As the glomeruli are relatively preserved, proteinuria is less marked than in glomerulonephritis (< 3 g daily). Casts are not usually present but white cells are plentiful.

Escherichia coli, *Streptococcus faecalis*, *Proteus* spp. or *Pseudomonas* spp are found in the urine.

Treatment

Treatment is aimed at eradicating predisposing contributory factors such as obstruction or stones and treating the infection, often with repeated courses of antibiotic. Unfortunately, once the parenchyma has been scarred it becomes vulnerable to blood-borne organisms and reinfection is likely, sometimes with a different and resistant organism. Consequently, antibiotics confer only temporary benefit and progressive renal damage is common.

Surgical treatment is indicated only when the disease is confined to one kidney. This is unusual but in such cases nephrectomy or partial nephrectomy may stop the symptoms of infection and make hypertension easier to control. Patients with end-stage renal failure require renal replacement therapy.

Pyonephrosis

The kidney becomes a multilocular sac containing pus or purulent urine. Pyonephrosis results from infection of a hydronephrosis, follows acute pyelonephritis or, most commonly, arises as a complication of renal calculus disease. Pyonephrosis is usually unilateral.

Clinical features

The classical triad of symptoms is anaemia, fever and a swelling in the loin. When the condition arises as an infected hydronephrosis, the swelling may be very large and the pyrexia very high and associated with rigors. Symptoms of cystitis may be prominent.

Investigations

Imaging may show a calculus and will demonstrate dilatation of the pus-filled collecting system.

Treatment

Pyonephrosis is a surgical emergency because the patient is threatened with permanent renal damage and lethal septicaemia. Parenteral antibiotics should be given immediately and the kidney drained. If the pus is too thick to be aspirated through a large percutaneous nephrostomy, consider open nephrostomy. In cases in which there is a stone, the stone should be removed. Nephrectomy may be appropriate when the kidney is destroyed and function on the other side is good.

Renal carbuncle

An abscess may form in the renal parenchyma as the result of blood-borne spread of organisms, especially coliforms or *Staphylococcus aureus*. Occasionally, the condition results from infection of a haematoma following a blow to the kidney. Renal carbuncle is most commonly seen in diabetics, intravenous drug abusers, those debilitated by chronic disease and patients with acquired immunodeficiency.

Pathology

The renal parenchyma contains an encapsulated necrotic mass.

Clinical features

There is an ill-defined tender swelling in the loin, persistent pyrexia and leucocytosis, signs that closely simulate those of perinephric abscess. In early cases there is no pus or bacteria in the urine, but these appear later. The space-occupying lesion in the kidney may be confused with a renal adenocarcinoma (Fig. 71.31).

Treatment

Resolution by antibiotic treatment alone is unusual. Formal open incision of the abscess may be necessary if the pus is too thick to be drained by percutaneous aspiration.

Figure 71.31 Longitudinal ultrasound scan through the upper pole of the left kidney demonstrates a renal carbuncle, outlined by crosses. S, spleen.

Perinephric abscess

The common causes of perinephric abscess are shown in Fig. 71.32. Other causes are infection of a perirenal haematoma and perinephric discharge of an untreated pyonephrosis or renal carbuncle. A mycobacterial perinephric abscess may arise by extension from a nearby tuberculous vertebra.

Clinical features

In perinephric abscess there is a high swinging pyrexia, abdominal tenderness and fullness in the loin (Fig. 71.33). Local signs present early if the infection starts in the lower part of the perinephric fat. Infection at the upper pole is masked by the lower ribs and signs in the loin are less. The white cell count is always markedly raised but there are characteristically no pus cells or organisms in the urine.

Imaging

The psoas shadow is obscured on the plain abdominal radiograph. There may be a reactionary scoliosis – with the concavity toward the abscess – and elevation and immobility of the diaphragm on the affected side. A calculus may be present. Ultrasonography and CT are diagnostic.

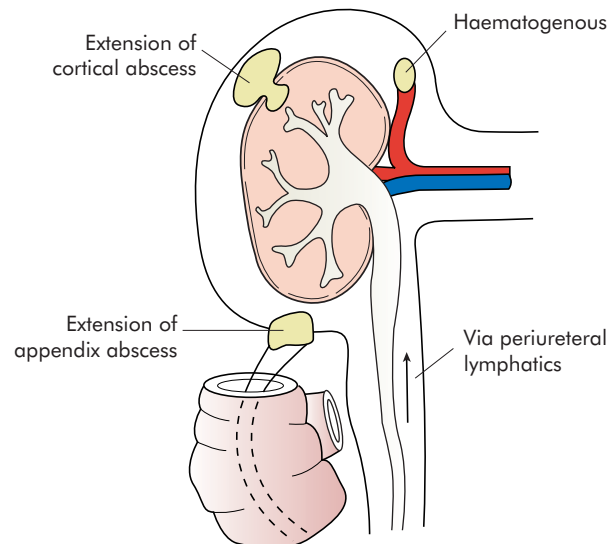

Figure 71.32 Sources of perinephric abscess.

Figure 71.33 A large perinephric abscess.

Treatment

Open drainage may be necessary if the abscess cannot be aspirated through a large percutaneous needle. A lumbar incision is made under antibiotic cover. This should be large enough to allow the surgeon to open pockets of pus and to explore for an unruptured cortical abscess, which may also be present. A specimen of pus is sent for culture and the wound is closed over a tube drain (Summary box 71.26).

Summary box 71.26**Management of perinephric abscess**

- Collections of pus in or around the kidney should be drained surgically if they cannot be aspirated by percutaneous needling

Renal tuberculosis**Aetiology and pathology**

Tuberculosis of the urinary tract arises from haematogenous infection from a distant focus that is often impossible to identify. The lesions are usually confined to one kidney. Tuberculous granulomas in a renal pyramid coalesce to form an ulcer. Mycobacteria and pus cells discharge into the urine. Untreated lesions enlarge and a tuberculous abscess may form in the parenchyma. The necks of the calyces and the renal pelvis stenosed by fibrosis confine the infection so that there is tuberculous pyonephrosis, sometimes localised to one pole of the kidney. Extension of pyonephrosis or tuberculous renal abscess leads to perinephric abscess and the kidney is progressively replaced by caseous material (putty kidney), which may be calcified (cement kidney). At any stage, the plain radiograph may show areas of calcification (pseudocalculi). Less commonly, the kidneys may be bilaterally affected as part of the generalised process of miliary tuberculosis (Fig. 71.34).

Renal tuberculosis is often associated with tuberculosis of the bladder and typical tuberculous granulomas may be visible in the bladder wall. In the male, tuberculous epididymo-orchitis may occur without apparent infection of the bladder.

Clinical features

Renal tuberculosis usually occurs between 20 and 40 years of age, and is twice as common in men as in women; the right kidney is affected slightly more often than the left.

Urinary frequency is often the earliest symptom and may be the only one. The patient complains of a progressive increase in both daytime and night-time frequency.

'Sterile' pyuria

In early cases the urine is pale and slightly opalescent. Routine urine culture is negative.

Pain

Painful micturition is a feature as soon as tuberculous cystitis sets in. First, there is a suprapubic pain if voiding is delayed; later, a burning pain accompanies micturition. When there is secondary infection, a superadded agonising pain referred to the tip of the penis or to the vulva is often associated with haematuria and strangury.

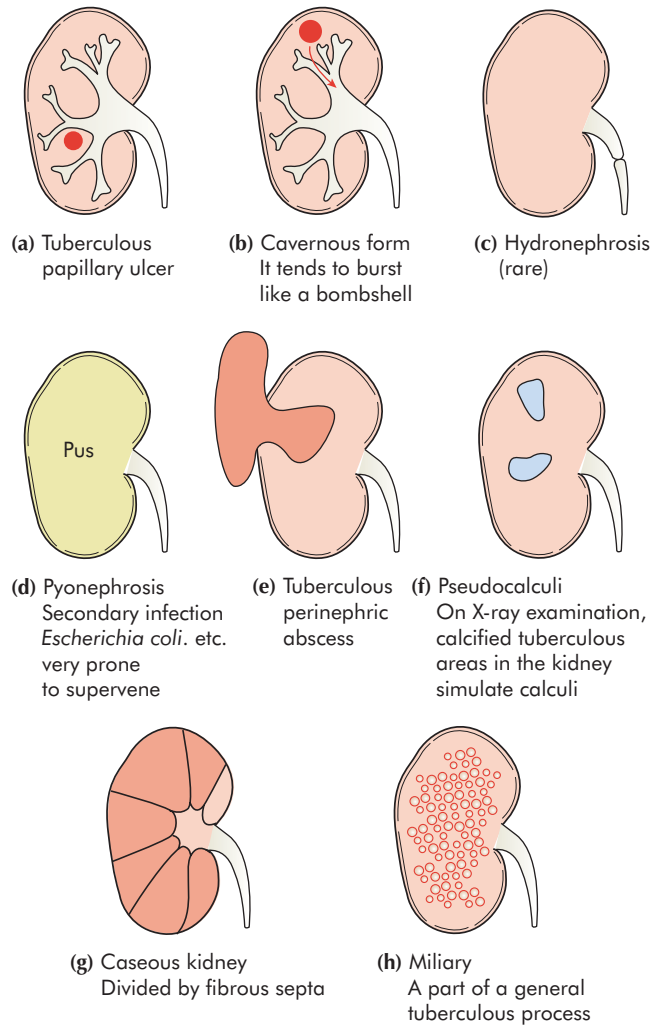

Figure 71.34 Types of lesion in renal tuberculosis.

Renal pain is often minimal but there may be a dull ache in the loin.

Haematuria

In 5% of cases, the first symptom is haematuria occurring from an ulcer on a renal papilla. The tuberculous lesion may be difficult to detect radiologically and mycobacteria may not be cultured from the urine until the onset of more suggestive symptoms months later.

A tuberculous kidney is oedematous and friable and is more liable to damage than a normal kidney.

Malaise and weight loss are usual and a low-level evening pyrexia is typical. A high temperature suggests secondary infection or dissemination, i.e. miliary tuberculosis.

On examination

It is unusual for a tuberculous kidney to be palpable. The prostate, seminal vesicles, vasa and scrotal contents should be examined for nodules or thickening (Summary box 71.27).

Summary box 71.27

Renal tuberculosis

- Should be considered when symptoms of cystitis continue despite treatment with antibiotics
- Is a cause of 'sterile pyuria'
- Results in chronic inflammation and scarring throughout the urinary tract, which may continue after anti-tuberculous treatment has been instituted
- May cause obstructive lesions throughout the urinary tract

Investigation

Bacteriological

Bacteriological examination of at least three complete specimens of early-morning urine should be sent for microscopy and culture before specific chemotherapy is started. Staining of the urine sediment with the Ziehl–Neelsen stain occasionally shows the presence of acid-fast bacilli, but proof that these are pathological mycobacteria must await prolonged culture on Löwenstein–Jensen medium. When the clinical picture is convincing it is permissible to start anti-tuberculous therapy in anticipation of the culture results some 6 weeks later.

Radiography

An abdominal radiograph may show calcified lesions.

Intravenous urography

Early in the disease, the normally clear-cut outline of a renal papilla may be rendered indistinct by the presence of ulceration. Later, there may be calyceal stenosis (Fig. 71.35) and/or hydronephrosis caused by stricture of the renal pelvis or the ureter draining the affected kidney; this may be more easily

Figure 71.35 Intravenous urogram showing a small localised tuberculous lesion with hydrocalyx (arrow). Healing took place with conservative treatment.

Franz Heinrich Paul Ziehl, 1857–1926, Neurologist, Lubeck, Germany.
 Friedrich Carl Adolf Neelsen, 1854–1894, Prosector, Stadt-Krankenhaus, Dresden, Germany.
 Ernst Lowenstein, b. 1878, Pathologist, Vienna, Austria.
 Carl Oluf Jensen, 1864–1934, Pathologist, Copenhagen, Denmark.

demonstrable by retrograde ureterography (Fig. 71.36). A tuberculous abscess appears as a space-occupying lesion, which causes adjacent calyces to splay out. The bladder may appear shrunken, with its wall irregular or thickened. In late stages there may be dilatation of the contralateral ureter from obstruction where the ureter passes through a thickened and oedematous bladder wall.

Cystoscopy

Cystoscopy is not routine in the investigation of urinary tuberculosis but is often performed because there has been haematuria or unexplained bladder symptoms. There may be little to see in the first stages of the disease, but later the urothelium is studded with granulomas that cluster particularly around the ureteric orifices. The tubercles may coalesce to produce a tuberculous ulcer. As the bladder wall fibroses, the bladder capacity decreases. Contraction of the fibrosed ureter tugs at the ureteric orifice, which is displaced upwards, its mouth wide open (the so called 'golf-hole' orifice).

Chest radiography

A chest radiograph is indicated to exclude an active lung lesion.

Treatment

Anti-tuberculous chemotherapy is best managed by a physician with experience of the most modern drug regimens and their potential adverse effects. The surgeon must ensure that the state of the urinary tract is reviewed during the first few weeks of therapy because the renal pelvis and ureter may stricture *after* treatment has started.

Prognosis in renal tuberculosis is good if the patient completes the course of chemotherapy.

Operative treatment

Operative treatment should be conservative, aiming to remove large foci of infection, which are difficult to treat with drugs, and correct the obstruction caused by fibrosis. The optimum time for surgery is between 6 and 12 weeks after the start of anti-tuberculous chemotherapy.

The surgeon needs a repertoire of procedures to deal with

Figure 71.36 Retrograde ureterogram showing advanced tuberculous of the right kidney. Right retrograde study shows multiple ureteric strictures and gross distortion of the internal architecture of the affected kidney.

various potential effects of urinary tuberculosis. An obstructed lower pole calyx may be drained into the upper ureter. A strictured renal pelvis needs a pyeloplasty. Ureteric stenosis and shortening may require a Boari operation or a bowel interposition, depending on the level and extent of the fibrosis. If the kidney has no function it is best to perform a nephroureterectomy (Fig. 71.37). A bladder too contracted to function as a reservoir for urine may be replaced with a neobladder fashioned from a loop of bowel in a substitution cystoplasty.

NEOPLASMS OF THE KIDNEY (SUMMARY BOX 71.28)

Summary box 71.28

Renal neoplasms

Benign neoplasms

- Adenoma
- Angioma
- Angiomyolipoma

Malignant neoplasms

- Wilms' tumour (nephroblastoma in children)
- Grawitz's tumour (adenocarcinoma, hypernephroma)
- Transitional cell carcinoma of the renal pelvis and collecting system
- Squamous carcinoma of the renal pelvis

Benign neoplasms

Adenoma

Pea-like cortical adenomas are occasionally discovered at post-mortem examination or incidentally during radiological imaging. They are asymptomatic and defined as benign.

Angioma

Angioma may cause profuse haematuria, often in young adults. The source of the bleeding may be difficult to diagnose without renal angiography.

Angiomyolipoma

Angiomyolipoma is an unusual tumour of the kidney that is often but not always associated with tuberous sclerosis. Its high fat content gives it a typical appearance on CT. Malignant elements are present in about one-quarter of them and may lead to metastasis.

Malignant neoplasms

Renal neoplasm in children

Wilms' tumour (synonym: nephroblastoma) (Fig. 71.38)

This is a mixed tumour containing blastemal, stromal and epithelial elements arising from embryonic nephrogenic tissue. The tumours are usually discovered during the first 5 years of life, usually in one pole of one kidney. Bilateral tumours pose a difficult clinical problem.

Pathology The cut surface of the tumour is tan coloured. A rapidly growing tumour is likely to be soft and friable in consistency.

Clinical features An abdominal tumour grows rapidly while the general well-being of the child deteriorates. The mass may be enormous compared with the tiny patient. Some patients are hypertensive.

Haematuria denotes extension of the tumour into the renal pelvis and the prognosis is less good.

Imaging by ultrasonography, CT or magnetic resonance imaging (MRI) confirms a solid space-occupying lesion in the kidney, with or without venous invasion, contralateral disease and distant spread.

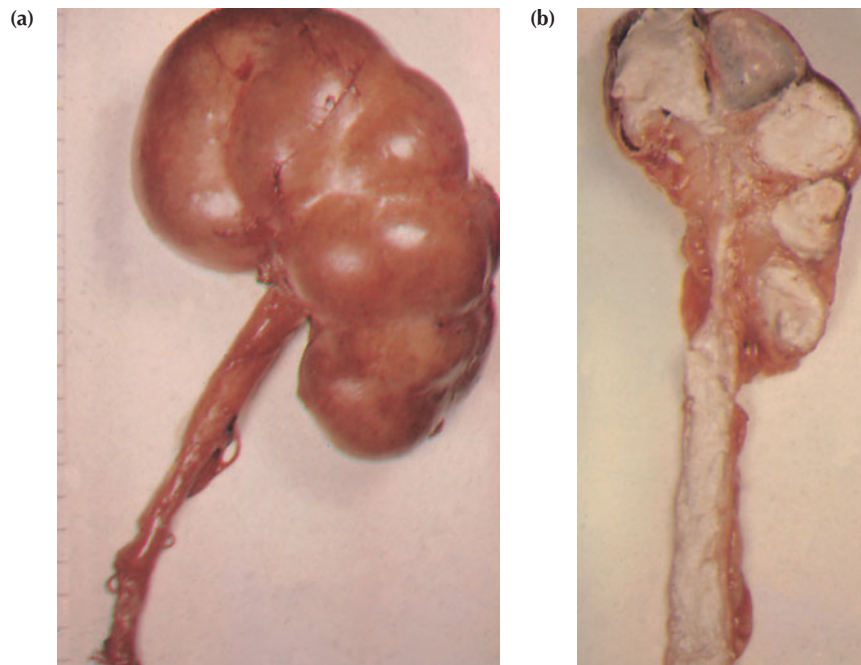

Figure 71.37 (a and b) Nephroureterectomy specimen from a patient with a kidney destroyed by tuberculous pyonephrosis.

Figure 71.38 Wilms' tumour.

Metastasis to the lungs occurs early. Liver, bone and brain metastases are rare. Lymphatic spread is uncommon.

Treatment These children are best treated in specialist paediatric oncology units. Most unilateral tumours are treated by chemotherapy followed by nephrectomy. Partial nephrectomy may be possible in patients with bilateral disease.

Prognosis With modern chemotherapy and surgery, long-term survival can be expected in more than 80% of patients. The prognosis is worse in those with metastases and in older children (Summary box 71.29).

Summary box 71.29

Nephroblastoma (Wilms' tumour)

- Usually presents in the first 5 years of life
- Typically presents with an abdominal mass
- May cause haematuria, abdominal pain or fever
- Metastasises to the lung
- Is best treated in a specialist paediatric oncology unit

Renal neoplasm in adults

Hypernephroma (synonym: Grawitz's tumour)

This adenocarcinoma, the most common neoplasm of the kidney (75% incidence), arises from renal tubular cells. Whether carcinoma arises in pre-existing adenomas is uncertain.

Pathology Moderate-sized tumours are spherical and often occupy the poles of a single kidney, most commonly the upper pole. Hilar tumours are less common. The cut surface is usually yellowish or dull white, semi-transparent, with areas of haemorrhage (Fig.

Paul Albert Grawitz, 1850–1932, Professor of Pathology, Greifswald, Germany, described adeno-carcinoma of the kidney in 1884.

71.39). The tumour is often divided into lobules, some of which are cystic. Larger tumours are irregular in shape with central haemorrhage and necrosis.

Microscopic structure The most common pattern is of solid areas of polyhedral or cubical clear cells with deeply stained, small, rounded nuclei and abundant cytoplasm containing lipids, cholesterol and glycogen. The cells are occasionally arranged as papillary cysts or tubules. Less commonly, the cells are granular (dark), and both clear and dark cells may be represented in the same tumour. The scanty stroma is richly vascular.

Spread The tumour is prone to grow into the renal vein. Cells are swept into the circulation and end up in the lungs, where they grow to form cannonball secondary deposits (Fig. 71.40).

Figure 71.39 Adenocarcinoma of the kidney (Grawitz's tumour).

Figure 71.40 Cannonball secondaries from a hypernephroma.

Metastasis to bone also occurs and a secondary deposit in a long bone may be the only sign of distant spread for a year or more. Highly vascular metastases may pulsate. Tumour extending beyond the renal capsule is liable to metastasise via the lymph nodes in the hilum of the kidney to the para-aortic nodes and beyond.

Clinical features Adenocarcinoma of the kidney is twice as common in men as in women. Haematuria is usually the presenting symptom, sometimes with clot colic. There may be a dragging discomfort in the loin or the patient may detect a mass. In men, a rapidly developing varicocele is a rare but impressive sign, occurring most often on the left side because the left gonadal vein is obstructed where it joins the left renal vein.

Atypical presentations In 25% of cases there are no local symptoms. The patient presents with symptomatic secondary deposits in bone (Fig. 71.41) or the lung (persistent cough or haemoptysis).

Occasionally, persistent pyrexia (37.8–38.9°C) with no evidence of infection is the only symptom. Pyrexia after nephrectomy suggests metastases.

A few patients present with constitutional symptoms and anaemia.

Polycythaemia occurs in 4% of cases as a result of the production of erythropoietin by tumour cells. The erythrocyte sedimentation rate is always raised above the 1–2 mm found in idiopathic polycythaemia vera. The blood count returns to normal after nephrectomy unless there are metastases. Other hormones, such as renin and calcitonin, may be produced by the tumour. Hypercalcaemia is common.

Nephrotic syndrome has been reported as a rare presentation of hypernephroma.

Figure 71.41 Arteriogram showing a vascular 'blush' due to metastasis in the femur from a Grawitz's tumour.

Investigation Intravenous urography is still an important component of the investigation of haematuria. The plain radiograph may show abnormal calcification in the tumour and distortion of the renal outline, which will be confirmed on the nephrographic film. The calyces may be stretched and distorted. It is important to know whether the contralateral kidney is working (Fig. 71.42).

Once a mass has been demonstrated in the kidney, a scan is needed to decide whether it is solid or cystic. Ultrasound will give this information. CT with enhancement will demonstrate the extent of the lesion more clearly and will show whether the hilar lymph nodes or renal vein are involved (Fig. 71.43).

Enthusiasm for renal angiography and preoperative embolisation has waned. Occasionally, a flush inferior cavagram is helpful

Figure 71.42 Intravenous urogram in a case of hypernephroma of the left kidney. The only symptom was one attack of painless haematuria. Note the displacement of the upper pole calyces by the mass.

Figure 71.43 Computerised tomography scan showing large bilateral renal adenocarcinomas.

to show the extent of caval involvement by tumour growing in from the renal vein.

A chest radiograph is essential to detect lung secondaries. An isotope bone scan will reveal deposits in bone.

Treatment If the tumour is confined to the kidney, treatment is nephrectomy with removal of the perinephric fat. Nephrectomy can be performed through a loin or a transverse or oblique upper abdominal incision. The transabdominal approach has the advantage that the renal pedicle and the inferior vena cava can be widely exposed.

The vascular pedicle should be ligated before the kidney is mobilised because handling the tumour may cause malignant cells to be released into the circulation. The first step in the procedure is to clean the renal artery and ligate it in continuity. This may be more difficult from an anterior approach because the artery lies behind the vein. However, once the artery is occluded, the tumour loses most of its profuse blood supply and massive bleeding during mobilisation becomes less likely. Gentle palpation of the renal vein ensures that there is no tumour in its lumen. An empty vein can be divided between ligatures. The renal artery is then divided and the kidney mobilised within its coverings. Aberrant vessels feeding the tumour must be carefully ligated or coagulated to avoid troublesome bleeding. The ureter is then traced downwards as far as is safe and divided between ligatures.

If the renal vein or the inferior vena cava is invaded, the surgeon must obtain control of the cava above and below the tumour extension as a first priority. If there is extension into the thorax, the cardiac team may be needed to put the patient on cardiac bypass so that tumour can, if necessary, be removed from the right side of the heart.

Adenocarcinoma of the kidney responds poorly to radiotherapy or conventional chemotherapy. There have been early promising results from clinical trials of the cytokine interleukin-2 in this condition.

Prognosis Removal of even the largest neoplasm may cure the patient. In operable cases, 70% of patients are well after 3 years and 60% after 5 years. Macroscopic involvement of the renal vein or its tributaries, invasion beyond the capsule and lymphatic involvement all worsen the prognosis (Summary box 71.30).

Summary box 71.30

Adenocarcinoma of the kidney

- Often presents with haematuria
- May be associated with pyrexia of unknown origin, polycythaemia, hypercalcaemia, anaemia and other paraneoplastic symptoms
- Metastasises via the bloodstream to bone, liver and lung (cannonball secondaries)
- Renal vein extension may embolise to the pulmonary circulation during nephrectomy

Papillary transitional cell tumours of the renal pelvis (Fig. 71.44)

These resemble those of the bladder but are much less common. They may invade the renal parenchyma and have a tendency to be multifocal and to distant spread. Multiple ureteric tumours are thought to arise from a field change that renders the whole

Figure 71.44 Papillary transitional cell tumour of the renal pelvis.

urothelium liable to metaplasia rather than seeding down the ureter. Whether the carcinogen is chemical or viral is uncertain.

Clinical features Haematuria is the most common symptom and usually causes the patient to seek help before the tumour mass becomes palpable.

The presence of malignant cells in the urine may indicate whether the tumour is well or poorly differentiated. There is some evidence that those with poorly differentiated tumours do better if they have a short course of radiotherapy before surgery. It is therefore useful to obtain cells from the tumour by sampling using a brush or catheter passed up the ureter under radiological control.

Intravenous urography usually demonstrates the tumour (Fig. 71.45). Retrograde pyelography may be helpful if the urogram is indistinct.

Figure 71.45 Intravenous urogram showing a filling defect in the left renal pelvis due to transitional cell carcinoma.

Treatment Conventional surgical treatment is by nephroureterectomy. The ureter must be disconnected with a cuff of bladder wall. If this is done by open surgery a second incision is needed to remove the kidney. Alternatively, the ureteric orifice can be widely resected with a resectoscope and the ureter delivered by a somewhat perilous blunt dissection from the upper abdominal wound used to remove the kidney. Some urologists argue that well-differentiated upper urinary tract transitional tumours should be treated conservatively by resection with appropriate steps taken to avoid the growth of tumour seeded in the percutaneous track.

Squamous cell carcinoma of the renal pelvis

This is rare and often associated with chronic inflammation and leucoplakia resulting from stone. The tumours are radiosensitive but metastasise early and the prognosis is poor.

Transitional cell tumours of the ureter

These are rare. They behave like tumours of the renal pelvis. Treatment is by nephroureterectomy.

About half of patients with tumours of the upper urinary tract will have tumours in the bladder at some stage. Follow-up by cystoscopy with regular urography is therefore necessary to detect recurrent tumours.

Balkan nephropathy Transitional cell tumours of the upper urinary tract have a very high incidence in certain areas of the Balkans. The same population has a high incidence of a form of primary nephropathy. The causative agent has not been identified with certainty but there seems to be an association with the consumption of grain products stored in a damp environment. Tumours that develop against a background of Balkan nephropathy should

The Balkans are the countries which occupy an area in the south-east of Europe. They lie south of the Danube and Sava rivers, and form a peninsula bounded on the east by the Aegean and Black Seas, on the west by the Adriatic and Ionian Seas, and on the south by the Mediterranean.

be treated by nephron-sparing surgery in view of the impaired overall renal function.

Nephrectomy for benign disease

Nephrectomy is now rarely performed for benign disease but may be necessary if the kidney is atrophic or dysplastic or the cause of accelerated hypertension. Non-functioning kidneys resulting from longstanding obstruction or stone disease are a potential site for infection and even malignancy. In a simple nephrectomy, the kidney is dissected free through the convenient plane between the capsule and its fatty coverings. If this plane is obscured by the scarring of previous surgery, a subcapsular nephrectomy may be safer. Laparoscopic nephrectomy is sometimes possible for small kidneys destroyed by benign disease but the technique requires special skills and the costs and benefits are under evaluation.

Hypertension and a unilateral renal lesion

Ischaemia of the renal parenchyma leads to the release of pressor agents that cause arterial hypertension. When a renal lesion is discovered during the investigation of hypertension, nephrectomy may make the hypertension more amenable to drug treatment.

The urinary bladder

LEARNING OBJECTIVES

To understand:

- The anatomy, vascular supply and innervation of the bladder in relation to function and disease
- The principles of management of bladder trauma, incontinence and fistulae
- The common causes of acute and chronic urinary retention and management
- The different types of bladder cancer and the principles of management

SURGICAL ANATOMY OF THE BLADDER

- It is lined by transitional epithelium covering the connective tissue lamina propria, which contains a rich plexus of vessels and lymphatics.
- When the detrusor muscle hypertrophies, the inner layer, covered by urothelium, stands out, resulting in the appearance of trabeculation.
- Over the trigone is a thin layer of smooth muscle to which the epithelium is closely adherent and which extends as a sheath around the lower ureters and into the proximal urethra.
- Around the male bladder neck is the smooth muscle internal sphincter innervated by adrenergic fibres, which prevents retrograde ejaculation.
- The distal urethral sphincter is a horseshoe-shaped mass of striated muscle that lies anterior and distal to the prostate, or in the proximal two-thirds of the female urethra. It is distinct from the pelvic floor and is supplied by S2–S4 fibres via the pudendal nerve and by somatic fibres passing through the inferior hypogastric plexus.

Fascial and ligamentous supports of the bladder

At the posterolateral bladder neck, condensations of fascia pass forward medially and laterally to the ureter to join with the prostatic fascia; this fascia needs to be divided during cystectomy. The puboprostatic ligaments are well-defined condensations of the anterior endopelvic fascia; they stretch from the front of the prostate to the periosteum of the pubis and lie lateral to the dorsal vein complex. The urachus and obliterated hypogastric arteries, together with the folds of peritoneum overlying them, are called the median and lateral umbilical ligaments. Condensations of fascia also occur around the superior and inferior vascular pedicles.

Arteries

The superior and inferior vesical arteries are derived from the anterior trunk of the internal iliac artery. Branches from the

obturator and inferior gluteal arteries (and from the uterine and vaginal arteries in females) also help to supply the bladder.

Veins

The veins form a plexus on the lateral and inferior surfaces of the bladder. In the male the prostatic plexus is continuous with the vesical plexus, which drains into the internal iliac vein. In the female similar large veins are continuous with the vaginal plexus.

Lymphatics

These accompany the veins and drain to nodes along the internal iliac vessels and then to the obturator and external iliac chains. Some lymphatics pass to nodes that are situated posteriorly to the internal iliac artery (hypogastric nodes).

INNERVATION (FIG. 72.1)

The parasympathetic input

This is derived from the anterior primary divisions of the second, third and fourth sacral segments (mainly S2 and S3). Fibres pass through the pelvic splanchnic nerves to the inferior hypogastric plexus, from where they are distributed to the bladder. The pelvic plexus can be damaged during deep pelvic operations.

The sympathetic input

This arises in the 11th thoracic to the second lumbar segments; fibres pass via the presacral hypogastric nerve (rather than via the sympathetic chains) to the inferior hypogastric plexus.

Somatic innervation

A somatic innervation passes to the distal sphincter mechanism via the pudendal nerves and also via fibres that pass through the inferior hypogastric plexus.

Functional aspects

Sympathetic nerves convey afferents from the fundus. Afferents

Figure 72.1 The nervous control of the bladder. Micturition is partly a reflex and partly a voluntary act.

arise from the mucosa, where they respond to touch, temperature and pain, and from the detrusor and lamina propria, where they convey stretch information. Afferents pass via the inferior hypogastric plexus to the posterior roots of S2–S4. Some aspects of micturition are centred in the pons, where detrusor contraction is coordinated with inhibition of the distal sphincter. Interruption of this pathway below the pons with preservation of the sacral cord is likely to result in a contractile detrusor and tonically active distal sphincter that will not relax during voiding (detrusor–sphincter dyssynergia).

CONGENITAL DEFECTS OF THE BLADDER

Bladder exstrophy (Fig. 72.2)

Clinical features

Bladder exstrophy occurs in 1:50 000 births (male–female ratio 4:1). In the male, the penis is broad and short, and bilateral

Figure 72.2 Ectopia vesicae in a male. A drop of urine (arrow) is seen at the left ureteric orifice, the corona glandis being retracted by threads (courtesy of G.D. Adhia, Bombay, India).

inguinal herniae may be present. There is separation of the pubic bones (Fig. 72.3). In epispadias alone, the pubes are united and external genitalia are almost normal, although in the female the clitoris is bifid (Fig. 72.4).

Treatment

The bladder is closed in the first year of life, usually following osteotomy of both iliac bones just lateral to the sacroiliac joints. Later, reconstruction of the bladder neck and sphincters is required. In some patients the reconstructed bladder remains small and requires augmentation. One-stage reconstruction is being practised in some major centres.

Less satisfactorily, urinary diversion can be carried out by means of ureterosigmoid anastomosis, an ileal or colonic conduit, or continent urinary diversion. Long-term complications include: (1) stricture at the site of anastomosis with bilateral hydronephrosis and infection; (2) hyperchloraemic acidosis; and (3) an increased (20-fold) risk of tumour formation (adenoma and adenocarcinoma) at the site of a ureterocolic anastomosis.

BLADDER TRAUMA

Bladder rupture

This can be intraperitoneal (20%) or extraperitoneal (80%) (Figs 72.5 and 72.6). Intraperitoneal rupture is usually secondary to a blow or fall on a distended bladder, more rarely to surgical damage. Extraperitoneal rupture is caused by blunt

Figure 72.3 Separation of the pubes in a case of ectopia vesicae (courtesy of the late Professor Grey Turner, London, England).

Figure 72.4 Female epispadias showing deficient sphincter and bifid clitoris.

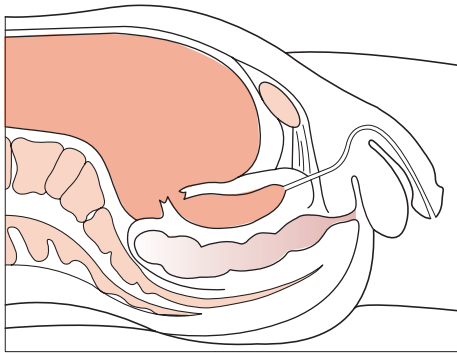

Figure 72.5 Intraperitoneal extravasation of urine.

Figure 72.6 Extraperitoneal extravasation of urine.

trauma or surgical damage. Gross haematuria can be absent. It may be difficult to distinguish extraperitoneal rupture from rupture of the membranous urethra (see Chapter 74). Intraperitoneal rupture is associated with sudden severe pain in the hypogastrium, often accompanied by syncope. The shock subsides and the abdomen distends and there is no desire to micturate. Peritonitis does not follow immediately if the urine is sterile; varying degrees of rigidity are present on examination.

Investigation

Computerised tomography (CT) is ideal. Plain erect radiographs may show a ground-glass appearance (fluid). Intravenous urography (IVU) may confirm a leak. Retrograde cystography will confirm the diagnosis (Fig. 72.7). It is important to image the patient after drainage of contrast as the full bladder may mask extravasation (Summary box 72.1).

Summary box 72.1

Bladder trauma

- Intraperitoneal or extraperitoneal
- Suspected if there is trauma and damage to the pelvis
- May be diagnosed by retrograde cystography

Treatment of intraperitoneal rupture

A lower midline laparotomy should be performed; the edges of the rent are trimmed and sutured with a single-layer 2/0 absorbable suture. A suprapubic and a urethral catheter are

Figure 72.7 Cystogram of a patient who has fallen over and developed severe abdominal pain. Leakage of contrast into the peritoneal cavity is seen.

placed. Very rarely, the rupture will be through an unsuspected tumour; a biopsy can be taken before suturing the defect. Laparoscopic approaches are also now being used.

Injury to the bladder during operation

The bladder may be injured in: (1) inguinal or femoral herniotomy; (2) hysterectomy; and (3) excision of the rectum. If the injury is recognised, the bladder must be repaired and catheter drainage maintained for 7 days. If it is not recognised, the treatment is similar to that of rupture of the bladder.

When accidental extraperitoneal perforation of the bladder occurs during endoscopic resection, drainage of the bladder with a urethral catheter and the administration of antibiotics usually suffice. If a mass of extravasated fluid is present it is best to place a small drain through a stab incision. A laparotomy will usually be required if an intraperitoneal perforation is caused by transurethral resection (Summary box 72.2).

Summary box 72.2

Management of bladder trauma

- Extravesical injury – catheter drainage for 10 days
- Intraperitoneal injury – laparotomy, repair and bladder drainage

RETENTION OF URINE (SEE ALSO CHAPTER 73)

Acute retention

There are many possible causes of acute retention of urine (Summary box 72.3).

Summary box 72.3

The most frequent causes of acute retention**Male**

- Bladder outlet obstruction (the commonest cause)
- Urethral stricture
- Acute urethritis or prostatitis
- Phimosis

Female

- Retroverted gravid uterus
- Bladder neck obstruction (rare)

Both

- Blood clot
- Urethral calculus
- Rupture of the urethra
- Neurogenic (injury or disease of the spinal cord)
- Smooth muscle cell dysfunction associated with ageing
- Faecal impaction
- Anal pain (haemorrhoidectomy)
- Intensive postoperative analgesic treatment
- Some drugs
- Spinal anaesthesia

Clinical features

- No urine is passed for several hours.
- Pain is present.
- The bladder is visible, palpable, tender (Fig. 72.8) and dull to percussion.
- Potential neurological causes should be excluded by checking reflexes in the lower limbs and perianal sensation.

Treatment

Treatment is to pass a fine urethral catheter (14F – French gauge is defined as the circumference in millimetres) and arrange urological management. Occasionally, in postoperative retention a warm bath can help (Figs 72.9–72.12).

Urethral catheterisation

Following a thorough hand wash, sterile gloves are donned. The genitalia are cleaned using soapy antiseptic. Lignocaine gel is inserted into the urethra, warning the patient that this may create stinging. The jelly should be massaged posteriorly in an

Figure 72.8 Distended bladder in a man who presented with retention of urine.

Figure 72.9 Cleaning of the penis before catheterisation.

Figure 72.10 Insertion of local anaesthetic before insertion of a catheter.

Figure 72.11 The use of a penile clamp to ensure that sufficient time is given to allow the anaesthetic to work before the catheter is inserted.

Figure 72.12 A selection of silicone catheters.

attempt to anaesthetise the sphincter region, and it is of advantage to place a penile clamp for several minutes. A small Foley catheter should be passed while the penis is held taut. In a female patient, the labia should be parted using the middle and index fingers of the left hand, which should not be moved once cleaning has been performed. Providing a stricture is not the cause, the catheter should pass freely. Once urine begins to drain it is wise to pass a few more centimetres of catheter into the bladder before the balloon is inflated to avoid inflation in the prostate. Force must not be used (Summary box 72.4).

Summary box 72.4

Catheterisation for acute retention of urine

Following catheterisation:

- Record the volume of urine drained
- Examine the abdomen to exclude other pathology (rupture of an aortic aneurysm, ureteric colic or diverticulitis can cause confusion)

If the catheter will not pass, it is usually due to poor technique, lack of anaesthesia, traumatisation of the urethra or a urethral stricture. Occasionally, a large prostatic middle lobe may prevent the catheter entering the bladder; sometimes a coude catheter will pass. If a catheter cannot be passed the following plan should be pursued.

Suprapubic puncture

Suprapubic puncture with commercially available catheters such as Cystofix or Lawrence Add-a-Cath catheters is straightforward provided that the bladder is palpable. The skin, fascia and retropubicspace are anaesthetised with 0.5% lignocaine. Correct placement is confirmed by aspiration. A large-bore needle is then placed into the bladder, down which a fine catheter is passed (Cystofix) and then secured in position. The other option is to place a plastic suprapubic trocar and cannula, which has a removable plastic strip on the side. A standard 12F Foley catheter can be passed down the cannula, the balloon is inflated, the cannula is extracted and the strip is pulled away from the catheter (Add-a-Cath). If urine cannot be aspirated through the fine-bore needle, passing a suprapubic trocar should not be attempted.

If these devices are not available, a catheter can be placed in the bladder under direct vision through a small incision under local anaesthetic.

Frederic Eugene Basil Foley, 1891–1966, Urologist, Anker Hospital, St Paul, MN, USA.

Urethral instrumentation

In a patient with a known stricture, an experienced urologist may elect to dilate the stricture or to take the patient to theatre to carry out an optical urethrotomy (see Chapter 74).

Chronic retention

In chronic retention there is no pain. These patients are at risk of upper tract dilatation because of high intravesical tension – they require urgent urological referral. Men with impaired renal function may develop postobstructive diuresis following catheterisation. Such men need careful monitoring, with replacement of inappropriate urinary losses by intravenous saline; they are also at risk of haematuria as the distended urinary tract empties. Often it is several days before full renal recovery occurs.

Retention with overflow

The patient is incontinent with small amounts of urine passing involuntarily from the distended bladder. It usually follows a neglected retention.

Indwelling catheters and closed systems of catheter drainage

The risk of ascending infection is decreased by connecting the catheter to sterile tubing connected to a collecting bag. Irrigations should be avoided unless clot retention occurs. When a catheter has been *in situ* for a few days, some degree of urethritis and bacteriuria is likely; changing a catheter then entails risks of severe infection if prophylactic antibiotics are not used (Fig. 72.13).

Acute retention due to drugs

A number of drugs can induce retention, including anti-histamines, anti-hypertensives, anti-cholinergics and tricyclic antidepressants.

The acute neuropathic bladder

- 1 Immediately after spinal cord injury, ‘spinal shock’ occurs (see Chapter 33), which may last for days or months. The detrusor is not able to contract, the bladder distends and overflow incontinence occurs. Neglected bladder distension will lead to

Figure 72.13 Modern Simpla bag used for continuous bladder drainage. (The nurse who is emptying the bag should be wearing disposable gloves to avoid contaminating the hands with organisms.)

damage to the detrusor, infection and ultimately renal failure. Management is as follows:

- 2 The bladder must be emptied by aseptic intermittent catheterisation performed two or three times daily or the use of an indwelling urethral catheter on continuous drainage, making sure that the patient has a high urinary output (3 litres per day) to combat infection. Currently, intermittent catheterisation is preferred as soon as the patient's spinal injury is stable.
- 3 Neurological examination must be performed to assess the level of sensory and motor loss. Ischaemic necrosis of the cord may extend below the upper level of cord injury. When sensory loss below the upper level is total, recovery is unlikely. Incomplete lesions may recover somatic and bladder function.
- 4 Demonstration of intact bulbocavernosus and anal reflexes indicates that the sacral cord and nerves are intact and that reflex bladder contractions are likely to develop, though they may be insufficient to empty the bladder. If there is persistent total loss of reflexes and perineal sensation then either the sacral cord or cauda equina is damaged. In such circumstances an acontractile bladder is likely. In cauda equina lesions there may be sensory, motor or mixed loss.
- 5 Full urodynamic assessment of bladder function should be undertaken when the injury is stable. This allows an accurate assessment of bladder and sphincter activity and will enable decisions to be made about further management; the prime aim is to prevent upper tract damage by promoting good bladder emptying (Summary box 72.5).

Summary box 72.5

Clinical management of spinal injury

- The bladder should be emptied during spinal shock by catheterisation
- Encourage high fluid intake
- Commence intermittent catheterisation
- When the patient is stable undertake full urodynamic evaluation

The following situations represent the typical patterns of bladder function seen after spinal cord injury.

Lesions above T10

Usually leads to an 'upper motor neurone' bladder with reflexes intact but isolated from higher control mechanisms. Such patients are at risk of autonomic dysreflexia.

Because of detrusor–sphincter dyssynergia, bladder contractions are high pressure and ineffective in producing bladder emptying; the bladder neck is normally open. If left untreated, upper tract dilatation and renal failure may result. Bladder capacity is usually decreased with the development of trabeculation and a typical 'fir-tree' appearance. Patients are incontinent during high-pressure phasic contractions because the sphincter resistance suddenly diminishes.

Some patients with low-pressure bladders that empty may be managed by means of condom drainage. Others will require clean intermittent self-catheterisation (CISC), popularised by Lapides. Patients with poor emptying, low bladder capacity and upper tract dilatation require treatment with endoscopic sphincterotomy and condom drainage. Some carefully selected patients may require bladder reconstruction.

Lesions involving the sympathetic outflow (T11, T12, L1, L2)

These patients are usually similar to the group with lesions above T10.

Damage to the sacral centre S2, S3, S4 and cauda equina lesions

Usually leads to a 'lower motor neurone' bladder, also found in spina bifida (myelodysplasia); the detrusor is acontractile. Abdominal straining can produce reasonable emptying but the mainstay is CISC. Some patients may have sensation of filling through the hypogastric nerves if T11 and T12 are intact. The bladder capacity may be good, but some patients have high resting pressures and high increases during bladder filling, which means that there is a risk to the upper urinary tract. The bladder neck is usually open and the distal sphincter mechanisms may be paralysed but of fixed resistance. Vesicoureteric reflux is common and upper tract damage is frequent in neglected cases. Patients who can achieve satisfactory bladder emptying by means of CISC usually have reasonable continence.

Bladder dysfunction after excision of the rectum or radical hysterectomy

Between 10% and 15% of patients undergoing radical rectal excision for cancer sustain damage to the inferior hypogastric plexus, leading to impotence in the male and neurogenic bladder dysfunction. This type of bladder dysfunction is similar to the cauda equina lesion. Postoperative retention in other patients may also be caused by simple bladder outlet obstruction. The best plan is to catheterise the patient to allow postoperative recovery and then carry out urodynamic investigation to determine the appropriate treatment.

INCONTINENCE OF URINE

Overall, urinary incontinence occurs in 5% of men and 20% of women. Up to 40% of women over the age of 60 years and 50% of institutionalised elderly patients experience regular episodes of urinary incontinence. Health problems include skin breakdown and depression, and loss of esteem and sexual activity. Continence is dependent on normal mobility and brain function allowing a perception of when it is socially acceptable to void, normal bladder sensation, normal voluntary detrusor contraction producing good bladder emptying, a normally competent sphincter mechanism, which relaxes appropriately during a voluntary detrusor contraction allowing good bladder emptying, and good bladder capacity with normally low pressures during filling. This is clearly a fine balance and several factors can cause incontinence. Several investigations are required for diagnosis of urinary incontinence (Summary box 72.6).

Summary box 72.6

Diagnosis of urinary incontinence

The following investigations are required:

- A careful history and physical examination and completion of frequency voiding charts
- Urodynamic testing in most patients and in all patients in whom surgical intervention is proposed
- Urine culture to exclude infection and measurement of serum creatinine

In selected cases IVU is carried out if a ureteric fistula is suspected, although ultrasound examination will often provide adequate details

Urodynamic testing

The key to the practical management of lower urinary tract dysfunction, and particularly incontinence, lies with urodynamic investigation. The principle is to artificially simulate bladder filling and emptying while obtaining pressure measurements (Fig. 72.14).

The patient attends with a full bladder and is allowed to void in private to measure the maximum urinary flow rate. After voiding, the residual urine is measured by ultrasound. A pair of catheters or a twin-lumen catheter is passed into the bladder, which allows the bladder to be filled at a rate of 50 ml min⁻¹ while a continuous recording of intravesical pressure is made. To obtain 'true' detrusor pressure, a second channel is required to assess intra-abdominal pressure, measured by means of a small intrarectal or intravaginal balloon. The bladder is filled until the patient states that the bladder is full. Radiographic screening may be carried out to assess bladder neck closure and urinary leakage during movement or coughing (stress incontinence) or during bouts of phasic detrusor pressure (detrusor instability). The patient is then asked to void at the end of bladder filling after the filling catheter has been removed (Fig. 72.15).

The normal bladder will accept approximately 400–550 ml when filled at room temperature at a rate of < 50 ml min⁻¹. The pressure increase in the bladder should be less than 15 cmH₂O. In addition, phasic pressure increases should not be seen. The normal voiding pressure should not exceed 60 cmH₂O in men and about 40 cmH₂O in women, with a flow rate of between 20 and 25 ml s⁻¹.

Common abnormalities identified during urodynamic testing in incontinence

Detrusor instability

Phasic increases in pressure give rise to urgency and urge incontinence (detrusor instability; Fig. 72.16). This abnormality is found in patients with neurogenic bladder dysfunction, such as in multiple sclerosis (MS) or Parkinson's disease or following a

Figure 72.14 Urodynamic study.

James Parkinson, 1755–1824, a General Practitioner of Shoreditch, London, England, published 'An Essay on the Shaking Palsy' in 1817.

Figure 72.15 A section of an ambulatory, natural-fill urodynamic trace. The rectal pressure is in red, the bladder pressure in blue and the subtracted detrusor trace in black. The orange trace is the output of an electronic nappy, which records urinary leakage. A cough is shown, which results in genuine stress incontinence.

Figure 72.16 A section of an ambulatory, natural-fill urodynamic trace. The rectal pressure is in red, the bladder pressure in blue and the subtracted detrusor trace in black. The orange trace is the output of an electronic nappy which records urinary leakage. Phasic activity is shown, which is detrusor instability resulting in urge incontinence.

stroke or spinal injury, when it is known as detrusor hyperreflexia. About 50% of men with bladder outflow obstruction have detrusor instability, and in about half of them the instability resolves after prostatectomy. Idiopathic detrusor instability is common and must be distinguished from genuine stress incontinence (GSI) in women before performing bladder neck suspension procedures.

Genuine stress incontinence

This is defined as urinary leakage occurring during increased bladder pressure when this is solely due to increased abdominal pressure and not to increased true detrusor pressure (see Fig. 72.15). It is caused by sphincter weakness.

Chronic urinary retention

Chronic urinary retention with overflow incontinence is recognised by a large residual volume of urine (Fig. 72.17) and is usually associated with high pressures during bladder filling.

Bladder outflow obstruction

Bladder outflow obstruction is associated with increased voiding pressures, often in excess of 90 cmH₂O (Fig. 72.18), coupled with low urinary flow rates.

Neurogenic dysfunction

Neurogenic bladder dysfunction may also be identified (Summary box 72.7).

Summary box 72.7

Uses of urodynamic testing

- To distinguish GSI (due to sphincter weakness) from detrusor instability in women (see Fig. 72.15)
- For the classification of neurogenic bladder dysfunction
- To distinguish bladder outflow obstruction from idiopathic detrusor instability in men
- To investigate incontinence or other lower urinary tract symptoms

Causes of incontinence

There are various ways of classifying the causes of incontinence.

- *Problems of social control.* Patients with dementia often have incontinence because of uninhibited detrusor hyperreflexia and impaired social perception.
- *Storage problems.* Patients with a small bladder capacity owing to fibrosis (tuberculosis, radiotherapy or interstitial cystitis) can develop incontinence. Patients with a small functional capacity owing to severe detrusor instability, neurogenic dysfunction or infection can develop incontinence.
- *Impairment of emptying.* Patients with chronic retention or neurogenic bladder dysfunction have small functional bladder capacities with detrusor overactivity causing incontinence, despite having large residual volumes of urine.
- *Weak sphincter.* This leads to GSI.

Figure 72.17 An ultrasound scan showing a large post-void residual urine.

Figure 72.18 A conventional urodynamic trace showing detrusor pressure during voiding. There has been a change of scale because the pressure was so high; voiding pressures are increased with a low flow rate, which is diagnostic of bladder outflow obstruction.

- *Fistulae.* Leakage from fistulae or upper tract duplication with an ectopic ureter.

The common causes may be classified into male, female or mixed-sex groups.

Male incontinence

Chronic urinary retention with overflow

This may be due to benign prostatic hypertrophy, carcinoma of the prostate, urethral stricture and, in younger men, hypertrophy of the bladder neck. Examination may reveal that the bladder is distended, and it can be confirmed by ultrasound scanning. The treatment is discussed in Chapter 73.

Post-prostatectomy

Post-prostatectomy incontinence may result from injury to the external sphincter mechanism. Treatment may necessitate insertion of an artificial urethral sphincter (Fig. 72.19).

Figure 72.19 The artificial urinary sphincter made by American Medical Systems.

Female incontinence

Stress incontinence

The most common cause is GSI although, in some parts of the world, vesicourethral fistulae as a result of neglected labour are common. It is usually found in multiparous women with a history of difficult labour. It can be found in normal young women who indulge in competitive trampolining and in patients with epispadias. The classical symptom is urine loss during coughing, laughing, sneezing or a sudden change of posture. The symptoms may change with the menstrual cycle. The volume of urine loss can be measured during an exercise test, which is performed by putting the patient through a standard set of tests with 300 ml of fluid in the bladder; in GSI the fluid losses usually range from 10 to 50 ml. Urinary frequency and urgency are often found in such patients as they try to avoid incontinence by frequent voiding.

Idiopathic detrusor instability can mimic GSI and coexist with it. It is important to make a correct preoperative diagnosis by urodynamic measurements, as the outcome of surgery is suboptimal in women with idiopathic detrusor instability.

Minor to moderate stress urinary incontinence can be controlled by pelvic floor exercises. However, if this fails, surgery is indicated. Standard operations include open colposuspension or the use of a minimally invasive approach involving the insertion of a transvaginal tape (TVT procedure).

Open colposuspension

This operation is carried out through a Pfannenstiel incision with the patient in the Lloyd-Davies position. The vaginal fascia is identified by sweeping the bladder off the vagina and three sutures are placed on each side between the vaginal fascia and the iliopubic ligament. A suprapubic catheter is placed. Voiding difficulties are frequent but usually temporary. It is best to warn women with large bladder capacities and low voiding pressures that this complication may occur and that they may be required to carry out CISC for a period. The operation is very successful for the treatment of GSI, with good results at 1 year in 90% of patients, which are maintained in about 80% of patients at 5 years.

Modifications of bladder neck suspension can also be achieved by minimally invasive approaches such as the transvaginal sling. This technique does reduce both hospital stay and postoperative morbidity.

Incontinence common to both sexes

Idiopathic detrusor overactivity

Phasic increases in bladder pressure may occur during filling in otherwise normal patients (idiopathic) or it may be found in neurogenic bladder dysfunction (when it is known as detrusor hyperreflexia) and bladder outflow obstruction. Idiopathic detrusor overactivity may be symptomless but usually results in symptoms of frequency, urgency, urge incontinence, nocturia or nocturnal incontinence (enuresis) depending on the severity of the instability. It must be distinguished from GSI and from bladder outflow obstruction before surgical treatment. Infection, tuberculosis or carcinoma *in situ* (CIS) should be excluded. The mainstay of treatment is the use of various anti-cholinergic

medications (oxybutynin and tolterodine). Severe symptoms resistant to conventional conservative treatment resulting in major impairment of quality of life may need more aggressive treatment such as enterocystoplasty or the injection of small doses of botulinum toxin (the toxin from *Clostridium botulinum*), known as BoTox, which blocks cholinergic neuromuscular transmission, at least for a time.

Ageing

Ageing can result in smooth muscle cell dysfunction, which can cause combinations of small functional capacity, detrusor overactivity, impaired bladder emptying and symptoms of lower urinary tract dysfunction.

Congenital

Congenital causes include ectopic vesicae and severe epispadias. The abnormal entry of an ectopic ureter distal to the sphincter complex or into the vagina in a female patient should theoretically result in total urinary incontinence. This is discussed in Chapters 6 and 71.

Trauma

Trauma, whether from pelvic surgery or associated with pelvic fracture, may result in disruption of the nerve supply to the bladder or urethra, or in fistula formation.

Infection

Lower urinary tract infection (UTI) may be sufficient to induce urinary incontinence. A history of frequency, burning and a fever should prompt the diagnosis. Symptoms will usually settle with a course of antibiotics, but in the case of recurrent infection further investigation of the urinary tract will clearly be indicated.

Neoplasia

Locally advanced cancers in the pelvis, particularly carcinoma of the cervix in a woman and carcinoma of the prostate in a man, may result in direct invasion of the sphincter mechanism causing incontinence; occasionally, fistula formation may occur in women.

Other causes

Constant dribbling of urine coupled with normal micturition

This occurs when there is a ureteric fistula or an ectopic ureter associated with a duplex system opening into the urethra beyond the urethral sphincter in females or into the vagina. The history is diagnostic, and intravenous pyelography or ultrasound scanning may reveal the upper pole segment, which is often poorly functioning. Treatment is by excision of the aberrant ureter and portion of kidney. A ureteric fistula can be difficult to diagnose and its demonstration may require retrograde ureterography and a high degree of suspicion.

Nocturnal enuresis

This is a condition of young children and young adults. Of course, the time at which children become dry at night varies and, in some, nocturnal enuresis is merely a delayed onset of continence. In others, it persists until late adolescence and is classified into primary and secondary nocturnal enuresis.

Hermann Johann Pfannenstiel, 1862–1909, Gynaecologist, Breslau, Germany, (now Wrocław, Poland), described this incision in 1900.
Oswald Lloyd-Davies, 1905–1987, Surgeon, St Mark's Hospital and The Middlesex Hospital, London, England.

Primary nocturnal enuresis occurs in patients with nocturnal enuresis alone and with no daytime symptoms. Often, they have been dry for a period, and the vast majority of patients will eventually become dry. In the meantime, a sympathetic approach to these children is essential. They often respond to a system of rewards using a 'star' chart. In addition, the use of DDAVP (a vasopressin analogue) can produce increased urinary concentration at night with a decrease in nocturnal incontinence. Other treatments include the use of amitriptyline and an alarm that wakes the child (or at least the child's parents) when incontinence occurs.

Treatments for incontinence

Treatments are listed below. Management is dependent on making a correct diagnosis.

Management and treatment

Problems of social functioning

Patients with dementia may respond to regular toileting. Anti-cholinergic agents can cause increased confusion in these patients and often, in severe cases, an indwelling catheter is needed.

Storage problems

Patients with a small bladder capacity because of fibrosis may require augmentation cystoplasty. Detrusor overactivity will require treatment with anti-cholinergic medication but, in severe cases, particularly in neuropathic patients at high risk of upper tract dilatation, bladder substitution (near-total supratrigonal cystectomy followed by the need for detubularised ileocaecal segment bladder substitution) or augmentation (enterocystoplasty) may be needed. These procedures should be carried out only after careful assessment in units used to dealing with such problems. Patients with very impaired mobility and MS may require ileal conduit diversion. The use of intravesical injections of BoTox has provided good improvements, and it may avoid or delay the need for major surgery.

Impaired bladder emptying

Patients with overflow incontinence because of bladder outflow obstruction will usually respond well to prostatectomy. Patients with impaired bladder emptying because of neurogenic bladder dysfunction should be treated in the first place by means of CISC.

Weak sphincter

Patients with GSI should be treated by means of pelvic floor exercises initially. Duloxetine can be used now as medical treatment for GSI. Bulking agents, such as macropastique, can be used and can provide good temporary solutions. Surgical treatment by means of colposuspension or TVT may be needed. Those with post-prostatectomy incontinence or neurogenic bladder dysfunction may need to be fitted with an artificial urinary sphincter (Fig. 72.19), if they are well motivated and mobile, but careful assessment is required.

Use of appliances

An indwelling catheter drained constantly into a leg urinal may be a satisfactory solution although, in some instances, diversion via an ileal conduit is necessary. In men, a condom urinary

appliance may be satisfactory and can avoid an indwelling catheter.

More major surgical treatments

Various types of urinary diversion

Urinary diversion may be required for the treatment of end-stage incontinence that is not otherwise treatable (see later in this chapter).

Bladder substitution procedures

The principle behind these operations is the creation of a low-pressure, large-capacity reservoir, which can be made using any segment of bowel isolated on its vascular pedicle (Figs 72.20–72.22). This is then detubularised by dividing its anti-mesenteric border and suturing this into a plate, which is then reconfigured into a spherical structure. This reservoir can then be anastomosed to the bladder remnant after excision of the fundus above the trigone. If necessary, the ureters can be reimplanted into the bowel segment. This new bladder will need to be emptied by means of CISC in up to 30% of cases.

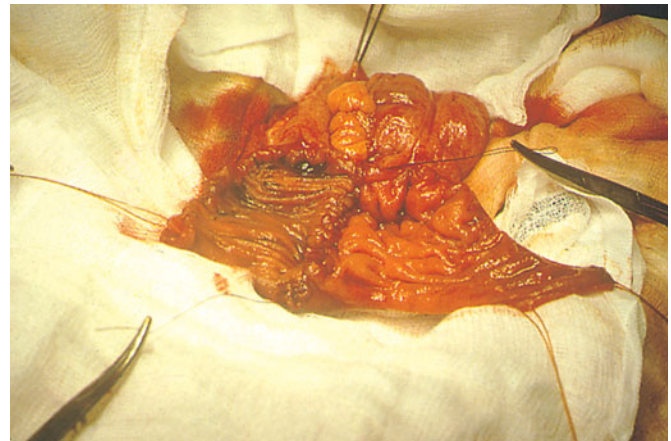

Figure 72.20 A vascularised ileocaecal segment being detubularised.

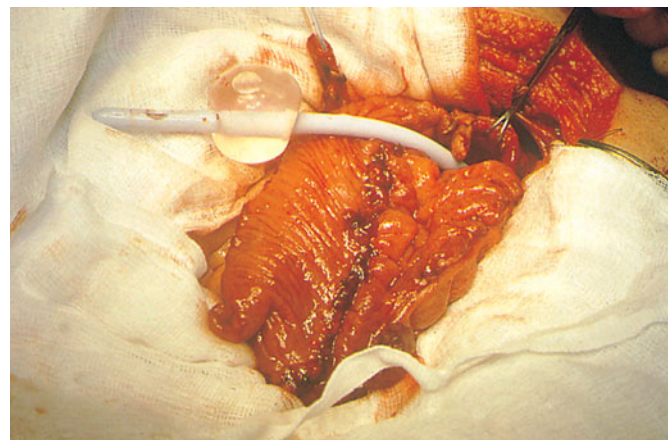

Figure 72.21 An ileocaecal segment being anastomosed to the trigone after near-total cystectomy; the left ureter is about to be implanted by means of a Camay–Le Duc anastomosis.

Figure 72.22 A capacious ileocaecal reservoir to be used in a patient requiring bladder substitution. These segments may be used for total bladder replacement, bladder substitution and the construction of continent diversion with a Mitrofanoff-type anti-incontinence mechanism (see later in the chapter).

'Clam' enterocystoplasty

This procedure was originally described by Bramble for the treatment of nocturnal enuresis. It has been used in the treatment of idiopathic detrusor instability. (Fig. 72.23). This procedure can also be used as an augmentation procedure in patients with neurogenic bladder dysfunction and a reasonable bladder capacity (approximately 300 ml).

Fitment of artificial urinary sphincter

See Fig. 72.19.

Summary

Treatments for incontinence can be summarised as follows:

- 1 *Devices for collection*: external penile condom, or an indwelling urethral or suprapubic catheter.

Figure 72.23 A 'clam' cystoplasty being performed. The ureteric orifices can be seen with the interureteric bar; the defect will be filled by a segment of detubularised ileum, performing a bladder augmentation.

Frank James Bramble, formerly Urologist, The Royal Victoria Hospital, Bournemouth, England.

- 2 *Drugs*: to decrease the strength of the bladder neck (e.g. α -adrenergic blockers); with mixed action on the bladder neck and central nervous system (e.g. tricyclic drugs); to inhibit bladder activity (e.g. anti-cholinergic drugs). Botulinum toxin is used in carefully selected patients. Duloxetine can now be used as medical treatment for GSI – it is a serotonin–noradrenaline (norepinephrine) reuptake inhibitor.
- 3 *Intermittent self-catheterisation*: to improve emptying.
- 4 *Increasing outlet*: pelvic floor physiotherapy; resistance colposuspension or TVT tapes or slings; periurethral injections of 'bulking agents' such as cross-linked collagen or other particles; use of the artificial urinary sphincter.
- 5 *Denervation of bladder*: S3 sacral nerve blockade, neurectomy or surgical transection of the bladder to inhibit bladder activity and improve functional capacity. These are rarely used nowadays because of the use of botulinum toxin and the clam cystoplasty or S3 nerve stimulation (see point 6).
- 6 *Sacral nerve stimulation devices* can improve incontinence. They involve percutaneous insertion of electrodes through the sacral foramina under radiological control and implantation of an electronic stimulator.
- 7 *Augmentation of bladder*: 'clam' enterocystoplasty, bladder capacity substitution with detubularised bowel segment.
- 8 *Urinary diversion*: ileal conduit, continent urinary diversion.

BLADDER STONES

Definition

A primary bladder stone is one that develops in sterile urine; it often originates in the kidney. A secondary stone occurs in the presence of infection, outflow obstruction, impaired bladder emptying or a foreign body.

Incidence

Until the twentieth century, bladder stone was a prevalent disorder among poor children and adolescents. Because of improved diet, especially an increased protein–carbohydrate ratio, primary vesical calculus is rare.

Composition and cystoscopic appearance

Most vesical calculi are mixed. An oxalate calculus is a primary calculus that grows slowly; usually, it is of moderate size and solitary, and its surface is uneven (Fig. 72.24). Although calcium oxalate is white, the stone is usually dark brown or black because of the incorporation of blood pigment. Uric acid calculi are round or oval, smooth and vary in colour from yellow to brown (Fig. 72.25). They occur in patients with gout but are also found in patients with ileostomies or with bladder outflow obstruction. A cystine calculus occurs only in the presence of cystinuria and is radio-opaque because of its high sulphur content. A triple phosphate calculus is composed of ammonium, magnesium and calcium phosphates and occurs in urine infected with urea-splitting organisms. It tends to grow rapidly. In some instances it occurs on a nucleus of one of the other types of calculus; more rarely it occurs on a foreign body (Figs 72.26 and 72.27). It is dirty white in colour and of chalky consistency.

A bladder stone is usually free to move in the bladder and it gravitates to the lowest part of the bladder. Less commonly, the stone is wholly or partially in a diverticulum, where it may be hidden from view.

Figure 72.24 A rough bladder stone.

Clinical features

Men are affected eight times more frequently than women. Stones may be asymptomatic and found incidentally.

Symptoms

Frequency is the earliest symptom and there may be a sensation of incomplete bladder emptying. Pain (strangury) is most often found in patients with a spiculated oxalate calculus. It occurs at the end of micturition and is referred to the tip of the penis or to the labia majora; more rarely it is referred to the perineum or suprapubic region. The pain is worsened by movement. In young boys, screaming and pulling at the penis with the hand at the end of micturition are indicative of bladder stone. Haematuria is characterised by the passage of a few drops of bright-red blood at the end of micturition, and is due to the stone abrading the vascular trigone. Interruption of the urinary stream is due to the stone blocking the internal meatus. Urinary infection is a common presenting symptom.

Examination

Rectal or vaginal examination is normal; occasionally, a large calculus is palpable in the female. Examination of the urine reveals microscopic haematuria, pus or crystals that are typical of the calculus, for example envelope-like in the case of an oxalate stone or hexagonal plates in the case of cystine calculi. In most patients the stone is visible on ultrasound or on a plain radiogram (Fig. 72.28). Imaging of the whole of the urinary tract should be undertaken to exclude an upper tract stone. Nearly all stones can be

Figure 72.25 Smooth uric acid-type stones.

Figure 72.26 Stone on a vaginal sling that had eroded into the bladder.

dealt with endoscopically. In men with bladder outflow obstruction, endoscopic resection of the prostate should be performed at the same time as the stone is dealt with.

Treatment

The cause of the stone should be sought and treated; this may include bladder outflow obstruction or incomplete bladder emptying in patients with neurogenic bladder dysfunction.

Figure 72.27 Uric acid stones that had formed on metal staples used to construct a colonic bladder augmentation.

Figure 72.28 Radiograph showing a vesical calculus (no contrast has been used).

Litholapaxy

The blind lithotrite (Fig. 72.29) was an early type of minimally invasive technique. Standard management now includes the optical lithotrite, electrohydraulic lithotrite, Holmium laser or ultrasound probe (Fig. 72.30). Other devices include the stone punch, which is useful to crush small fragments further so that they can be evacuated with an Ellik evacuator. Contraindications to perurethral litholapaxy are extremely rare:

- *urethral*: a urethral stricture that cannot be dilated sufficiently; when a patient is aged below 10 years;
- *bladder*: a contracted bladder;
- *stone characteristics*: a very large stone.

Ultrasound lithotripsy is extremely safe but appropriate only for small stones. Laser lithotripsy with the holmium laser can deal

Milo Ellik, B. 1905, American Urologist.

Figure 72.29 'Blind' lithotrite used to crush bladder stones.

Figure 72.30 An endoscopic ultrasound probe, which is used to fragment bladder or kidney stones.

with most large stones. Once small fragments are produced, the optical lithotrite can be used to finish the job. For evacuation of the fragments, fluid (200 ml) is introduced into the bladder. The evacuator, filled with solution, is fitted on to the sheath. The bulb is compressed slowly and then permitted to expand; the returning solution carries with it fragments of stone.

Percutaneous suprapubic litholapaxy

It is possible to insert a needle into the bladder and then pass a guidewire. As in percutaneous nephrolithotomy, Alken metal dilators can be passed over the guidewire to dilate the track and an Amplatz sheath inserted followed by a large-bore nephroscope. This is the best method to use if it is not possible to carry out litholapaxy per urethram because of a narrow urethra.

Removal of a retained Foley catheter

A retained Foley catheter is usually caused by the channel that connects the balloon to the side arm becoming blocked, usually at the end near the balloon. The best way of dealing with this problem is to further inflate the balloon with 20 ml of water and then burst the balloon percutaneously using a needle under ultrasound screening. If the balloon bursts, it is important to subsequently cystoscope the patient to ensure that any fragments are removed before they can form a foreign body calculus. Cutting off the side arm and attempting to clear the channel with a wire is only occasionally successful.

FOREIGN BODIES IN THE BLADDER

The most common foreign body in the bladder is a fragment of catheter balloon (see above). Occasionally, a foreign body enters through the wall of the bladder, for example non-absorbable

P. Alken, Urologist, The University of Heidelberg, Germany.

sutures used in an extravesical pelvic operation. Complications include:

- lower UTI;
- perforation of the bladder wall;
- bladder stone.

Treatment

A small foreign body can usually be removed per urethram by means of an operating cystoscope. Occasionally, a suprapubic approach using the percutaneous insertion of a cystoscope is needed.

DIVERTICULAE OF THE BLADDER

Definition

The normal intravesical pressure during voiding is about 35–50 cmH₂O; however, pressures as great as 150 cmH₂O may be reached by a hypertrophied bladder endeavouring to force urine past an obstruction. This pressure causes the lining between the inner layer of hypertrophied muscle to protrude, forming multiple saccules. If one or more, but usually one, saccule is forced through the bladder wall, it becomes a diverticulum (Fig. 72.31). Congenital diverticula are the result of a developmental defect.

Aetiology of diverticulae

Congenital diverticulae

These are situated in the midline anterosuperiorly and represent the unobliterated vesical end of the urachus.

Pulsion diverticula

The usual cause is bladder outflow obstruction.

Pathology

The mouth of the diverticulum is situated above and to the outer side of one ureteric orifice. Exceptionally, it is near the midline behind the interureteric ridge. The size varies from 2 to 5 cm, but they may be larger. Diverticula are lined by bladder mucosa and the wall is composed of fibrous tissue only (compare with a traction

diverticulum). A large diverticulum enlarges in a downward direction and sometimes may obstruct a ureter – probably because of peridiverticular inflammation.

Complications

Recurrent urinary infection

As the pouch cannot empty itself efficiently, there remains a stagnant pool of urine within it. Peridiverticulitis can cause dense adhesions between the diverticulum and surrounding structures. Squamous cell metaplasia and leucoplakia are infrequent complications.

Bladder stone

This develops as a result of stagnation and infection. The stone often protrudes into the bladder.

Hydronephrosis and hydroureter

This is extremely rare and is a consequence of peridiverticular inflammation and fibrosis.

Neoplasm

Neoplasm arising in a diverticulum is an uncommon complication (< 5%). The prognosis is dependent on the stage of the tumour (see below).

Clinical features

An uninfected diverticulum of the bladder usually causes no symptoms. The patient is nearly always male (95%) and over 50 years of age. Symptoms are those of associated urinary tract obstruction, recurrent infection and pyelonephritis. Haematuria (due to infection, stone or tumour) is a symptom in about 30%. In a few patients micturition occurs twice in rapid succession (the second act may follow a change of posture).

Diagnosis

Diverticula are usually discovered incidentally on cystoscopy or ultrasound (Figs 72.32–72.34).

Indications for operation

Operation is necessary only for the treatment of complications. Provided the diverticulum is small and associated outflow obstruction has been dealt with by prostate resection, there is no reason to resect the diverticulum. Even a large diverticulum may not require treatment in the absence of infection or other complications.

Figure 72.33 Occasional appearance of a diverticulum with inadequate distension of the bladder.

Figure 72.34 Bladder diverticulum demonstrated by ultrasound.

Combined intravesical and extravesical diverticulectomy

A ureteric stent is passed up the ureter on the affected side and the anterior bladder wall is exposed through a suprapubic incision. The bladder is incised in the midline and the diverticulum is packed with a strip of gauze. The neck of the diverticulum is separated from the ureter and when the pouch is free it is severed from the bladder. The resulting defect is closed in a single layer with 2/0 absorbable sutures. A suprapubic catheter is left in place and an extravesical drain is inserted. An alternative method, if the sac is densely adherent, is to carry the incision in the bladder down to the rim of the diverticular orifice, then to detach the diverticulum together with its fibrous rim. The incision in the bladder is closed and the diverticulum left in position with a corrugated drain placed into it for 2–3 days. The track fibroses rapidly after removal of the drain. If bladder outlet obstruction is present, prostatectomy should be carried out at the same time as the diverticulectomy, using any appropriate method [transurethral resection of the prostate (TURP), laser or open] (Summary box 72.8).

Summary box 72.8

Bladder diverticula

- Bladder diverticula are most frequently diagnosed incidentally by cystoscopy or urinary tract imaging
- The presence of a diverticulum – even quite a large one – is not an indication for diverticulectomy unless symptoms or cancer are present

Traction diverticulum (synonym: hernia of the bladder)

A portion of the bladder protruding through the inguinal or femoral hernial orifice occurs in 1.5% of such herniae treated by operation (Fig. 72.35).

URINARY FISTULAE

Congenital urinary fistulae

The causes of congenital urinary fistulae include:

- Ectopia vesicae.
- A patent urachus – the presence of a urinary leak from the umbilicus, present at birth or commencing soon after, suggests this diagnosis. In adult life, infection in a urachal cyst may produce a fistula and adenocarcinoma may occur (Figs 72.36 and 72.37). Treatment is by means of excision of the urachal tract and closure of the bladder once distal obstruction has been excluded.
- In association with imperforate anus (see Chapters 6 and 69).

Figure 72.35 (a) Intraperitoneal, (b) paraperitoneal and (c) extraperitoneal hernia of the bladder, in relation to a hernial sac.

Figure 72.36 An operative photograph showing a large urachal cyst in which adenocarcinoma formation has occurred. A partial cystectomy with total removal of the urachal remnant is about to be carried out.

Figure 72.37 A computerised tomography scan of the same patient as in Figure 72.36, showing a large urachal cyst closely approximated to the dome of the bladder.

Traumatic urinary fistulae

Perforating wounds, damage not recognised during surgery or poor healing and avascular necrosis following radiotherapy and surgery may lead to fistula formation. Also, clot retention occurring after an open bladder operation may lead to dehiscence of the wound and a fistula, which will heal quickly provided the bladder is kept empty with an indwelling catheter.

Vesicovaginal fistulae

Aetiology

- *Obstetric.* The usual cause is protracted or neglected labour.
- *Gynaecological.* The operations chiefly causing this complication are total hysterectomy and anterior colporrhaphy.
- *Radiotherapy.*
- *Direct neoplastic infiltration.* Exceptionally, carcinoma of the cervix ulcerates through the anterior fornix to implicate the bladder.

When an injury to the bladder is recognised and repaired, leakage is uncommon, but escape of urine will quickly follow if such damage passes unnoticed. However, most vesicovaginal fistulae are the result of ischaemic necrosis of the bladder because of prolonged pressure of the fetal head in obstetric cases. In gynaecological cases, the ischaemia is brought about by grasping the bladder wall in an artery forceps, including the bladder wall in a suture or perhaps even by local oedema or haematoma. Leakage

because of necrosis of tissue seldom manifests itself before 7 days after the operation. An intractable fistula following radiotherapy for carcinoma of the cervix uteri may arise from avascular necrosis years after the apparent cure of the original lesion.

Clinical features

There is leakage of urine from the vagina and excoriation of the vulva. Vaginal examination may reveal a localised thickening on its anterior wall or in the vault. On inserting a vaginal speculum, urine will be seen escaping from an opening in the anterior vaginal wall.

The 'three-swab test'

The differential diagnosis between a ureterovaginal and vesicovaginal fistula can be made by placing a swab in the vagina and injecting a solution of methylene blue through the urethra; the vaginal swab becomes coloured blue if a vesicovaginal fistula is present. Cystoscopy and bilateral retrograde ureterography provide a more reliable demonstration. An IVU should be performed to exclude a coincidental ureterovaginal fistula (ureterovaginal fistula occurs with vesicovaginal fistula in about 10% of cases). Usually, the IVU shows some upper tract dilatation resulting from partial obstruction.

Treatment

Just occasionally, conservative management of a vesicovaginal fistula following hysterectomy, by urethral bladder drainage, is successful; however, the majority of fistulae will require definitive surgical repair. A low fistula (subtrigonal) is best repaired per vaginam. The fistula is exposed, the bladder is closed using absorbable sutures and the vagina subsequently closed with a separate layer. A urethral catheter should be left *in situ* for at least 10 days. For higher (supratrigonal) fistulae a transvaginal approach can be difficult. These patients should always be cystoscoped before the repair procedure and bilateral ureterograms performed. For high fistulae a suprapubic approach is the best method in most hands; however, some experts will aim to carry out vaginal closure in most cases that have not involved complex surgery or radiotherapy.

To repair a ureterovaginal fistula, an extraperitoneal approach to the ureter via the previous Pfannenstiel incision is made. Considerable adhesions will be encountered, but the ureter can usually be found above the level of the injury and followed down. Reimplantation into the bladder is often required. Depending on the amount of ureter lost, it may be possible to achieve reimplantation with a psoas hitch procedure. If the gap is too large a Boari flap of anterior bladder wall should be cut and brought over to meet the ureter and a reimplant performed. The most important principle of ureteric reimplantation is that there should be no tension on the repair.

Fistulae from renal pelvis to skin or gut

Tuberculosis of a kidney may result in a fistula to the duodenum, colon or skin. Similarly, a pyonephrosis may discharge into the gut or onto the skin. Duodenal ulcer involving the pelvis of the right kidney, Crohn's disease involving the renal pelvis or ureter,

Achille Boari, nineteenth century Italian Surgeon.
Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

or cases of xanthogranulomatous pyelonephritis may cause fistulae. A longstanding urinoma will occasionally fistulate into the gut.

Fistulae arising from infection

The most common cause is diverticulitis of the colon. Fistulae may also follow Crohn's disease, appendix abscess or pelvis sepsis after acute salpingitis, or pelvic surgery.

The onset of a fistula from diverticular disease may well be treated as a simple urinary infection. The diagnosis can be difficult to make, but on cystoscopy a patch of oedema on the left side of the vault is suggestive and bubbles of gas may be seen (Fig. 72.38). A cystogram may reveal the fistula. The passage of gas per urethram in a patient is most suggestive (provided that diabetes resulting in urinary infection with a gas-forming organism is excluded).

Treatment of fistulae caused by diverticular disease

In most patients a single-stage operation is indicated provided that the surgeon is experienced in colonic surgery. At laparotomy, the communication is separated, the hole in the bladder being closed and patched with omentum, and the segment of diseased bowel resected; it is most important to ensure that the left colon and, if necessary, the splenic flexure are fully mobilised to facilitate a tension-free, well-vascularised anastomosis. The bladder is drained by a urethral catheter.

Fistulae caused by carcinoma

By the time that a fistula between the bowel and the bladder has developed, the tumour is usually locally advanced but may be operable.

Urethral fistulae in the male

These occur as the result of infection above a stricture producing a paraurethral abscess that ruptures into the urethra, allowing extravasation to occur suddenly into the scrotum and perineum. Urine and infection extend into the upper 2.5 cm of the thigh and lower abdominal wall. Widespread cellulitis and tissue necrosis (which may lead to Fournier's gangrene) may occur unless drainage of urine is achieved by suprapubic cystotomy and the tissue planes are freely drained by inguinal and scrotal incisions.

Figure 72.38 Cystoscopic view of a vesicointestinal fistula. Bubbles of gas can be seen issuing from the orifice of the fistula.

Jean Alfred Fournier, 1832–1915, French Syphilologist, and Founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.

Neoplastic fistulae

Primary bladder tumours very rarely produce fistulae. Involvement of the bladder by tumours of the cervix, uterus, colon and rectum can produce fistulae, as may sarcoma of the small gut. Carcinoma of the prostate rarely produces a rectal fistula. Treatment is difficult and in most cases only palliative relief can be given. It is rarely in the patient's interest to carry out urinary diversion, although minimally invasive techniques such as placement of ureteric stents can be helpful in palliating symptoms (Summary box 72.9).

Summary box 72.9

Fistulae

- A fistula is a communication between two epithelium-lined surfaces
- Most urinary fistulae are vesicovaginal and result from obstetric trauma; an associated ureterovaginal fistulae occurs in about 10% of cases
- A 'three-swab test' is used to aid the diagnosis. An examination under anaesthesia, vaginoscopy, and cystoscopy and IVU should be performed and, if necessary, retrograde ureterography
- Conservative management is rarely successful
- The principles of repair include good exposure, excision of diseased tissue and tension-free vascularised repair in anatomic layers
- Fistulae caused by radiation, cancer and sepsis can be complex with multiple tracts
- The persistence of a fistula on the skin implies the presence of distal obstruction, chronic infection, such as tuberculosis, or a foreign body, such as a stone or non-absorbable ligature

LOWER URINARY TRACT INFECTION AND CYSTITIS

Infection of the bladder gives rise to symptoms of frequency, urgency, suprapubic discomfort, dysuria and cloudy offensive urine. These symptoms are often known as 'cystitis'. Lower UTIs are much more common in women than in men, particularly in the under 50s. It should be remembered that a lower UTI is often associated with upper tract colonisation and the presence of associated loin pain, pyrexia, rigors and malaise (these symptoms represent complicated infection and should be taken seriously as serious sepsis can ensue).

Isolated infection

A single episode of lower tract infection occurs frequently in females and is rarely complicated.

Recurrent infection

Recurrent infection may be associated with an underlying predisposing cause or may be a result of bacterial resistance. In healthy women, infection after intercourse can occur without any demonstrable abnormality of the urinary tract. Repeated attacks of UTI in women, or a single attack in a man or a child of either sex, should always be followed by investigation to discover and treat the cause; sometimes, however, no cause can be found. Asymptomatic bacteriuria is common and investigation may fail to demonstrate any underlying cause.

Infection in males

Although more common in female adults, the incidence of infection is higher in male infants as underlying urinary tract abnormalities are more frequent. Complicated or recurrent infection in adult males warrants prompt antibiotic therapy and investigation to exclude an underlying cause.

Infection in pregnancy

The incidence of asymptomatic bacteriuria in pregnant women is twice as high as in non-pregnant women. Simple uncomplicated infection can be treated following urine culture with an appropriate antibiotic that is not contraindicated in pregnancy, such as cephalosporin or ampicillin. Non-responsive infection may require intravenous therapy and an ultrasound scan.

Predisposing causes of urinary tract infection

- Incomplete emptying of the bladder, secondary to bladder outflow obstruction, a bladder diverticulum, neurogenic bladder dysfunction or decompensation of the detrusor muscle.
- A calculus, foreign body or neoplasm.
- Incomplete emptying of the upper tract, dilatation of the ureters associated with pregnancy, or vesicoureteric reflux. In childhood, the mainstay of treatment of vesicoureteric reflux is antibiotic therapy; operation is reserved for those with recurrent infection despite antibiotics or with severe upper tract dilatation.
- Oestrogen deficiency, which may give rise to lowered local resistance.
- Colonisation of the perineal skin by strains of *Escherichia coli* expressing molecules that facilitate adherence to mucosa.
- Diabetes.
- Immunosuppression.

Avenues of infection

Ascending infection from the urethra is the most common route (see Chapter 70). The organisms originate in the bowel, contaminate the vulva and reach the bladder. The passage of urethral instruments may cause infection in either sex, especially when the bladder contains residual urine (Fig. 72.39). Other routes are less common and include descending infection from the kidney (tuberculosis), haematogenous spread, lymphogenous spread and spread from adjoining structures (fallopian tube, vagina or gut).

Bacteriology

Bacterial virulence factors affect the ability of a pathogen to infect the host. The possession of pili (rod-shaped structures) that project from the outer membrane increases adhesiveness. The type of pilus can be used to classify the pathogen involved. *Escherichia coli* is the most common organism followed by *Proteus mirabilis*, *Staphylococcus epidermidis* and *Streptococcus faecalis*. Infection with other organisms or infection with mixed organisms is found in patients with neurogenic bladder dysfunction or those with a longstanding indwelling urethral catheter. These organisms include *Pseudomonas*, *Klebsiella*, *Staphylococcus aureus* and

Figure 72.39 Complications liable to follow the changing of a urethral catheter in the presence of urethritis (courtesy of C.G. Scorer, FRCS, London, England).

various streptococci. Tuberculous infection is considered below. The presence of pus cells without organisms calls for examination for *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae*. Having eliminated these possibilities, the underlying condition may be abacterial cystitis, CIS, renal papillary necrosis, stones or incomplete treatment of a urinary infection.

Clinical features

These include frequency, pain, haematuria and pyuria. Pyrexia and rigors are not associated with a simple UTI but are a sign of upper tract infection or septicaemia.

Examination

On examination there is tenderness over the bladder. Initial and midstream urine specimens should be collected in a male as acute prostatitis may be present (see below), which will lead to threads in the initial specimen. The midstream specimen must be subjected to microscopy and culture, and the sensitivity of any organisms assessed.

Treatment

Treatment should be commenced immediately and modified if necessary when the bacteriological report is to hand. The patient is urged to drink. Appropriate first-line antibiotics depend on local likely sensitivities but would include trimethoprim or one of the quinolones. Failure to respond indicates the need for further investigation to exclude predisposing factors. It is important to check for associated allergies or other drugs or conditions that might preclude the use of some antibiotics [e.g. concomitant administration of methotrexate and trimethoprim (both inhibit tetrahydrofolate reductase)].

Gabriele Falloppio (Fallopius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, The Czech Republic; Zurich, Switzerland, and the Rush Medical College, Chicago, IL, USA.

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany, (now Wrocław, Poland).

Investigation

Investigation may be needed in the male or when recurrent infection occurs. This includes measurement of urinary flow rates and post-void residual urine. IVU, ultrasound scan or CT scanning will usually be carried out together with cystoscopy. Difficult cases may require urodynamic investigation (Summary box 72.10).

Summary box 72.10

UTI in adults

- Isolated UTI in adults is not infrequent and is more common in women
- Recurrent or complicated infection (haematuria, rigors) warrants appropriate antimicrobial therapy and investigation
- Investigation to exclude a predisposing cause includes urinalysis, microscopy and culture, upper tract imaging and cystoscopy
- *Mycobacterium tuberculosis*, *Neisseria gonorrhoeae* or *Mycoplasma genitalium* should be suspected if pus cells are present but urine culture is negative
- Cancer, especially CIS, masquerading as infection may be diagnosed as abacterial cystitis

SPECIAL FORMS OF LOWER URINARY TRACT INFECTION

Acute abacterial cystitis (acute haemorrhagic cystitis)

The patient presents with severe UTI. Pus is present in the urine but no organism can be cultured. It is commonly sexually acquired but tuberculous infection and CIS must be ruled out. The underlying causative organism may be *Mycoplasma* or herpes simplex virus. Cyclophosphamide can also cause this problem.

Frequency–dysuria syndrome (urethral syndrome)

This consists of symptoms of lower tract infection but with negative urine cultures. CIS, tuberculosis and interstitial cystitis should be excluded. Most urologists advise patients to adopt general measures such as wearing cotton underwear, using simple soaps, adopting general perineal hygiene measures and voiding after intercourse. Other treatments include cystoscopy and urethral dilatation, although the benefits remain doubtful.

Tuberculous urinary infection

Tuberculous urinary infection is secondary to renal tuberculosis. Early tuberculosis of the bladder commences around the ureteric orifice or trigone, the earliest evidence being pallor of the mucosa due to submucous oedema. Subsequently, tubercles may be seen and, in longstanding cases, there is marked fibrosis and the capacity of the bladder is greatly reduced (Fig. 72.40).

Treatment

Tuberculous infection usually responds rapidly to anti-tuberculous drugs but occasionally the involved kidney and ureter have to be removed. If the bladder remains of low capacity, patients will have severe symptoms and the upper tracts are at risk because of high filling pressures and vesicoureteric reflux. Such patients, after

Figure 72.40 Retrograde cystograph showing an exceedingly contracted ('thimble') bladder in a case of tuberculous cystitis.

appropriate chemotherapy, respond well to bladder augmentation. The ureters may need reimplantation.

Bladder augmentation by ileocystoplasty or caecocystoplasty

The fibrosed supratrigonal bladder is removed and the bladder augmented with a segment of bowel. This may consist of intact caecum, a detubularised segment of ileum or a detubularised ileocaecal segment (see Figs 72.20–72.22, p. 1322–3).

Interstitial cystitis (Hunner's ulcer)

For practical purposes, this is confined to women. The first symptom is increased frequency; pain, relieved by micturition and aggravated by jarring and overdistension of the bladder, is another characteristic symptom. In most patients pyuria and urinary infection are absent. Haematuria also occurs. The aetiology remains as obscure as it was when Guy Hunner described the condition in 1914. It consists of a chronic pancystitis, often with marked infiltration with lymphocytes and macrophages. Fibrosis of the vesical musculature and areas of avascular atrophy of the epithelium occur. Ulceration of the mucosa occurs in the fundus of the bladder. In severe cases the bladder capacity is reduced to 30–60 ml. The characteristic linear bleeding ulcer is caused by splitting of the mucosa when the bladder is distended under anaesthesia. Inflammation of all coats of the bladder is present with granulation tissue in the submucosa underlying the ulcer. The muscularis is hypertrophied and the peritoneum in proximity to the area of maximum disease is thickened. The inflammation may involve the trigone, the urethra and, in severe cases, the

Guy Leroy Hunner, 1868–1951, Gynaecologist, The Johns Hopkins Hospital, Baltimore, MD, USA.

peritoneum. Pronounced mast cell infiltration is seen but is not specific. It is important to check urinary cytology and to biopsy the mucosa to exclude underlying neoplastic disease.

On cystoscopy the characteristic ulcer is found in the fundus, but it may be absent. This area bleeds readily as the bladder is decompressed. Treatment is difficult and unsatisfactory. Hydrostatic dilatation under anaesthesia may give relief for some months. Instillation of dimethylsulphoxide results in improvement in some patients. Other drugs that have been tried include intravesical heparin, oral ranitidine and steroid therapy. Patients with severe symptoms may well require cystectomy and orthotopic bladder substitution. In patients with severe inflammation involving the trigone and urethra, this operation may not result in complete relief and some type of urinary diversion may be needed.

Alkaline encrusting cystitis

Alkaline encrusting cystitis is rare and is due to urea-splitting organisms causing phosphatic encrustations on the bladder mucosa of elderly women. There are symptoms of chronic UTI and a plain radiograph shows the bladder outline. The encrustations may be removed by bladder irrigation and the infection treated with appropriate antibiotics.

Cystitis cystica

Under the influence of chronic inflammation the surface epithelium sends down buds, resulting in minute cysts filled with clear fluid, most abundant on the trigone. This is frequently found in patients with recurrent frequency and dysuria.

SCHISTOSOMIASIS OF THE BLADDER (SEE CHAPTER 5)

Geographical distribution

The disease is endemic in Egypt, parts of Africa, Israel, Syria, Saudi Arabia, Iran, Iraq and the shores of China's great lakes. Dwellers of the Nile valley have suffered for centuries. Marshes or slow-running fresh water provide the habitat for the freshwater snail (*Bulinus truncatus*) that is the intermediate host.

Mode of infestation

The disease is acquired through exposure of the skin to infected water, which usually occurs while bathing. The free-swimming, bifid-tailed embryos (cercariae) of the trematode *Schistosoma haematobium* penetrate the skin. Shedding their tails, they enter blood vessels and are swept to all parts of the body but they flourish in the liver where they live on erythrocytes and develop into male and female worms. Sexual maturity having been attained, the nematodes leave the liver and enter the portal vein. The male worm bends into the shape of a gutter (the gynaecophoric canal) into which a female worm nestles, and the pair makes its way towards the inferior mesenteric vein. *Schistosoma haematobium* has an affinity for the vesical venous plexus, which it reaches through the portosystemic anastomotic channels.

Having reached the bladder the female worm eventually enters a submucous venule which is so small that she completely blocks it. She now proceeds to lay about 20 ova in a chain; each ovum is provided with a terminal spine that penetrates the vessel wall. A heavily infected subject passes hundreds of ova a day. If

the ova reach fresh water, the low osmotic pressure causes rupture and the ciliated miracidium emerges. To survive, it must reach and penetrate the intermediate snail host within 36 hours. Within the snail's liver, the miracidium enlarges and gives rise to myriads of daughter cysts, which are set free on the death of the snail. A single miracidium begets thousands of cercariae to complete the life cycle.

Clinical features

After penetration of the skin, urticaria lasting about 5 days can occur (swimmer's itch). Following an incubation period of 4–12 weeks, a high evening temperature, sweating and asthma, together with leucocytosis and eosinophilia, occur. Usually, an asymptomatic period of several months supervenes before the ova are released, causing the typical early sign and symptom of intermittent, painless, terminal haematuria. Men are affected three times more frequently than women.

Examination of the urine

The last few millilitres of an early-morning urine specimen are collected and centrifuged. Examination on several consecutive days may be required, but a negative result does not exclude bilharziasis, especially in patients no longer resident in bilharzial districts. Antibody detection by enzyme-linked immunosorbent assay (ELISA) using *Schistosoma mansoni* adult microsomal antigen (MAMA) can be performed. The test is positive 1 month after infection and is specific for *Schistosoma mansoni* and *Schistosoma haematobium*.

Cystoscopy

Depending on the length of time for which the disease has remained untreated, cystoscopy will reveal one or more of the following:

- 1 *Bilharzial pseudotubercles* are the earliest specific appearance of the disease. (Fig. 72.41).
- 2 *Bilharzial nodules* (Fig. 72.42) are caused by the fusion of tubercles.
- 3 'Sandy patches' are the result of calcified dead ova with degeneration of the overlying epithelium (Fig. 72.43).
- 4 *Ulceration* is the result of sloughing of the mucous membrane containing dead ova (Fig. 72.44).
- 5 *Fibrosis* is mainly the result of secondary infection.
- 6 *Granulomas*. Bilharzial masses are caused by the aggregation of nodules.
- 7 *Papillomas* are more pedunculated (Fig. 72.45).
- 8 *Carcinoma* is a common end result in grossly infected bilharziasis of the bladder that has been neglected for years.

Treatment

Safe and effective drugs are available for the treatment of schistosomiasis, including praziquantel taken in three doses of 20 mg kg⁻¹ (total 60 mg kg⁻¹) 4 hours apart. It takes many months for dead ova to be expelled and, even after repeated courses and healing of the bladder lesion, living bilharzial worms have been found at necropsy in the portal system.

Theodor Maximilian Bilharz, 1825–1862, Professor of Zoology, Cairo, Egypt. Sir Patrick Manson, 1844–1922, practised in Formosa (now Taiwan), and Hong Kong before becoming Physician to the Dreadnought Hospital, Greenwich, London, England. He is regarded as The Founder of Tropical Medicine.

Figure 72.42 Bilharzial nodules (courtesy of N. Makar).

Figure 72.43 'Sandy patches' (courtesy of N. Makar).

Figure 72.44 Bilharzial ulcer (courtesy of N. Makar).

Other complications, requiring specific treatment, include the following:

- urinary calculi;
- stricture of the ureters;
- prostatoseminal vesiculitis;
- fibrosis of the bladder and bladder neck (Fig. 72.46);
- bilharzial urethral strictures;
- squamous bladder cancer.

NEOPLASMS OF THE BLADDER

In total, 95% of primary bladder tumours originate in transitional epithelium; the remainder arise from connective tissue (angioma, myoma, fibroma and sarcoma) or are extra-adrenal pheochromocytomas.

Secondary tumours of the bladder are common and most frequently arise from the sigmoid and rectum, the prostate, the uterus or the ovaries, although bronchial neoplasms may also spread to the bladder.

Figure 72.46 Bilharzial contracture of the bladder, with ureteric reflux (courtesy of H. Talib, Baghdad, Iraq).

Pathology

Benign papillary tumours

The papilloma consists of a single frond with a central vascular core with villi; it looks like a red sea anemone (Figs 72.47 and 72.48). Inverted papilloma is a condition in which the proliferative cells penetrate under normal mucosa so that the lesion is covered with smooth urothelium. It is benign.

Figure 72.47 Papillary tumour with daughter implantation ('kiss' cancer).

Figure 72.48 Endoscopic photograph of a pTa bladder tumour about to be resected.

CARCINOMA OF THE BLADDER

Histological types of bladder cancer include urothelial, squamous and adenocarcinoma [or mixed, as a result of metaplasia in a transitional cell carcinoma (TCC)]. Over 90% are urothelial in origin. Pure squamous carcinoma is uncommon (approximately 5%), except in areas where bilharzia is endemic. Primary adenocarcinoma, which arises either from the urachal remnant or from areas of glandular metaplasia, accounts for 1–2% of cases.

Urothelial cell carcinoma

Aetiology

Cigarette smoking is the main aetiological factor (40% of cancers). Occupational exposure to urothelial carcinogens remains common. The first suspicion of a chemical cause for bladder cancer was raised by Rehn in 1895 when he recorded a series of tumours in workers in aniline dye factories. Hueper showed that 2-naphthylamine was carcinogenic in dogs. Subsequent investigation demonstrated that the following compounds may be carcinogenic:

- 2-naphthylamine;
- 4-aminobiphenyl;
- benzidine;
- chlornaphazine;
- 4-chloro-*o*-toluidine;
- *o*-toluidine;
- 4,4'-methylene bis(2-chloroaniline);
- methylene dianiline;
- benzidine-derived azo dyes.

Occupations associated with an increased risk of bladder cancer are:

- textile workers;
- dye workers;
- tyre rubber and cable workers;
- petrol workers;
- leather workers;
- shoe manufacturers and cleaners;
- painters;
- hairdressers;
- lorry drivers;
- drill press operators;
- chemical workers;
- rodent exterminators and sewage workers.

Bladder cancer became a prescribed industrial disease (No. 39) in 1953, and previously exposed workers may be entitled to compensation. Balkan nephropathy is associated with an increased incidence of upper tract urothelial tumours (see Chapter 71).

A series of genetic events has been clearly implicated in cancer formation but is outside the remit of this chapter. Activation of dominantly acting oncogenes such as *ras* and *c-erbB-1* and *-2*, and transcription factors such as E2F3, have been reported in bladder cancer, as has the inactivation of tumour-suppressor genes such as *p53*, *p21*, *p16* and the retinoblastoma gene. Activation of many other genes occurs including those coding for

Ludwig Rehn, 1849–1930, Surgeon, Frankfurt am Main, Germany.

The Balkans are the countries which occupy an area in the south-east of Europe. They are south of the Danube and the Sava rivers, and form a peninsula bounded on the east by the Aegean and Black seas, on the west by the Adriatic and Ionian seas, and on the south by the Mediterranean.

enzymes that dissolve the basement membrane, such as the metalloproteinases (stromelysin, collagenases and elastase), lysosomal enzymes such as the cathepsins and others including urinary plasminogen activators; angiogenic factors [e.g. vascular endothelial growth factor (VEGF)] and other peptide growth factors such as the epidermal growth factor and its receptor also have a role to play. These changes are common to several tumour types, including prostate cancer (Summary box 72.11).

Summary box 72.11

Urothelial cell carcinoma of the bladder

- The fourth most common non-dermatological malignancy in men (male–female ratio 3:1)
- Strongly associated with smoking and chemical exposure in western societies
- Strongly associated with *Schistosoma haematobium* infection (bilharzial bladder cancer) in regions where the parasite is endemic
- Reducing incidence in countries where smoking is decreasing

Tumour staging and grading

Study of the biological behaviour of transitional cell cancer of the bladder shows that cancers fall into the three following groups. Depth of invasion (T) from the tumour–node–metastasis (TNM) classification and grade (World Health Organization I, II or III) are important factors in planning treatment and determining prognosis in bladder cancer.

- Non-muscle-invasive pTa (Fig. 72.48) and pT1 tumours account for 70% of all new cases; these are known as ‘superficial’ bladder cancer. It is crucial to distinguish pTa tumours from superficially invasive pT1 disease. Histological examination may reveal invasion of the lamina propria (pT1) but not of the muscle or no invasion of lamina propria (pTa). These tumours may be single or multiple – single papillary pTa tumours account for a significant proportion of bladder cancers and carry an excellent prognosis.
- Muscle-invasive disease accounts for 25% of new cases. Such tumours carry a much worse prognosis as they are subject to local invasion and distant metastasis.
- Flat, non-invasive CIS (primary CIS) accounts for 5% of new cases. Unless diagnosed and treated promptly it carries a poor prognosis (Summary box 72.12).

Summary box 72.12

Bladder cancer staging

- Cystoscopy and resection of tumour with separate resection of the tumour base is essential for accurate analysis of invasion into detrusor muscle
- Bimanual examination should be performed after resection of the tumour
- Upper tract imaging by IVU is essential. CT to stage invasive disease for lymph node metastasis is preferred

Superficial bladder cancer (pTa and pT1)

These are usually papillary tumours that grow in an exophytic fashion into the bladder lumen (Figs 72.47 and 72.48). They may be

single or multiple and may appear pedunculated, arising on a stalk with a narrow base, but if the tumours are less well differentiated they are more solid with a wider base. The mucosa around the tumour is often rather oedematous, with angry-looking, dilated blood vessels. These areas may contain *in situ* changes (concomitant CIS).

The urothelium elsewhere in the bladder may appear rather oedematous and velvety; this suggests a generalised ‘field change’ with the presence of widespread CIS. The most common sites for superficial tumours are the trigone and lateral walls of the bladder.

After initial complete treatment by endoscopic transurethral resection (TUR), patients with pTa or pT1 disease may develop two problems:

- About 50–70% develop recurrent tumours that may be single or multiple, and the recurrences may occur on one or on many occasions. The recurrent tumours are usually of the same stage or grade as the primary tumour. High-grade, multiple tumours with concomitant CIS are most likely to develop recurrent disease.
- About 15% will develop a recurrent tumour that invades the bladder muscle. The risk of such progression increases with high-grade disease, pT1 disease, multiple primary disease and concomitant CIS. Many urologists now regard the presence of pT1 grade 3 tumours as an indication for offering the patient immediate cystectomy because of the excellent outcome.

This behaviour provides the rationale for performing check cystoscopies. The factors that result in an increased recurrence and progression rate are:

- high grade;
- pT1 disease;
- concomitant CIS;
- multiple primary tumours;
- recurrent disease at the first check cystoscopy 3 months after diagnosis.

Patients presenting with a solitary grade 1 or grade 2 pTa tumour without concomitant CIS, which does not recur within the first 6 months, have an excellent outcome.

Patients with high-grade pTa or pT1 disease are at high risk and should be counselled very carefully. The options include a course of bacille Calmette–Guérin (BCG) followed by careful assessment or immediate cystectomy. The presence of persistent disease after a single course of BCG is reason to offer cystectomy (Summary box 72.13).

Summary box 72.13

Superficial bladder cancer

- Does not invade the detrusor muscle but can extend to the lamina propria
- Extension to the lamina propria (pT1) is a significant risk factor for progression to invasive disease, especially if associated with high-grade disease and CIS
- The incidence of recurrence of this disease can be reduced by intravesical chemotherapy and immunotherapy
- High-risk superficial disease (any grade 3 disease) is best managed by BCG immunotherapy followed by radical treatment if disease persists

Albert Leon Charles Calmette, 1863–1933, and Jean-Marie Camille Guérin, 1872–1961, Microbiologists at the Institute Pasteur, at Lille in France, introduced the Bacille Calmette–Guérin in 1908.

Muscle-invasive transitional cell carcinoma

Muscle-invasive tumours are nearly always solid (Fig. 72.49) although there may be a low tufted surface. These tumours are often large and broad based, having an irregular, ulcerated, appearance within the bladder. The incidence of metastases, whether from lymphatic invasion in the pelvis or blood-borne to the lung, liver or bones, is much more common and will cause the death of 30–50% of patients (Summary box 72.14).

Summary box 72.14

Invasive bladder cancer

- Invasive bladder cancer should be staged by an accurate bimanual examination performed under anaesthesia before and after resection of the tumour
- CT or magnetic resonance imaging should be performed to identify lymph node involvement and distant spread
- Radical therapy in the form of radical cystectomy and thorough lymph node dissection is the primary treatment
- Neoadjuvant cisplatin-based chemotherapy improves survival rates
- External beam radiotherapy is an option for patients who are unfit for, or who decline, cystectomy
- Locally advanced disease may be downstaged by radiotherapy or chemotherapy to enable salvage cystectomy

In situ carcinoma

The histological appearance of irregularly arranged cells with large nuclei and a high mitotic index replacing the normally well-ordered urothelium is known as CIS. It may occur alone (primary CIS) or in association with a new tumour (concomitant CIS) or it may occur later in a patient who has previously had a tumour (secondary CIS). It can only be diagnosed when a biopsy is examined under the microscope. It may cause severe symptoms of dysuria, suprapubic pain and frequency (hence its old name of malignant cystitis). It carries a risk for the patient of developing a malignant muscle-invasive cancer. Without treatment, 50% will die of bladder cancer.

Pure squamous cell carcinoma of the bladder

Squamous cell tumours tend to be solid and are nearly always associated with muscle invasion. This is the most prevalent form

Figure 72.49 Radical cystectomy specimen showing a large solid bladder cancer with total removal of the bladder and prostate.

of bladder cancer in areas where bilharzia is endemic. Squamous cell tumours may be associated with chronic irritation caused by stone disease in the bladder as a result of metaplasia.

Pure adenocarcinoma

Adenocarcinoma accounts for approximately 1–2% of all bladder cancers. It usually arises in the fundus of the bladder at the site of the urachal remnant. Occasionally, primary adenocarcinomas arise at other sites and probably originate from areas of glandular metaplasia. Such tumours need to be distinguished from secondary cancer.

CLINICAL FEATURES OF BLADDER CARCINOMA

Painless gross haematuria is the most common symptom and is indicative of a bladder carcinoma until proven otherwise. Often, however, the patient fails to declare the symptom to their GP. The bleeding may give rise to clot formation and clot retention.

Constant pain in the pelvis usually heralds extravesical spread. There is often frequency and discomfort associated with urination. Pain in the loin or pyelonephritis may indicate ureteric obstruction and hydronephrosis. A late manifestation is nerve involvement causing pain that is referred to the suprapubic region, groins, perineum, anus and into the thighs.

It is also important to assess the patient as a whole. Many are elderly men who have been lifelong smokers and who suffer from chronic obstructive airway disease or cardiovascular disease. Their suitability for major surgery must be borne in mind.

INVESTIGATION OF BLADDER CARCINOMA

Urine

Urine should be cultured and examined cytologically for malignant cells. This is not a good screening test but a positive result is highly specific. New tests are being developed based on the presence of antigens such as nuclear matrix proteins (NMP22) or mini-chromosome maintenance (MCM) proteins, which may be able to detect new or recurrent tumours.

Blood

Estimation of haemoglobin and the level of serum electrolytes and urea should be carried out.

IVU or ultrasound scanning

This should be performed on all patients with painless haematuria. Occasionally, the preliminary film shows a faint shadow of an encrusted neoplasm of the bladder. The most common radiological sign is a filling defect (Fig. 72.50). Occasionally, irregularity of the bladder wall may herald the presence of an invasive tumour. Hydronephrosis may occur if a superficial tumour grows up the intramural ureter or if direct invasion of the ureteric wall occurs. Ultrasound scanning should be carried out if the kidney is non-functioning.

Cross-sectional imaging

Non-contrast CT is being used in some centres instead of IVU or ultrasound scanning for the immediate management of patients

Figure 72.50 Intravenous urography showing a filling defect in the region of the right ureteric orifice.

with gross painless haematuria. For staging when a muscle-invasive bladder cancer is suspected, contrast-enhanced CT is used, ideally before TURBT. False-positive pT3 disease can be diagnosed if a CT scan is carried out soon after TURBT. Magnetic resonance imaging is being used more frequently (Fig. 72.51) and can demonstrate lymph node metastasis or muscle invasion.

Cystourethroscopy

Cystourethroscopy is the mainstay of diagnosis and should always be performed on patients with haematuria. It can be carried out with a rigid instrument under general anaesthesia or with a flexible instrument under local anaesthesia. The urethra is inspected at the initial insertion of the instrument (urethroscopy) and the bladder is then examined in a systematic fashion (cystoscopy).

Bimanual examination

A bimanual examination with the patient fully relaxed under general anaesthesia should be performed both before and after endoscopic surgical treatment of these tumours. The bladder should be empty. Once there is muscle invasion the differentiation between pT2 and pT3 disease depends on whether a mass is palpable bimanually at the end of the procedure (pT3). When invasion has spread into the prostate in a man or the vagina in a woman it is classified as pT4a. If the tumour is fixed to the lateral pelvic side wall it is staged as pT4b.

Figure 72.51 (a) Cross-sectional magnetic resonance imaging showing a 'cystogram' and a bladder cancer. (b) Cross-sectional magnetic resonance imaging showing invasive bladder cancer.

TREATMENT FOR CARCINOMA OF THE BLADDER

Superficial tumours

Endoscopic surgery

The tumour should be carefully resected in layers using a resectoscope. The base of the tumour is sent separately for histological examination. Small pinch biopsies are taken near to and distant from the primary lesion when CIS is suspected (inflamed or velvety appearance). After removal of the tumour, two or three further loops of tissue from the base should be sent separately so that the pathologist can accurately determine whether there is lamina propria or muscle invasion. The base of the tumour is then coagulated, so achieving haemostasis. The appearance of pale-yellow glistening fat will indicate a perforation of the bladder. Should this occur before the resection is complete, it may be prudent to stop the resection and place a catheter in the bladder for a few days. In this instance the procedure could be completed some 2 weeks later. The bimanual examination is repeated at the end of the endoscopic procedure. Following these procedures, an

irrigating catheter is left *in situ* for 48 hours to prevent clot retention of urine. There is good evidence that a single dose of mitomycin (Mitomycin C; 40 mg in 60 ml of fluid) instilled into the bladder before catheter removal decreases the risks of recurrence in patients with pTa and pT1 grade 1 and 2 disease.

Patients with larger solid tumours should have adequate material resected for histological staging and grading. If possible and straightforward, the mass of the tumour should be resected as completely as possible – even when pT2 or pT3 disease is suspected.

Follow-up

Most urologists agree that patients with a single low- or medium-grade pTa tumour can safely be treated by resection alone plus a single instillation of mitomycin, followed up with regular cystoscopies.

The treatment of patients with multiple low- or medium-grade pTa tumours can be by either resection alone or resection followed by a 6-week course of intravesical chemotherapy with mitomycin, doxorubicin or epirubicin.

The treatment of pT1 disease is difficult. Approximately 30% of tumours are understaged at first resection. For this reason, a repeat cystoscopy and resection of the tumour base is advocated within 6 weeks. Many urologists would offer immediate cystectomy to a patient with a high-grade pT1 tumour, particularly if it were multiple or accompanied by CIS, because of the 30–50% risk of progression to muscle invasion. Others will treat such patients by endoscopy followed by immunotherapy with intravesical BCG. The most effective treatment of solitary medium-grade pT1 disease remains uncertain, but a reasonable approach would be endoscopic resection followed by reresection of the area after 6 weeks, followed by intravesical BCG.

Follow-up cystoscopies are essential; they may be carried out under local anaesthesia with a flexible cystoscope or under general anaesthesia if the urologist feels that the patient is at high risk of recurrence. They should be performed at 3-monthly intervals over the first year; following this the time interval between cystoscopies can be determined according to the presence or absence of further disease. In total, 30% of patients will never develop another tumour so that, if the bladder has remained clear after 2 years, annual inspection may be adequate. For patients who go on to develop multiple recurrences within the bladder at each examination, the cystoscopies need to be maintained at frequent intervals so that the growths can be resected. These patients are at a greater risk of their disease progressing; although intravesical chemotherapy can decrease the recurrence rate, no reduction in progression rates has been found.

Open surgical excision

This should be totally avoided. If by some error a bladder containing a tumour is entered, then the tumour may be removed with a diathermy needle and the base coagulated and the bladder closed. Postoperative radiotherapy to the wound will diminish the chance of tumour implantation.

Invasive tumours

The treatment of cancer with proven muscle invasion remains a subject for debate. Whatever the modality of treatment employed, few centres have 5-year survival figures of more than 50%. There is a move towards primary surgical treatment in most

centres. The use of systemic chemotherapy with a combination of agents – cisplatin, methotrexate, doxorubicin and vinblastine (M-VAC) or cisplatin plus gemcitabine given before (neoadjuvant) radical cystectomy – has been shown to be of benefit. The current evidence is that neoadjuvant chemotherapy improves survival by about 5–7%.

Radiotherapy

External beam radiotherapy

External beam radiotherapy is usually given at 60 Gy over a 4- to 6-week period. There is a complete response rate of 40–50%. Unfortunately, some patients do not respond and others exhibit only a partial response, with pTa or pT1 tumour remaining in the bladder giving rise to a risk of recurrence. Patients with residual disease after radiotherapy should be offered ‘salvage cystectomy’ if they are fit. Proponents of radiotherapy claim that it avoids the need to remove the bladder in some patients and allows men to retain potency. Radiotherapy is not without complications, and during the course of treatment will cause urinary frequency and also diarrhoea. Late complications can leave the bladder contracted and fibrosed, in which case it may need to be removed for palliative reasons. Late complications affecting the rectum should be uncommon, especially if lateral fields of irradiation are employed.

Surgery

Partial cystectomy

This should be limited to the treatment of small adenocarcinomas of the bladder.

Radical cystectomy and pelvic lymphadenectomy

This is now standard treatment for localised pT2–pT3 disease without evidence of secondary spread or of CIS that has not responded to BCG. Before contemplating radical surgery to remove the bladder, it is important to have evidence that surgical cure is attainable. A CT scan of the pelvis may locally overstage the bladder if a recent resection has been carried out, although the finding of grossly enlarged pelvic, iliac or para-aortic nodes or liver metastases will alter the decision for cystectomy. A bone scan [using technetium-99m (^{99m}Tc)] will help to show whether there is spread to bone.

Operation

Alternative drainage for urine is necessary following removal of the bladder. The standard procedure is to perform an ileal conduit. Male patients should be counselled about the onset of erectile impotence and absent ejaculation following the operation; they should also be told about alternative forms of urinary diversion, which include continent urinary diversions and orthotopic bladder replacement.

Patients should be seen by a stoma care therapist, who will help to advise the patient and will try different ileostomy bags to ensure that the correct site is chosen, avoiding skin creases so that one does not end up with the disaster of a leaking urinary ileostomy. A decision is made about whether the male urethra is to be removed (depending on the estimated risk of recurrence within the urethra); a urethrectomy is usually indicated in patients with primary CIS or those with tumour invading the prostate stroma. Many surgeons are now offering total replacement of the bladder after cystectomy.

The patient should receive prophylactic antibiotics including metronidazole, cefuroxime and amoxicillin, and low-dose heparin.

The abdomen is opened through a long midline incision extending down to the symphysis pubis. The liver and the retroperitoneum are checked for evidence of metastases, and the operability of the bladder is assessed. A bilateral pelvic lymphadenectomy is performed, removing external iliac nodes, internal iliac nodes and the nodes in the obturator fossae. The vessels passing to the bladder from the side wall are ligated in continuity; these include the obliterated hypogastric vessels, the superior vesical artery, the middle vesical veins, and the inferior vesical arteries and veins. The ureters are then divided. The posterior ligaments extending from the pararectal area to the back of the bladder are ligated and divided, and the layer posterior to Denonvilliers's fascia is opened up. The endopelvic fascia is then divided on each side and the puboprostatic ligaments are divided. A ligature is passed between the dorsal vein complex and the urethra, and the former is ligated and divided. The urethra is then mobilised and divided. The ligaments lateral to the prostate are divided and the bladder is removed. In women, the uterus and anterior vaginal wall need to be included. Women must be counselled about the loss of ovarian and uterine function.

An isolated loop of ileum is then prepared on its own mesentery, and continuity of the small bowel restored. The ureters are then implanted into the bowel and the ileostomy is created. Meticulous care must be taken to close all mesenteric windows, thus avoiding internal hernias. If the bladder is to be replaced orthotopically, a reservoir made from detubularised bowel (usually an ileocaecal segment or ileum) is created and anastomosed to the urethra after implantation of the ureters.

The operative mortality rate associated with cystectomy used to be considerable but is now < 2%. Late complications include urethral recurrence (about 5–8%), which is increased in the presence of multifocal tumours, CIS and, particularly, invasion of prostatic stroma (Fig. 72.52).

Leucoplakia

This condition is simply squamous metaplasia of the bladder. Profuse production of keratin may result in the passing of white particles in the urine. It cannot be treated easily. Localised areas may be resected endoscopically. Diffuse leucoplakia of the bladder is pre-malignant and results in squamous cancer of the bladder. Careful cystoscopic assessment is required and the condition may require cystectomy.

Figure 72.52 Urethrectomy specimen from a patient who has previously undergone a radical cystectomy showing new transitional cell tumour formation in the urethra.

Charles Pierre Denonvilliers, 1808–1872, Professor of Anatomy, and later of Surgery, Paris, France.

Endometriosis

Endometriosis within the bladder wall is rare but can have the appearance of a vascular bladder tumour or a tumour that contains chocolate-coloured or bluish cysts. The swelling enlarges and bleeds during menstruation. If medical management fails, by means of danazol or luteinising hormone-releasing hormone (LHRH) agonists, further treatment is usually by means of partial cystectomy or full-thickness endoscopic resection, depending on its site. The condition may be part of more widespread disease. Endometriosis is also a cause of ureteric stricture.

INTERNAL AND EXTERNAL URINARY DIVERSION

Indications

Diversion of the urine may be either a temporary expedient to relieve distal obstruction or a permanent procedure when the bladder has been removed or has lost normal neurological control and in cases of incurable fistula or irremovable obstruction.

Methods of urinary diversion

Temporary methods use prosthetic materials, the most common being a urinary catheter. In elderly patients unfit for prostatectomy, and in some patients with terminal carcinoma of the prostate, an indwelling silicone urethral Foley catheter changed every 3 months is a satisfactory method of drainage. A suprapubic placement is an alternative to urethral placement. The major drawback of long-term catheterisation is infection secondary to the associated bacteriuria that invariably develops. Ureteric obstruction can be relieved by placement of internal 'double-J' pigtail ureteric stents, which can remain for 4–5 months but are usually changed every 3 months. As an alternative, a nephrostomy tube, inserted percutaneously by ultrasound and fluoroscopic imaging, is effective when internal stent placement is not feasible.

Permanent urinary diversion

External diversion

Ileal conduit

Permanent urinary tract diversion is most commonly performed by conduit diversion. The ureters are implanted into a short, isolated segment of ileum (Fig. 72.53a) or, less commonly, colon. The conduit diverts the urine onwards to a cutaneous stoma for collection in an ileostomy bag. This form of diversion is well established and associated with a low complication rate of less than 10%. The main complication is ureteroileal stricture, which can be limited by spatulation of the distal ureters and an end-to-end anastomosis as described by Wallace (Fig. 72.53a). Stenosis at the ileocutaneous site is less frequent, and a short isoperistaltic conduit limits the formation of a residual urine volume, reducing infection and avoiding the problems of reabsorption of urine. In some cases, when the pelvic area has been subjected to radiation, the lower ureters may be unhealthy; a high division with insertion of the ureters into an ileal loop above the root of the mesentery may then be wiser (Fig. 72.54).

The site for the stoma must be chosen before operation, in

David Mitchell Wallace, 1913–1992, Urologist, St Peter's Hospital, London, England.

Figure 72.53 Diversion of urine. Favoured methods: (a) ileal conduit; the ureters are spatulated and anastomosed to ileum end-to-side (insert); (b) ureterosigmoidostomy; (c) ileal neobladder with anti-reflux long afferent limb.

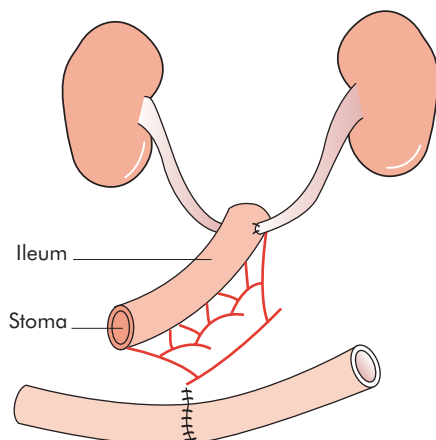

Figure 72.54 Ureteroileostomy (after D.M. Wallace, FRCS).

consultation with a stoma care therapist; the site is marked indelibly on the skin.

Operative details A coil of ileum, approximately 15–20 cm long and 30 cm from the ileocaecal valve, with its blood supply intact, is isolated. The left ureter is brought behind the mesorectum. The ureters may be joined to the ileum either end-to-side or end-to-end after anastomosing of the distal spatulated ureters to form a plate (Wallace). The distal end of the coil is brought out through an incision made at the site identified before operation; a disc of skin and fat is removed, a cruciate incision is made in the fascia and the muscle is split. The stoma is made about 2–3 cm long. It is evaginated initially by means of four sutures passing through the skin, the ileal loop as it passes through the opening and the cut edge of the ileum.

Internal urinary diversion

Colon and rectum

The advantage of diverting urine into the colon is that no collecting apparatus is necessary. Clearly, however, the anal sphincter must be competent. Before ureterosigmoidostomy is undertaken, the patient must prove that he or she can control at least 200 ml of fluid in the rectum. The disadvantage of the operation is that the renal tract is exposed continuously to infection from the faeces; this can be minimised by constructing an anti-reflux procedure. Various diversions are described; the Mainz II ureterosigmoidostomy creates a cul-de-sac type low-pressure reservoir in the sigmoid into which the ureters are placed (see Fig. 72.53b). This reduces reflux, and bowel content, although in contact with urine, takes a direct route to the rectum. In the long term, cancer can develop at long-standing ureterocolic junctions (Fig. 72.55).

Bladder reconstruction

Over the past decade, several techniques have been developed to allow a near-spherical urinary reservoir to be formed out of various lengths of bowel that are detubularised. These may consist of ileum, ileum and caecum or sigmoid colon (see Fig. 72.53c). The ureters can then be reimplanted in these reservoirs in an anti-reflux manner and the reservoir anastomosed to the membranous urethra in the male (see Figs 72.20–72.22,

Figure 72.55 An anterior resection of the rectum specimen in a patient aged 18 years who has previously undergone ureterosigmoidostomy for the treatment of bladder exstrophy.

p. 1322–3). About 15–30% of patients cannot empty the neobladder completely and will need to perform intermittent self-catheterisation. The results are good in selected younger patients after radical cystectomy.

Continent urinary diversion

A similar concept is used in the construction of continent diversions. A urinary reservoir is made as described above and the ureters are attached to the reservoir. A continence mechanism is then made to connect the reservoir to the skin. This is the complication-prone part of the operation. The continence mechanism may be made of an invaginated loop of ileum supported by three rows of staples (Kock pouch) or from the appendix, buried in an anti-reflux manner in a submucosal tube (Mitrofanoff; Fig. 72.56). Alternatively, a length of ileum can be made into a tube (of a similar size to the appendix) after excision of the anti-mesenteric ileum and buried in a submucosal tunnel in an anti-reflux way. Clearly, these operations are complex, with the potential for increased postoperative complications.

Bladder substitution and augmentation

In patients with contraction of the bladder because of tuberculosis or with neuropathic dysfunction and a small bladder capacity, the bladder may need to be augmented. Similar techniques to those used to perform a bladder replacement can be utilised to make a near-spherical pouch from detubularised bowel, which can then be attached to the trigone or bladder neck after a near-total cystectomy (see Figs 72.20–72.22, p. 1322–3). The ureters are then reimplanted. The facility to provide a continence mechanism must be available if needed in the neuropathic patient. This may comprise an artificial urinary sphincter or a colposuspension in the female.

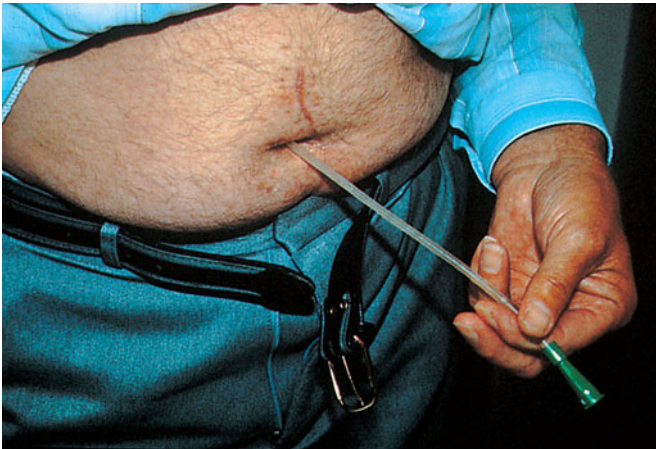

Figure 72.56 A patient with a pT3a bladder cancer who has previously undergone cystoprostatectomy and urethrectomy. A detubularised ileocaecal reservoir has been made with the ureters implanted in submucosal tunnels. The appendix has been implanted within the reservoir in a submucosal tunnel to provide the continence mechanism. The appendix has been brought to the umbilicus and is catheterised 4- to 6-hourly to empty the reservoir.

Paul Mitrofanoff, B. 1934, Professor of Paediatric Surgery, Rouen, France.

Complications of internal diversion

Stricture

Ureterosigmoidostomy was first used by Chaput in 1894. Subsequent modifications included those made by Coffey and Grey Turner. In these methods the ureters were cut obliquely and pulled into the gut by a stitch – the ends were not stitched to the gut wall – and stenosis was common. Nesbit, Cordonnier and Leadbetter all recognised that these strictures could be prevented by anastomosing mucosa to mucosa.

Reflux of urine

High-pressure activity within a segment of gut can cause reflux of potentially infected urine at high pressure to the kidneys. In the long term, this can cause renal impairment. The principle of a low-pressure reservoir for both neobladder and ureterosigmoidostomy (Mainz II) reduces this. In addition, an anti-reflux mechanism, used in neobladder construction, is created by anastomosing the ureters to a non-detubularised 20-cm segment of small bowel, which is in continuity with the neobladder (see Fig. 72.53c).

Metabolic consequences of internal diversion

Resorption of solutes

This depends upon the following factors: (1) the area of bowel that is exposed to urine; and (2) the length of time that the urine is in contact with the bowel epithelium.

The biochemical changes associated with urinary diversion are due to a combination of reabsorption of chloride and urea and progressively diminishing tubular function as a result of pyelonephritis. Diarrhoea with loss of potassium-containing mucus may exacerbate the loss of potassium. The typical changes of a hyperchloraemic acidosis with potassium depletion occur more frequently with ureterosigmoid diversion than with a colonic and ileal neobladder. When severe, the patient develops loss of appetite, weakness, thirst and diarrhoea. Coma may ensue. Mild acidosis, unrecognised over a long period, produces osteomalacia. Bone pain and even pathological fracture can occur. Renal impairment from pyelonephritis and reabsorption from the mucosa are seen less frequently after ileal or colonic conduit formation, continent urinary diversion or orthotopic bladder substitution. In fact, they are seen very infrequently except in patients with pre-existing renal impairment and unsatisfactory emptying of the urinary reservoir. Malabsorption can occur with the loss of terminal ileum and small bowel. The loss of terminal ileum can result in vitamin B12 deficiency and so monitoring of vitamin B12 and folate is recommended after the first year.

Treatment

Patients should be instructed to empty the rectum or continent reservoir or neobladder 3-hourly by day. In patients who have undergone ureterosigmoidostomy and in whom acidosis is present, a rectal tube should be inserted at night to drain the urine continuously. The patient should take a mixture of potassium citrate and sodium bicarbonate three times a day (2 g of each, either as crystals

or as tablets). Regular serum biochemical analyses, including calcium, are required.

Established hyperchloraemic acidosis is usually associated with marked dehydration and the mainstay of treatment is administration of intravenous saline. The patient may be given small doses of sodium bicarbonate to half-correct the pH deficit if it is severe and additional intravenous potassium. This should be coupled with appropriate systemic antibiotic treatment.

Risk of malignancy

There is a risk of cancer developing in bowel used to reconstruct the urinary tract. When the urine is not mixed with faeces, the incidence is small, becoming significant after 15–18 years. The major risk of malignancy was discovered when ureterosigmoidostomy construction enabled free mixing of urine and faeces. The

development of sigmoid reservoirs into which the ureters are inserted has reduced this risk.

The prostate and seminal vesicles

LEARNING OBJECTIVES

To understand:

- The relationship of anatomical structure and biochemical function to the development and treatment of benign and malignant disease of the prostate
- The terminology used to describe lower urinary tract symptoms and to know their causes as well as the treatment options available
- Which investigations are appropriate for carcinoma of the prostate
- Clinical staging of carcinoma of the prostate and how staging contributes to the complex decision-making process for the best treatment option

EMBRYOLOGY

From the primitive urethra, a series of solid epithelial buds develop and become canalised in a matter of weeks. The surrounding mesenchyme forms the muscular and connective tissue of the gland and has a major role in differentiation (stromal epithelium interactions). Skene's tubules, which open on either side of the female urethra, are the homologue of the prostate.

SURGICAL ANATOMY

The contemporary classification of the prostate into different zones was based on the work of McNeal (Fig. 73.1). He showed that it is divided into the peripheral zone (PZ), which lies mainly posteriorly and from which most carcinomas arise, and a central zone (CZ), which lies posterior to the urethral lumen and above the ejaculatory ducts as they pass through the prostate; the two zones are rather like an egg in an eggcup. There is also a periurethral transitional zone (TZ), from which most benign prostatic hyperplasia (BPH) arises. Smooth muscle cells are found throughout the prostate but, in the upper part of the prostate and bladder neck, there is a separate sphincter muscle that subserves a sexual function, closing during ejaculation. Resection of this tissue during prostatectomy is responsible for retrograde ejaculation. The distal striated urethral sphincter muscle is found at the junction of the prostate and the membranous urethra; it is horse-shoe shaped with the bulk lying anteriorly and is quite distinct from the muscle of the pelvic floor (Fig. 73.1).

The glands of the peripheral zone (Fig. 73.2), lined by columnar epithelium, lie in the fibromuscular stroma, and their ducts, which are long and branched, open into posterolateral grooves on

Figure 73.1 Sagittal diagram of the prostate just lateral to the urethra showing the division into the different zones described by McNeal. The transitional zone is the area from which most benign prostatic hyperplasia (BPH) arises.

either side of the verumontanum. The glands of the CZ and TZ are shorter and unbranched. All these ducts, the common ejaculatory ducts and the prostatic utricle open into the prostatic urethra.

BPH starts in the periurethral transitional zone and, as it increases in size, it compresses the outer PZ of the prostate, which becomes the false capsule. There is also the outer true fibrous anatomical capsule, and external to this lie condensations of endopelvic fascia known as the periprostatic sheath of endopelvic fascia. Between the anatomical capsule and the prostatic sheath lies the abundant prostatic venous plexus. The prostatic sheath is

Alexander Johnston Chalmers Skene, 1828–1900, Professor of Gynecology, Long Island Hospital, Brooklyn, New York, NY, USA.

contiguous with the fascia of Denonvilliers, which separates the prostate and its coverings from the rectum. The neurovascular bundles supplying autonomic innervation to the corpora of the penis are in very close relationship to the posterolateral aspect of the prostatic capsule and are at risk of damage during radical cystoprostatectomy or radical prostatectomy; inadvertent diathermy in the region of these nerves may be the cause of uncommon erectile impotence after transurethral prostatectomy.

PHYSIOLOGY

The prostate has a sexual function, but it is unclear how important its secretions are to human fertility. That the normal adult prostate undergoes atrophy after castration was known to John Hunter.

Systemic hormonal influences (endocrine) and local growth factors (paracrine and autocrine)

The growth of the prostate is governed by many local and systemic hormones whose exact functions are not yet known. The main hormone acting on the prostate is testosterone, which is secreted by the Leydig cells of the testes under the control of luteinising hormone (LH), itself secreted from the anterior pituitary under the control of hypothalamic luteinising hormone-releasing hormone (LHRH). LHRH has a short half-life and is released in a pulsatile manner. This pulsatile release is important, as receptors for LHRH will become desensitised if permanently occupied. The administration of LHRH analogues in a continuous, non-pulsatile manner exploits the concept of receptor desensitisation and forms the basis for androgen deprivation therapy in prostate cancer. Testosterone is converted to 1,5-dihydrotestosterone (DHT) by the enzyme 5α -reductase, which is found in high concentration in the prostate and the perigenital skin (type II). Other androgens are secreted by the adrenal cortex, but their effects are minimal in the normal male. Oestrogenic steroids are also secreted by the adrenal cortex and, in the ageing male, may play a part in disrupting the delicate balance between DHT and local peptide growth factors, and

hence increase the risk of BPH. Increased levels of serum oestrogens, by acting on the hypothalamus, decrease the secretion of LHRH (and hence LH) and thereby decrease serum testosterone levels. Thus, pharmacological levels of oestrogens cause atrophy of the testes and prostate by means of reductions in testosterone.

Other locally acting peptides are secreted by the prostatic epithelium and mesenchymal stromal cells in response to steroid hormones. These include epidermal growth factor, insulin-like growth factors, basic fibroblast growth factor and transforming growth factors alpha and beta. These undoubtedly play a part in normal and abnormal prostatic growth, but as yet their functions are unclear (Summary box 73.1).

Summary box 73.1

Androgenic hormones

- Androgenic hormones, which drive prostate growth, are derived from several sources
- The majority of testosterone (90%) is secreted by the Leydig cells of the testes under the control of LH, secreted from the anterior pituitary
- Metabolised adrenal androgen accounts for the remaining 5–10% of testosterone
- Testosterone is converted to DHT by the enzyme 5α -reductase type II, which is found in high concentration in the prostate and the perigenital skin
- DHT has five times the potency of testosterone

Elaboration and secretion of prostate-specific antigen and acid phosphatases

Prostate-specific antigen (PSA) is a glycoprotein that is a serine protease. Its function may be to facilitate liquefaction of semen, but it is a marker for prostatic disease. It is measured by an immunoassay, and the normal range can differ a little from laboratory to laboratory. There is no real normal upper limit. The levels increase with age, with prostate cancer and with BPH. There are age-related values but, in general, in men aged 50–69 years, a level of about 3–4 ng ml⁻¹ would prompt a discussion about the need for prostate biopsy. Its level in men with metastatic prostate cancer is usually increased to > 30 ng ml⁻¹ and falls to low levels after successful androgen ablation. Men with locally confined prostate cancer usually have serum PSA levels < 10–15 ng ml⁻¹. Although PSA is a reliable marker for the progression of advanced disease, it is neither specific nor sensitive in the differential diagnosis of early prostate cancer and BPH, as both diseases are compatible with PSA in the range of 3–15 ng ml⁻¹. PSA measurement has superseded measurement of serum acid phosphatase. In summary, about 25% of men with a PSA of 4–10 ng ml⁻¹ have prostate cancer (i.e. it is not very specific), and about 15–20% of men with a PSA of 1–4 ng ml⁻¹ have prostate cancer. In general, one would advise men aged 50–69 years to undergo prostate biopsy if the PSA was more than ~ 3 ng ml⁻¹. The threshold would be lower in younger men with a strong family history.

BENIGN PROSTATIC HYPERPLASIA

Aetiology of benign prostatic hyperplasia

Hormones

Serum testosterone levels slowly but significantly decrease with advancing age; however, levels of oestrogenic steroids are not

decreased equally. According to this theory, the prostate enlarges because of increased oestrogenic effects. It is likely that the secretion of intermediate peptide growth factors plays a part in the development of BPH (Summary box 73.2).

Summary box 73.2

Benign prostatic hyperplasia (BPH)

- Occurs in men over 50 years of age; by the age of 60 years, 50% of men have histological evidence of BPH
- Is a common cause of significant lower urinary tract symptoms in men and is the most common cause of bladder outflow obstruction in men > 70 years of age

Pathology

BPH affects both glandular epithelium and connective tissue stroma to variable degrees. These changes are similar to those occurring in breast dysplasia (see Chapter 50), in which adenosis, epitheliosis and stromal proliferation are seen in differing proportions. BPH typically affects the submucous group of glands in the transitional zone, forming a nodular enlargement. Eventually, this overgrowth compresses the PZ glands into a false capsule and causes the appearance of the typical 'lateral' lobes.

When BPH affects the subcervical CZ glands, a 'middle' lobe develops that projects up into the bladder within the internal sphincter (Fig. 73.3). Sometimes, both lateral lobes also project into the bladder, so that, when viewed from within, the sides and back of the internal urinary meatus are surrounded by an intravesical prostatic collar.

Effects of benign prostatic hyperplasia

It is important to realise that the relationship between anatomical prostatic enlargement, lower urinary tract symptoms (LUTS) and urodynamic evidence of bladder outflow obstruction (BOO) is complex (Fig. 73.4). Pathophysiologically, BOO may be caused in part by increased smooth muscle tone, which is under the control of α -adrenergic agonists (Summary box 73.3).

Figure 73.3 Diagram of late-stage bladder outflow obstruction (BOO) showing enlargement of the prostate from benign prostatic hyperplasia (BPH), trabeculation of the bladder with smooth muscle hypertrophy and fibrosis.

Figure 73.4 Diagrammatic representation of the relation between symptoms of prostatism, benign prostate hyperplasia (BPH) and uroynamically proven bladder outflow obstruction (BOO).

Summary box 73.3

Consequences of BPH

- No symptoms, no BOO
- No symptoms, but urodynamic evidence of BOO
- Lower urinary tract symptoms, no evidence of BOO
- Lower urinary tract symptoms and BOO
- Others (acute/chronic retention, haematuria, urinary infection and stone formation)

Anatomically, the effects are as follows:

- **Urethra.** The prostatic urethra is lengthened, sometimes to twice its normal length, but it is not narrowed anatomically. The normal posterior curve may be so exaggerated that it requires a curved catheter to negotiate it. When only one lateral lobe is enlarged, distortion of the prostatic urethra occurs.
- **Bladder.** If BPH causes BOO, the musculature of the bladder hypertrophies to overcome the obstruction and appears trabeculated (Fig. 73.5). Significant BPH is associated with increased blood flow, and the resultant veins at the base of the bladder are apt to cause haematuria.

Lower urinary tract symptoms (LUTS)

In both sexes, non-specific symptoms of bladder dysfunction become more common with age, probably owing to impairment of smooth muscle function and neurovesical coordination. Not all symptoms of disturbed voiding in ageing men should therefore be attributed to BPH causing BOO. Urologists prefer the term LUTS and discourage the use of the descriptive term 'prostatism'.

The following conditions can coexist with BOO, leading to difficulty in diagnosis and in predicting the outcome of treatment:

- idiopathic detrusor overactivity (see Chapter 72);
- neuropathic bladder dysfunction as a result of diabetes, strokes, Alzheimer's disease or Parkinson's disease (see Chapter 72);

Alois Alzheimer, 1864–1915, a Neurologist who worked at Heidelberg and Munich, before being appointed Professor of Psychiatry at Breslau, Germany, (now Wrocław, Poland).

James Parkinson, 1755–1824, a General Practitioner of Shoreditch, London, England who published 'An Essay on the Shaking Palsy' in 1817.

Figure 73.5 Trabeculation of the bladder from prostatic obstruction. When viewed from within, bands of muscle fibres can be seen – trabeculation. Between these hypertrophied bundles, there are shallow depressions, i.e. sacculations. Sometimes, one of the saccules (rarely two or more) continues to enlarge and forms a diverticulum (courtesy of the late Professor K.A.L. Aschoff, Freiburg, Germany).

- degeneration of bladder smooth muscle giving rise to impaired voiding and detrusor instability;
- BOO due to BPH.

Lower urinary tract symptoms can be described as:

- voiding
 - hesitancy (worsened if the bladder is very full);
 - poor flow (unimproved by straining);
 - intermittent stream – stops and starts;
 - dribbling (including after micturition);
 - sensation of poor bladder emptying;
 - episodes of near retention.
- storage
 - frequency;
 - nocturia;
 - urgency;
 - urge incontinence;
 - nocturnal incontinence (enuresis).

LUTS are usually assessed by means of scoring systems, which give a semi-objective measure of severity. However, some symptoms do not give an accurate picture of the underlying pathophysiological problem. For instance, a man with severe detrusor instability may void only small volumes and hence he will have a sensation of poor flow because low voided volumes (< 100 ml) are associated with low flow rates.

Severe irritative symptoms are usually associated with detrusor instability. Post-micturition dribbling is now known not to be a consequence of BOO and is not usually improved by prostatectomy.

Bladder outflow obstruction

This is a urodynamic concept based on the combination of low flow rates in the presence of high voiding pressures. It can be

diagnosed definitively only by pressure–flow studies. This is because symptoms are relatively non-specific and can result from detrusor instability, neurological dysfunction and weak bladder contraction. Even low measured peak flow rates (< 10–12 ml s⁻¹) are not absolutely diagnostic because, in addition to BOO, weak detrusor contractions or low voided volumes (owing to instability) can be the cause. Nonetheless, flow rates provide a useful guide for everyday clinical management.

Urodynamically proven BOO may result from:

- BPH;
- bladder neck stenosis;
- bladder neck hypertrophy;
- prostate cancer;
- urethral strictures;
- functional obstruction due to neuropathic conditions.

The primary effects of BOO on the bladder are as follows:

- *Urinary flow rates decrease* (for a voided volume > 200 ml, a peak flow rate of > 15 ml s⁻¹ is normal (Fig. 73.6), one of 10–15 ml s⁻¹ is equivocal and one < 10 ml s⁻¹ is low (Fig. 73.7)).
- *Voiding pressures increase* (pressures > 80 cmH₂O are high (Fig. 73.8), pressures between 60 and 80 cmH₂O are equivocal and pressures < 60 cmH₂O are normal).

The long-term effects of bladder outflow obstruction are as follows:

- 1 The bladder may decompensate so that detrusor contraction becomes progressively less efficient and a residual urine develops.
- 2 The bladder may become more irritable during filling with a decrease in functional capacity partly caused by detrusor over-activity (see Chapter 76), which may also be caused by neurological dysfunction or ageing, or may be idiopathic.

Figure 73.6 Normal flow rate. The voided volume is well in excess of 350 ml, and the maximum flow rate is in excess of 25 ml s⁻¹.

Figure 73.7 Diagram of a low flow rate showing a rather low voided volume of about 200 ml, but with markedly decreased flow rate. Such a flow rate could be caused by a urethral stricture, bladder outflow obstruction or a weak detrusor.

Figure 73.8 Conventional urodynamic trace showing detrusor pressure during voiding. There has been a change in scale because the pressure was so high; voiding pressures are increased with a low flow rate. This is diagnostic of bladder outflow obstruction.

Aside from symptoms, the complications of BOO are as follows:

- 1 *Acute retention* of urine is sometimes the first symptom of BOO. Postponement of micturition is a common precipitating cause; overindulgence in beer and confinement to bed on account of intercurrent illness or operation are other causes.
- 2 *Chronic retention*. In patients in whom the residual volume is > 250 ml or so (Fig. 73.9), the tension in the bladder wall increases owing to the combination of a large volume of residual urine and increased resting and filling bladder pressures (a condition known as high-pressure chronic retention). The increased intramural tension results in functional obstruction of the upper urinary tract with the development of bilateral hydronephrosis (Figs 73.10 and 73.11). As a result, upper tract infection and renal impairment may develop. Such men may present with overflow incontinence, enuresis and renal insufficiency. These symptoms should alert the doctor to the presence of this condition.
- 3 *Impaired bladder emptying*. If the bladder decompensates with the development of a large volume of residual urine, urinary infection and calculi are prone to develop.

Figure 73.9 An ultrasonogram showing a large post-void residual urine.

Figure 73.10 Intravenous urogram from a patient with symptoms of outflow obstruction and a moderate post-micturition residual urine. The patient did not undergo treatment.

Figure 73.11 Intravenous urogram from the same patient as in Figure 73.10 but carried out some years later. The patient had developed chronic urinary retention and renal impairment owing to upper urinary dilatation.

- 4 *Haematuria*. This may be a complication of BPH. Other causes must be excluded by carrying out an intravenous urography (IVU), cystoscopy, urine culture and urine cytological examination.
- 5 Other than pain from retention, pain is not a symptom of BOO, and its presence should prompt the exclusion of acute retention, urinary infection, stones, carcinoma of the prostate and carcinoma *in situ* of the bladder.

ASSESSMENT OF THE PATIENT WITH LOWER URINARY TRACT SYMPTOMS

History

Symptom score sheets such as the International Prostate Symptom Score (IPSS) assign a score which gives information regarding the severity of symptoms at the outset and changes over time and following intervention. The IPSS assessment should include an assessment of quality of life, which is a reflection of the degree of 'bother' caused by a patient's symptoms. In addition to the IPSS, a frequency–volume diary completed by the patient before attending the clinic is invaluable in revealing fluid intake habits, diurnal variation in outputs and low-volume, frequent voiding. These assessments are routinely performed at lower urinary tract clinics but can be elicited by a thorough clinical history (Summary box 73.4).

Summary box 73.4

Investigations of men with LUTS

Essential investigations

- Urine analysis by dipstick for blood, glucose and protein
- Urine culture for infection
- Serum creatinine
- Urinary flow rate and residual volume measurement

Additional investigations

- PSA if indicated
- Pressure–flow studies

Abdominal examination

Abdominal extension is usually normal. In patients with chronic retention, a distended bladder will be found on palpation, on percussion and sometimes on inspection with loss of the transverse suprapubic skin crease. General physical examination may demonstrate signs of chronic renal impairment with anaemia and dehydration. The external urinary meatus should be examined to exclude stenosis, and the epididymides are palpated for signs of inflammation.

Rectal examination

In benign enlargement, the posterior surface of the prostate is smooth, convex and typically elastic, but the fibrous element may give the prostate a firm consistency. The rectal mucosa can be made to move over the prostate. Residual urine may be felt as a fluctuating swelling above the prostate. It should be noted that, if there is a considerable amount of residual urine present, it pushes the prostate downwards, making it appear larger than it is.

The nervous system

The nervous system is examined to eliminate a neurological lesion. Diabetes mellitus, tabes dorsalis, disseminated sclerosis,

cervical spondylosis, Parkinson's disease and other neurological states may mimic prostatic obstruction. If these are suspected then a pressure–flow urodynamic study should be carried out to diagnose BOO. Examination of perianal sensation and anal tone is useful in detection of an S2 to S4 cauda equina lesion.

Serum prostate-specific antigen

The difficulty here is the uncertain benefit of early detection and radical treatment of prostate cancer – this is dealt with in the section on prostate cancer. Certainly, men should be informed about the test, the risks of the prostate biopsy that might be required and the risks of the detection of a cancer that we are not certain how best to treat, as well as the positive aspects of the early discovery of a small prostate cancer. After suitable counselling, measurement of serum PSA may be helpful. Men in whom a diagnosis of early prostate cancer might influence treatment option (such as those under 70 years or those with a positive family history who might be offered radical treatment) should be offered a PSA measurement. If this is in excess of 2.5–4 nmol l⁻¹, then transrectal ultrasound scanning (TRUS) plus multiple transrectal biopsies (10 biopsies) should be considered.

If rectal examination is quite normal with no suspicion of cancer, and if no change in treatment policy would in any case result from the diagnosis of early prostate cancer, then there is little point in the routine measurement of PSA in men with uncomplicated BOO. However, because of the fear of future litigation, many find it easier to offer a PSA test.

Flow rate measurement

For this to be meaningful, two or three voids should be recorded, and the voided volume should be in excess of 150–200 ml. This usually means the patient attending a special flow rate clinic. A typical history and a flow rate < 10 ml s⁻¹ (for a voided volume of > 200 ml; Fig. 73.7) will be sufficient for most urologists to recommend treatment. Usually, a flow rate measurement will be coupled with ultrasound measurement of post-void residual urine.

There are pitfalls in the measurement of flow rates. The machine must be accurately calibrated. The patient must void volumes in excess of 150 ml, and two or three recordings are needed to obtain a representative measurement. Decreased flow rates and symptoms of prostatism may be seen in:

- BOO;
- low voided volumes (characteristically in men with detrusor instability);
- men with weak bladder contractions (low pressure–flow voiding).

Pressure–flow urodynamic studies (Fig. 73.8)

Details of these studies are outlined in Chapter 72. They should be performed on the following patients:

- men with suspected neuropathy (Parkinson's disease, dementia, longstanding diabetes, previous strokes, multiple sclerosis);
- men with a dominant history of irritative symptoms and men with lifelong urgency and frequency;
- men with a doubtful history and those with flow rates in the near normal range (~ or > 15 ml s⁻¹);
- men with invalid flow rate measurements (because of low voided volumes).

Blood tests

Serum creatinine, electrolytes and haemoglobin should be measured.

Examination of urine

The urine is examined for glucose and blood; a midstream specimen should be sent for bacteriological examination, and cytological examination may be carried out if carcinoma *in situ* is thought possible.

Upper tract imaging

Most urologists no longer carry out imaging of the upper tract in men with straightforward symptoms. Obviously, if infection or haematuria is present, then the upper tract should be imaged by means of intravenous urogram or ultrasound scan.

Cystourethroscopy

Inspection of the urethra, the prostate and the urothelium of the bladder should always be done immediately prior to prostatectomy, whether it is being done transurethral or by the open route to exclude a urethral stricture, a bladder carcinoma and the occasional non-opaque vesical calculus. The decision of whether to perform prostatectomy must be made before cystoscopy. This should be based on the patient's symptoms, signs and investigations. Direct inspection of the prostate is a poor indicator of BOO and the need for surgery.

Transrectal ultrasound scanning

There is no need to carry this out routinely. Accurate estimation of prostatic size is also possible by means of transrectal or trans-abdominal ultrasound scanning.

MANAGEMENT OF MEN WITH BENIGN PROSTATIC HYPERPLASIA OR BLADDER OUTFLOW OBSTRUCTION

Strong indications for treatment (usually prostatectomy) include:

- 1 *Acute retention* (see Chapter 72) in fit men with no other cause for retention (drugs, constipation, recent operation, etc.) (accounts for 25% of prostatectomies).
- 2 *Chronic retention and renal impairment*: a residual urine of 200 ml or more, a raised blood urea, hydronephrosis or hydroureter demonstrated on urography and uraemic manifestations (accounts for 15% of prostatectomies).
- 3 *Complications of bladder outflow obstruction*: stone, infection and diverticulum formation.
- 4 *Haemorrhage*: occasionally, venous bleeding from a ruptured vein overlying the prostate will require prostatectomy to be performed.
- 5 *Elective prostatectomy for severe symptoms*: this accounts for about 60% of prostatectomies. Increasing difficulty in micturition, with considerable frequency day and night, delay in starting and a poor stream are the usual symptoms for which prostatectomy is advised. Frequency alone is not a strong indication for prostatectomy. The natural progression of outflow obstruction is variable and rarely gets worse after 10 years.

Severe symptoms, a low maximum flow rate ($< 10 \text{ ml s}^{-1}$) and an increased residual volume of urine (100–250 ml) are relatively strong indications for operative treatment. The exact cut-off for operative or non-operative treatment will depend on careful discussion between the patient and the urologist (Summary box 73.5).

Summary box 73.5

Options for treatment of LUTS secondary to BPH

- Conservative measures include watchful waiting in conjunction with fluid restriction and reduction in caffeine intake
- Drug therapy is with α -blockers or, in men with a large prostate, a 5 α -reductase inhibitor, or both
- Interventional measures include transurethral resection of the prostate (TURP), which remains the 'gold standard'; consider open prostatectomy for large glands

Acute retention

The management of retention is discussed in detail in Chapter 72. Once the bladder has been drained by means of a catheter, the patient's fitness for treatment is determined. If retention was not caused by drugs or constipation, then prostatectomy would usually be the correct management. Unfit men or those with dementia may be treated by means of indwelling prostatic stents or a catheter. Similar comments apply to men with chronic retention once renal function has been stabilised by catheterisation. The role of α -adrenergic drugs followed by a trial of catheter has been tested and found to be successful in certain groups with a short history and a low residual volume of urine, but the recurrence rate becomes cumulatively high.

Special problems in the management of chronic retention (see Chapter 72 for general management of retention)

Men with chronic retention who have relatively low volumes of residual urine and who do not have symptoms suggestive of co-existent infection and with good renal function do not necessarily require catheterisation before proceeding to prostatectomy on the next available list. For those who are uraemic, urgent catheterisation is mandatory to allow renal function to recover and stabilise. Haematuria often occurs following catheterisation owing to collapse of the distended bladder and upper tract, but settles within a couple of days.

Uraemic patients with chronic retention are often dehydrated at the time of admission. Owing to the chronic back pressure on the distal tubules within the kidney, there is loss of the ability to reabsorb salts and water. The result, following release of this pressure, may be an enormous outflow of salts and water, which is known as post-obstructive diuresis. It is for this reason that a careful fluid chart, daily measurements of the patient's weight and serial estimations of creatinine and electrolytes are essential. Intravenous fluid replacement is required if the patient is unable to keep up with this fluid loss. These patients are often anaemic and may require a blood transfusion once fluid balance is stabilised (if haemoglobin is $< 9 \text{ g l}^{-1}$).

Indications for elective treatment in men with LUTS secondary to BPH

Following careful assessment (see section on the assessment of men with LUTS), the following questions should be answered:

- 1 Have they failed a preliminary trial of medical therapy? Commonly, men will have been treated with α -blockers or 5 α -reductase inhibitors and will have failed treatment. They are then referred by their general practitioner to the urologist.
- 2 Is BOO present? In many cases, the findings of significant symptoms (assessed by symptom scoring), a benign prostate supplemented by the finding of a low maximum flow rate [$< 10\text{--}12\text{ ml s}^{-1}$ for a good voided volume ($> 200\text{ ml}$)] will suffice to make a reasonable working diagnosis of BOO. In some men, particularly those with irritative symptoms, suspected neurological disease or those with technically imperfect flow rate measurements, pressure–flow studies will need to be performed.
- 3 How severe are the symptoms and what are the risks of doing nothing? Severe symptoms and a large residual volume of urine will usually require treatment. Men with mild symptoms, good flow rates ($> 15\text{ ml s}^{-1}$) and good bladder emptying (residual urine $< 100\text{ ml}$) may be safely managed by reassurance and review: such patients rarely develop severe complications such as retention in the long term.
- 4 Is the man fit for operative treatment?
- 5 What treatments are available, what are the outcomes and do the side-effects justify treatment?

Treatment

Men with symptoms attending for elective treatment (excluding acute and chronic retention)

Conservative treatment

It is in men with relatively mild symptoms, reasonable flow rates ($> 10\text{ ml}^{-1}$) and good bladder emptying (residual urine $< 100\text{ ml}$) that careful discussion over the merits and side-effects of operative treatment is warranted. Waiting for a period of 6 months after careful discussion of the diagnosis is indicated. After this, a repeat assessment of symptoms, flow rates and ultrasound scan is helpful; many men with stable symptoms will elect to leave matters be. Advice over limiting fluid intake in the evening and careful use of propantheline to help with irritative symptoms is also useful.

Drugs

In men who are very concerned about the development of sexual dysfunction after transurethral resection of the prostate (TURP), the use of drugs may be helpful. Two classes of drug have been used in the treatment of men with BOO. α -Adrenergic blocking agents inhibit the contraction of smooth muscle that is found in the prostate. The other class of drug is the 5 α -reductase inhibitors, which inhibit the conversion of testosterone to DHT, the most active form of androgen. These drugs, when taken for a year, result in a 25% shrinkage of the prostate gland. Both groups of drugs are effective; however, α -blockers work more quickly and, although the 5 α -reductase inhibitors have fewer side-effects, they need to be taken for at least 6 months, and their effect is greatest in patients with large ($> 50\text{ g}$) glands. Drug therapy results in improvements in maximum flow rates by about 2 ml s^{-1} more than placebo and results in mild (20%) improvement in symptom

scores. TURP, however, results in improvements in maximum flow rates from $9\text{ to }18\text{ ml s}^{-1}$ and a 75% improvement in symptom scores. These drugs are expensive in comparison with their effectiveness, and a significant proportion of men who try these drugs will subsequently undergo TURP. They may be best targeted at men who have failed an initial trial of watchful waiting and who wish to avoid surgery for a period.

Operative treatment

Apart from the strong indications for operative treatment mentioned above, the most common reason for TURP is a combination of severe symptoms and a low flow rate $< 12\text{ ml s}^{-1}$. The key is to assess symptoms carefully and to counsel men about side-effects and likely outcome before advising operative treatment.

Counselling men undergoing prostatectomy

Men undergoing prostatectomy need to be advised about the following:

- 1 *Retrograde ejaculation.* This occurs in about 65% of men after prostatectomy.
- 2 *Erectile impotence.* This occurs in about 5% of men, usually those whose potency is waning.
- 3 *The success rate.* On the whole, men with acute and chronic retention do well from the symptomatic point of view. Ninety per cent of men undergoing elective operation for severe symptoms and urodynamically proven BOO do well in terms of symptoms and flow rates. Only about 65% of those with mild symptoms or those with weak bladder contraction as the cause of their symptoms do well. Men with unobstructed detrusor instability do not respond well to TURP. This is the reason for carefully documenting the severity of symptoms and flow rates (supplemented when necessary by pressure–flow studies) before deciding on treatment.
- 4 *The risk of reoperation.* After TURP, this is about 15% after 8–10 years.
- 5 *The morbidity rate.* Death after TURP is infrequent ($< 0.5\%$), severe sepsis is found in about 6% and severe haematuria requiring transfusion of more than 2 units of blood occurs in about 3%. After discharge, about 15–20% of men subsequently require antibiotic treatment for symptoms of urinary infection. Risk factors for complications include admission with retention, prostate cancer, renal impairment and advanced age.

Methods of performing prostatectomy

The prostate can be approached (1) transurethally (TURP), (2) retropubically (RPP), (3) through the bladder (transvesical; TVP) or (4) from the perineum (Fig. 73.12).

Transurethral resection of the prostate

TURP has largely replaced other methods unless diverticulectomy or the removal of large stones necessitates open operation; over 95% of men being treated by urologists can be dealt with by TURP. Perhaps the greatest advance in the history of transurethral surgery was marked by the development of the rigid lens system of Professor Harold Hopkins. His lenses, illuminated by a fibreoptic light source, permit unparalleled visualisation of

Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, The University of Reading, Reading, England.

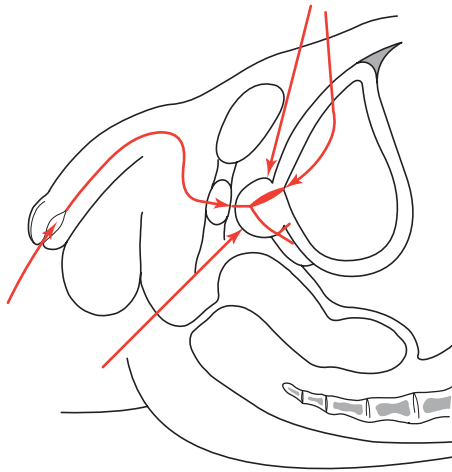

Figure 73.12 The surgical approaches to the prostate.

the working field. Men with indwelling catheters, those with recent urinary infection, those with chronic retention or those with prosthetic material or heart valves should receive broad-spectrum prophylactic antibiotics with amoxicillin plus cefuroxime or gentamicin intravenously at induction of anaesthesia.

Strips of tissue are cut from the bladder neck down to the level of the verumontanum (Fig. 73.13). Cutting is performed by a high-frequency diathermy current, which is applied across a loop mounted on the hand-held trigger of the resectoscope. Coagulation of bleeding points can be accurately achieved, and damage to the external sphincter is avoided provided one uses the verumontanum as a guide to the most distal point of the resection. The 'chips' of prostate are then removed from the bladder using an Ellik evacuator. The risks of hyponatraemia are reduced by using 1.5% isotonic glycine for irrigation, and the recent introduction of continuous-flow resectoscopes makes the procedure swift and safe in experienced hands. At the end of the procedure, careful haemostasis is performed, and a three-way,

Figure 73.13 Endoscopic photograph of transurethral prostatectomy.

Milo Ellik, a twentieth century American Urologist.

self-retaining catheter irrigated with isotonic saline is introduced into the bladder to prevent any further bleeding from forming blood clots. Irrigation is continued until the outflow is pale pink, and the catheter is usually removed on the second or third post-operative day. In men with small prostates or bladder neck dyssynergia or stenosis, it is better to divide the bladder neck and prostatic urethra with a diathermy 'bee-sting' electrode.

Retropubic prostatectomy (Millin)

Using a low, curved transverse suprapubic Pfannenstiel incision, which includes the rectus sheath, the recti are split in the midline and retracted to expose the bladder. With the patient in the Trendelenburg position, the surgeon separates the bladder and the prostate from the posterior aspect of the pubis. In the space thus obtained, the anterior capsule of the prostate is incised with diathermy below the bladder neck, care being taken to obtain complete control of bleeding from divided prostatic veins by suture ligation. The prostatic adenoma is exposed and enucleated with a finger. A wedge is taken out of the posterior lip of the bladder neck to prevent secondary stricture in this region. The exposure of the inside of the prostatic cavity is good, and control of haemorrhage is achieved with diathermy and suture ligation of bleeding points before closure of the capsule over a Foley catheter (inserted per urethram) draining the bladder.

Transvesical prostatectomy

The bladder is opened, and the prostate enucleated by putting a finger into the urethra, pushing forwards towards the pubes to separate the lateral lobes, and then working the finger between the adenoma and the false capsule. In Freyer's operation (1901), the bladder was left open widely and drained by a suprapubic tube with a 16-mm lumen in order to allow free drainage of blood and urine. Harris (1934) advocated control of the prostatic arteries by lateral stitches inserted with his boomerang needle, the bladder wall was closed and the wound drained.

Perineal prostatectomy (Young)

This has now been abandoned for the treatment of BPH.

After treatment

Most urologists irrigate the bladder with sterile saline by means of a three-way Foley catheter for 24 hours or so.

Complications

Local

Haemorrhage is a major risk following prostatectomy whatever the surgical approach. Care should be taken in diathermising

Terence John Millin, 1903–1980, Surgeon, The Westminster Hospital, London, England, described the operation of retropubic prostatectomy in 1945.
 Hermann Johann Pfannenstiel, 1862–1909, Gynaecologist, Breslau, Germany, (now Wroclaw, Poland), described this incision in 1900.
 Friedrich Trendelenburg, 1844–1924, Professor of Surgery, Rostock (1875–1882), Bonn (1882–1895), and Leipzig (1895–1911), Germany. The Trendelenburg Position was first described in 1885.
 Frederic Eugene Basil Foley, 1891–1966, Urologist, Anker Hospital, St Paul, MN, USA.
 Sir Peter Johnston Freyer, 1852–1921, Surgeon, St Peter's Hospital for Stone, London, England.
 Samuel Harry Harris, 1881–1937, Urologist, Lewisham Hospital, Sydney, NSW, Australia.
 Hugh Hampton Young, 1870–1945, Director, The James Buchanan Brady Urological Institute, Baltimore, MD, USA.

arterial bleeding points after TURP; they are often better seen when the rate of inflow of fluid is decreased. In the recovery room, one should check that the bladder is draining adequately; if it is not, this may indicate that a clot is blocking the eye of the catheter. The bladder should be promptly washed out using strict aseptic technique. The catheter should be changed by the surgeon. Only rarely is it necessary to return the patient to the operating room.

Secondary haemorrhage tends to occur after the patient has been discharged. All men should be warned about this possibility and given appropriate advice to rest and to have a high fluid intake. It is usually minor in degree but if clot retention occurs, the patient will need to be readmitted, a catheter will have to be passed and the bladder washed out.

Perforation of the bladder or the prostatic capsule can occur at the time of transurethral surgery. This usually occurs from a combination of inexperience in association with a large prostate or heavy blood loss. If the field of vision becomes obscured by heavy blood loss, it is often prudent to achieve adequate haemostasis and abandon the operation, swallowing one's pride on the understanding that a second attempt may be necessary. A large perforation with marked extravasation may require the insertion of a small suprapubic drain. Rectal perforation should be extremely rare.

Sepsis

Bacteraemia is common even in men with sterile urine and occurs in over 50% of men with infected urine, prolonged catheterisation or chronic retention. Septicaemia can occur in these patients shortly after operation or when the catheter is removed. In men at high risk, the use of prophylactic antibiotics is recommended. Wound infection following open prostatectomy is common if a urethral catheter has been *in situ* for a number of days before the operation. The most worrying aspect of infection is the early rigor following surgery. If left undetected and untreated, this may progress to frank septicaemia with profound hypotension. A blood culture should be taken and antibiotics given parenterally, e.g. amoxicillin plus cefuroxime, or gentamicin.

Incontinence

Incontinence is inevitable if the external sphincter mechanism is damaged. The bladder neck is rendered incompetent by any prostatectomy and, therefore, an intact distal sphincter mechanism is essential for continence. Damage to the sphincter may occur at open prostatectomy and following transurethral surgery if the resection extends beyond the verumontanum. If pelvic floor physiotherapy is ineffective, then the only satisfactory treatment is the fitting of an artificial urinary sphincter. In some patients, detrusor instability contributes to the incontinence. The use of anti-cholinergic agents or imipramine or duloxetine may help.

Retrograde ejaculation and impotence

Impotence in men with good sexual function before surgery is uncommon, but retrograde ejaculation occurs commonly (> 50%) because of disruption to the bladder neck mechanism.

Urethral stricture

This may be secondary to prolonged catheterisation, the use of an unnecessarily large catheter, clumsy instrumentation or the presence of the resectoscope in the urethra for too long a period. These strictures arise either just inside the meatus or in the bulbar urethra. An early stricture can usually be managed by simple

bougination but, later on, it may be necessary to cut the densely fibrotic stricture with the optical urethrotome. The routine use of an Otis urethrotomy prior to TURP reduces the incidence of postoperative stricture.

Bladder neck contracture

Occasionally, a dense fibrotic stenosis of the bladder neck occurs following overaggressive resection of a small prostate. It may be due to the overuse of coagulating diathermy. Transurethral incision of the scar tissue is necessary.

Reoperation

It is now well known that, after 8 years, 15–18% of men with BPH will undergo repeat TURP (the rate after open prostatectomy is about 5%). The reasons include a technically imperfect primary procedure and a speculative repeat operation in men with symptoms who are cystoscoped after operation.

General complications

Death occurs in about 0.2–0.3% of men undergoing elective prostatectomy. In very elderly men, in men with prostate cancer admitted as an emergency with acute or chronic retention or in those with very large prostates, the 30-day death rate may be in the order of 1%.

Cardiovascular

Pulmonary atelectasis, pneumonia, myocardial infarction, congestive cardiac failure and deep venous thrombosis are all potentially life-threatening conditions that can affect this elderly and often frail group of men.

Water intoxication

The absorption of water into the circulation at the time of transurethral resection can give rise to congestive cardiac failure, hyponatraemia and haemolysis. Accompanying this, there is frequently confusion and other cerebral events often mimicking a stroke. The incidence of this condition has been reduced since the introduction of isotonic glycine for performing the resections and the use of isotonic saline for postoperative irrigation. The treatment consists of fluid restriction.

Osteitis pubis

This is rare.

Newer treatments

In general, newer, minimally invasive treatments occupy a position intermediate between TURP and drug treatment. In the last decade, technological innovations led to the introduction of novel minimally invasive treatments for prostatectomy. Tissue ablation techniques using hyperthermia and laser energy were associated with minimal morbidity and could often be performed as out-patient procedures. Many of the initial studies reporting treatment success were poorly designed and over a short duration. Longer-term follow-up and randomised controlled trials have failed to confirm significant benefit from these techniques. More recently, the holmium laser, a pulsed solid-state laser, has been used to enucleate the prostate adenoma. This approach involves excision of parts of the prostate using a cutting laser and

then morcellating the excised prostate fragments, which fall back into the bladder so that they can be removed. Morbidity with this procedure is low and short-term results favourable; long-term follow-up will be necessary to determine whether this treatment will have a role to play in the management of BOO. The green light laser is now being used to vaporise the prostate tissue, but has not yet been shown to be as durable as holmium laser treatment or TURP, because the amount of tissue removed is usually less.

Intraurethral stents (Fig. 73.14)

These devices are possibly helpful in the management of men with retention who are grossly unfit (classified by the American Society of Anesthesiologists as ASA grade IV). These men are rare cases.

BLADDER OUTFLOW OBSTRUCTION CAUSED BY THE BLADDER NECK

Aetiology

This condition usually occurs in men, but can rarely affect children of both sexes and women. It may be due to muscular hypertrophy or fibrosis of the tissues at the bladder neck following TURP.

Clinical syndromes

Owing to muscle hypertrophy or dyssynergia

Marion described a series of cases in which muscular hypertrophy of the internal sphincter in a young person had resulted in the development of a vesical diverticulum or hydronephrosis (Marion's disease or 'prostatism sans prostate'). It is thought that dyssynergic contraction of the smooth muscle of the bladder neck (bladder neck dyssynergia) may account for some cases of BOO.

Owing to fibrosis

The symptoms are similar to those of prostatic enlargement but are a consequence of scarring after TURP.

Treatment

The management of these patients depends on achieving an accurate diagnosis. For this, urodynamic investigation is often necessary, which should demonstrate raised voiding pressures and diminished flow rate.

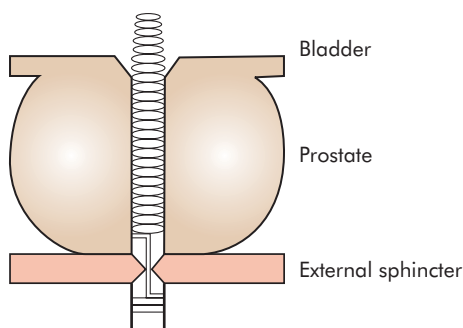

Figure 73.14 Diagram showing one type of prostatic stent *in situ*.

Jean Baptiste Camille Marion, 1869–1932, Professor of Urology, The Faculty of Medicine, Paris, France.

Drugs

The presence of α -adrenergic receptors in the region of the bladder neck and prostatic urethra allows pharmacological manipulation of the outflow to the bladder.

α -Blocking drugs

Alfuzosin, 2.5 mg b.d. to t.d.s. (to a total maximum of 10 mg day⁻¹), doxazosin, 1 mg nocte (up to a maximum of 8 mg day⁻¹), indoramin, 20 mg b.d. (increased to a total maximum of 100 mg day⁻¹ in divided doses), prazosin 500 mg b.d. (maintenance up to 2 mg day⁻¹) and terazosin, 1 mg nocte (to a total maximum of 10 mg day⁻¹), can be very useful, causing relaxation of the bladder neck. These drugs are not target specific, and patients must be warned of the possibility of postural hypotension.

Transurethral incision

Transurethral incision of the bladder neck is the operation of choice. Sometimes symptoms recur, but this is usually due to inadequate division of the fibres of the bladder neck.

Congenital valves of the prostatic urethra

See Chapter 74.

PROSTATIC CALCULI

Prostatic calculi are of two varieties: endogenous, which are common, and exogenous, which are comparatively rare.

An exogenous prostatic calculus is a urinary (commonly ureteric) calculus that becomes arrested in the prostatic urethra. This is considered in Chapter 71.

Endogenous prostatic calculi are usually composed of calcium phosphate combined with about 20% organic material.

Clinical features

Prostatic calculi are usually symptomless, being discovered on TRUS, on radiography of the pelvis, during prostatectomy or associated with carcinoma of the prostate or chronic prostatitis. In cases associated with severe chronic prostatic infection, the associated fibrosis and nodularity are difficult to differentiate from carcinoma. On radiographs or ultrasound scans, these stones are often seen to form a horseshoe (Fig. 73.15) or a circle.

Treatment of prostatic calculi

They usually require no treatment.

Conservative measures

Associated chronic prostatic infection may be treated by means of ciprofloxacin or trimethoprim.

Transurethral resection

Transurethral resection will often release small calculi as the strips of prostatic tissue are excised. Others are passed per urethram at a later date.

Corpora amyloacea

Corpora amyloacea are tiny calcified lamellated bodies found in the glandular alveoli of the prostates of elderly men and apes, but not in the prostates of animals lower in the phylogenetic scale than anthropoids. Corpora amyloacea are probably the forerunners of endogenous prostatic calculi.

Figure 73.15 Endogenous prostatic calculi.

CARCINOMA OF THE PROSTATE

Carcinoma of the prostate is the most common malignant tumour in men over the age of 65 years. In England and Wales in 2004, 30 000 men were registered and 10 000 died from it; the corresponding figures in the USA were 260 000 and 35 000 respectively. If histological section of prostates at autopsy is performed, increasingly frequent foci of microscopic prostate cancers are found with increasing age. These foci of prostate cancer have variable potential for progressing clinically to metastatic disease. About 10–15% of younger men who develop prostate cancer have a positive family history of the disease, but the aetiology is unclear. Throughout the world, rates of microscopic foci of prostate cancer are constant, but rates of clinically evident disease are low in men in Japan and China. Carcinoma of the prostate usually originates in the PZ of the prostate (Fig. 73.2), so ‘prostatectomy’ for benign enlargement of the gland confers no protection from subsequent carcinoma.

Pathology

Serial sections of prostates obtained at routine necropsy demonstrate prostate carcinoma in 25% of men between 50 and 65 years of age. The incidence in men over 80 years is in the region of 70% (Franks). Most of these neoplasms are tiny and (if life had continued) might have remained latent for years.

The following types of prostate cancer occur:

- microscopic latent cancer found on autopsy or at cystoprostatectomy;
- tumours found incidentally during TURP (T1a and T1b) or following screening by PSA measurement (T1c);

- early, localised prostate cancer (T2);
- advanced local prostate cancer (T3 and T4);
- metastatic disease, which may arise from a clinically evident tumour (T2, T3 or T4) or from an apparently benign gland (T0, T1), i.e. occult prostate cancer.

It should be noted that only the last two groups cause symptoms, and such tumours are not curable. Only screening or the treatment of incidentally found tumours can result in cure of the disease. The problem is that many such tumours would never progress during the patient’s lifetime; herein lies the problem with prostate cancer (Summary box 73.6).

Summary box 73.6

Prostate cancer detection

- The incidence has increased, and opportunistic PSA testing has enabled the detection of early-stage disease
- It is not yet clear whether national screening programmes for prostate cancer should be instigated
- Patients should be counselled about the investigations and treatment options available before a PSA test is performed

Screening for prostate cancer

The cancer detection rate using measurement of PSA is between 2% and 4%, and approximately 30% of men with an elevated PSA will have prostate cancer confirmed by biopsy. Unfortunately, 20% of men with clinically significant prostate cancer will have PSA values within the normal range. There is therefore controversy over the usefulness of PSA alone as a screening procedure. Currently, a number of prospective trials aimed at determining whether or not PSA testing reduces the disease-specific mortality of prostate cancer are under way. At present, in Europe, population-based screening is performed only within the confines of clinical trials.

Histological appearances

The prostate is a glandular structure consisting of ducts and acini; thus, the histological pattern is one of an adenocarcinoma. The prostatic glands are surrounded by a layer of myoepithelial cells. The first change associated with carcinoma is the loss of the basement membrane, with glands appearing to be in confluence. As the cell type becomes less differentiated, more solid sheets of carcinoma cells are seen. A classification of the histological pattern based on the degree of glandular de-differentiation and its relation to stroma has been devised by Gleason. Prostate cancers exhibit heterogeneity within tissue, and so two histological areas of prostate are each scored between 1 and 5. The scores are added to give an overall Gleason score of between 2 and 10; this (and the volume of the cancer) appears to correlate well with the likelihood of spread and the prognosis.

Local spread

Locally advanced tumours tend to grow upwards to involve the seminal vesicles, the bladder neck and trigone and, later, the

Donald F. Gleason, b. 1920, Pathologist, University of Minnesota, Minneapolis, MN, USA.

tumours tend to spread distally to involve the distal sphincter mechanism. Further upward extension obstructs the lower end of one or both ureters, obstruction of both resulting in anuria. The rectum may become stenosed by tumour infiltrating around it, but direct involvement is rare.

Spread by the bloodstream

Spread by the bloodstream occurs particularly to bone; indeed, the prostate is the most common site of origin for skeletal metastases, followed in turn by the breast, the kidney, the bronchus and the thyroid gland. The bones involved most frequently by carcinoma of the prostate are the pelvic bones and the lower lumbar vertebrae. The femoral head, rib cage and skull are other common sites.

Lymphatic spread

Lymphatic spread may occur (1) via lymphatic vessels passing to the obturator fossa or along the sides of the rectum to the lymph nodes beside the internal iliac vein and in the hollow of the sacrum and (2) via lymphatics that pass over the seminal vesicles and follow the vas deferens for a short distance to drain into the external iliac lymph nodes. From retroperitoneal lymph nodes, the mediastinal nodes and occasionally the supraclavicular nodes may become implicated.

Staging using the tumour, node, metastasis (TNM) system (Fig. 73.16)

- 1 *T1a, T1b and T1c*. These are incidentally found tumours in a clinically benign gland after histological examination of a prostatectomy specimen. T1a is a tumour involving less than 5% of the resected specimen; these tumours are usually well or moderately well differentiated. T1b is a tumour involving > 5% of the resected specimen. T1c tumours are impalpable tumours found following investigation of a raised PSA.
- 2 *T2a disease* presents as a suspicious nodule (Fig. 73.17) on rectal examination confined within the prostate capsule and involving one lobe. T2b disease involves both lobes.
- 3 *T3 tumour* extends through the capsule (T3a, uni- or bilateral extension. T3b, seminal vesical extension).

Figure 73.16 Tumour, node, metastasis (TNM) staging system for prostate cancer.

Figure 73.17 Transrectal ultrasound scan of a T2 nodule in the prostate.

- 4 *T4* is a tumour that is fixed or invading adjacent structures other than seminal vesicles – rectum or pelvic side wall (Summary box 73.7).

Summary box 73.7

The natural history of prostate cancer

This depends on the stage and grade of disease:

T1 and T2

- The progression rate of well-differentiated T1a prostate cancer is very low: 10–14% after 8 years. For moderately differentiated tumours, the rate is about 20%
- For T1b and T2 tumours, the rate is in excess of 35%

T3 and T4 (M0)

- About 50% progress to bony metastases after 3–5 years

M1

- The median survival of men with metastatic disease is about 3 years

Clinical features

Only advanced disease gives rise to symptoms, but even advanced disease may be asymptomatic. Symptoms of advanced disease include:

- BOO;
- pelvic pain and haematuria;
- bone pain, malaise, 'arthritis', anaemia or pancytopenia;
- renal failure;
- locally advanced disease or even asymptomatic metastases, which may be found incidentally on investigation of other symptoms.

Early prostate cancer is asymptomatic and may be found:

- incidentally following TURP for clinically benign disease (T1);
- as a nodule (T2) on rectal examination (Summary box 73.8).

Summary box 73.8

The presentation of men with prostate cancer

- Often men are asymptomatic, and detection is by opportunistic PSA testing
- Cancer is detected in men describing LUTS or may present with symptoms from metastatic disease

Rectal examination

Rectal examination can detect nodules within the prostate and advanced disease. TRUS may be used to access the local stage and can be combined with a needle core biopsy (Fig. 73.18). Irregular induration, characteristically stony hard in part or in the whole of the gland (with obliteration of the median sulcus), suggests carcinoma. Extension beyond the capsule up into the bladder base and vesicles (Fig. 73.19 demonstrates normal vesicles) is diagnostic, as is local extension through the capsule (Fig. 73.20).

Prostatic biopsy

If there is suspicion of prostate cancer, because of local findings, a raised PSA or metastatic disease, then a transrectal biopsy

Figure 73.18 Obtaining a specimen of prostatic tissue by means of a TruCut biopsy needle.

Figure 73.19 Transrectal ultrasound scan showing normal seminal vesicles.

Figure 73.20 Transrectal ultrasound scan showing local extension of a T3 prostate cancer.

using an automated gun is recommended. Routine local anaesthetic is used to decrease pain. About 10 systematic biopsy cores are obtained as well as biopsy of any suspicious areas. Broad-spectrum antibiotic cover is given to all patients to reduce the incidence of sepsis. If there are associated symptoms of BOO, then either:

- a TURP can be performed, which will provide diagnostic material and symptomatic relief;
- a transrectal biopsy can be carried out. If the diagnosis is positive and there is locally advanced disease, then hormone ablation can provide good symptomatic relief without the need for operation.

General blood tests

These are normal in early disease but, in metastatic disease, there may be leuco-erythroblastic anaemia secondary to extensive marrow invasion, or anaemia may be secondary to renal failure. There may be thrombocytopenia and evidence of disseminated intravascular coagulopathy with increased fibrinogen degradation products (FDPs).

Liver function tests

These will be abnormal if there is extensive metastatic invasion of the liver. The alkaline phosphatase may be raised from either hepatic involvement or secondaries in the bone. These can be distinguished by measurement of isoenzymes or gamma-glutamyltransferase.

Prostate-specific antigen

This is discussed earlier in this chapter. It is good at following the course of advanced disease. It is lacking in sensitivity and specificity in the diagnosis of early localised prostate cancer. Nevertheless, the finding of a PSA $> 10 \text{ nmol ml}^{-1}$ is suggestive of cancer and $> 35 \text{ ng ml}^{-1}$ is almost diagnostic of advanced prostate cancer. A decrease in PSA to the normal range following hormonal ablation is a good prognostic sign.

Acid phosphatase

Acid phosphatase has been superseded by measurement of PSA.

Radiological examination

Radiographs of the chest may reveal metastases in either the lung fields or the ribs. An abdominal radiograph may show the characteristic sclerotic metastases in lumbar vertebrae and pelvic bones (Fig. 73.21). The bone appears dense and coarse, and it is sometimes difficult to distinguish the change from that in Paget's disease of bone. Nevertheless, osteolytic metastases are very common in prostate cancer and may coexist with sclerotic ones. Information about the upper urinary tracts can be obtained by excretion urography or ultrasound.

Cross-sectional imaging with magnetic resonance imaging and TRUS

Magnetic resonance imaging (MRI) with a high tesla magnet (1.5–3 T) is the most accurate method of staging local disease.

Transrectal ultrasound scanning can also be used. Locally extensive disease (T2) can be diagnosed with increased sensitivity by TRUS (Fig. 73.17) compared with rectal examination, but many tumours will still be missed. This problem remains a real one in screening for early prostate cancer; in comparison with breast cancer, with mammography detecting 70–80% of tumours, TRUS plus rectal examination and measurement of PSA will detect only 30–50% of cancers that are known to be present on autopsy studies (although it may detect the larger, more significant cancers).

Bone scan

Once the diagnosis has been established, it would be normal to perform a bone scan as part of the staging procedure if the PSA were $> 10 \text{ nmol ml}^{-1}$ or if the biopsy showed high-grade cancer. If the PSA is $< 10 \text{ nmol ml}^{-1}$, then a bone scan would be performed only on clinical indications. The bone scan is performed by the injection of technetium-99m, which is then monitored using a gamma camera. It is more sensitive in the diagnosis of

Figure 73.21 Osseous metastases of the pelvic bones in carcinoma of the prostate (courtesy of L.N. Pyrah, Leeds, UK).

Sir James Paget, 1814–1899, Surgeon, St Bartholomew's Hospital, London, England, described osteitis deformans in 1877.

metastases (Fig. 73.22) than a skeletal survey, but false positives occur in areas of arthritis, osteomyelitis or a healing fracture.

Lymphangiography

This is no longer carried out. If accurate information is required, then pelvic lymphadenectomy can be performed by means of laparoscopic surgery.

Bone marrow aspiration

Sometimes, examination of the bone marrow will reveal the presence of metastatic carcinoma cells.

Treatment of carcinoma of the prostate

Early disease

Curative treatment can only be offered to patients with early disease (T1a, T1b, T1c and T2). T1a disease found incidentally at TURP is by definition low volume and usually well differentiated. This stage can often be managed by active surveillance, with 3- to 6-monthly digital rectal examination (DRE) and PSA measurement, considering treatment if there is evidence of disease progression. The options available for T1b, T1c and T2 disease need to take into account patient age, performance status and lifestyle preferences. The treatment of patients with advanced disease (T3, T4 or any M0) is only palliative (Summary box 73.9).

Figure 73.22 Bone scan showing multiple hot-spots suggestive of metastatic disease in a man with prostate cancer.

Summary box 73.9

Treatment and stage

- Treatment options for prostate cancer depend on stage of disease, life expectancy of the patient and patient preference
- PSA, DRE and biopsy Gleason grade are used to predict pathological stage
- Localised cancer can be treated by radical prostatectomy, radiation therapy and active monitoring
- Treatment of advanced disease is palliative, and hormone ablation remains the first-line therapy

Radical prostatectomy

Radical prostatectomy is only suitable for localised disease (T1 and T2) and should be carried out only in men with a life expectancy of > 10 years. Exclusion of metastases would require a negative bone scan, chest radiograph and a serum PSA < 20 nmol ml⁻¹. It is a procedure that should be performed only by experienced surgeons when there is a high chance of cure. It results in a high incidence of impotence, but a low incidence of severe stress incontinence (< 2%), which may require the fitting of an artificial urinary sphincter. It involves removal of the prostate down to the distal sphincter mechanism in addition to the seminal vesicles (Fig. 73.23). The bladder neck is reconstituted and anastomosed to the urethra. Recent modifications to this operation by Professor Patrick Walsh of the Johns Hopkins Hospital in Baltimore have led to the realisation that careful dissection in early-stage disease can lead to preservation of the neurovascular bundles that lie behind the prostate. This modification has led to the preservation of erectile function in about 60–70% of cases. Recently, laparoscopic approaches to radical prostatectomy, sometimes supported by robotic techniques, have been introduced.

Radical radiotherapy for early prostate cancer

External beam radiotherapy (EBRT) can be administered in fields that conform to the contours of the prostate, thereby limiting exposure of adjacent tissues. Survival rates following the

Figure 73.23 Radical prostatectomy specimen for a T2a prostate cancer. Preoperative PSA was 6 ng l⁻¹; postoperative levels remained undetectable at 8 years. The patient is fully continent.

Patrick C. Walsh, Professor of Urology, Johns Hopkins Hospital, Baltimore, MD, USA.

treatment of T1 and low-volume T2 disease are not greatly different from those following radical prostatectomy, although histological evidence of persistent tumour is found within the prostate in about 30% of treated patients. Patients with locally advanced disease (T3) may be treated by radiotherapy, but most urologists treat such patients by means of androgen ablation. The treatment requires the patient to attend hospital on a daily basis for between 4 and 6 weeks. Some local complications are inevitable, namely irritation of the bladder with urinary frequency, urgency and sometimes urge incontinence and similar problems affecting the rectum with diarrhoea and, occasionally, late radiation proctitis. Development of erectile dysfunction occurs less frequently than following radical prostatectomy, but is present in up to 30% of cases.

Brachytherapy

Under transrectal ultrasound guidance, radioactive seeds are permanently implanted into the prostate. A computer program converts accurate ultrasound measurements of the prostate gland to construct a plan of the gland. Under anaesthesia, the patient is placed in the lithotomy position and, according to the template plan, seeds are placed through transperineal needles. The radioisotopes commonly used are iodine-125 and palladium-103. These isotopes deliver an intense, confined radiation dose, which falls off rapidly to spare the surrounding structures. Brachytherapy is gaining widespread acceptance for the treatment of lower grade low-volume T1 disease. A major factor is the reduced perioperative complications and generally low morbidity. Long-term cancer survival results from institutions specialising in the procedure are encouraging.

Advanced disease

There is still debate about the timing of androgen ablation treatment in patients with locally advanced or metastatic disease without symptoms. The options are androgen deprivation at diagnosis or careful review, reserving active treatment for the later development of symptoms. Patients with poorly differentiated disease are at risk of a catastrophic event such as spinal cord compression; in these patients, early androgen ablation can prolong the time to complications. Also, patients with local or general symptoms should be offered androgen deprivation.

Orchidectomy

Orchidectomy is performed to carry out androgen ablation in the treatment of locally advanced (T3 or T4) disease or of metastatic disease. In 1941, prostate cancer was shown to be responsive to such treatment by Charles Huggins, the only urologist to win a Nobel Prize. Bilateral orchidectomy, whether total or subcapsular, will eliminate the major source of testosterone production.

Medical castration

Medical forms of androgen ablation have been available since the discovery of stilbestrol. The other commonly available treatment to reduce testosterone levels to the castrate range is LHRH agonists. These agents initially stimulate hypothalamic LHRH receptors but, because of their constant presence (rather than the

Charles Brenton Huggins, 1901–1997, Professor of Surgery, The University of Chicago, IL, USA, shared the 1966 Nobel Prize for Physiology or Medicine for his work on cancer of the prostate.

normal diurnal rhythm), they then downregulate them, resulting in cessation of pituitary LH production and, hence, a decrease in testosterone production. In the first 10 days or so, serum testosterone levels may increase, and it is wise to give flutamide, bicalutamide or cyproterone acetate for this period. LHRH agonists may be given by monthly or 3-monthly depot injection.

Other treatments that block the androgen receptor have become available recently. Cyproterone acetate also has some progestogenic effect, while flutamide and bicalutamide are pure anti-androgen. In general, oral anti-androgen monotherapy has not been shown to be as good as LHRH agonists or orchidectomy.

Complete androgen blockade

Complete androgen blockade has been advocated as being likely to result in increased life expectancy and an increased time to progression in a fitter sub-group of men with advanced prostate cancer. The concept is that of abolishing the testicular secretion of testosterone by means of orchidectomy or the use of LHRH therapy and then inhibiting the effects of adrenal androgenic steroids by means of androgen receptor blockade with flutamide, bicalutamide or the use of cyproterone acetate. Recent overviews of randomised trials do not confirm earlier reports of effectiveness.

General radiotherapy

Radiotherapy for symptomatic metastases is an excellent form of palliative treatment, often producing dramatic pain relief in men with hormone-relapsed prostate cancer that can last up to 6 months. When multiple sites are involved, intravenous radiopharmaceuticals such as strontium-89 can be employed. Strontium is a bone-seeking isotope that delivers effective radiotherapy to metastatic areas. It appears to be as effective as hemibody irradiation in the treatment of men with metastatic hormone-relapsed disease; however, the duration of response has been disappointing.

Chemotherapy

Cytotoxic agents in the treatment of these men have proved disappointing, but whether this is because the tumour is inherently insensitive or because these elderly men will not tolerate effective doses is uncertain. Recent trials of docetaxel have shown improvements in survival, but only by a few months.

Summary of treatment

- 1 *Incidentally diagnosed T1a and T1b disease.* For men in their 70s, conservative treatment would usually be the correct approach. Radical surgical treatment might be considered in the younger (< 70 years) man with this form of the disease, although even in this group, some men will elect to pursue a conservative course when counselled about risks vs. benefits.
- 2 *Localised T1c and T2 disease.* In younger, fitter men (< 70 years), this may be treated by radical prostatectomy or radical radiotherapy. Active monitoring remains an option, particularly for more elderly patients with low-grade disease. In the elderly patient with outflow obstruction, transurethral resection with or without hormone therapy is indicated. The benefit of radical treatment over a conservative approach is likely to be about 25%, given that progression to metastatic disease is of this order of magnitude after 10 years.
- 3 *Locally advanced T3 and T4 disease.* These patients are at significant risk of disease progression. Early androgen ablation is

favoured if close follow-up is not possible. For the sexually active, a careful conservative approach with the adoption of androgen ablation when symptoms arise is reasonable. Androgen ablation coupled with radiotherapy is standard treatment for younger men with T3 disease.

- 4 *Metastatic disease.* Once metastases have developed, the outlook is poor. For patients with symptoms, there is no dilemma; androgen ablation will provide symptomatic relief in over two-thirds of patients. For patients with asymptomatic metastases, the timing of treatment is less clear. Systemic chemotherapy with docetaxel should be considered in younger, fitter men.

PROSTATITIS

In both acute and chronic prostatitis, the seminal vesicles and posterior urethra are usually also involved.

Acute prostatitis

Aetiology

Acute prostatitis is common, but underdiagnosed. The usual organism responsible is *Escherichia coli*, but *Staphylococcus aureus*, *Staphylococcus albus*, *Streptococcus faecalis*, *Neisseria gonorrhoeae* or *Chlamydia* may be responsible. The infection may be haematogenous from a distant focus, or it may be secondary to acute urinary infection.

Clinical features

General manifestations overshadow the local: the patient feels ill, shivers, may have a rigor, has 'aches' all over, especially in the back, and may easily be diagnosed as having influenza. The temperature may be up to 39°C. Pain on micturition is usual, but not invariable. The urine contains threads in the initial voided sample, which should be cultured. Perineal heaviness, rectal irritation and pain on defaecation can occur; a urethral discharge is rare. Frequency occurs when the infection involves the bladder. Rectal examination reveals a tender prostate; one lobe may be swollen more than the other, and the seminal vesicles may be involved. A frankly fluctuant abscess is uncommon.

Treatment

Treatment must be rigorous and prolonged or the infection will not be eradicated and recurrent attacks may ensue. Spread of infection to the epididymides and testes may occur. Prolonged treatment with an antibiotic that penetrates the prostate well is indicated (trimethoprim or ciprofloxacin).

Prostatic abscess

In addition to the foregoing symptoms and signs, the advent of a prostatic abscess is heralded by the temperature rising steeply with rigors. Antibiotics disguise these features. Severe, unremitting perineal and rectal pain with occasional tenesmus often cause the condition to be confused with an anorectal abscess. Nevertheless, if a rectal examination is performed, the prostate will be felt to be enlarged, hot, extremely tender and perhaps fluctuant. Retention of urine is likely to occur and, in such men, suprapubic catheterisation is best.

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wrocław, Poland).

Treatment

The abscess should be drained without delay:

- 1 The abscess can be drained by perurethral resection – unroofing the whole cavity.
- 2 The perineal route is rarely indicated unless there is marked periprostatic spread.

Chronic prostatitis

Many urologists find the diagnosis of chronic prostatitis and ‘prostatodynia’ very difficult, for many men present with perigenital pain, testicular pain, prostatic pain exacerbated by sexual intercourse or pain that apparently renders sexual intercourse out of the question. Psychosexual dysfunction in such patients may be the underlying problem. The diagnosis of chronic prostatitis has to be based on:

- persistent threads in voided urine;
- prostatic massage showing pus cells with or without bacteria in the absence of urinary infection.

Aetiology

This is thought to be the sequel of inadequately treated acute prostatitis. While pus is present in the prostatic secretion, the responsible organism is often difficult to find. Other organisms such as *Chlamydia* species may be responsible for chronic abacterial prostatitis.

Clinical features

The clinical features are extremely varied. Only men with symptoms of posterior urethritis, prostatic pain and perigenital pain accompanied by intermittent fever and pus cells or bacteria in the post-prostatic massage specimen should be diagnosed as having chronic prostatitis.

Diagnosis

The three-glass urine test is valuable. If the first glass with the initial voided sample shows urine containing prostatic threads, prostatitis is present.

Rectal examination of the prostate may be normal or may show a soft, boggy and tender prostate.

Examination of the prostatic fluid obtained by prostatic massage should show pus cells and bacteria.

Urethroscopy may reveal inflammation of the prostatic urethra, and pus may be seen exuding from the prostatic ducts. The verumontanum is likely to be enlarged and oedematous. In many men with the symptoms described above, all investigations are normal.

Treatment

Antibiotic therapy should be administered only in accordance with bacteriological sensitivity tests. Trimethoprim penetrates well into the prostate. If *Trichomonas* or anaerobes are the responsible agent, a rapid response is obtained from administration of flagyl (metronidazole, 200 mg t.d.s. for 7 days to both partners). If *Chlamydia* is suspected, doxycycline is the antibiotic treatment of choice. It is uncertain whether prostatic massage helps in eradicating the infection.

Prostatodynia

This diagnosis is made by the presence of perigenital pain in the absence of any objective evidence of prostatic inflammation.

Whether the syndrome has any relationship with the prostate is unclear.

TUBERCULOSIS OF THE PROSTATE AND SEMINAL VESICLES

Tuberculosis of the prostate and seminal vesicles is rare and associated with renal tuberculosis. In 30% of cases, there is a history of pulmonary tuberculosis within 5 years of the onset of genital tuberculosis.

Tuberculosis of one or both seminal vesicles may be found when examining a patient with chronic tuberculous epididymitis, no symptoms being referable to the internal genitalia. On rectal examination, the affected vesicle is found to be nodular.

When the prostate is involved, rectal examination reveals nodules in one or both lateral lobes. Patients with tuberculous prostatitis usually present with the following:

- urethral discharge;
- painful, sometimes blood-stained, ejaculation;
- mild ache in the perineum;
- infertility;
- dysuria;
- abscess formation.

Special forms of investigation

Radiography sometimes displays areas of calcification in the prostate and/or the seminal vesicles.

Bacteriological examination of the seminal fluid yields positive cultures for tubercle bacilli.

Treatment

The general treatment is that for tuberculosis. If a prostatic abscess forms, it should be drained transurethraly.

SEMINAL VESICLES**Acute seminal vesiculitis**

Acute seminal vesiculitis occurs in association with prostatitis. Prior to the antibiotic treatment of gonorrhoea, gonococcal vesiculitis was common.

Chronic seminal vesiculitis

Chronic seminal vesiculitis usually presents with haematospermia and pain on intercourse. TRUS demonstrates the features of distension and thickening and the presence of turbid fluid. The treatment is the same as for chronic prostatitis.

Tuberculous seminal vesiculitis

The clinical features and treatment have been discussed above.

Diverticulum of the seminal vesicle

Diverticulum of the seminal vesicle occurs occasionally. In such cases, the kidney of that side is absent, and the diverticulum represents an abortive ureteric bud. It is a cause of persistent infection.

Cyst of the seminal vesicle

A cyst of the seminal vesicle is uncommon and rarely requires treatment. It may be removed by dissection through an incision

similar to that for perineal prostatectomy, if it is large or giving rise to symptoms.

Urethra and penis

CHAPTER

74

LEARNING OBJECTIVES

To recognise and understand:

- The common congenital abnormalities of the urethra
- The management of urethral trauma and urethral stricture
- The common diseases of the penis and the principles of their surgical management

THE MALE URETHRA

Anatomy

The male urethra is a tubular structure extending from the bladder neck to the external urinary meatus at the tip of the glans penis. During its course through the prostate it is compressed from each side by the lateral lobes of the prostate, giving it a slit-like configuration. The verumontanum is a small hillock of tissue indented at its crown by a pit called the utriculus masculinus. The verumontanum marks the proximal extent of the external urethral sphincter and is an important landmark for urologists performing transurethral resection of the prostate. The distal urethra is invested by erectile tissue of the corpus spongiosus. It is normally flattened anteroposteriorly but distends when filled with fluid. The most proximal section distends most and is known as the urethral bulb.

The external urethral sphincter is composed of striated muscle within the urethral wall. In the female it extends for almost the whole length of the short urethra.

Congenital abnormalities

Urethral stricture

This rare condition may be associated with duplication of the urethra. Usually, symptoms are delayed until adolescence, when it may be indistinguishable from a stricture due to unrecognised urethral injury in childhood. A single treatment by optical urethrotomy or dilatation is usually effective.

Posterior urethral valves

These folds of urothelium cause obstruction to the urethra of boys. They are usually just distal to the verumontanum but they may be within the prostatic urethra. They are flap valves and so, although urine does not flow normally, a urethral catheter can be passed without difficulty. Dilatation of the urinary tract now commonly leads to diagnosis by ultrasound scanning before birth. Other cases present with urinary infection in the neonatal period. Sometimes the valves are incomplete and the patient is symptom

free until adolescence or adulthood. Posterior urethral valves need to be detected and treated as early as possible to avoid the development of renal failure.

The valves can be difficult to see on urethroscopy because the flow of irrigant sweeps them into the open position. If the bladder is filled with contrast medium, the dilatation of the urethra above the valves can be demonstrated on a voiding cystogram. The bladder is hypertrophied and often shows diverticula. Typically, there is vesicoureteric reflux into dilated upper tracts (Summary box 74.1).

Summary box 74.1

Congenital urethral valves

- Posterior urethral valves cause obstruction to the urinary tract in young boys
- Antenatal ultrasound scanning typically shows urinary tract dilatation in affected boys

Treatment

A suprapubic catheter is inserted to relieve the back pressure and allow the effects of renal failure to subside before definitive treatment by transurethral resection of the valves.

Hypospadias (see also Chapter 6)

Hypospadias occurs in one in 200–300 boys and is the most common congenital malformation of the urethra. The external meatus opens on the underside of the penis or the perineum, and the ventral aspect of the prepuce is poorly developed ('hooded prepuce').

Hypospadias is classified according to the position of the meatus:

- *Glanular hypospadias*. This is common and does not usually require treatment. The normal site of the external meatus is marked by a blind pit, although it occasionally connects by a channel to the ectopic opening on the underside of the glans.

- *Coronal hypospadias*. The meatus is placed at the junction of the underside of the glans and the body of the penis.
- *Penile and penoscrotal hypospadias*. The opening is on the underside of the penile shaft (Fig. 74.1).
- *Perineal hypospadias*. This is the most severe abnormality. The scrotum is bifid and the urethra opens between its two halves. There may be testicular maldescent, which may make it difficult to determine the sex of the child.

The more severe varieties of hypospadias represent an absence of the urethra and corpus spongiosum distal to the ectopic opening. The absent structures are represented by a fibrous cord, which deforms the penis in a downward direction (chordee).

Treatment

Glanular hypospadias does not need treatment unless the meatus is stenosed, in which case a meatotomy is performed. Surgery is indicated for other forms of hypospadias to improve sexual function, to correct problems with the urinary stream and for cosmetic reasons. A variety of plastic surgical procedures is described to correct the chordee and to re-site the urethral opening. Most procedures use preputial skin and so circumcision should be avoided until the hypospadias has been repaired. Operations for hypospadias are best performed by a paediatric urologist (Summary box 74.2).

Summary box 74.2

Hypospadias

- Avoid circumcision as prepuce may be used in procedures to correct the abnormality

Figure 74.1 Penile hypospadias. The patient passes urine through the orifice demonstrated by the probe.

Epispadias

Epispadias is very rare. In penile epispadias, the opening on the dorsum is associated with upward curvature of the penis (Fig. 74.2). Epispadias usually coexists with bladder exstrophy and other severe developmental defects.

Injuries to the male urethra

Rupture of the bulbar urethra

There is a history of a blow to the perineum, usually due to a fall astride a projecting object. In the days of sailing ships, the common cause was falling astride a spar; the modern equivalent is seen among workers losing their footing on scaffolding. Cycling accidents, loose manhole covers (Fig. 74.3) and gymnasium accidents astride the beam account for a number of cases.

Clinical features

The signs of a ruptured bulbar urethra are retention of urine, perineal haematoma and bleeding from the external urinary meatus (Summary box 74.3).

Figure 74.2 Glandular epispadias.

Figure 74.3 The type of accident that results in a ruptured bulbar urethra (after V.J. O'Connor).

Summary box 74.3

Urethral injury

Suspect urethral injury after blunt perineal trauma when:

- The man goes into retention
- There is massive perineal swelling
- There is blood at the urethral meatus

Preliminary assessment and treatment

The patient should be treated with appropriate analgesic drugs. He should be discouraged from passing urine if rupture of the urethra is suspected. A full bladder should be drained with a catheter placed by percutaneous suprapubic puncture (Fig. 74.4). This reduces urinary extravasation and allows investigations to establish the extent of the urethral injury. If the patient has passed urine when first seen and there is no extravasation, the rupture, if any, is partial and a catheter is not needed. In any case, it is probably wise to administer a course of prophylactic antibiotics.

Treatment

The main worry is that injudicious urethral catheterisation will convert a partial tear into a complete transection of the urethra. The initial treatment described above is to be recommended for those who go into urinary retention after the accident, especially if there is bleeding from the urethra. More information may be obtained by an ascending urethrogram or even a flexible cystoscopy to assess the injury. Very occasionally, if the facilities for passing a percutaneous suprapubic catheter are not available, it may be permissible to try to pass a soft, small-calibre urethral catheter without force. This may allow a few patients to avoid the open placement of a suprapubic tube into the bladder.

If the urethral tear is complete, the suprapubic catheter should remain until arrangements can be made to repair it. Some surgeons advocate early open repair of the urethra with excision of the traumatised section and spatulated end-to-end reanastomosis of the urethra (Fig. 74.5). Others wait longer before embarking upon a repair operation but may attempt to find a way across the gap in the urethra using a urethroscope. This allows a urethral catheter to be placed so that the ends of the urethra are aligned while healing occurs (Summary box 74.4).

Figure 74.4 Kit for percutaneous suprapubic drainage of the bladder.

Figure 74.5 Open repair of a ruptured bulbar urethra.

Summary box 74.4

Urethral trauma

- It is safest to insert a suprapubic catheter before referral to a urologist

Complications

Subcutaneous extravasation of urine occurs in complete rupture if the patient attempts to pass urine.

Stricture is a common sequel to urethral trauma, whether there is a partial or complete tear or simply periurethral bruising. Infection may also play a part.

Rupture of the membranous urethra

Intrapelvic rupture of the membranous urethra occurs near the apex of the prostate (Fig. 74.6). Like extraperitoneal rupture of the bladder, it may be caused by penetrating wounds, but it is most usually a result of pelvic fracture.

Fracture of the pubic and ischial rami is most likely to result when sudden force is applied to one lower limb in a car accident or in landing on one leg after falling from a height. There is an associated disruption of the sacroiliac joint so that one half of the pelvis and ischiopubic ramus is pushed up above the other. This applies a traction force on the symphysis pubis, which is firmly bound by ligaments to the back of the symphysis pubis. The torn ends of the urethra may be widely displaced by this type of injury.

In another type of pelvic fracture the patient suffers a front-to-back compression of the pelvis in a blow directly from the front. A 'butterfly fracture' of the pubic rami on each side occurs. When the compressive force is relieved, the pubic fragment springs back so that the ends of the torn urethra are close. About 10–15% of cases of fractured pelvis have associated urethral injury.

Clinical features

The most common causes of pelvic fracture are road traffic accidents, severe crush injuries and falls. Often, the management of

Figure 74.6 Intrapelvic rupture of the urethra. Note the displacement of the bladder.

injuries to the head, thorax and abdomen and long bones must take precedence and the overriding priority is to keep the patient alive by appropriate resuscitation.

A suprapubic catheter should be inserted as soon as practicable. The type of urethral injury can often be deduced from the plain radiograph – a major urethral disruption is almost certain if there is significant displacement of the pubic bones. If the prostate is displaced, it may be out of reach or ‘high’ on rectal examination. An ascending urethrogram with water-based contrast may be justified if there is doubt.

There may be associated injury to the bladder with either an intraperitoneal or extraperitoneal rupture. The former is associated with the onset of peritonitis and, if suspected, demands exploration and repair of the bladder even if laparotomy is not indicated by other injuries. Extraperitoneal rupture of the bladder causes symptoms that are difficult to distinguish from those of rupture of the membranous urethra. There is pain, bruising and dullness to percussion above the umbilicus. If there is a significant bladder rupture it must be repaired, a suprapubic catheter inserted and the retroperitoneal space drained (Summary box 74.5).

Summary box 74.5

Lower urinary tract injury in pelvic trauma

When the lower urinary tract is injured in a patient who has suffered multiple trauma:

- Definitive treatment can usually be deferred if a suprapubic catheter is in place
- Exploration is needed if there is evidence of rupture of the bladder, especially if it is intraperitoneal

Complications

Stricture The main complication of urethral trauma is urethral stricture. When the injury is severe and the disrupted ends of the urethra are far apart, the stricture is likely to be very difficult to treat. Because of this worry, some surgeons urge that an attempt should be made to realign the urethra as soon as the emergency is over. Often this will coincide with an attempt to reposition the pelvic fragments with the possibility of external fixation. If a way through the stricture can be found with a flexible or rigid urethroscope, a urethral catheter may be inserted. Alternatively, an open repair of the urethra can be attempted. Some experts prefer to allow a longer period of recovery before attempting to correct the urethral injury.

Many of these patients need a full-scale urethroplasty, especially if the ends of the urethra are poorly aligned. Often the ends of the urethra are widely displaced and there is extensive fibrosis and even ectopic calcification the gap. Occasionally, the ends are so far apart that they can be apposed only by cutting away the pubic bone. The management of a severe urethral stricture should be in the hands of a specialist.

Urinary incontinence If the external urethral sphincter is destroyed, continence of urine will depend upon the bladder neck mechanism. Subsequent surgical manoeuvres such as prostatectomy, which destroys the bladder neck, may cause incontinence.

Impotence Erectile impotence is common after pelvic fracture with urethral injury and is presumed to be the result of damage to

the nerve supply of the penis. Some patients can achieve erection with prostaglandin injections, a vacuum device or an orally active agent such as sildenafil.

Orthopaedic For management of the fractured pelvis see Chapter 27.

Extravasation of urine Superficial extravasation is likely with complete rupture of the bulbar urethra and in ruptured urethral abscess. The extravasated urine is confined in front of the mid-perineal point by the attachment of Colles’ fascia to the triangular ligament and by the attachment of Scarpa’s fascia just below the inguinal ligament. The external spermatic fascia stops it getting into the inguinal canals. Extravasated urine collects in the scrotum and penis and beneath the deep layer of superficial fascia in the abdominal wall. Treatment is by urgent operation to drain the bladder by suprapubic cystostomy. Deep extravasation occurs with extraperitoneal rupture of the bladder or intrapelvic rupture of the urethra. It can also occur if the ureter is damaged or if there is perforation of the prostatic capsule or bladder during transurethral resection. Urine extravasates in the layers of the pelvic fascia and the retroperitoneal tissues. Treatment is by suprapubic cystostomy and drainage of the retroperitoneal space.

Inflammation of the urethra

Inflammatory conditions of the urethra include:

- meatal ulcer;
- urethritis:
 - gonococcal urethritis;
 - non-specific urethritis;
 - Reiter’s disease.

Ulceration of the urethral meatus

Meatal ulcer is quite common in circumcised boys and may be delayed for up to 2 years from circumcision. Lack of protection by the prepuce seems to be the excitatory cause, with friction from clothing and ammoniacal dermatitis contributory factors. Devascularisation caused by ligation of the frenular artery may possibly play a part. The ulcer forms a scab that blocks the meatus and the child can pass urine only by bursting the scab. This hurts, so the boy screams; a tiny amount of blood may be passed as well. The process causes fibrosis, which can result in an acquired pinhole meatus. Meatal stenosis may also follow hypospadias repair or be a complication of phimosis caused by balanitis xerotica obliterans. With a pinhole meatus, spraying or dribbling is common and there is a risk of chronic retention of urine with renal impairment.

Treatment

Local measures to soften the scab and alkalise the urine are often curative. A few need meatotomy. The meatus is opened by cutting on to a fine probe placed in the anterior urethra. The cut edges of urothelium and skin are sewn together with an

Antonio Scarpa, 1747–1832, Professor of Anatomy, Pavia, Italy.

Hans Conrad Julius Reiter, 1881–1969, President of the Health Service and Honorary Professor of Hygiene, Berlin, Germany, described this condition in 1916.

absorbable suture. If the stenosis recurs a skin flap can be laid in as a meatoplasty to widen the meatus (Fig 74.7).

Gonorrhoeal urethritis

Gonorrhoea is a sexually transmitted disease caused by *Neisseria gonorrhoeae* (gonococcus), a Gram-negative kidney-shaped diplococcus that infects the anterior urethra in men, the urethra and cervix in women and the oropharynx, rectum and anal canal in both sexes, but especially men.

Gonorrhoea in men usually declares itself by urethral discomfort and urethral discharge up to 10 days after exposure. There is often scalding dysuria. In some there may be no symptoms other than slight discharge.

Investigations

Pus and gonococci are present in the Gram-stained urethral smear. The passage of pus in the first part of the urinary stream can be demonstrated as haziness in the first glass of a two-glass test. Treatment should not wait upon the results of urethral culture when the clinical picture and urethral smear are typical.

Complications

Complications are uncommon in the UK and are all prevented by effective treatment. Local complications include posterior urethritis, prostatitis (acute or chronic), acute epididymo-orchitis, periurethral abscess and urethral stricture. Gonococcal arthritis, iridocyclitis, septicaemia and endocarditis are even more unusual.

Treatment

Treatment is with antibiotics, usually ciprofloxacin or penicillin, and will usually be in the hands of a genitourinary physician.

Contact tracing is important in controlling the spread of the disease.

Gonorrhoea in women affects primarily the urethra and cervix and is often symptomless. It can never be diagnosed on clinical grounds alone. Almost three-quarters of all female patients attend initially as a result of contact tracing. Symptoms, which are present in 50% or less, consist of a mild dysuria or slight urethral discharge, which can go unnoticed by the patient. If Skene's tubules are emptied by milking the urethra against the posterior pubic ramus, a bead of pus may appear at the urethral meatus. There may be some reddening or erosion of the cervix with a mucopurulent cervical plug, but copious vaginal discharge is more likely to be due to concomitant trichomonal vaginitis.

Complications

Gonococcal proctitis occurs in at least 60–70% of cases and is usually symptomless. About 10% suffer from salpingitis, which, if bilateral, may lead to infertility.

Gonorrhoea in the newborn

This is now rare but it used to be an important cause of blindness.

Non-specific urethritis (synonym: non-gonococcal urethritis)

This is a form of urethritis that is diagnosed by exclusion of gonorrhoea and other known infections. Some 40% of cases are due to *Chlamydia trachomatis* and some are shown to be caused by *Ureaplasma urealytica*. The causative agent in up to 50% of cases is unknown.

Clinical features

Dysuria and a mucopurulent urethral discharge appear up to 6 weeks after sexual intercourse. The urine is usually grossly clear but may contain 'threads' or pus cells. Epididymitis is not uncommon and urethral stricture rarely results. In women, the condition presents as a form of urethrotigonitis and may be very resistant to diagnosis.

Treatment

Treatment with oxytetracycline or doxycycline is usually effective although relapse is common, especially in men, in whom the prostate may act as a reservoir of infection. It is important to treat both partners as reinfection is probable if this is not done. Urethroscopy is not indicated.

Reiter's disease

Reiter's disease (synonym: sexually acquired reactive arthritis) is usually sexually transmitted in the UK but elsewhere is more commonly dysenteric in origin. Subacute urethritis 4–6 weeks after contact is associated with a clear, viscid discharge that is free from organisms. A few days later, conjunctivitis, unilateral then bilateral, occurs in 50% of cases. In more severe cases there is anterior uveitis. Usually, in 10 days to 2 weeks, arthritis supervenes, but it is not an invariable feature of the condition. Another concurrent manifestation is keratoderma blennorrhagicum, consisting of nodules, vesicles and pustules, frequently found on the sole of the foot (Fig. 74.8).

Figure 74.7 (a–e) Meatoplasty. The strictured meatus is incised and a flap of penile skin is laid in to form a funnel-shaped meatal opening.

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wrocław, Poland).

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900), and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

Alexander Johnston Chalmers Skene, 1828–1900, Professor of Gynecology, Long Island Hospital, Brooklyn, New York, NY, USA.

Figure 74.8 Reiter's disease – keratoderma blennorrhagicum of the heel.

Differential diagnosis

This is principally from gonorrhoea, which must be excluded by blood culture. In Reiter's disease, the urethritis and arthritis are milder and the incubation period is longer than that of gonorrhoea.

Prognosis

The urethritis and conjunctivitis frequently subside after a few weeks but the arthritis may persist for months. Severe anterior uveitis and frequently recurrent attacks suggest a poor outlook.

Treatment

The ophthalmic complications are treated with eye baths and shades. Mydriatics and topical steroids are indicated for iritis. Other symptoms may prove difficult to control, and patients with severe disease should be under the care of a specialist in genitourinary medicine.

Urethral stricture

Causes of urethral stricture

The causes of urethral stricture are:

- inflammatory:
 - post-gonorrhoeal;
- congenital;
- traumatic;
- instrumental:
 - indwelling catheter;
 - urethral endoscopy;
- postoperative:
 - open prostatectomy;
 - amputation of penis.

Post-gonorrhoeal stricture

This is less common since the introduction of effective antibiotic treatment for gonorrhoea. The stricture is most commonly in the bulbar urethra but post-meatal strictures are also seen.

Pathology Infection in the periurethral glands persists after inadequately treated gonorrhoea. The infection spreads to cause a periurethritis, which heals by fibrosis. Most strictures appear within 1 year of infection but may not cause difficulty in micturition for 10–15 years.

Clinical features The first symptoms are usually those of bladder outflow obstruction with straining to void and poor urinary stream. The relative youthfulness of the patient often rules out prostatic enlargement, which characteristically occurs after the age of 50. As the stream becomes narrower micturition is prolonged and is followed by dribbling as a result of urine trickling from the dilated urethra proximal to the stricture. Urinary frequency by day and night is also common and is due to incomplete bladder emptying, infection or both.

A well-established stricture may be palpable as scarring along the line of the urethra. If the stricture is tight enough, the patient will go into acute retention. If this happens there is a danger that ham-fisted attempts to pass a urethral catheter will result in a false passage. If a patient has gone into retention because of a urethral stricture, its lumen will be too narrow to pass even a tiny catheter.

Urethroscopy allows the stricture to be viewed as a circumferential scar (Fig. 74.9). Openings of false passages commemorate misguided attempts to pass a urethral catheter.

Urethrography using a water-miscible gel containing contrast medium will show the extent and severity of the stricture or failure of the medium to pass beyond the tightness, indicating complete stenosis (Figs 74.10 and 74.11).

Figure 74.9 Urethroscopic appearance of a urethral stricture.

Figure 74.10 Ascending urethrogram showing urethral stricture of the membranous urethra following fracture of the pelvis.

Figure 74.11 Gonorrhoeal stricture of the bulbar urethra. Note that some of the contrast has entered the penile veins.

Congenital stricture

This has been considered previously.

Traumatic stricture

The stricture that follows neglected or untreated rupture of the membranous urethra is sometimes a complete loss of continuity. In patients with a traumatic stricture, a transpubic urethroplasty is often needed to bridge the gap.

Post-instrumental stricture

This follows endoscopy or catheterisation and may affect any part of the urethra. Some surgeons recommend prophylactic dilatation or urethrotomy before transurethral surgery to try to avoid this complication. Some cases of stricture seem to be due to sensitivity to chemicals from a catheter, but most are the result of a combination of trauma, infection and pressure necrosis.

Stricture after prostatectomy

Postoperative stricture follows 4% of prostatectomies, irrespective of the method employed. The stricture is usually in the proximal part of the prostatic urethra and is also known as bladder neck stenosis. If it cannot be managed by dilatation, bladder neck stenosis should be treated by transurethral incision and resection of the stricture.

Postoperative stricture is also a complication of amputation of the penis (see below).

Complications of urethral stricture

Complications include:

- retention of urine;
- urethral diverticulum;
- periurethral abscess;
- urethral fistula;
- hernia, haemorrhoids and rectal prolapse caused by abdominal straining to void urine.

Treatment of urethral stricture

Treatment of urethral stricture is by:

- dilatation:
 - gum-elastic bougie;
 - filiform and follower;
 - metal sounds;

- self-dilatation with Nélaton catheter;
- urethrotomy:
 - internal visual urethrotomy;
- urethroplasty:
 - excision and end-to-end anastomosis;
 - patch urethroplasty.

Dilatation is the old treatment for stricture. Under aseptic conditions, the urethra is stretched using graduated dilators. With care and gentleness the procedure can be performed under local urethral anaesthesia with lignocaine gel. The drawback of dilatation is that it is performed 'blind', so there is always a danger of making the stricture worse by causing a false passage. This is most likely with an inexperienced operator unfamiliar with the complexities of an individual patient's urethra. With any urinary tract instrumentation, infection is a danger, and fatal septicaemia can follow a supposedly straightforward dilatation. Urethral dilatation still has a place in elderly men with short strictures that recur infrequently. In these patients, occasional bouginage may be preferable to more complex procedures. Some patients can dilate their own urethras by intermittently passing a soft Nélaton catheter (Summary box 74.6).

Summary box 74.6

Urethral dilatation

- Urethral dilatation for stricture is liable to cause additional urethral damage if performed inexpertly

Instruments

Strictures have been treated by surgeons for centuries and there are many different dilating instruments. A simple stricture may be dilated using metal sounds (Fig. 74.12), so called because they were originally used to 'sound' for stones in the bladder, or gum-elastic bougies (Fig. 74.13). These must be wielded with great care as it is easy to make a false passage. Filiforms are gum-elastic filaments that can be passed through the lumen of a urethral stricture (Fig. 74.14). This is usually best done under direct vision using a urethroscope. Once the lumen has been located with its tip, the other end of the filiform is screwed on to a 'follower', a gum-elastic bougie with a

Figure 74.12 Metal dilators ('sounds').

Auguste Nélaton, 1807–1873, Professor of Surgery, Paris, France.

Figure 74.13 Gum-elastic bougies.

Figure 74.14 Filiform bougies with followers.

screw thread at its tip for the purpose. As the follower is advanced, the filiform guides it safely through the stricture. Once the stricture has been partially dilated by followers of increasing size, it is often safe to change to metal dilators. Patients who have had an optical urethrotomy are sometimes taught to keep the stricture open by regular self-dilatation with a urethral catheter of a suitable size.

Operative treatment

Internal urethrotomy is performed using the optical urethrotome. The stricture is cut under visual control using a knife passed through the sheath of a rigid urethroscope. The stricture is usually cut at the 12 o'clock position, taking care not to cut too deeply into the vascular spaces of the corpus spongiosum that surrounds the urethra. Other cuts can be made until there is a wide passage through the strictured segment of urethra. Many surgeons leave a catheter for 1–2 days afterwards but there is no evidence that this makes a significant difference to the effectiveness of the procedure. A single urethrotomy seems to give a permanent cure of uncomplicated stricture in about 50% of patients. The main complications are infection and bleeding. It is possible to get lost when trying to cut a way through a very tight stricture. This is especially true when there are false passages because of previous dilatation attempts. It helps to pass a guidewire to establish the true lumen of the urethra (Summary box 74.7).

Summary box 74.7

Endoscopic urethrotomy

- Cures about 50% of simple strictures
- May be supplemented by intermittent self-dilatation postoperatively with improved success rate

Urethroplasty

The simplest urethroplasty involves excision of the stenosed length of urethra and reanastomosis of the spatulated cut end (see Fig. 74.5, p. 1364). This operation is possible only if the stricture is relatively short because there must be no tension at the suture line. If end-to-end anastomosis is not feasible, a large number of different plastic surgical procedures are available to replace the fibrosed urethra using free full-thickness or pedicled skin grafts. The Orandi–Blandy operation makes use of a myocutaneous patch of perineal skin and dartos muscle (Fig. 74.15) whereas Turner–Warwick favoured penile skin. Buccal mucosa, readily harvested as a free graft, has the advantage of flourishing in both wet and dry conditions.

Urethroplasty should be considered when simpler means fail. The procedure can be very demanding, especially when the stricture is the result of pelvic trauma and the urethra is encased in hard fibrosis. A prolonged hospital stay is usual while the graft heals.

Diverticulum of the male urethra (synonym: urethral pouch)

This is usually congenital and represents a partial duplication of the urethra. Acquired cases are uncommon. They are sometimes seen as a result of increased intraurethral pressure behind a stricture. Others are caused by the longstanding presence of a foreign body such as a stone or calculus in the urethra.

Treatment is by excision of the diverticulum and removal of the cause if possible.

Periurethral abscess

Periurethral abscesses can be penile, bulbar or chronic.

Penile periurethral abscess

A penile periurethral abscess arises as an acute gonococcal infection of one of the glands of Littre. The tender induration felt on

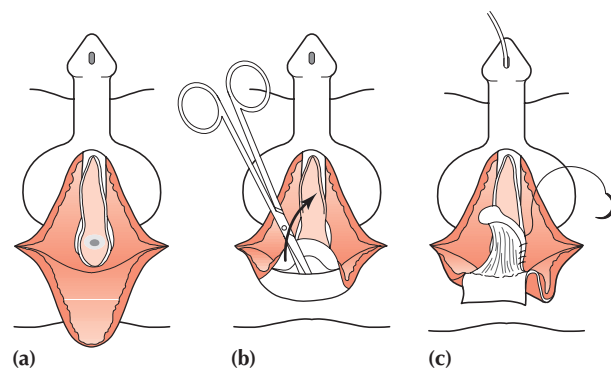

Figure 74.15 The pedicled patch urethroplasty of Orandi and Blandy. (a) A U-shaped incision in the perineum is developed to form a flap. The strictured urethra is incised. (b) A patch of skin attached to the underlying dartos muscle is separated from the tip of the U-shaped flap. (c) The patch is sutured in place to widen the strictured urethra. The blood supply to the patch comes from the underlying dartos muscle.

 Alexis Littre, 1658–1726, Surgeon, and Lecturer in Anatomy, Paris, France.

the underside of the penis points and discharges externally, often leaving a fistula.

Treatment

An anterior urethrotomy will encourage the abscess to burst into the urethra. When the abscess lies behind a stricture, it should be opened externally.

Bulbar periurethral abscess

A bulbar periurethral abscess is a spreading cellulitis caused by infection with streptococci and anaerobic organisms, possibly associated with a stricture. Extravasation of urine is not unusual.

Clinical features

There is perineal pain with pyrexia, rigors and tachycardia. Tenderness and swelling rapidly spread from the perineum to the penis and the anterior abdominal wall.

Treatment

Antibiotics are essential. Collections of pus should be drained and the urethra should be defunctioned by a suprapubic urinary catheter.

Chronic periurethral abscess

A chronic periurethral abscess sometimes results from a long-standing urethral stricture (Fig. 74.16). The multiple loculi of pus should be drained and the stricture treated. Urethral fistula occurs either spontaneously or as a result of incision of the abscess.

Urethral fistula

The most frequent cause of urethral fistula is bursting or incision of a periurethral abscess. If the fistulae arise behind a tight stricture there may be multiple openings (watering-can perineum). A fistula can also follow urethroplasty if there is necrosis of part of the graft.

Treatment

If the stricture is cured, some fistulae heal themselves. Occasionally, urethroplasty is indicated.

Urethral calculi

Urethral calculi can arise primarily behind a stricture or in an infected urethral diverticulum. More commonly, the stone is a renal calculus that has migrated to the urethra via the bladder.

Figure 74.16 Chronic periurethral abscess.

Clinical features

Migratory calculi cause sudden pain in the urethra soon after an attack of ureteric colic. There is blockage to the flow of urine and, if the stone is small, the force of the jet will expel it from the external urethral meatus. Larger stones get stuck and must be removed endoscopically. It is sometimes possible to feel the calculus as a hard lump in the urethra, but if there is doubt the diagnosis is confirmed by urethroscopy.

A stone formed within the urethra is less likely to cause recognisable symptoms and is usually detected during urethroscopy or bouginage.

Treatment

A stone in the prostatic urethra is displaced back into the bladder and treated by lithopaxy or suprapubic cystotomy as if it were a bladder stone. Calculi in more distal parts of the urethra are removed by basketing under vision or fragmented *in situ* using the electrohydraulic or ultrasonic lithotripter. It may be necessary to perform a meatotomy to deliver the stone. Open removal by external urethrotomy is rarely necessary.

Neoplasms

Polyps are a relatively common finding in the prostatic urethra, where they may result from chronic infection.

Genital warts acquired by sexually transmitted infection are sometimes found in the anterior urethra as an extension of warts on the skin of the glans penis.

Angioma of the urethra is a very rare cause of urethral bleeding.

Carcinoma of the urethra is relatively rare. Multifocal transitional cell cancers of the bladder are sometimes associated with tumours in the prostatic urethra and occasionally more distally. Though superficial and susceptible to local ablation by diathermy or laser, they are associated with a tendency to distant spread. Squamous carcinoma can develop in an area of squamous metaplasia sometimes seen with a urethral stricture. It carries a poor prognosis even if the patient is treated by radical surgery. Bloody urethral discharge without infection should raise the suspicion that the patient has a urethral tumour.

THE FEMALE URETHRA

Abnormalities of the female urethra include:

- prolapse;
- stricture;
- diverticulum;
- caruncle;
- papillomata acuminata;
- carcinoma.

Prolapse

Prolapse occurs in later life and is usually symptomless. Prolapse of the urethral lining also occurs as a congenital abnormality, when it causes discomfort proportional to the degree of prolapse.

Stricture

This is uncommon in women but follows urethritis or, more commonly, the trauma of a difficult labour. Urinary retention, usually chronic, is an occasional result. True urethral strictures in women respond well to dilatation and should not be confused with a

spasm of the urethral muscle of obscure cause, which sometimes causes retention in women, particularly after they have had unrelated surgery. The condition, which was described by Fowler and Kirby, is associated with an abnormal myotonic discharge in the urethral sphincter, which can be detected on an electromyogram. The patients remain in retention after urethral dilatation and many of them require intermittent self-catheterisation for life.

Diverticulum (synonym: urethrocele)

Diverticulum is more common in women than men. Some seem to be congenital. Others are acquired by rupture of a distended urethral gland or injury of the urethra during childbirth. Urine within the diverticulum becomes infected, causing local pain and repeated bouts of cystitis. Purulent urine is discharged if the urethra is compressed with a finger placed in the vagina. Excision of the diverticulum through the anterior vaginal wall is effective, but care must be taken not to damage the urethral sphincter.

Caruncle

This is common in elderly women. It presents as a soft, raspberry-like, pedunculated granulomatous mass about the size of a pea, attached to the posterior urethral wall near the external meatus. It is composed of highly vascular connective tissue stroma infiltrated with pus cells.

Clinical features

There may be frequency of micturition and pain afterwards. Occasionally, there is bleeding. A urethral prolapse is less tender and is not pedunculated.

Treatment

Treatment is by excision and diathermy coagulation of the base of the stalk. The patient should be given antibiotics to treat the underlying chronic urethritis.

Papillomata acuminata

Papillomata acuminata are the same as the sexually transmitted warts that occur on the penis. They are treated in the same way. In African women, papillomata acuminata are common and may grow to such a large size during pregnancy that they obstruct labour and necessitate a Caesarean section (Bowesman).

Carcinoma of the urethra

This occurs twice as often in women as in men. Whether a caruncle can become malignant is disputed, but caruncles and tumours often occur close together. Malignant swellings of the urethra feel harder than benign ones.

Treatment by radiotherapy or radical surgery is often ineffective. The overall prognosis is poor.

THE PENIS

Phimosis (see also Chapter 6)

Phimosis is overdiagnosed. The physiological adhesions between the foreskin and the glans penis may persist until 6 years of age or

more, giving the false impression that the prepuce will not retract. Rolling back the prepuce causes its inner lining to pout and the meatus comes into view. This condition should not be confused with true phimosis in boys, with scarring of the prepuce, which will not retract without fissuring. In these cases the aperture in the prepuce may be so tight as to cause urinary obstruction. Urinary difficulty with residual urine and back pressure effects on the ureters and kidney is far more commonly caused by meatal stenosis, which may be masked by the prepuce. Phimosis occurs as a result of balanitis xerotica obliterans (BXO), a curious condition in which the normally pliant foreskin becomes thickened and will not retract. It is difficult to keep the penis clean and there is both a problem with hygiene and, in later life, an increased susceptibility to carcinoma.

Treatment is by circumcision.

Circumcision

Apparently, circumcision did not originate among the Jewish people: they took the practice either from the Babylonians or from African tribes, probably the latter. It had been practised in West Africa for over 5000 years.

Indications

In infants and young boys, circumcision is most usually performed at the request of the parents for social or religious reasons. Medical indications for circumcision in boys include true phimosis caused by BXO (rare under the age of 5 years); recurrent attacks of balanoposthitis; and recurrent urinary tract infections with an abnormal upper urinary tract. Phimosis may result from misguided attempts by parents to expose the glans forcibly.

In adults, circumcision is indicated because of an inability to retract for intercourse, for splitting of an abnormally tight frenulum, for balanitis and sometimes before radiotherapy for carcinoma of the penis (Summary box 74.8).

Summary box 74.8

Circumcision

- Is most commonly performed for cultural reasons
- Is not indicated for failure of retraction caused by congenital adhesions between the glans penis and the prepuce
- Is indicated when there is true phimosis with balanoposthitis or obstruction to urinary flow

Technique in an infant

Applying a clamp or bone forceps across the prepuce distal to the glans with blind division of the foreskin is to be condemned. To see one boy with partial or total amputation of the glans is enough to realise the folly of this technique. It is far better to perform a proper circumcision under direct vision as in an adult.

The Plastibel (Hollister) is used as shown in Fig. 74.17: the ring separates between 5 and 8 days postoperatively.

Technique in adolescents and adults

In adolescents and adults the following method is preferable. The prepuce is held in artery forceps and put on a gentle stretch. A circumferential incision in the penile skin is made at the level of the corona using a knife. The prepuce is then slit up the midline dorsally to within 1 cm of the corona. This converts the foreskin

Figure 74.17 The Plastibel (Hollister) device for circumcision in infants. (a) The foreskin is freed and retracted. (b) After the Plastibel device has been slipped into place over the glans penis, the foreskin is ligated over the groove of the bell and redundant foreskin is cut away. (c) This shows the completed operation (courtesy of Professor Asal Y. Izzidien Al-Samarrai, King Saud University, Riyadh, Saudi Arabia).

into two flaps connected at the midline anteriorly. When the undersurface of the prepuce has been separated from the glans, the inner layer of each flap is incised with a second circumferential incision, leaving about 0.5 cm of the inner layer of the

prepuce distal to the corona. Cutting the remaining connective tissue completes the excision (Fig. 74.18). Monopolar diathermy must be avoided in operations on the penis in small boys because there is a danger that the small current path will cause coagulation at the base of the penis. Haemostasis is important in circumcision, however, and vessels should be secured by bipolar diathermy or ligated with non-absorbable material. The cut edges of the skin are approximated using interrupted sutures and the layers in the immediate region of the frenulum are brought neatly together using a mattress suture (Fig. 74.19) (Summary box 74.9).

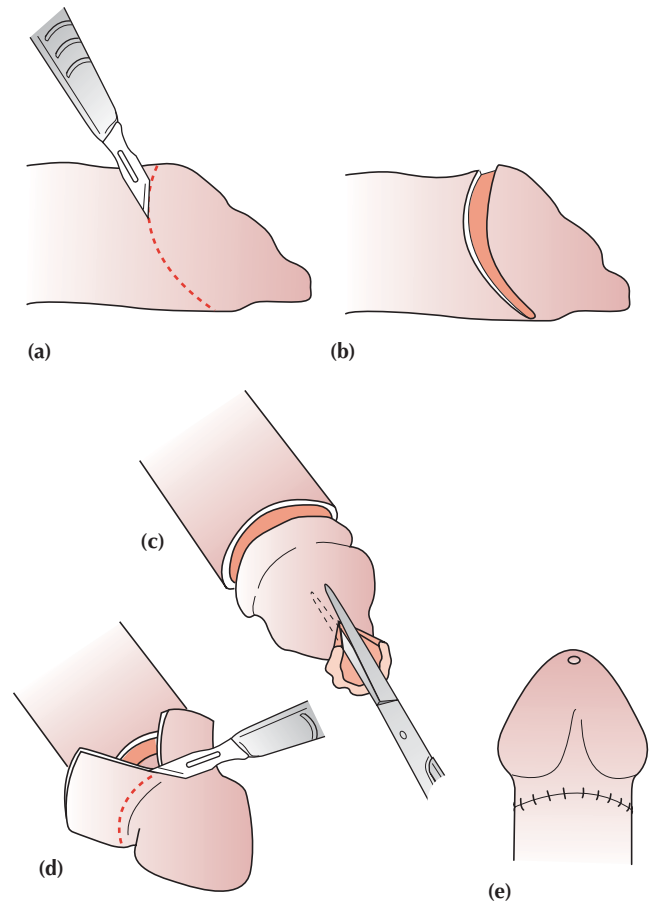

Figure 74.18 (a–e) Stages in circumcision.

Figure 74.19 The 'four in one' frenular stitch.

Summary box 74.9

Warning

- Never use monopolar diathermy when performing circumcision

Preputial calculi

Late in life, chronic posthitis may lead to adhesions between the prepuce and the glans and closure of the orifice of the preputial sac. Preputial calculi result from the accumulation beneath a non-retractable foreskin of inspissated smegma, urinary salts or both.

Injuries

Avulsion of the skin of the penis

Entanglement of clothing in rotating machinery is the usual cause. Repair is effected by burying the shaft of the penis in the scrotum (Fig. 74.20) with subsequent release at the time of a definitive plastic surgical repair.

Fracture of the penis

Fracture of the penis is an uncommon accident, usually occurring when the erect penis is bent violently downwards during intercourse. The extravasation of blood causes great pain and swelling. In early cases, incision and drainage of the clot with suture of the defect in the tunica of the ruptured corpus cavernosum gives acceptable results.

Strangulation of the penis

Strangulation of the penis by rings placed on the penis, usually for sexual reasons, can cause venous engorgement which prevents their removal. It may help to aspirate the corpora cavernosa but often the ring must be cut off with a ring cutter or hacksaw.

Paraphimosis

A tight foreskin once retracted may be difficult to return and a paraphimosis results. In this condition, the venous and lymphatic return from the glans and distal foreskin is obstructed and these structures swell, causing even more pressure within the obstructing ring of prepuce. Icebags, gentle manual compression and injection of a solution of hyaluronidase in normal saline may help to reduce the swelling. Such patients can be treated by circumcision if careful manipulation fails. A dorsal slit of the prepuce under local anaesthetic may be enough in an emergency.

Figure 74.20 Covering the denuded shaft of the penis by burying it in a scrotal tunnel.

Inflammations

Balanoposthitis

Inflammation of the prepuce is known as posthitis; inflammation of the glans is balanitis. The opposing surfaces of the two structures are often involved, hence the term balanoposthitis. Skin conditions such as lichen planus and psoriasis affect the penis and, indeed, may be localised there. Drug hypersensitivity reactions can affect the skin of the penis.

In mild cases, the only symptoms are itching and some discharge. In more severe inflammation, the glans and foreskin are red-raw and pus exudes. Balanoposthitis is associated with penile cancer, diabetes and phimosis. Monilial infections are quite common under the prepuce.

Treatment is by broad-spectrum antibiotics and local hygiene measures.

Other abnormalities

Chordee

Chordee (French = corded) is a fixed bowing of the penis caused by hypospadias or, more rarely, chronic urethritis. Erection is deformed and sexual intercourse may be impossible. Treatment is usually surgical.

Peyronie's disease

Peyronie's disease is a relatively common cause of deformity of the erect penis. On examination, hard plaques of fibrosis can usually be palpated in the tunica of one or both corpora cavernosa. The plaques may be calcified (Fig. 74.21). The presence of the unyielding plaque tissue within the normally elastic wall of the corpus cavernosum causes the erect penis to bend, often dramatically, towards the side of the plaque. The aetiology is uncertain but it may be a result of past trauma – there is an association with Dupuytren's contracture.

Treatment is difficult. Some cases continue to progress. Others seem to remit after 3–5 years. Various drug treatments have been suggested but their beneficial effect is hard to prove in such a chronic condition. When the deformity of the penis is causing distress, it may be possible to straighten it by placing non-absorbable sutures in the corpus cavernosum opposite the plaque. This reduces the elasticity in this region to balance that caused by the plaque (Nesbitt's operation) (Summary box 74.10).

Figure 74.21 Penile calcification in Peyronie's disease (courtesy of Dr S.S. Rawat, Riyadh, Saudi Arabia).

Francois de la Peyronie, 1678–1747, Surgeon to King Louis XIV of France, and Founder of the Royal Academy of Surgery, Paris, France.
Baron Guillaume Dupuytren, 1777–1835, Surgeon, Hôtel Dieu, Paris, France, described this condition in 1831.
Thomas Nesbitt, Urological Surgeon, Nashville, TN, USA.

Summary box 74.10

Peyronie's disease

- Medical treatments are often ineffective
- The disease is typically self-limiting
- Surgery may be indicated to correct deformity that interferes with sexual function

Persistent priapism

The penis remains erect and becomes painful. This is a pathological erection and the glans penis and corpus spongiosum are not involved. The condition is usually seen as a complication of a blood disorder such as sickle cell disease or leukaemia. However, it can sometimes follow therapeutic injection of papaverine or even an abnormally prolonged bout of otherwise normal sexual activity. A tiny proportion is caused by malignant disease in the corpora cavernosa or the pelvis. Priapism is rarely seen as a consequence of spinal cord disease.

Treatment

An underlying cause should be excluded. The patient should be referred for specialist urological care. If aspiration of the sludged blood in the corpora cavernosa fails to cause detumescence, and repeated injection of metaraminol or 1:100 000 adrenaline (epinephrine) solution is ineffective, it may be necessary to decompress the penis by an anastomosis between the corpus spongiosum and one of the corpora cavernosa. The outlook for normal erectile function is poor (Summary box 74.11).

Summary box 74.11

Prolonged priapism

- Prolonged priapism is associated with erectile dysfunction, especially if surgical decompression by shunt formation is performed

Carcinoma**Aetiology**

Circumcision soon after birth confers immunity against carcinoma of the penis. Later circumcision does not seem to have the same effect. Chronic balanoposthitis is known to be a contributory factor, and there are definite precarcinomatous states:

- leucoplakia of the glans, similar to the condition seen on the tongue;
- longstanding genital warts, which may rarely be the site of malignant change;
- Paget's disease of the penis.

Paget's disease of the penis (synonym: erythroplasia of Queyrat)

Paget's disease of the penis is 'a persistent rawness of the glans like a longstanding balanitis followed by cancer of the substance of

Sir James Paget, 1814–1899, Surgeon, St Bartholomew's Hospital, London, England. Auguste Queyrat, B. 1872, Dermatologist, Paris, France, described this condition in 1911.

the penis' (Sir James Paget). Treatment is by circumcision, observation and excision if the lesion does not resolve.

Pathology

Carcinoma of the penis may be flat and infiltrating or papillary (Fig. 74.22). The former often starts as leucoplakia and the latter results from an existing papilloma. Local growth continues for months or years. The earliest lymphatic spread is to the inguinal and then to the iliac nodes. Once the growth breaches the partial barrier formed by the fascial sheath of the corpora cavernosa it spreads rapidly and iliac lymph node involvement is common (Fig. 74.23). Distant metastatic deposits are infrequent.

Clinical features

About 40% of patients are under 40 years of age. Mild discomfort and light discharge are often neglected and the disease progresses slowly. By the time the patient presents, the growth is often large and secondary infection causes a foul bloody discharge. There is little or no pain.

In total, 60% present with inguinal lymph node enlargement but in half of these this is caused by sepsis. In most, the prepuce

Figure 74.22 Carcinoma of the penis (courtesy of Dr V.K. Kapoor, All India Institute of Medical Sciences, Delhi, India).

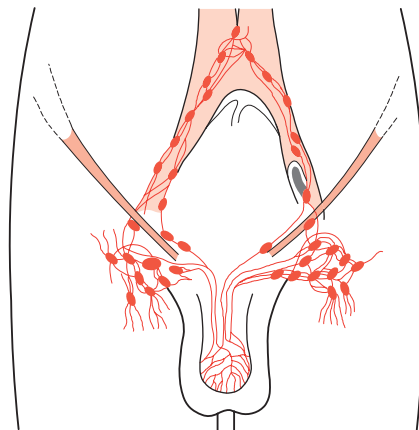

Figure 74.23 The lymphatic drainage of the penis. Superficial lymphatics drain to the inguinal and deep lymphatics to the iliac lymph nodes (after Archie L. Dean).

is non-retractile and must be split to view the lesion. A biopsy should be performed to make the diagnosis.

Untreated, the whole glans may be replaced by a fungating offensive mass. Later, the inguinal nodes erode the skin of the groin and the death of the patient may result from erosion of the femoral or external iliac artery.

Treatment

Radiotherapy is effective (60–70% survival rate at 5 years) for small cancers. Circumcision precedes treatment, which may be delivered by implanted radioactive tantalum wires, by external beam radiation or by means of a radioactive mould applicator applied externally to the penis.

Surgery is for large anaplastic growths, if there is infiltration of the shaft and when radiotherapy fails. Partial amputation is used for distal growths when adequate clearance of the tumour is possible. When an advanced, infiltrating or anaplastic lesion is present, total amputation is necessary.

Treatment of associated enlarged inguinal lymph nodes should usually be delayed until at least 3 weeks after local treatment of the primary lesion. Enlargement caused by infection will usually show signs of subsiding with antibiotic treatment if necessary. Block dissection is indicated if there is persistent enlargement that needle aspiration biopsy shows to be caused by tumour. The 5-year survival rate falls to 35% in these cases. If surgery to the nodes is impossible, radiotherapy may cause a worthwhile temporary regression (Summary box 74.12).

Summary box 74.12

Carcinoma of the penis

- Relatively uncommon
- Enlargement of superficial inguinal lymph nodes may be caused by infection or metastatic spread
- May be treated by a combination of surgery and radiotherapy

Buschke–Löwenstein tumour

Buschke–Löwenstein tumour is uncommon. It has the histological pattern of a verrucous carcinoma. It is locally destructive and invasive but appears not to spread to lymph nodes or to metastasise. Treatment is by surgical excision.

Secondary cancer of the penis

Secondary cancer of the penis as a result of spread from a primary tumour of the bladder, rectum or prostate is uncommon.

SEXUALLY TRANSMITTED GENITAL INFECTIONS

Genital herpes

Genital herpes is caused by sexual transmission of the herpesvirus hominis (type 2, occasionally type 1). Recurrent attacks occur in 50% or more of cases. Pain along the distribution of the sensory nerve, usually genitofemoral, precedes the eruption by 2 days and

may be particularly severe around the anus. A group of tiny vesicles rapidly erodes to form shallow yellow- or red-based ulcers. In female patients, the ulcers often spread on to the thighs during the attack. Involvement of the urethra may cause retention of urine, which may persist for up to 14 days if there is radiculitis of the S2 and S3 nerve roots. Aciclovir has been shown to be effective in treating genital herpes but it does not prevent recurrences.

A child born to a mother with active infection is susceptible to a fatal generalised herpes infection in the neonatal period. Caesarean section should be considered in these circumstances. There is an increased risk of carcinoma of the cervix and annual cytology for life is recommended.

Lymphogranuloma venereum

Lymphogranuloma venereum is a sexually transmitted tropical disease caused by *Chlamydia trachomatis* (*Chlamydia A*) types L1–L3. The primary lesion is a fleeting, painless, genital papule or ulcer often unnoticed by the patient.

The inguinal glands become enlarged and painful in both sexes between 2 weeks and 4 months after infection. The masses of nodes mat together above and below the inguinal ligament to give the ‘sign of the groove’. The overlying skin reddens and there may be fluctuation. In women, there may be a proctitis, which can go on to produce a rectal stricture if untreated. Lymphatic obstruction leads to lymphoedema in the perineum and occasionally the lower limbs. Urethritis and urethral stricture occur in men.

Confirmation is by isolating *Chlamydia A* from the lesion and by immunological tests to detect antibodies against the organism.

Treatment is by a combination of antibiotics, which may include sulphonamide, oxytetracycline and erythromycin. The multilocular bubo should not be incised; aspiration is permissible to reduce discomfort.

Granuloma inguinale

This is a chronic and slowly progressive ulcerative tropical disease affecting the genitals and surrounding tissue but occasionally occurring elsewhere in the body. It is usually sexually transmitted and is most common among socially deprived people. The incubation period varies greatly but is frequently 7–30 days.

Clinical course

A painless vesicle or indurated papule, usually on the external genitals but occasionally elsewhere on the skin, gradually erodes into a slowly extending ulcer with a beefy-red, granulomatous base. More chronic lesions may become greyish, especially at the edges, where, after months or years, malignant change may develop. The ulcerated area may bleed if touched but is surprisingly painless. Without treatment healing is only partial and keloid is common.

Diagnosis is by microscopy of material from the edges of the ulcer, which shows the presence of short Gram-negative rods within the cytoplasm of the large mononuclear cells.

Treatment is by oxytetracycline, streptomycin or cotrimoxazole.

Abraham Buschke, 1868–1943, Dermatologist, Berlin, Germany.

A Caesarean section is the operation of delivering the foetus by an incision into the uterus, usually through the abdominal wall.

Condylomata acuminata (synonym: genital warts)

Genital warts are caused by infection with human papillomavirus and are sexually transmitted. Ordinary skin warts can occur on the genitals by direct contact with a finger lesion, but they are less moist and soft and less often pedunculated than the genital variety. The lesions most commonly occur under the prepuce in the coronal sulcus but may be found elsewhere, including inside the urinary meatus (Fig. 74.24). In women, genital warts are most commonly found on the vulva but they may line the vagina and occur on the cervix. Perianal warts are common.

Other associated sexually transmitted diseases should be excluded: in women mainly candidiasis and *Trichomonas* infection and in men syphilis or gonorrhoea. Genital warts may complicate human immunodeficiency virus (HIV) infection.

Treatment is by chemical or physical means. Podophyllin 25% in spirit is often effective as a topical application. It is applied to the wart taking great care to avoid the surrounding skin and washed off after 6 hours or so.

If chemical methods fail, the warts can be excised or they can be ablated with cryosurgery, electrosurgery or laser. Circumcision is sometimes advised if there are florid lesions under the foreskin.

Figure 74.24 Penile warts.

Testis and scrotum

LEARNING OBJECTIVES

To recognise and understand:

- Imperfect testicular descent and appreciate the main indications for intervention
- Testicular torsion as a urological emergency
- The principles of the management of varicocele, hydrocele and epididymal cysts
- The classification and management of testicular tumours
- The treatment options for infertile men

DEFINITIONS

Incomplete descent of the testis

The testis is arrested in some part of its path to the scrotum.

Ectopic testis

The testis is abnormally placed outside this path.

ANATOMY OF THE TESTIS

The testes develop in the retroperitoneum below the kidneys in early fetal life. About the same time as the wolffian duct becomes the epididymis and vas deferens, the precursor of the gubernaculum develops as a fold of peritoneum. The processus vaginalis starts as a dimple of peritoneum in about the 10th week of gestation and precedes the testis in its journey through the abdominal wall down to the scrotum. The fully developed gubernaculum contains muscle fibres but it is still not clear what part it plays in testicular descent. Maternal chorionic gonadotrophin stimulates growth of the testis and may stimulate its migration. Imperfectly developed testes tend to descend incompletely.

The anatomy of the adult testis reflects its embryonic development. The testicular arteries originate high up in the retroperitoneum, from the abdominal aorta on the left and from the renal artery on the right. The venous drainage finds its way to the left renal vein and the inferior vena cava. For much of their course the testicular artery and vein run parallel to the ipsilateral ureter, for which they may be mistaken during retroperitoneal surgery.

The epididymis extends as a fleshy strip on the posterior aspect of the testis and is palpable as a separate structure. The vas deferens takes its origin from the epididymis. It can be felt above

the testis as a firm tubular structure entering the external inguinal ring. In the inguinal canal, the vas deferens is invested by the cremasteric muscle along with the other components of the spermatic cord.

INCOMPLETELY DESCENDED TESTIS (SEE ALSO CHAPTER 6)

Incidence

About 4% of boys are born with one or both testes incompletely descended. About half of these reach the scrotum during the first month of life, but full descent after that is uncommon. The condition is sometimes missed at birth and discovered later in life. In a few cases, the presence of a hernia, testicular pain or acute torsion directs attention to the abnormality. In 10% of unilateral cases there is a family history.

Pathology

Incompletely descended testes are often macroscopically normal in early childhood but by puberty the testis is poorly developed compared with its intrascrotal counterpart. The epithelial elements are immature histologically and by late puberty irreversible destructive changes halt spermatogenesis and limit the production of androgens.

An incompletely descended testis brought down in early childhood often functions satisfactorily (Summary box 75.1).

Summary box 75.1

Undescended testis

- Testes absent from the scrotum after 3 months of age are unlikely to descend fully
- An incompletely descended testis tends to atrophy as puberty approaches
- Early repositioning of an incompletely descended testis can preserve function

Kaspar Friedrich Wolff, 1733–1794, Professor of Anatomy and Physiology, St Petersburg, Russia.

Clinical features

The condition is more common on the right and is bilateral in 20% of cases. Secondary sexual characteristics are typically normal.

The testis may be:

- intra-abdominal, lying extraperitoneally above the internal inguinal ring;
- inguinal, in which case it may or may not be palpable (Fig. 75.1);
- in the superficial inguinal pouch, in which case it must be distinguished from retractile testis.

During childhood the testes are mobile and the cremasteric reflex is active. In some boys, any stimulation of the skin of the scrotum or thigh causes the testis to disappear into the inguinal canal. Simply exposing the parts can also do this so that the testis is never seen in an intrascrotal position. The scrotum is normal as opposed to underdeveloped, which is usually seen with true incomplete descent. When the cremaster relaxes, the tell-tale bulge of the testis reappears only to vanish when the scrotal skin is touched again. A retractile testis can be gently milked from its position in the inguinal region to the bottom of the scrotum. A diagnosis of true incomplete descent should be made only if this is not possible. In infancy, most inapparent testes are retractile. They are normal and require no treatment (Summary box 75.2).

Summary box 75.2

Retractile testis

- Retractile testes are more common than incompletely descended testes and require no treatment

Hazards of incomplete descent are:

- sterility in bilateral cases (especially intra-abdominal testes);
- pain as a result of trauma;
- an associated indirect inguinal hernia is often present and may cause symptoms;
- torsion;
- epididymo-orchitis in an incompletely descended right testis can mimic appendicitis;

Figure 75.1 A cryptorchid in a boy aged 12 years. Note the retracted underdeveloped scrotum. In cases of retractile testis, the scrotum is relatively well developed.

- atrophy of an inguinal testis before puberty may possibly be caused by recurrent minor trauma;
- increased liability to malignant disease; cancer is more common in an incompletely descended testes – orchidopexy may or may not diminish the risk but it does improve the prospect of early diagnosis (Summary box 75.3).

Summary box 75.3

Orchidopexy

- An increased liability to malignant disease is not necessarily corrected by orchidopexy but early diagnosis of a tumour is easier

Surgical treatment

Orchidopexy is usually performed after the age of 1 year to avoid the risks of operating on a tiny patient. Testes should be brought down into the scrotum before the boy starts school. In bilateral cases it is usual to operate on one side at a time.

Orchidopexy

In orchidopexy (synonym: orchiopexy), the testis and spermatic cord are mobilised and the testis is repositioned in the scrotum. The operation is performed through a short incision over the deep inguinal ring. The inguinal canal is exposed by division of the external oblique aponeurosis in the direction of its fibres.

Mobilisation begins with isolation of the indirect inguinal hernial sac, which lies anterior to the cord. The sac is fragile but with care it can be swept laterally to reveal filmy strands that join the neck of the sac to the cord. The fibrous strands are divided and the spermatic vessels are dissected free of the peritoneum until there is a sufficient length of liberated cord to place the testis in the scrotum without tension. Division of the cremaster and the coverings of the cord may give more length, but the tiny vas and testicular vessels are vulnerable to injury. The empty hemiscrotum is stretched with a finger passed into it through the inguinal incision to give enough room for the testis.

The testis is placed in a pouch constructed between the dartos muscle and the skin (Fig. 75.2). An alternative to the

Figure 75.2 The testis is mobilised and retained in a pouch constructed between the dartos muscle and skin.

dartos pouch is to take the testis through the scrotal septum (Ombredanne's operation).

Failure to bring the testis down

Sometimes a two-stage procedure is successful: the testis is mobilised as far as possible and anchored with a suture and the mobilisation is completed 6 months later. Orchidectomy should be considered if the incompletely descended testis is atrophic, particularly if the patient is past puberty and the other testis is normal.

Hormone treatment with human chorionic gonadotrophin is appropriate only when there is established hypogonadism.

ECTOPIC TESTIS

The sites of ectopic testis are:

- at the superficial inguinal ring;
- in the perineum;
- at the root of the penis;
- in the femoral triangle.

An ectopic testis is usually fully developed. The main hazard is liability to injury.

INJURIES TO THE TESTIS

Rupture by a blow is uncommon because of the testis's mobility within the scrotum. Contusion and rupture are associated with a collection of blood around the testis and cannot usually be distinguished with certainty without exploration. The haematocele (Fig. 75.3) should be drained and the tunica albuginea repaired after evacuation of haematoma. A severely damaged testis may have to be removed.

Traumatic displacement occasionally follows a blow. The displaced testis usually lies in one of the sites of ectopic testis and can be returned to its normal position by manipulation before it becomes anchored by fibrosis (Summary box 75.4).

Summary box 75.4

Scrotal trauma

- Scrotal exploration should be considered when there is massive swelling and pain after scrotal trauma

Figure 75.3 Longitudinal scan of testicle with haematocele (H) at lower pole.

Louis Ombredanne, 1871–1956, Surgeon, Hôpital des Enfants Malades, Paris, France.

ABSENT TESTIS

'Vanishing' testis describes a condition in which a testis develops but disappears before birth. The most likely cause for this is pre-natal torsion. True agenesis of the testis is rarer. Laparoscopy is useful in distinguishing these causes of clinically absent testis from intra-abdominal maldescent.

TORSION OF THE TESTIS

Predisposing causes

Torsion of the testis is uncommon because the normal testis is anchored and cannot rotate. For torsion to occur one of several abnormalities must be present:

- Inversion of the testis is the most common predisposing cause. The testis is rotated so that it lies transversely or upside down.
- High investment of the tunica vaginalis causes the testis to hang within the tunica like a clapper in a bell (Fig. 75.4).
- Separation of the epididymis from the body of the testis permits torsion of the testis on the pedicle that connects the testis with the epididymis (Fig. 75.5).

Normally, when there is a contraction of the abdominal muscles, the cremaster contracts as well. In the presence of one of the abnormalities described above, the spiral attachment of the cremaster favours rotation of the testis around the vertical axis. Straining at stool, lifting a heavy weight and coitus are all possible precipitating factors. Alternatively, torsion may develop spontaneously during sleep.

Figure 75.4 Testicular torsion. (a) Normal attachment. (b) An abnormally high attachment of the tunica vaginalis predisposes to torsion – the 'bell-clapper'.

Figure 75.5 Testicular torsion. Separation of the testis from the epididymis – torsion about the pedicle between them.

Clinical features

Testicular torsion is most common between 10 and 25 years of age although a few cases occur in infancy. Symptoms vary with the degree of torsion. Most commonly there is sudden agonising pain in the groin and the lower abdomen. The patient feels nauseated and may vomit.

Torsion of a fully descended testis is usually easily recognised. The testis seems high and the tender twisted cord can be palpated above it. In mumps orchitis the cord is not particularly thickened. The onset of redness of the skin and a mild pyrexia may result in the condition being confused with epididymo-orchitis in the older patient; however, in epididymo-orchitis there will usually be dysuria associated with the accompanying urinary infection. Elevation of the testis reduces the pain in epididymo-orchitis and makes it worse in torsion. Very occasionally, torsion can be convincingly mimicked by a small tense strangulated inguinal hernia compressing the cord and causing compression of the pampiniform plexus.

Doppler ultrasound scan will confirm the absence of the blood supply to the affected testis, but performing this test may squander vital minutes. If there is any doubt about the diagnosis, the scrotum should be explored without delay.

An empty oedematous hemiscrotum suggests that a tender lump at the external inguinal ring is a torted testis rather than a strangulated hernia.

Treatment

In the first hour or so it may be possible to untwist the testis by gentle manipulation. If manipulation is successful, pain subsides and the testis is out of danger. Arrangements should be made for early operative fixation to avoid recurrent torsion.

Exploration for torsion can be performed through a scrotal incision. If the testis is viable when the cord is untwisted it should be prevented from twisting again by fixation with non-absorbable sutures between the tunica vaginalis and the tunica albuginea. The other testis should also be fixed because the anatomical predisposition is likely to be bilateral. An infarcted testis should be removed – the patient can be counselled later about a prosthetic replacement. It is not possible to recover the testis that has been torted for several days and little is gained by immediate exploration. The affected testis will become woody-hard and atrophy to a fibrous nodule. The other testis should be fixed (Summary box 75.5).

Summary box 75.5

Testicular torsion

- Prompt exploration, untwisting and fixation is the only way to save the torted testis
- The patient should be counselled and consented for orchidectomy before exploration
- The anatomical abnormality is bilateral and the contralateral testis should also be fixed

Torsion of a testicular appendage is sometimes mistaken for acute epididymo-orchitis and cannot be distinguished with certainty

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the ‘Doppler Principle’ in 1842.

from testicular torsion. The most common structure to twist is the appendix of the testis (the pedunculated hydatid of Morgagni). Immediate operation with ligation and amputation of the twisted appendage cures the condition.

Idiopathic scrotal oedema is an oddity that occurs between the age of 4 and 12 years and must be differentiated from torsion. The scrotum is very swollen but there is little pain or tenderness. The swelling may extend into the perineum, groin and penis. It is thought to be an allergic phenomenon; occasionally there is eosinophilia. The swelling subsides after a day or so but may recur (Fig. 75.6).

VARICOCELE

A varicocele is a varicose dilatation of the veins draining the testis.

Surgical anatomy

The veins draining the testis and the epididymis form the pampiniform plexus. The veins become fewer as they traverse the inguinal canal and at or near the inguinal ring they join to form one or two testicular veins, which pass upwards behind the peritoneum. The left testicular vein empties into the left renal vein, the right into the inferior vena cava below the right renal vein. The testicular veins may have valves near their terminations, but these are often absent. There is an alternative (collateral) venous return from the testes through the cremasteric veins, which drain mainly into the inferior epigastrics.

Aetiology

Most varicoceles present in adolescence or early adulthood, usually on the left. In many cases the dilated vessels are cremasteric veins and not part of the pampiniform plexus.

Obstruction of the left testicular vein by a renal tumour or after nephrectomy is a cause of varicocele in later life; characteristically, the varicocele does not decompress in the supine position.

Clinical features

Varicocele is usually symptomless but there may be an annoying dragging discomfort that is worse if the testis is unsupported. The scrotum on the affected side hangs lower than normal (Fig. 75.7), and on palpation, with the patient standing, the varicose plexus

Figure 75.6 Oedema of the scrotum.

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, Padua, Italy for 59 years. He is regarded as the Founder of Morbid Anatomy.

Figure 75.7 Large varicocele in a pendulous scrotum. Note the left inguinal hernia.

feels like a bag of worms. There may be a cough impulse. If the patient lies down the veins empty by gravity and this provides an opportunity to ensure that the underlying testis is normal to palpation. In longstanding cases the affected testis is smaller and softer than its fellow owing to a minor degree of atrophy. It is widely believed that varicocele causes infertility but the evidence is inconclusive.

Varicocele and spermatogenesis

Of all the possible causes of primary infertility, oligospermia is one of the most difficult to treat. Because varicocele is relatively common, some of those with oligospermia have a varicocele, and it is tempting to blame this for the infertility. Perhaps the presence of the unilateral varicocele somehow interferes with the normal temperature control of the scrotum, which keeps the testes at some 2.5°C below rectal temperature. Unfortunately, there is little evidence that varicocelectomy improves semen quality or the rate of conception (Summary box 75.6).

Summary box 75.6

Varicocele

- Varicocele is a common condition and tends to recur after surgical treatment. Its association with subfertility is difficult to prove

Treatment

Operation is not indicated for asymptomatic varicocele. The simplest procedure is laparoscopic ligation of the testicular vein above the inguinal ligament where the pampiniform plexus has coalesced into one or two vessels. However, when facilities are available, embolisation of the testicular vein under radiographic control is probably the treatment of choice. Because of the presence of plentiful collateral veins, recurrence is common after all types of varicocele surgery.

HYDROCELE

A hydrocele is an abnormal collection of serous fluid in a part of the processus vaginalis, usually the tunica. Acquired hydroceles are primary or idiopathic, or secondary to testicular disease.

Aetiology

A hydrocele can be produced in four different ways (Fig. 75.8):

- by excessive production of fluid within the sac, e.g. secondary hydrocele;
- by defective absorption of fluid; this appears to be the explanation for most primary hydroceles although the reason why the fluid is not absorbed is obscure;
- by interference with lymphatic drainage of scrotal structures;
- by connection with the peritoneal cavity via a patent processus vaginalis (congenital).

Hydrocele fluid contains albumin and fibrinogen. If the contents of a hydrocele are allowed to drain into a collecting vessel, the liquid does not clot; however, the fluid coagulates if mixed with even a trace of blood that has been in contact with damaged tissue.

Clinical features

Hydroceles are typically translucent and it is possible to 'get above the swelling' on examination of the scrotum.

Primary vaginal hydrocele is most common in middle and later life but can also occur in older children. The condition is particularly common in hot countries. Because the swelling is usually painless it may reach a prodigious size before the patient presents for treatment. The testis may be palpable within a lax hydrocele, but an ultrasound scan is necessary to visualise the testis if the hydrocele sac is tense. Be wary of an acute hydrocele in a young man; there may be a testicular tumour (Summary box 75.7).

Summary box 75.7

Testicular malignancy and hydrocele

- Testicular malignancy is an uncommon cause of hydrocele that can be excluded by ultrasound examination of the scrotum

About 5% of inguinal hernias are associated with a vaginal hydrocele on the same side.

In congenital hydrocele, the processus vaginalis is patent and connects with the peritoneal cavity. The communication is usually too small to allow herniation of intra-abdominal contents. Pressure on the hydrocele does not always empty it but the hydrocele fluid may drain into the peritoneal cavity when the child is lying down; thus, the hydrocele is often intermittent. Ascites should be considered if the swellings are bilateral.

Encysted hydrocele of the cord is a smooth oval swelling near the spermatic cord, which is liable to be mistaken for an inguinal

Figure 75.8 (a) Vaginal hydrocele (very common). (b) 'Infantile' hydrocele. (c) Congenital hydrocele. (d) Hydrocele of the cord.

hernia. The swelling moves downwards and becomes less mobile if the testis is pulled gently downwards.

Hydrocele of the canal of Nuck is a similar condition in females. The cyst lies in relation to the round ligament and is always at least partially within the inguinal canal.

Complications of hydrocele

- Rupture is rare.
- Transformation into a haematocele occurs after trauma or if there is spontaneous bleeding into the sac.
- The sac may calcify.

Treatment

Congenital hydroceles are treated by herniotomy if they do not resolve spontaneously (see Chapter 6).

Established acquired hydroceles often have thick walls. Unless great care is taken to stop bleeding after excision of the wall, haemorrhage from the cut edge is liable to cause a large scrotal haematoma. Lord's operation is suitable when the sac is reasonably thin-walled (Fig. 75.9). There is minimal dissection and the risk of haematoma is reduced. Eversion of the sac with placement of the testis in a pouch prepared by dissection in the fascial planes of the scrotum is an alternative (Jaboulay's procedure) (Fig. 75.10).

Cannula drainage of the hydrocele fluid is simple, but it always

Figure 75.9 Lord's operation. A series of interrupted absorbable sutures is used to plicate the redundant tunica vaginalis. When these are tied, the tunica bunches at its attachment to the testis.

Figure 75.10 Jaboulay's procedure. The hydrocele sac is everted and anchored with sutures.

Anton Nuck, 1650–1692, Professor of Anatomy and Medicine, Leiden, The Netherlands.

Peter Herent Lord, Contemporary, Formerly Surgeon, Wycombe General Hospital, High Wycombe, Buckinghamshire, England.

Mathieu Jaboulay, 1860–1913, Professor of Surgery, Lyons, France.

reaccumulates within a week or so (see Gibbon below). It may be suitable for men unfit for scrotal surgery even under regional anaesthesia. Injection of sclerosants such as tetracycline is effective but painful.

Secondary hydrocele is most frequently associated with acute or chronic epididymo-orchitis. It is also seen with torsion of the testis and with some testicular tumours. A secondary hydrocele is usually lax and of moderate size: the underlying testis is palpable. If a tumour is suspected, the hydrocele should not be punctured for fear of needle-track implantation of malignant cells. A secondary hydrocele subsides when the primary lesion resolves.

Post-herniorrhaphy hydrocele

Post-herniorrhaphy hydrocele is a relatively uncommon complication of inguinal hernia repair.

Hydrocele of a hernial sac

Hydrocele of a hernial sac occurs when the neck of the sac is occluded by adhesions or an omental plug.

Filarial hydroceles and chyloceles

Filarial hydroceles and chyloceles account for up to 80% of hydroceles in tropical countries where the parasite *Wuchereria bancrofti* is endemic. Filarial hydroceles follow repeated attacks of filarial epididymo-orchitis. They vary in size and may develop slowly or very rapidly. Occasionally, the fluid contains liquid fat, which is rich in cholesterol. This is caused by rupture of a lymphatic varix with discharge of chyle into the hydrocele. In longstanding chyloceles there are dense adhesions between the scrotum and its contents. Filarial elephantiasis supervenes in a small number of cases.

Treatment is by rest and aspiration. The more usual chronic cases are treated by excision of the sac.

Haematocele

Haematocele usually results from vessel damage during needle drainage of a hydrocele. Prompt refilling of the sac, pain, tenderness and reduced transillumination confirm the diagnosis. Acute haemorrhage into the tunica vaginalis sometimes results from testicular trauma with or without testicular rupture. If the haematocele is not drained, a clotted haematocele usually results.

Clotted haematocele

Clotted hydrocele may result from a slow spontaneous ooze of blood into the tunica vaginalis. It is usually painless and may be mistaken for a testicular tumour. Indeed, a tumour may present as a haematocele.

Treatment is by orchidectomy unless the testis is indubitably benign. As a rule, it is impossible to be certain until the mass has been bisected. The testis is often compressed and relatively useless (Fig. 75.11).

Edward Gibbon, 1737–1794, the author of 'The Decline and Fall of the Roman Empire', was greatly embarrassed by a large hydrocele. The second time that it was tapped it became infected, and Gibbon died a few days later. The hydrocele was associated with a large scrotal hernia which had probably been punctured.

Otto Eduard Heinrich Wucherer, 1820–1873, a German Physician who practised in Brazil, South America.

Joseph Bancroft, 1836–1894, an English Physician working in Australia.

Figure 75.11 A longstanding haematocele. The testis has been flattened by prolonged pressure.

CYSTS ASSOCIATED WITH THE EPIDIDYMIS

There are several types of cyst associated with the epididymis (Summary box 75.8).

Summary box 75.8

Cysts associated with the epididymis

- Are separate from the testis on palpation
- Unless large or uncomfortable may be treated conservatively when diagnosed with certainty using ultrasound

Epididymal cysts

These are filled with a crystal-clear fluid. They are very common, usually multiple and vary in size at presentation. They represent cystic degeneration of the epididymis.

Clinical features

Cysts of the epididymis are usually found in middle age and are often bilateral. The clusters of tense cysts feel like a tiny bunches of grapes. They should be brilliantly transilluminable. The presence of a scrotal mass always raises the possibility of a testicular neoplasm, but epididymal cysts are almost always quite separate from the testis proper and this is a reassuring sign.

Treatment

Aspiration is useless because the cysts are multilocular. If they are causing discomfort they should be excised. Excision may interfere with the export of sperm from the testis on that side.

Cysts of a testicular appendage

Cysts of a testicular appendage are usually unilateral and are felt as small globular upper pole swellings. Such cysts are liable to torsion and should be removed if they cause symptoms.

Spermatocele

This is a unilocular retention cyst derived from some portion of the sperm-conducting mechanism of the epididymis.

Clinical features

A spermatocele typically lies in the epididymal head above and behind the upper pole of the testis. It is usually softer and laxer than other cystic lesions in the scrotum but, like them, it transilluminates. The fluid contains spermatozoa and resembles barley water in appearance. Spermatoceles are usually small and unobtrusive.

Treatment

Small spermatoceles can be ignored. Larger ones should be aspirated or excised through a scrotal incision.

EPIDIDYMO-ORCHITIS

Inflammation confined to the epididymis is epididymitis; infection spreading to the testis is epididymo-orchitis.

Acute disease

Mode of infection

Infection reaches the epididymis via the vas from a primary infection of the urethra, prostate or seminal vesicles. In men with outflow obstruction, epididymitis may result from a secondary urinary infection – a high pressure in the prostatic urethra causes reflux of infected urine up the vasa. In young men, the most common sexually transmitted infection causing epididymitis is now *Chlamydia*, but gonococcal epididymitis is still prevalent; both cause urethritis. Blood-borne infections of the epididymis are less common but may be suspected when there is *Escherichia coli*, streptococcal, staphylococcal or *Proteus* infection without evidence of urinary infection.

Clinical features

The initial symptoms are those of urinary infection. Later, an ache in the groin and a fever herald the onset of epididymitis. The epididymis and testis swell and become painful. The scrotal wall, at first red, oedematous and shiny, may become adherent to the epididymis. Resolution may take 6–8 weeks to complete. Occasionally, an abscess may form and discharge of pus may occur through the scrotal skin.

Acute epididymo-orchitis can follow any form of urethral instrumentation. It is particularly common when an indwelling catheter is associated with infection of the prostate. The incidence of acute postoperative epididymitis after prostatectomy has been greatly reduced by closed drainage, catheter care and the early use of antibiotics.

Acute tuberculous epididymitis should be considered when the vas is thickened and there is little response to the usual antibiotics.

Acute epididymo-orchitis develops in about 18% of males suffering from mumps, usually as the parotid swelling is waning. The main complication is testicular atrophy, which may cause infertility if the condition is bilateral (which is not usual). Partial

Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the bacterium *coli commune* in 1886.

atrophy is associated with persistent testicular pain. Mumps epididymitis sometimes occurs in the absence of parotitis, especially in infants. The epididymis and testis may be involved by infection with other enteroviruses and in brucellosis and lymphogranuloma venereum.

Treatment

Doxycycline (100 mg daily) is the treatment of choice for young men with chlamydial infection. If an organism is isolated from the urine, this simplifies the choice of antibiotic. Otherwise, treatment is with an agent that is active against a broad spectrum of urinary tract pathogens. The patient should drink plenty of fluid. Local measures can help to reduce pain. The scrotum is supported on a sling made of broad adhesive tape attached between the thighs. The inflamed organ rests on a pad of cotton wool placed on the sling.

Antibiotic treatment should continue for 2 weeks or until the inflammation has subsided. If suppuration occurs, drainage is necessary. The patient should be warned that the testis may atrophy (Summary box 75.9).

Summary box 75.9

Acute epididymo-orchitis

- May be secondary to urinary infection or urethritis
- Is a complication of catheterisation or instrumentation of the urinary tract
- May need aggressive treatment with parenteral antibiotics

Chronic disease

Chronic tuberculous epididymo-orchitis usually begins insidiously.

Aetiology

The frequency with which the lower pole is attacked first indicates that the infection is retrograde from a tuberculous focus in the seminal vesicles.

Clinical features

Typically, there is a firm discrete swelling of the lower pole of the epididymis, which aches a little. The disease progresses until the whole epididymis is firm and craggy behind a normal-feeling testis. There is a lax secondary hydrocele in 30% of cases, and a characteristic beading of the vas may be apparent as a result of subepithelial tubercles. The seminal vesicle feels indurated and swollen. In neglected cases, a tuberculous 'cold' abscess forms, which may discharge. The body of the testis may be uninvolved for years but the contralateral epididymis often becomes diseased.

In two-thirds of cases there is evidence of renal tuberculosis or previous disease. Otherwise, patients typically appear healthy.

The urine and semen should be examined repeatedly for tubercle bacilli in all patients with chronic epididymo-orchitis. An intravenous urogram and a chest radiograph should be performed.

Treatment

Secondary tuberculous epididymitis may resolve when the primary focus is treated.

Treatment with anti-tuberculous drugs is less effective in

genital tuberculosis than in urinary tuberculosis. If resolution does not occur within 2 months, epididymectomy or orchidectomy is advisable. A course of anti-tuberculous chemotherapy should be completed even if there is no evidence of disease elsewhere.

Chronic non-tuberculous epididymitis usually follows the failure of an acute attack to resolve. The condition is difficult to distinguish from tuberculosis but the swelling may be larger and smoother. It is essential to exclude urethral stricture causing reflux of urine down the vas. If alternative granulomatous conditions such as sarcoidosis have been eliminated, chronic epididymitis should be treated with antibiotics. Epididymectomy or orchidectomy should be considered if there is no resolution after 4–6 weeks of conservative treatment.

ORCHITIS

Syphilitic orchitis is now uncommon. There are three types:

- bilateral orchitis, which is a feature of congenital syphilis;
- interstitial fibrosis, which causes painless destruction of the testis;
- gumma of the testis, which presents as a unilateral painless swelling of the testis that grows slowly; it is very difficult to distinguish from a neoplasm without surgical exploration.

Leprous orchitis causes testicular atrophy in over 25% of male lepers.

TUMOURS OF THE TESTES

The lymphatic drainage of the testes is to the para-aortic lymph nodes near the origin of the gonadal vessel. Lymphatics from the medial side of the testis may run with the artery to the vas and drain into a node at the bifurcation of the common iliac artery. The contralateral para-aortic lymph nodes are sometimes involved by tumour spread, but the inguinal lymph nodes are affected only if the scrotal skin is involved.

Most testicular neoplasms are malignant; testicular neoplasm is one of the most common forms of cancer in young men. Maldescent undoubtedly predisposes to malignancy. Even when the testis is located in the scrotum, tumours often escape detection until they have metastasised. Campaigns for regular testicular self-examination help raise awareness of the condition and may lead to earlier diagnosis (Summary box 75.10).

Summary box 75.10

Testis tumours

- A scrotal lump that cannot be felt separately from the testis may be a malignant tumour
- Lymphatic spread is to the retroperitoneal and intrathoracic lymph nodes
- Pulmonary metastases suggest that the tumour is a teratoma

Tumours of the testis are classified according to their predominant cellular type:

- seminoma (40%);
- teratoma (32%);

- combined seminoma and teratoma (14%);
- interstitial tumours (1.5%);
- lymphoma (7%);
- other tumours (5.5%).

Teratomas tend to occur in younger men, with the peak incidence being between 20 and 35 years, whereas the peak incidence of seminoma is between 35 and 45 years. Seminoma is rare before puberty.

Seminoma

A seminoma compresses neighbouring testicular tissue (Fig. 75.12). The enlarged testis is smooth and firm. The cut surface is homogeneous and pinkish cream in colour. Occasionally, fibrous septa form lobules. In rapidly growing tumours there may be areas of necrosis.

A seminoma consists of oval cells with clear cytoplasm and large, rounded nuclei with prominent acidophilic nucleoli. Sheets of cells resembling spermatocytes are separated by a fine fibrous stroma. Active lymphocytic infiltration of the tumour suggests a good host response and a better prognosis.

Seminomas metastasise via the lymphatics (Fig. 75.13) and haematogenous spread is uncommon.

Figure 75.12 Seminoma of the testis.

Figure 75.13 Lymphatic drainage of the testes to para-aortic lymph nodes.

Teratoma

A teratoma arises from totipotent cells in the rete testis and often contains a variety of cell types, of which one or more predominate. The tumour may be tiny but can reach the size of a coconut. Even a large tumour is moulded by the tunica albuginea so that the overall outline of the testis is maintained although the surface may be distorted.

The usual type of teratoma is yellowish in colour with cystic spaces containing gelatinous fluid (Fig. 75.14). Nodules of cartilage are often present.

Histology

- *Teratoma differentiated* (TD) (uncommon): has no histologically recognisable malignant components but it can metastasise. The best known is a dermoid cyst, which may contain cartilage and muscle as well as glandular elements.
- *Malignant teratoma intermediate, teratocarcinoma* (MTI; types A and B) (most common): contains definitely malignant and incompletely differentiated components. There is mature tissue in type A but not in type B.
- *Malignant teratoma anaplastic* (MTA), *embryonal carcinoma*: contains anaplastic cells of embryonal origin. Cells presumed to be from the yolk sac are often responsible for elevated alpha-fetoprotein levels. MTA is not always radiosensitive.
- *Malignant teratoma trophoblastic* (MTT) (uncommon): contains within other cell types a syncytial cell mass with malignant villous or papillary cytotrophoblasts (choriocarcinoma). It often produces human chorionic gonadotrophin (HCG). Spread by the bloodstream and lymphatics is early. It is one of the most malignant tumours known.

Interstitial cell tumours

Interstitial cell tumours arise from Leydig or Sertoli cells. A Leydig cell tumour masculinises; a Sertoli cell tumour feminises.

Prepubertal interstitial cell tumours excrete androgens, which

Figure 75.14 Teratoma of the testis – note the solid and cystic areas (courtesy of Dr Keith Simpson, London).

Franz von Leydig, 1821–1908, Professor of Histology successively at Würzburg, Tübingen, and Bonn, Germany.
 Enrico Sertoli, 1842–1910, Professor of Experimental Physiology, Milan, Italy.

cause sexual precocity and extreme muscular development. Regression of the symptoms after orchidectomy may be incomplete because of hypertrophy of the contralateral testis.

Postpubertal interstitial cell tumours usually arise from Sertoli cells with output of feminising hormones leading to gynaecomastia, loss of libido and aspermia. As a rule, the tumour is benign and orchidectomy cures.

Clinical features

The patient may not seek advice for several months after first noticing that he has a testicular lump. A sensation of heaviness occurs when the testis is two or three times its normal size, but a minority of patients experience pain. Recent trauma to the affected side calls attention to the testicular enlargement but does not initiate the neoplasm.

The testis is enlarged, smooth, firm and heavy. Later, one or more softer protruberances may be palpable. Testicular sensation is often lost, but the sign should be elicited with care to avoid disseminating the disease. If present, a lax secondary hydrocele does not usually obscure the underlying tumour. The epididymis becomes more difficult to feel when it is flattened or incorporated in the growth. The vas is never thickened and rectal examination is normal. The diagnosis is confirmed by ultrasound scanning of the testis (Fig. 75.15).

Secondary retroperitoneal deposits may be palpable, especially just above the umbilicus on the ipsilateral tumour. There may be hepatic enlargement. Sometimes, an enlarged supraclavicular node is the presenting sign of a testicular tumour (Fig. 75.16). A chest radiograph may show pulmonary metastases especially when the primary tumour is a teratoma (Fig. 75.17).

Occasionally, the predominant symptoms are those of metastatic disease. Intra-abdominal disease may cause abdominal or lumbar pain and the mass may be discovered in the epigastrium. Lung metastases are usually silent but they can cause chest pain, dyspnoea and haemoptysis in the later stages of the disease. The primary tumour may not have been noticed by the patient, and indeed may be so tiny that it can be detected only by ultrasonography or operative exploration.

Atypical cases may simulate epididymo-orchitis; there may even be a urinary infection. All testicular swellings should be

Figure 75.15 Testicular ultrasound: the homogeneous tissue of the testicular teratoma on the left of the image produces multiple ultrasound reflections.

Figure 75.16 Distribution of metastases in teratoma of the testis.

Figure 75.17 Cannonball metastases from carcinoma of the testis.

treated with suspicion, and failure to respond to antibiotics raises the possibility of a cancer. Rarely, patients present with severe pain and acute enlargement of the testis because of haemorrhage into a neoplasm. Between 1% and 5% of cases have gynaecomastia (mainly the teratomas).

The hurricane tumour is a malignancy that kills in a matter of weeks. A few teratomas grow slowly with increasing enlargement of the testis over 2 or 3 years.

Treatment of testicular tumours

Staging is an essential step in planning treatment:

- Blood is collected to enable the levels of tumour markers (HCG, alpha-fetoprotein and lactate dehydrogenase) to be measured. Tumour marker levels can be used to monitor the response to treatment.
- A chest radiograph shows whether there are pulmonary deposits.
- Orchidectomy is essential to remove the primary tumour and to obtain histology.
- Computerised tomography (CT) and magnetic resonance imaging (MRI) are the most useful means of detecting secondaries and for monitoring the response to therapy.

Scrotal exploration and orchidectomy for suspected testicular tumour

The spermatic cord is displayed by dividing the external oblique aponeurosis through a groin incision. A soft clamp placed across

the cord stops dissemination of malignant cells as the testis is mobilised into the wound. If necessary, the testis should be bisected along its anterior convexity to examine its internal structure. If there is a tumour or doubts still remain even after frozen section, the cord should be double ligated and divided at the level of the inguinal ring and the testis removed.

Staging of testicular tumours

The stages are:

- stage 1: testis lesion only – no spread;
- stage 2: nodes below the diaphragm only;
- stage 3: nodes above the diaphragm;
- stage 4: pulmonary or hepatic metastases.

Management by staging and histological diagnosis (after orchidectomy)

Seminomas are radiosensitive and excellent results have been obtained by irradiating stage 1 and stage 2 tumours. More recently, the tumour has been shown to be highly sensitive to cisplatin, which is already being used for patients with metastatic disease. Experts are divided as to whether patients with stage 1 disease should be treated with adjuvant chemotherapy.

Teratomas are less sensitive to radiation. Stage 1 tumours can be managed by monitoring the levels of serum markers and by repeated CT. Teratomas at stages 2–4 are managed by chemotherapy. Cisplatin, methotrexate, bleomycin and vincristine have been used in combination with great success. There are also those who advocate adjuvant chemotherapy for stage 1 teratomas, arguing that effective prophylaxis is less troublesome to the patient than prolonged surveillance.

Retroperitoneal lymph node dissection is sometimes needed when retroperitoneal masses remain after chemotherapy (Fig. 75.18). The tissue removed may contain only necrotic tissue, but some patients have foci of mature teratoma or active malignancy. The operation can be formidable if the tumour is large, and retrograde ejaculation is likely unless steps are taken to preserve the sympathetic outflow to the bladder neck.

Figure 75.18 Computerised tomography scan showing a large residual retroperitoneal mass after chemotherapy.

Prognosis

Prognosis of testicular tumours depends on the histological type and the stage of the growth.

Seminoma

If there are no metastases, 95% of patients will be alive 5 years after orchidectomy and radiotherapy or chemotherapy. If there are metastases, the survival rate drops to 75%.

Teratoma

A 5-year survival rate of more than 85% is achievable in patients with stage 1 or 2 teratoma. Among patients with stage 3 and 4 disease, the 5-year survival rate is about 60% and getting better with improvements in chemotherapy (Summary box 75.11).

Summary box 75.11

Testis tumour markers and prognosis

- Tumour markers help to make the diagnosis and to follow the effectiveness of treatment
- Prognosis is excellent when the patient is treated with combination chemotherapy in a cancer centre

Testicular tumours in children

These are usually anaplastic teratomas. They occur before the age of 3 years and are often rapidly fatal.

TUMOURS OF THE EPIDIDYMISS

These may be benign mesothelioma or malignant sarcoma or secondary carcinoma. They are extremely rare but should not be forgotten when the patient presents with a non-cystic lump in the epididymis.

THE SCROTUM

Idiopathic scrotal oedema

This is described above (see under Torsion of the testis p. 1379).

Idiopathic scrotal gangrene

Idiopathic scrotal gangrene (synonym: Fournier's gangrene) is an uncommon and nasty condition (Fig. 75.19). It is a vascular disaster of infective origin that is characterised by:

- sudden scrotal inflammation;
- rapid onset of gangrene leading to exposure of the scrotal contents;
- the absence of any obvious cause in over half the cases.

The condition can follow minor injuries or procedures in the perineal area, such as a bruise, scratch, urethral dilatation, injection of haemorrhoids or opening of a periurethral abscess.

Haemolytic streptococci (sometimes microaerophilic) are associated with other organisms (*Staphylococcus*, *E. coli*, *Clostridium welchii*) in a fulminating inflammation of the subcutaneous

Jean Alfred Fournier, 1832–1915, Syphilologist, Founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.
William Henry Welch, 1850–1934, Professor of Pathology, Johns Hopkins University, Baltimore, MD, USA.

Figure 75.19 Fournier's gangrene.

tissues, which results in an obliterative arteritis of the arterioles to the scrotal skin (cf. gangrene of the abdominal wall).

Clinical features

There is sudden pain in the scrotum, prostration, pallor and pyrexia. Cellulitis spreads until the entire scrotal coverings slough, leaving the testes exposed but healthy.

Treatment

Expert microbiological advice should be obtained. The organisms are usually sensitive to gentamicin and a cephalosporin, which are given until the bacteriological report is available. Wide excision of the necrotic scrotal skin provides the best possible drainage and stops the spread of the gangrene. Many patients die despite active treatment (Summary box 75.12).

Summary box 75.12

Fournier's gangrene

- Idiopathic scrotal gangrene (Fournier's gangrene) requires early and aggressive treatment if the patient is to survive

Filarial elephantiasis of the scrotum

Filarial elephantiasis of the scrotum is caused by obstruction of the pelvic lymphatics by *W. bancrofti* with superadded infection and lymphangitis. In longstanding cases, the enormously swollen scrotum may bury the penis (Fig. 75.20). There is no medical treatment available for this condition. The principle of surgical treatment is the construction of new lymphatic pathways using plastic surgery. In very advanced cases, excision of the affected skin with implantation of the testes into the thighs and a skin graft to the penis may be the only curative treatment.

Non-filarial elephantiasis

Non-filarial elephantiasis can result from fibrosis of the lymphatics caused by lymphogranuloma venereum.

Sebaceous cysts

Sebaceous cysts are common in the scrotal skin. They are usually small and multiple (Fig. 75.21).

Figure 75.20 Elephantiasis of the scrotum burying the penis (courtesy of Mr S. Bhattacharjee, Lucknow, India).

Carcinoma of the scrotum

Known in the nineteenth century as an occupational hazard for chimney sweeps (described by Pott) and mule spinners, the majority of modern cases of squamous carcinoma of the scrotum arise with no obvious aetiological factor. Unlike carcinoma of the penis, carcinoma of the scrotum is almost unknown in India and Asiatic countries.

Clinical features

The growth starts as a wart or ulcer (Fig. 75.22) and as it grows it may involve the testis.

Treatment

The growth is excised with a margin of healthy skin. If associated enlargement of the inguinal nodes does not subside with antibiotics, a bilateral block dissection should be carried out up to the external nodes.

MALE INFERTILITY

Testicular failure

The semen may contain no sperm (azoospermia), few sperm (oligospermia) or predominantly abnormal sperm. The cause is

Percival Pott, 1714–1788, Surgeon, St Bartholomew's Hospital, London, England, described chimney sweeps' cancer of the scrotum in 1775. In those days the chimney sweep's apprentice climbed up inside the chimney.

Figure 75.21 Sebaceous cysts of the scrotum (courtesy of Dr R. Kaje MS, Jimper, India).

presumably some form of testicular dysfunction, which may follow mumps infection, exposure to radiation or testicular trauma but is more often of unknown aetiology. The normal feedback mechanism to control the production of gonadotrophic hormones is disturbed if there is testicular atrophy and the serum

Figure 75.22 Carcinoma of the scrotum with bilateral enlargement of the inguinal lymph nodes (courtesy of Department of Medical Photography, Cardiff Royal Infirmary, Cardiff, UK).

levels of luteinising hormone and follicle-stimulating hormone will be high. In some patients with azoospermia, the testicular biopsy shows a failure of sperm development. Many treatments have been attempted but the results have been disappointing.

Obstruction

Azoospermia may also be caused by obstruction of the pathway of spermatozoa from the testis to the ejaculatory ducts via the epididymis. Testicular biopsy will show active spermatogenesis. If the site of the obstruction can be identified by vasography it may be possible to perform a bypass operation. Unfortunately, even in the best hands, the results of epididymovasostomy are poor.

In some couples there appears to be an immunological basis for the infertility, with clumping of sperm exposed to serum or cervical mucus.

Intracytoplasmic sperm injection (ICSI) has revolutionised the management of male factor infertility. Spermatozoa harvested from the ejaculate, by aspiration of the epididymis or even from testicular biopsy can be injected *in vitro* into ova obtained from the mother. Embryos are then transferred into the mother's uterus at the four- to six-cell stage (Summary box 75.13).

Summary box 75.13

Male infertility

- Atrophy of the testis is associated with raised levels of gonadotrophin in the blood
- Testicular biopsy will show whether azoospermia is a result of obstruction or failure of sperm maturation
- If spermatozoa can be harvested they can be used in ICSI with a fertility rate of around 30%

Vasectomy for sterilisation

Vasectomy for sterilisation is a common and effective contraceptive procedure. It should be undertaken only after the couple has been carefully counselled. Both partners need to know that the operation is performed to make the man permanently sterile. They should be warned that normal contraceptive precautions should continue until the success of the operation is confirmed by semen analysis performed 12–16 weeks after surgery. They should also be warned of the possibility of spontaneous recanalisation, which may restore fertility unexpectedly (Summary box 75.14).

Summary box 75.14

Vasectomy

- Counselling before vasectomy should include mention of the irreversibility of the procedure, the possibility of spontaneous recanalisation and the risk of chronic scrotal pain postoperatively

Vasectomy is easily and painlessly performed under local anaesthetic. The vasa are delivered through tiny bilateral scrotal incisions or through a single midline scrotal incision. For medico-legal reasons it is wise to remove a segment of each vas to prove that it has been successfully divided. Burying the cut ends or turning them back on themselves probably helps to prevent them rejoining.

Reversal of vasectomy may not restore fertility even if technically successful because of the presence of autoantibodies developed against the sequestered sperm. A success rate of 60–80% may be possible if the operation is performed within 3–4 years of vasectomy.

Gynaecology

LEARNING OBJECTIVES

To understand:

- Pelvic anatomy and reproductive physiology
- The common causes of vaginal bleeding and acute pain in early pregnancy
- The surgical management of acute pelvic inflammatory disease, endometriosis, uterine fibroids and ovarian tumours

ANATOMY

The female external genitalia are described as the vulva, which is bordered by the mons veneris anteriorly and the labio-crural folds posterolaterally. The introitus tends to be open in parous women but otherwise appears closed by the apposing labia majora. The labia minora are folds of skin that fuse anteriorly to form the clitoris, which contains erectile tissue similar to the penis. The fourchette is the posterior part of the introitus, which must stretch considerably to allow the delivery of a baby.

The vagina is an elastic, distensible tube, approximately 10 cm long, passing upwards and backwards from the introitus. The cervix protrudes into the vault of the vagina, dividing it into anterior, posterior and lateral fornices. Pelvic structures can be felt in the posterior and lateral fornices on bimanual examination, as the vaginal vault sits just below the pouch of Douglas (the area at the bottom of the pelvic cavity bordered by the uterus anteriorly and rectum posteriorly). The urethra and bladder neck sit above the anterior wall of the vagina; the perineal body and rectum behind the posterior wall (Fig. 76.1).

The uterus, consisting of a body and a cervix, is a pear-shaped structure that is flattened anteroposteriorly giving its cavity a flat, triangular shape. The uterus is supported partly by ligaments attached to the cervix (transverse cervical, pubocervical and uterosacral) consisting of condensed connective tissue. The cervix is a canal, approximately 2 cm long, connecting the external os, which can be seen on speculum examination, to the internal os, where the cervix enters the uterine cavity. The length of the uterine cavity, including the cervical canal, is approximately 6 cm in nulliparous women and approximately 8 cm in parous women. The walls of the uterus are 1–2 cm thick and composed of muscular tissue (myometrium). The uterine cavity is lined with endometrium, a tissue that undergoes cyclical changes in response to ovarian hormones (see the next section).

At the uterine fundus, on either side, are the cornua by which the uterus is connected to each fallopian tube. These are thin, muscular tubes, approximately 10 cm long, which connect the

peritoneal and uterine cavities. They are divided into four parts: intramural, isthmus, ampulla and fimbriated opening, which picks up the oocyte following its release at the time of ovulation. The tubes are very narrow in the isthmic and intramural parts but they widen in the ampullary region. Each tube is contained within the upper part of the broad ligament, a fold of peritoneum on either side of the uterus, which also contains blood vessels and the round and ovarian ligaments. The fimbriated opening and part of the ampulla, however, are free and closely associated with the ovary on either side. The ovaries are flattened, ovoid structures, approximately 3–4 cm long, suspended from the back of the broad ligament on either side of the pelvis. The ovarian blood vessels are contained within the infundibulopelvic ligaments, which are continuations of the broad ligaments to the pelvic brim on either side.

Figure 76.1 Female anatomy.

James Douglas, 1675–1742, Anatomist and Male Midwife, London, England.

Gabriele Falloppio, (Falloppius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy.

The cervix is located in the centre of the bony cavity of the pelvis and the uterus can be pivoted around this point. It is usually angled forwards (anteverted) at approximately 90° relative to the vagina. It is usually freely mobile but filling of the bladder or changes in position may rotate it backwards. In some women the uterus is retroverted, either because of weak ligaments or because the uterus becomes adherent as the result of a disease process such as endometriosis. The uterus may also be angled forward (anteflexed) relative to the cervix when anteverted or backwards (retroflexed) when retroverted, in which case it can usually be felt in the pouch of Douglas on vaginal examination. The commonest cause of an enlarged uterus, aside from pregnancy, is the presence of fibroids (benign tumours of the myometrium) growing inside or outside the uterus. When fibroids are present, the overall size of the uterus is described in terms of weeks of pregnancy as it expands forwards and upwards into the abdominal cavity with increasing gestational age (Fig. 76.1).

REPRODUCTIVE PHYSIOLOGY

The menstrual cycle is under the control of circulating hormones produced within the hypothalamic–pituitary–ovarian axis. Thus, gonadotrophin-releasing hormone (GnRH) produced in the hypothalamus stimulates the pituitary to produce follicle-stimulating hormone (FSH) and luteinising hormone (LH), which in turn control how the ovary produces an oocyte on a monthly basis and also the hormones oestrogen and progesterone. These hormones have an effect on many structures in the body but principally on the endometrium, which prepares itself to receive a fertilised egg during the course of the menstrual cycle. In the first half (proliferative or follicular phase) of the cycle, following menstruation, the endometrium starts to regrow or proliferate in response to oestrogen produced by the growing ovarian follicle. The endometrium becomes thick and spongy during this phase of the cycle, associated with considerable angiogenesis.

Ovulation occurs at midcycle, on approximately day 14 (day 1 of the cycle is defined as the first day of menstruation), following which the follicle is transformed into the corpus luteum. In the second half (secretory or luteal phase) of the cycle the endometrium thickens even more in response to the hormone progesterone, produced by the corpus luteum (Fig. 76.2).

If fertilisation occurs the fertilised egg is transported along a fallopian tube into the uterine cavity and then implants in the endometrium. If fertilisation does not occur or if the fertilised egg

fails to implant, the endometrium is shed and menstruation occurs. Bleeding (a 'period') tends to last for 4 days but can range from 2–6 days. Typically, about 40 ml of blood is lost during each period; if the bleeding is heavy (i.e. greater than 80 ml), blood clots may form. The whole process then starts again in the next menstrual cycle.

If fertilisation does occur, the duration of the pregnancy (gestational age) is traditionally calculated from the first day of the last menstrual period (LMP); however, ovulation may occur earlier or considerably later than day 14 or the woman's recollection of the date of the LMP may be incorrect, which means that calculating gestational age on the basis of the LMP alone may be inaccurate. This explains the alternative practice of calculating gestational age using ultrasound measurements of fetal size.

VAGINAL BLEEDING IN EARLY PREGNANCY

A miscarriage is defined as the spontaneous loss of an intra-uterine pregnancy at less than 24 weeks' gestation. A miscarriage usually starts with painless vaginal bleeding, at which point it is defined as a *threatened miscarriage*. The bleeding may then become heavier with associated uterine cramps, at which point it becomes an *inevitable miscarriage*. Blood clots and products of conception (i.e. fetal and placental tissue) are then passed through the cervical os until the uterus is emptied (defined as a *complete miscarriage*). Sometimes, not all of the products of conception are passed spontaneously (defined as an *incomplete miscarriage*) and the woman may require an evacuation of retained products of conception (ERPC) to remove what is left of the pregnancy. The operation involves passing a plastic suction curette through the cervix into the uterine cavity. The current Royal College of Obstetricians and Gynaecologists (RCOG) recommendations are for ERPC to be considered if there is persistent excessive bleeding, haemodynamic instability, evidence of infected retained tissue or suspected gestational trophoblastic disease. Serious operative complications, which are fortunately rare, include uterine perforation with, possibly, intra-abdominal trauma (e.g. bowel damage), cervical tears and haemorrhage.

In the case of a miscarriage, on vaginal examination there is typically no cervical excitation (pain on moving the cervix) or tenderness in the vaginal fornices, which are signs associated with an ectopic pregnancy. The uterus feels the right size or smaller for the gestational age. The internal cervical os, by definition, is closed if the miscarriage is threatened or complete and open if the miscarriage is inevitable or incomplete. If the fetus has not developed (defined as a *missed abortion*) the uterus will feel small for the gestational age and there may have been no bleeding, in which case the os will be closed. In such circumstances the os will need to be dilated before performing the ERPC.

An ultrasound scan is usually performed to determine whether there is a viable intrauterine pregnancy present. It may not be possible to determine the precise location of the pregnancy because the woman has had a complete miscarriage, the pregnancy is not sufficiently advanced or she has an ectopic

Figure 76.2 Endocrine cycle. E₂, oestrogen; FSH, follicle-stimulating hormone; LH, luteinising hormone; P, progesterone.

pregnancy that is not visible on ultrasound. For these reasons it is important to establish the gestational age as accurately as possible, on the basis of the LMP and the length of the menstrual cycle as well as with any other relevant information, e.g. fertility treatment. It is still not uncommon, especially in early pregnancy, to make the diagnosis of a miscarriage on clinical grounds alone, for example in the case of:

- heavy vaginal bleeding with clots and associated uterine cramps;
- no history of abdominal pain;
- no cervical excitation or tenderness in the vaginal fornices;
- no risk factors for an ectopic pregnancy, e.g. a past history of pelvic inflammatory disease (PID) or previous tubal surgery.

Vaginal bleeding in early pregnancy may also result from a local cause such as a cervical lesion (which may first manifest as bleeding after intercourse) or, rarely, trauma.

VAGINAL BLEEDING IN THE NON-PREGNANT STATE

Bleeding in the non-pregnant state may occur at the time of an expected menstrual period, between periods (intermenstrual bleeding) or after intercourse (post-coital bleeding). It may also occur after surgical instrumentation of the uterus and/or cervix, including insertion of an intrauterine contraceptive device (IUCD). The principal causes of these types of bleeding are shown in Table 76.1.

The mainstay of management is to identify and treat pathology (except in women < 40 years old with heavy, menstrual periods in whom pathology is very rarely found; these women tend to be treated symptomatically). This usually involves ultrasound examination and an endometrial biopsy, either under direct vision at hysteroscopy or blindly with a Pipelle. The indications for endometrial biopsy are shown in Summary box 76.1.

Summary box 76.1

Indications for endometrial biopsy

Endometrial biopsy should be considered in the following women:

- All women > 40 years old with abnormal bleeding
- Younger women with major risk factors for endometrial hyperplasia/cancer:
 - Polycystic ovarian syndrome
 - Obesity
 - Tamoxifen treatment
- Unopposed oestrogen therapy
- Family history of endometrial/colon cancer, especially hereditary non-polyposis colorectal cancer
- Younger women who fail to respond to conventional treatment

Women taking tamoxifen – the selective oestrogen receptor modulator used in breast cancer treatment – represent a special group because the drug can induce endometrial polyps, hyperplasia, cancer and, rarely, uterine sarcomas, which are much more aggressive. Tamoxifen treatment results in a doubling of the risk of endometrial cancer after 1–2 years of treatment and a

Table 76.1 Causes of vaginal bleeding in the non-pregnant state

Menstrual	Endometrial polyp/malignancy ^a Fibroids
Intermenstrual	Vaginal trauma/malignancy Cervical polyp/malignancy Endometrial polyp/malignancy
Post-coital	Vaginal malignancy ^a Cervical ectropion/polyp/malignancy

^a These cancers occur principally in post-menopausal women.

quadrupling after 5 years. The relationship is time dependent and dose independent and the risk does not decrease after stopping treatment. There is no clear consensus regarding the need for screening and which method to use; the alternative, more common, approach is to investigate only those women who develop post-menopausal bleeding with tamoxifen use. Aromatase inhibitors such as anastrozole, letrozole and exemestane, which are also used in the treatment of breast cancer but whose effects are not mediated via the oestrogen receptor, are associated with less endometrial pathology than tamoxifen and it has even been suggested that aromatase inhibitors may reverse abnormalities induced by tamoxifen.

Women with hereditary non-polyposis colorectal cancer (HNPCC) and those who are at high risk of developing HNPCC are another special group as the lifetime risk of developing endometrial cancer is as high as 60%. Unlike sporadic cases of endometrial cancer, which are usually diagnosed during the sixth and seventh decades, the mean age at diagnosis in HNPCC patients is the fifth decade. However, it appears that 5-year survival rates in HNPCC patients with endometrial cancer are similar to those in women with sporadic disease. International guidelines suggest that these women should be screened annually from the age of 35 with transvaginal ultrasound, to measure endometrial thickness and look for polyps, and with endometrial biopsy.

Menstrual bleeding may be excessively heavy, irregular or frequent in the absence of pathology; this is known as dysfunctional uterine bleeding. Medical treatments used to reduce the amount of menstrual loss include tranexamic acid, mefenamic acid and the combined oral contraceptive (COC). It may be necessary to stop the bleeding completely using high-dose progestagens, the COC taken continuously or a GnRH agonist, which induces a menopause-like state. Increasingly, an intrauterine system (IUS) similar to a conventional coil, which releases levonorgestrel, is offered to patients as an alternative; it has the added advantage of being a reliable contraceptive.

The surgical treatments for excessive bleeding and their principal operative complications are described in Table 76.2; they are divided into those procedures that retain the uterus and those that do not. The ovaries may or may not be removed at the same time depending upon the woman's age and any co-existing pathology. The aim of all of the ablation methods is to reduce menstrual bleeding by ablating the endometrial layer and some of the underlying myometrium using electrical, thermal or laser energy. Amenorrhoea is not guaranteed but the procedures are less invasive and costly than hysterectomy. Clearly, none of these surgical treatments is suitable for women who wish to conceive.

Table 76.2 Surgical treatments for excessive vaginal bleeding

Treatment	Route	Major operative risks
Removal of uterus: hysterectomy		
Subtotal (cervix retained)	Abdominal; laparoscopic	Damage to ureter, bladder or bowel; may result in fistula; risks of laparoscopy
Total (cervix removed)	Abdominal; vaginal; laparoscopic; laparoscopic-vaginal	
Retention of uterus: endometrial ablation		
Thermal balloon	Device inserted into uterine cavity	Uterine perforation
Cryotherapy	Device inserted into uterine cavity	Uterine perforation
Microwave	Device inserted into uterine cavity	Uterine perforation; thermal damage to pelvic organs (especially bowel)
Transcervical resection of endometrium	Hysteroscopic	Bleeding; fluid overload; uterine perforation; thermal damage to pelvic organs (especially bowel)

Abnormal bleeding can also be caused by invasive carcinoma of the cervix, the incidence of which has been reduced by screening programmes that aim to detect the precancerous state – cervical intraepithelial neoplasia (CIN) – using cervical cytology. In the UK, this is carried out every 3–5 years in women aged between 20 and 65 years. Infection with certain human papillomavirus (HPV) serotypes (16, 18, 31 and 33) is associated with an increased risk of invasive disease. Abnormalities in cervical cytology are followed up by microscopic examination of the cervix (colposcopy). CIN may be treated with local ablation (cryocautery, cold coagulation, electrodiathermy or laser) or excision [large loop excision of the transformation zone (LLETZ)].

ACUTE PELVIC PAIN IN EARLY PREGNANCY

Ectopic pregnancy

An ectopic pregnancy is one that grows outside the uterine cavity, almost always in a fallopian tube (rare sites include the ovary, cervix and broad ligament). As the ectopic grows the placenta infiltrates blood vessels within the fallopian tube, which can cause bleeding within the tube and bleeding into the peritoneal cavity. Further growth of the ectopic pregnancy can rupture the fallopian tube causing substantial intraperitoneal blood loss. It is the commonest cause of maternal death in the first trimester and accounts for 9% of maternal deaths in the UK. The major risk factors for ectopic pregnancy are shown in Summary box 76.2.

Summary box 76.2

Risk factors for ectopic pregnancy

- Previous pelvic inflammatory disease
- Smoking
- Older age
- Previous spontaneous miscarriage
- Previous medical termination
- History of infertility
- Previous use of an intrauterine contraceptive device

An ectopic pregnancy may be suspected on clinical grounds but making the diagnosis can be difficult because the presentation is so variable and can mimic that of a miscarriage (Summary box 76.3).

Summary box 76.3

Differential diagnoses for acute pain in early pregnancy

- Ectopic pregnancy
- Miscarriage
- Urinary tract infection
- Ovarian accident
- Pain unrelated to pregnancy e.g. acute appendicitis

There may be a history of lower abdominal pain with a small amount of vaginal bleeding at 4–6 weeks' gestation. On vaginal examination there may be cervical excitation and tenderness in the vaginal fornices; the cervical os is closed. Alternatively, the woman may not have any symptoms or physical findings. The urinary pregnancy test is usually positive. Modern monoclonal antibody-based urine tests can detect the beta subunit of human chorionic gonadotropin (β -hCG) at levels of 25 IU l⁻¹, which are reached 9 days post-conception, i.e. on day 23 of the menstrual cycle assuming ovulation occurred on day 14.

A transvaginal ultrasound scan should be performed if the diagnosis is suspected. The complete absence of an intrauterine gestational sac with a positive pregnancy test increases the probability of an ectopic pregnancy unless the pregnancy is not sufficiently advanced for the sac to be seen on ultrasound in the uterus. An ectopic pregnancy is more likely if fluid is seen in the pelvis or an adnexal mass is seen on ultrasound.

In equivocal cases, measuring serum levels of β -hCG can help to establish the diagnosis. β -hCG levels double every 48 hours if the pregnancy is viable and intrauterine. Levels tend to be static or the rise is less than double over a 48-hour period if the pregnancy is ectopic. A single level above approximately 1500 IU l⁻¹ in association with an empty uterus on ultrasound is highly suggestive of an ectopic pregnancy. The best diagnostic test is laparoscopy (Fig. 76.3); occasionally, however, if the pregnancy is not sufficiently advanced, the ectopic pregnancy is too small to be seen in the fallopian tube. There is also a view that a laparoscopy should only be performed once a miscarriage has been excluded because of the surgical and anaesthetic risks associated with the procedure.

Once an ectopic pregnancy has been diagnosed at laparoscopy, a salpingectomy is usually performed. A salpingostomy

Figure 76.3 Laparoscopy showing an ectopic pregnancy.

may be performed instead as some gynaecologists maintain that subsequent intrauterine pregnancy rates are higher and recurrent ectopic rates lower following conservative surgery. Laparoscopy is the preferred approach because it is associated with shorter operation times, less intraoperative blood loss, shorter hospital stays and similar subsequent intrauterine pregnancy rates.

In practice, the type of operation chosen depends on factors such as the following:

- *The amount of bleeding:* an immediate laparotomy may be required if the woman has lost a great deal of blood.
- *The state of the tube,* i.e. the size of the ectopic pregnancy and whether or not it has ruptured (in general, if the ectopic pregnancy is too large the chances of conservative surgery being successful are small; if it has ruptured there is little point in trying to be conservative).
- *The state of the other tube:* one usually tries to be as conservative as possible if the other tube has been affected by PID (i.e. it is closed or densely adherent to other pelvic organs).
- *Previous ectopic pregnancy or tubal surgery:* one usually performs a salpingectomy if a woman has had a previous ectopic pregnancy or tubal surgery in the same tube.
- *The woman's fertility intentions:* one usually performs a salpingectomy if a woman does not want more children.

Sometimes, the ectopic pregnancy is located at the very end of the tube, in which case it may be possible simply to 'milk' it out, thereby conserving the tube. The principal disadvantage of this method is that some residual trophoblastic tissue can be left inside the tube. The tissue often survives and continues to grow, which can cause intra-abdominal bleeding. The best method for determining whether all of the tissue has been removed at surgery is to measure serial serum β -hCG levels, which should fall to zero over time if all of the tissue has been removed; β -hCG levels remain constant or rise if there is residual trophoblastic tissue, which may necessitate another laparoscopy to remove the tube.

In the USA, many women avoid surgery altogether by being treated with intramuscular injections of methotrexate, which is toxic to trophoblastic tissue. The drug has some side-effects and the treatment carries the risks associated with residual trophoblastic tissue, namely internal bleeding and the eventual need for a laparoscopy. In the UK, methotrexate seems to be used only in those patients who are at increased surgical risk (e.g. the morbidly obese or those with extensive pelvic adhesions).

After treatment, the patient who still has one or both tubes should be warned that she is at increased risk of another ectopic pregnancy. She should therefore be encouraged to present as early as possible in a subsequent pregnancy to rule out this diagnosis.

INFECTION

The overwhelming majority of cases of acute PID are caused by ascending infection, which is often sexually transmitted. Rarer causes include spread from other pelvic organs, e.g. the appendix. *Chlamydia trachomatis* is the most common organism responsible for PID; the prevalence of *Neisseria gonorrhoeae* varies depending upon the locality. Infection involves the upper genital tract, particularly the endometrium and fallopian tubes. Risk factors include young age at first sexual activity, a high number of sexual partners and current use of an IUCD; infection may also follow a surgical procedure, e.g. termination of pregnancy.

There are no definitive criteria for the diagnosis of acute PID. Most clinicians rely instead upon the presence of one or more of the following features, which are suggestive of the diagnosis:

- lower abdominal pain and tenderness;
- deep dyspareunia (pain on intercourse);
- abnormal vaginal or cervical discharge;
- cervical excitation and adnexal tenderness;
- fever $> 38^{\circ}\text{C}$.

The differential diagnoses include endometriosis, urinary tract infection, appendicitis and gastrointestinal dysfunction. A raised neutrophil count and an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) level support the diagnosis. Ultrasound may be useful if there appear to be hydrosalpinges present and/or tubo-ovarian abscesses. All women with suspected PID should be screened for *N. gonorrhoeae* and *C. trachomatis* by taking endocervical with or without urethral swabs. *Chlamydia trachomatis* is an intracellular organism; therefore, samples obtained for diagnostic purposes should contain cellular material. It is important to wipe off any discharge before inserting the swab inside the cervical os and firmly rotating it against the endocervix.

The RCOG guidelines recommend a low threshold for empirical treatment because the consequences of failing to treat acute PID effectively are so significant. Treatment should commence as soon as samples have been obtained for culture even though the results are unavailable; it should include a broad-spectrum antibiotic against coliforms and anaerobic species, which are responsible for secondary infection. Contact tracing and treatment, if possible, are essential (Summary box 76.4).

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute Breslau, Germany, (now Wrocław, Poland).

Summary box 76.4

Treatment of pelvic inflammatory disease

- Because of the lack of definitive clinical diagnostic criteria, a low threshold for the empirical treatment of PID is recommended.
- Women with suspected PID should be screened for gonorrhoea and *Chlamydia*. Testing for gonorrhoea should be with an endocervical specimen, tested via culture (direct inoculation on to a culture plate or transport of the swab to the laboratory within 24 hours) or using a nucleic acid amplification test (NAAT). Screening for *Chlamydia* should also be from the endocervix, preferably using a NAAT. Taking an additional sample from the urethra increases the diagnostic yield for gonorrhoea and *Chlamydia*. A first-catch urine sample provides an alternative sample
- Out-patient antibiotic treatment should be commenced as soon as the diagnosis is suspected. Treatment should be based on one of the following regimens:
 - 400 mg oral ofloxacin twice a day plus 400 mg oral metronidazole twice a day for 14 days; or
 - 250 mg intramuscular ceftriaxone immediately or 2 g intramuscular cefoxitin immediately with 1 g oral probenecid, followed by 100 mg oral doxycycline twice a day plus 400 mg metronidazole twice a day for 14 days
- Admission to hospital is appropriate in the following circumstances:
 - surgical emergency cannot be excluded
 - clinically severe disease
 - tubo-ovarian abscess
 - PID in pregnancy
 - lack of response to oral therapy
 - intolerance to oral therapy
- In more severe cases, in-patient antibiotic treatment should be based on intravenous therapy, which should be continued until 24 hours after clinical improvement and followed by oral therapy. Recommended regimens are:
 - 2 g intravenous cefoxitin three times a day plus 100 mg intravenous doxycycline twice a day (oral doxycycline may be used if tolerated), followed by 100 mg oral doxycycline twice a day plus 400 mg oral metronidazole twice a day for a total of 14 days; or
 - 900 mg intravenous clindamycin three times a day plus intravenous gentamicin: 2 mg kg⁻¹ loading dose followed by 1.5 mg kg⁻¹ three times a day (a single daily dose of 7 mg kg⁻¹ may be substituted), followed by 450 mg oral clindamycin four times a day to complete 14 days or 100 mg oral doxycycline twice a day plus 400 mg oral metronidazole twice a day to complete 14 days or 400 mg intravenous ofloxacin twice a day plus 500 mg intravenous metronidazole three times a day for 14 days

Inadequate or inappropriate treatment is associated with a significant risk of developing infertility, ectopic pregnancy, Fitz-Hugh–Curtis syndrome (an extrapelvic manifestation of PID associated with right upper quadrant pain, which probably results from inflammation of the liver capsule and diaphragm) and

Thomas Fitz-Hugh, Jr, 1894–1963, Physician, Chief of the Hematological Section, The University Hospital, The University of Pennsylvania, Philadelphia, PA, USA.
Arthur H. Curtis, 1881–1955, Professor of Obstetrics and Gynecology, The Northwestern Medical School, Chicago, IL, USA.

chronic pelvic pain in the future. The risk of infertility is obviously of great concern. Approximately 20% of women treated for PID will become infertile because of tubal damage; > 50% of tubal infertility cases are due to *Chlamydia* although, interestingly, many of these women do not report a history of PID (Summary box 76.5). In total, 6% of women will have an ectopic pregnancy in the first pregnancy following an episode of acute PID, a figure that is approximately 10 times greater than the rate in the general population.

Summary box 76.5

Chlamydia and gonorrhoea testing

There is a need to test women (especially those sexually active under the age of 25) who present with:

- Purulent vaginal discharge
- Post-coital/intermenstrual bleeding
- Mucopurulent cervicitis
- Inflamed/friable cervix (which may bleed on contact)
- Urethritis
- Suspected pelvic inflammatory disease
- Reactive arthritis

The majority of suspected cases are treated in the community but hospital admission is advisable if there is doubt about the diagnosis or symptoms/signs are severe. In hospital, antibiotics should be given intravenously until 24 hours after clinical improvement. If there is an intrauterine contraceptive device *in situ*, it should be removed with adequate counselling regarding pregnancy risk and future contraception.

Severe PID manifests as a tubo-ovarian abscess, so named because the fallopian tube and ovary become blended into a single, pus-filled, inflammatory mass, which is usually adherent to the uterus and surrounding bowel. The infection may have progressed from a milder form of PID or, increasingly, it may result from the introduction of infection or bowel damage at transvaginal oocyte aspiration in a patient undergoing *in vitro* fertilisation (IVF). Modern medical practice is to manage tubo-ovarian abscesses (Fig. 76.4) conservatively unless the patient fails to

Figure 76.4 Pelvic inflammatory disease.

respond to intravenous antibiotics and systemic support. The response is judged to be inadequate if the woman remains systemically unwell, her symptoms do not improve, fever is not reduced, the white blood cell count does not fall and there is no evidence on ultrasound of the abscess becoming smaller. In such circumstances, surgical treatment is necessary, i.e. adhesiolysis and drainage of the abscess, at laparotomy or laparoscopy. As most women with a tubo-ovarian abscess are in the reproductive years, the intention is always to be as conservative as possible at surgery. Rarely, however, if the abscess has ruptured (Fig. 76.5) and the patient is extremely ill, then hysterectomy and bilateral salpingo-oophorectomy may be necessary.

Abscess drainage under radiological guidance, e.g. a transgluteal approach via the greater sciatic foramen under computerised tomography (CT) guidance, is sometimes performed. Transvaginal ultrasound-guided aspiration has also been advocated. It is clearly less invasive and there are claims that the method is as effective as surgery; however, it carries additional risks such as bowel damage.

UTEROVAGINAL PROLAPSE

Congenital weakness of the pelvic floor ligaments and fascia may be found in conditions such as spina bifida and bladder exstrophy. Far more common, however, are the acquired forms of pelvic floor damage caused by prolonged or difficult labour and multiparity. A gradual increase in denervation of the striated muscle of the pelvic floor with age and oestrogen deficiency at the menopause can also occur in nulliparous women (Fig. 76.6).

A minor degree of prolapse may be asymptomatic but with more significant degrees the patient complains of 'something coming down'. A cystocele (bladder prolapse) and a cystourethrocele lead to the sensation of a lump in the vagina and may also be associated with incontinence and recurrent urinary infections. Uterine descent can lead to backache; with complete prolapse of the uterus (procidentia) there may be vaginal discharge, ulceration of the vaginal skin and bleeding. A rectocele (prolapse

Figure 76.5 Pelvic inflammatory disease with rupture of a pelvic abscess.

of the rectum into the vagina) may cause difficulties with defaecation or a sensation of incomplete defaecation, which is relieved by digital reduction of the prolapse.

Non-surgical management of uterovaginal prolapse is with physiotherapy, hormone replacement therapy and the use of vaginal rings and pessaries. The vinyl ring is inserted between the posterior fornix and the pubic bone. The main complication is vaginal ulceration and infection leading to discharge and bleeding; it is advisable, therefore, to replace the rings frequently. The aims of surgical management are usually to correct the prolapse, treat any associated incontinence and preserve coital function if appropriate. The surgical procedures are intended to restore the uterovaginal anatomy and position. They may be carried out using a vaginal or abdominal approach or increasingly by a laparoscopic or minimal access approach with the use of vaginal slings and tapes (Table 76.3).

Table 76.3 Surgical treatments for uterovaginal prolapse

Condition	Treatment
Urethrocele/cystocele (Fig. 76.6a)	Traditionally, an anterior vaginal wall repair (anterior colporrhaphy) was performed vaginally; now replaced by vaginally inserted tape [transvaginal tape (TVT) or transobturator tape (TOT)] or mesh slings
Uterine prolapse (Fig. 76.6b)	If family complete, a vaginal hysterectomy with an anterior vaginal wall repair if necessary. If the uterus is to be preserved use either amputation of the cervix with suturing of the transverse cervical ligaments vaginally (Manchester repair) or laparoscopic plication of the uterosacral ligaments (McCall suture)
Enterocoele (Fig. 76.6c)	Similar technique to repair of a hernia. The vaginal skin is opened and the hernial sac repaired
Vault prolapse (Fig. 76.6d)	Sacrospinous fixation or sacrocolpopexy; the vault is attached to the sacrum using a non-absorbable suture
Rectocele (Fig. 76.6e)	Posterior colporrhaphy: the posterior vaginal wall is opened, the rectum returned to its normal position and redundant vaginal skin is excised. A laparoscopic approach to repairing the defect in the pelvic floor with or without the use of a mesh is now more popular and as there is no resulting scarring in the vaginal skin the incidence of post-surgery dyspareunia is less

The Manchester repair was introduced at St Mary's Hospital for Women and Children, Manchester, England.

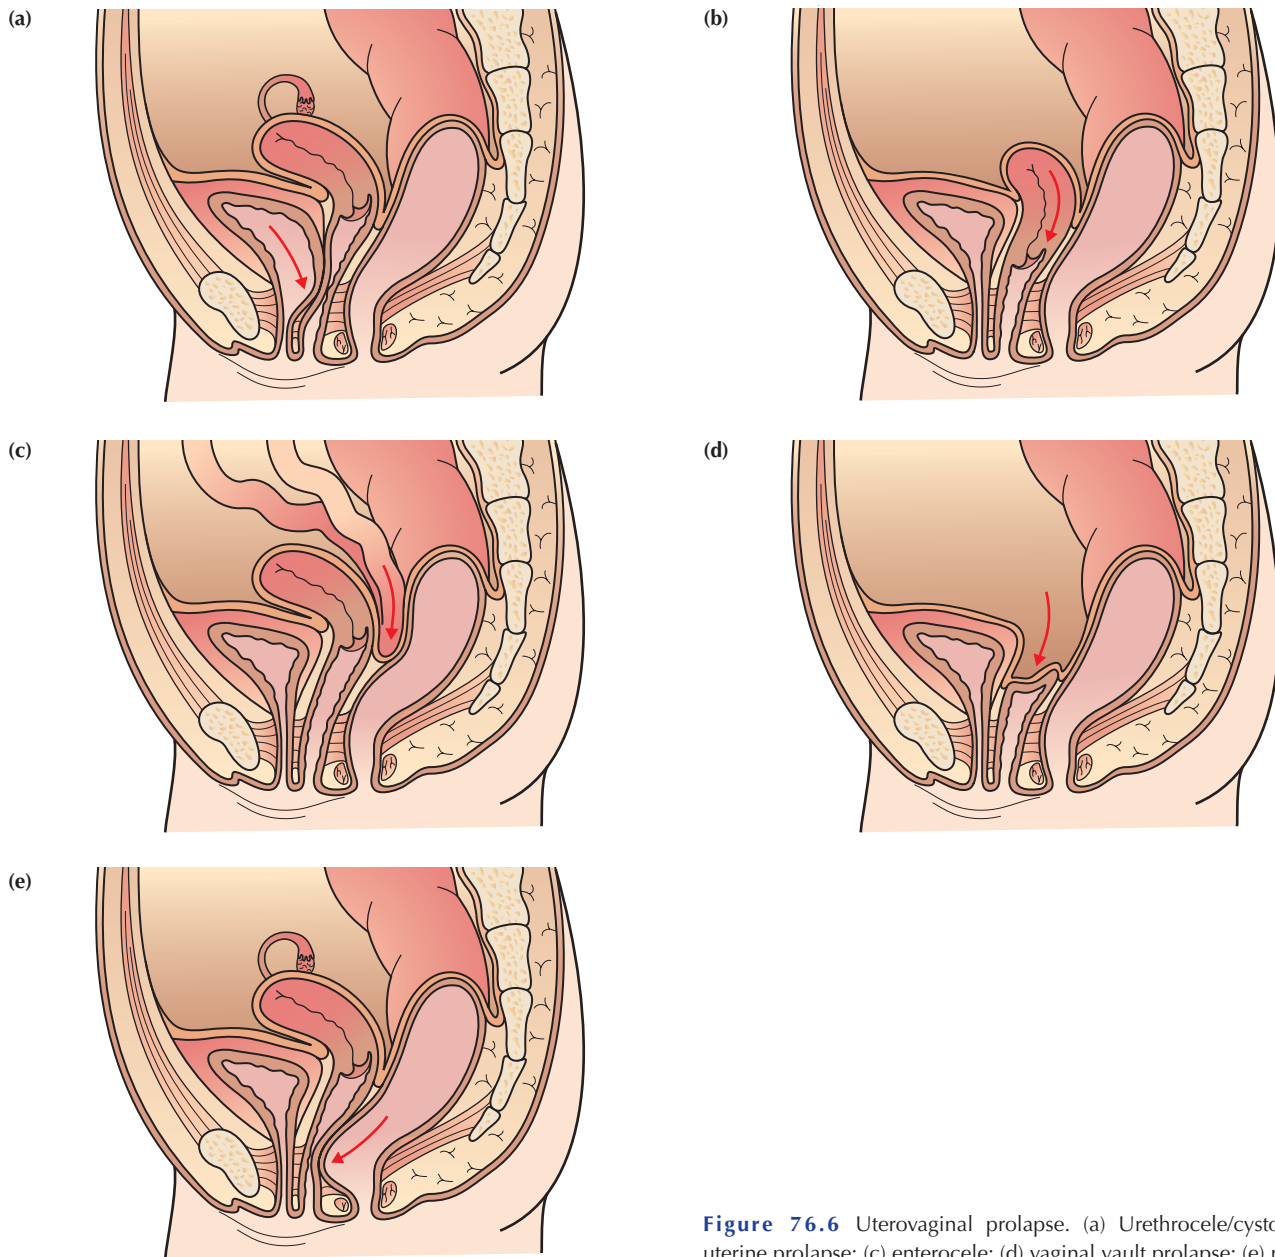

Figure 76.6 Uterovaginal prolapse. (a) Urethrocele/cystocele; (b) uterine prolapse; (c) enterocele; (d) vaginal vault prolapse; (e) rectocele.

TUMOURS

Uterine fibroids (leiomyomas)

Fibroids are benign, well-circumscribed, smooth muscle tumours of the uterus. Most women will have more than one fibroid, varying in diameter from 1–10 cm, which are typically found in the following locations (Fig. 76.7):

- *Subserosal* – may cause pressure symptoms (see below); if pedunculated, they can be difficult to distinguish from an ovarian tumour.
- *Intramural* – may similarly cause pressure symptoms; associated with infertility and heavy periods.
- *Submucosal* – associated with infertility, recurrent pregnancy

loss and heavy periods; if pedunculated, may occasionally extrude through the cervical os.

- *Rare sites* include the broad ligament and cervix.

Women with uterine fibroids will present with heavy and/or irregular menstrual bleeding, pressure symptoms or problems conceiving, especially if there is a fibroid in the uterine cavity. The pressure symptoms include pelvic discomfort, urinary incontinence, frequency and retention, constipation and backache. When large fibroids are present, back pressure may cause or exacerbate varicosities. Although these symptoms are common, it is important to note that some women with fibroids are asymptomatic. Rarely, women may present acutely with pain arising from torsion of a pedunculated fibroid or red degeneration, especially in pregnancy.

Figure 76.7 Uterine fibroids.

Figure 76.8 Magnetic resonance imaging of uterine fibroids.

The diagnosis is usually apparent on bimanual and/or abdominal examination, on the basis of finding an enlarged uterus with attached swellings. The principal differential diagnosis is an ovarian tumour; as a general rule, the uterus is felt separately on vaginal examination if an ovarian tumour is present although not if the structures are adherent to each other. Ultrasound can usually distinguish fibroids from ovarian tumours; if not, magnetic resonance imaging (MRI) is clinically useful (Fig. 76.8) but, sometimes, it may be necessary to perform a laparoscopy to distinguish between the two pathologies (Fig. 76.9)

Emergency surgical treatment is only required if there is substantial menstrual bleeding or uncontrollable pain; these are rare events. Otherwise, the woman has time to consider her treatment options, which include shrinkage of the fibroids by inducing a hypo-oestrogenic state with a GnRH agonist, uterine artery embolisation (UAE), myomectomy (removal of the individual fibroids) and hysterectomy. The choice depends upon the woman's age and fertility intentions, the size and number of fibroids and their location (it is particularly important to know if there are fibroids in the cavity, especially if the woman is trying to conceive).

A GnRH agonist will usually shrink fibroids but this class of

Figure 76.9 Laparoscopic view of a fibroid of the uterine fundus.

drug has the disadvantage that treatment cannot be continued indefinitely because of the associated effect on bone mineral density; in addition, the fibroids tend to regrow to their original size when treatment is discontinued. UAE is becoming increasingly popular as an alternative to surgery. It involves blocking the blood supply to the fibroids using an angiographic technique, in which particles are embolised into each uterine artery via an angiographic catheter in a similar manner to the well-established technique for treating massive post-partum haemorrhage. Following embolisation the fibroids usually shrink, bringing symptomatic relief, i.e. decreased menstrual bleeding and fewer pressure symptoms. Complications include arterial injury at the site of catheter insertion, severe pain as a result of uterine ischaemia, infection, and ovarian damage and thromboembolism (a small number of deaths have been reported from uterine infection and pulmonary embolism). There is no consensus regarding the suitability of the technique for women who wish to conceive. Numerous pregnancies have been reported in women who have had UAE but concern still exists regarding the possible adverse effects on myometrial strength and ovarian function, which might affect a woman's chances of conceiving, carrying the pregnancy and delivering normally.

Myomectomy (performed at laparotomy or increasingly at laparoscopy) involves the removal of pedunculated, subserosal and/or intramural fibroids and closure of any defects left in the uterine wall. Surgical complications are unusual; in exceptional circumstances, however, a hysterectomy may be necessary because of uncontrollable blood loss. Fibroids in the uterine cavity should be removed hysteroscopically; the risks of the procedure are similar to those for transcervical resection of the endometrium (TCRE) (see above).

Endometriosis

Endometriosis – defined as the presence of endometrial-like tissue in extrauterine sites – is a complex genetic trait that affects up to 10% of women in the reproductive years. The symptoms associated with the disease include severe dysmenorrhoea, chronic pelvic pain, ovulation pain, deep dyspareunia, cyclical symptoms related to the involvement of other organs (e.g. bowel

or bladder) with or without abnormal bleeding, infertility and chronic fatigue. However, the predictive value of any one symptom or set of symptoms remains uncertain as each can have other causes (e.g. irritable bowel syndrome) and a significant proportion of affected women are asymptomatic.

The most commonly affected sites are the pelvic organs and peritoneum, although distant sites such as the lungs are occasionally affected (resulting in symptoms such as recurrent haemoptysis at the time of menstruation). The extent of the disease varies from a few, small lesions on otherwise normal pelvic organs to large, ovarian, endometriotic cysts (endometriomas). There can be extensive fibrosis in structures such as the uterosacral ligaments (Fig. 76.10) and adhesion formation causing marked distortion of pelvic anatomy (Fig. 76.11). Disease severity can be assessed simply by describing the operative findings or, quantitatively, using various classification systems, but there is little correlation between such systems and the type or severity of pain symptoms.

Figure 76.10 Endometriosis seen on the uterosacral ligament.

Figure 76.11 Bilateral ovarian endometriosis with pelvic adhesions.

Endometriosis typically appears as superficial 'powder-burn' or 'gunshot' lesions on the ovaries, serosal surfaces and peritoneum – black, dark-brown or bluish puckered lesions, nodules or small cysts containing old haemorrhage surrounded by a variable extent of fibrosis (Fig. 76.12). Atypical or 'subtle' lesions are also common, including red implants (petechial, vesicular, polypoid, haemorrhagic, red flame-like) and serous or clear vesicles. Other appearances include white plaques or scarring and yellow-brown peritoneal discoloration of the peritoneum. Ovarian endometriomas usually contain thick fluid like tar. They are distinguishable from simple haemorrhagic ovarian cysts because, typically, they are densely adherent to the peritoneum of the ovarian fossa. The surrounding fibrosis may involve the bowel. Deeply infiltrating endometriotic nodules represent another disease type. They extend more than 5 mm beneath the peritoneum and may grow into the uterosacral ligaments, vagina, bowel, bladder or ureters; when such lesions grow into the vagina they may be visible on speculum examination as 'blue-domed' cystic lesions in the posterior fornix.

The diagnosis of endometriosis is usually made on visual inspection of the pelvis at laparoscopy; non-invasive diagnostic tools, such as ultrasound scanning, can reliably detect only severe forms of the disease, i.e. endometriomas. The treatment options are limited because the cause is uncertain; treatments include hormonal drugs to suppress ovarian function and surgical ablation of endometriotic lesions with, if necessary, total abdominal hysterectomy and bilateral salpingo-oophorectomy. Women may require multiple admissions for surgery and/or prolonged treatment with costly drugs that have problematic side-effects. Lastly, patients with endometriosis may be at increased risk of ovarian cancer (especially endometrioid and clear-cell types) and non-Hodgkin's lymphoma, which adds to the burden of the disease.

Finding pelvic tenderness, a fixed retroverted uterus, tender

Figure 76.12 Endometriosis seen on the peritoneal surface of the diaphragm.

Thomas Hodgkin, 1798–1866, Curator of the Museum, and Demonstrator of Morbid Anatomy, Guy's Hospital, London, England.

uterosacral ligaments or enlarged ovaries on examination is suggestive of endometriosis. The diagnosis is more certain if deeply infiltrating nodules are found on the uterosacral ligaments or in the pouch of Douglas and/or visible lesions are seen in the vagina or on the cervix. The findings may, however, be normal.

For a woman who has completed her family, hysterectomy plus bilateral salpingo-oophorectomy and removal of all the endometriosis present offers a good chance of cure. However, surgical treatment in a woman who wishes to conceive in the future aims to be as conservative as possible, ensuring in particular that ovarian function is preserved. The aim is to remove all of the endometriotic tissue and restore anatomy to normal by lysing adhesions. The standard (preferably laparoscopic) methods used are ovarian cystectomy and tissue excision or ablation with electrodiathermy, thermal coagulation or laser. The surgical risks include those for any laparoscopic procedure, as well as damage to the ureters and bowel; the risks are increased if deeply infiltrating disease is present, particularly if there is bowel wall involvement.

Benign ovarian tumour and cysts

Overall, 90% of ovarian tumours are benign although there is an increased risk of malignancy in older women. Ovarian tumours are subdivided into five main categories according to the World Health Organization's classification system (Table 76.4).

The most common solid tumours in young women are cystic teratomas (known more commonly as dermoid cysts), which typically contain a variety of tissues including hair, teeth and bone. Benign ovarian tumours are often asymptomatic and may present coincidentally, for example when an abdominal radiograph reveals the appearance of a tooth in the abdomen or pelvis. Conversely, they may present with pain, abdominal swelling and pressure effects. The pain may be the result of torsion or bleeding inside the cysts. Management will depend to some extent on the age of the woman and the characteristics of the cyst. In older women a conservative approach is reasonable only if the risks of malignancy are low (see Ovarian cancer). In younger women (< 35 years) the cyst can be followed by serial ultrasound scanning as many will regress – haemorrhagic corpus luteal cysts, for example, will often shrink after 3–4 months treatment with a COC. If there is uncontrollable pain, haemodynamic collapse or a suspicion of torsion, or the cyst does not regress, then laparoscopic ovarian cystectomy with conservation of ovarian tissue is the treatment of choice. As the vast majority of oocytes lie within 5 mm of the surface of the ovary, a carefully carried out cystectomy can leave a normally functioning ovary (Fig. 76.13) (Summary box 76.6).

Figure 76.13 Ovarian cystectomy.

Summary box 76.6

Management of benign ovarian cysts

- Masses are usually detected incidentally but may be suggested by symptoms and signs
- A pregnancy test is done to exclude ectopic pregnancy
- Transvaginal ultrasonography can usually confirm the diagnosis. If results are indeterminate, MRI or CT may help. Masses with radiographic characteristics of cancer (e.g. cystic and solid components, surface excrescences, multilocular appearance, irregular shape) require excision
- Tumour markers may help in the diagnosis of specific tumours
- In women of reproductive age, simple, thin-walled cystic adnexal masses of 5–8 cm (usually follicular) without characteristics of cancer do not require further investigation unless they persist for more than three menstrual cycles
- Most ovarian cysts < 8 cm resolve without treatment; serial ultrasonography is carried out to document resolution. Cyst removal (ovarian cystectomy) via laparoscopy or laparotomy may be necessary for cysts ≥ 8 cm, cysts that persist for more than three menstrual cycles and haemorrhagic corpus luteum cysts with peritonitis
- Cystic teratomas require removal via cystectomy if possible. Oophorectomy is carried out for fibromas, cystadenomas, cystic teratomas > 10 cm and cysts that cannot be surgically removed from the ovary

Table 76.4 Classification of ovarian tumours

Epithelial tumours	Represent about 75% of all ovarian tumours and 90–95% of ovarian malignancies
Sex cord–stromal tumours	Represent about 5–10% of all ovarian neoplasms
Germ cell tumours	Represent about 15–20% of all ovarian neoplasms
Metastatic tumours	Represent about 5% of ovarian malignancies; usually arise from breast, colon, endometrium, stomach and cervical cancers
Other	A small number of other types of neoplasms, which develop from ovarian soft tissue or non-neoplastic processes

Ovarian cancer

Ovarian cancer is the sixth most common malignancy amongst women worldwide and the leading gynaecological cause of death in the developing world. In the UK, over 6000 women die annually from ovarian cancer. Over 90% of cancers arise from the surface epithelium of the ovary (which has the same embryological origins as the peritoneum); the majority are sporadic rather than inherited. The peak incidence is in the age range of 60–70 years. The overall 5-year survival rate is less than 50% because approximately two-thirds of women present with advanced disease. The usual presenting symptoms are:

- abdominal distension and/or pain;
- weight gain and increased girth (ascites);
- urinary obstruction.

However, over half of all women present initially to a speciality other than gynaecology, with often vague symptoms caused by metastatic disease, e.g. shortness of breath, gastrointestinal disturbance or a change in bowel habit. Consequently, it is important to include ovarian cancer in the differential diagnosis of any woman presenting with recent onset of persistent, non-specific, abdominal symptoms (including those whose abdomen and pelvis appears normal on clinical examination).

Ultrasound is the first-line investigation if an ovarian mass is suspected on clinical grounds. The features suggestive of malignancy on ultrasound include the presence of:

- cyst complexity (number of locules, wall structure, thickness of septae, fluid echogenicity);
- solid papillary projections into the cyst;
- bilateral lesions;
- ascites;
- intra-abdominal metastases.

The level of cancer antigen 125 (CA-125; a glycoprotein expressed on tissue derived from coelomic and müllerian epithelia) in serum is measured; the normal cut-off value is 35 U ml⁻¹. Elevated levels are found in 50% of patients with stage I disease and > 90% of those with advanced disease. However, CA-125 levels are also elevated in other cancers, e.g. pancreas, breast, lung and colon. Levels may even be raised during menstruation; in benign conditions such as endometriosis, PID and liver disease; if ascites or other effusions are present; and after a recent laparotomy. The value of combining the ultrasound and CA-125

measurements is such that a post-menopausal woman with a simple, unilateral, unilocular cyst of < 5 cm in diameter and a normal serum CA-125 level should be managed conservatively (Summary box 76.7).

Summary box 76.7

Basic tests on suspicion of ovarian malignancy

- **Ultrasonography:** findings that suggest cancer include a solid component, surface excrescences, size > 6 cm, irregular shape and low vascular resistance on transvaginal Doppler flow studies
- A pelvic mass plus ascites usually indicates ovarian cancer but sometimes indicates Meigs' syndrome (a benign fibroma with ascites and right hydrothorax)
- CT or MRI is usually carried out before surgery to determine the extent of the cancer
- Tumour markers, including the β subunit of human chorionic gonadotropin (β -hCG), lactate dehydrogenase, α -fetoprotein, inhibin and CA-125, are also measured
- CA-125 is elevated in 80% of advanced epithelial ovarian cancers but may be mildly elevated in endometriosis, pelvic inflammatory disease, pregnancy, fibroids, peritoneal inflammation and non-ovarian peritoneal cancer

Unfortunately, there are still no effective screening methods for ovarian cancer for the general population. Hence, the results of the UK Collaborative Trial of Ovarian Cancer Screening are eagerly awaited. The study aims to randomise 200 000 post-menopausal women to a control arm or one of two screening strategies: primary screening using measurement of serum CA-125 levels followed by transvaginal ultrasound as a second-line test or transvaginal ultrasound alone.

There is also no consensus regarding how women who are at high risk because of a family history should be screened, i.e. those with a first-degree relative affected by cancer within a family that meets one of the following criteria:

- two or more individuals with ovarian cancer, who are first-degree relatives of each other;
- one individual with ovarian cancer at any age and one with breast cancer diagnosed at < 50 years, who are first-degree relatives of each other (or second-degree relatives if the transmission is paternal);

Table 76.5 Staging of ovarian cancer

Stage I	Growth limited to the ovaries
Stage II	Growth involving one or both ovaries with pelvic extension
Stage III	Tumour involving one or both ovaries with histologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastasis equals stage III. Tumour is limited to the true pelvis but with histologically proven extension to the small bowel or omentum
Stage IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present there must be positive cytology to classify a case as stage IV. Parenchymal liver metastasis equals stage IV

Johannes Peter Müller, 1801–1858, Professor of Anatomy and Physiology, Berlin, Germany, described the paramesonephric duct in 1825.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

Joe Vincent Meigs, 1892–1964, Gynaecological Surgeon, Massachusetts General Hospital, Boston, MA, USA.

A first degree relationship is that between parent and child.

A second degree relationship is that between siblings (ie via the parent), and between a grand-parent and a grand-child.

- one relative with ovarian cancer at any age and two with breast cancer diagnosed at < 60 years, who are connected by first-degree relationships (or second-degree relationships if the transmission is paternal);
- known carrier of relevant cancer gene mutations (e.g. *BRCA1* or *BRCA2*);
- untested first-degree relative of a predisposing gene carrier;
- three or more family members with colon cancer or two with colon cancer and one with stomach, ovarian, endometrial, urinary tract or small bowel cancer in two generations. One of these cancers must be diagnosed at < 50 years;
- an individual with both breast and ovarian cancer.

Some genetic mutations are known to predispose women to ovarian cancer: *BRCA1* and *BRCA2* and the mismatch repair genes associated with HNPCC families. *BRCA1* mutations confer a 30% lifetime risk of ovarian cancer up to the age of 60; the figure for *BRCA2* mutations is 27% up to the age of 70. The mismatch repair genes confer an increased lifetime risk of ovarian cancer of 9–12%, in addition to the increased risk of endometrial cancer (see Vaginal bleeding in the non-pregnant state, p. 1393). Referral to a specialist cancer genetics service is advisable. Women at high risk of ovarian cancer may be offered prophylactic oophorectomy, especially as they may also be at increased risk of breast cancer and there is some evidence to suggest that oophorectomy reduces breast cancer risk in these women. Unfortunately, there is no proven role for screening in women at high risk.

Staging (Table 76.5) is performed at laparotomy via a midline incision if disease is suspected preoperatively by:

- careful evaluation of all peritoneal surfaces;
- four washings of the peritoneal cavity: diaphragm, right and left abdomen, pelvis;
- infracolic omentectomy;
- selected lymphadenectomy of the pelvic and para-aortic lymph nodes;
- biopsy and/or resection of any suspicious lesions, masses and any adhesions;
- random blind biopsies of normal peritoneal surfaces, including that from the undersurface of the right hemidiaphragm, bladder reflection, cul-de-sac, right and left paracolic recesses and both pelvic side walls;
- total abdominal hysterectomy and bilateral salpingo-oophorectomy;
- appendicectomy for mucinous tumours; if a routine appendicectomy results in an intraoperative suspicion of a mucinous tumour, the surgeon should take washings and a biopsy from any suspicious area.

Surgery is the mainstay of treatment for ovarian cancer. The staging laparotomy and histological findings provide accurate information about prognosis and postoperative therapy. The general principle is cytoreductive surgery followed by combination chemotherapy; only a minority of patients with ovarian cancer need bowel resected during the primary procedure or surgery for recurrent disease. The only exception to this rule is a young woman with stage I disease or a borderline tumour who requests unilateral oophorectomy to conserve her fertility.

Stage IA or IB/grade 1 epithelial adenocarcinoma requires no postoperative therapy. Stage IA or IB/grade 2 or 3 cancers and stage II cancers require six courses of chemotherapy (typically, paclitaxel and carboplatin). Stage III or IV cancer requires six courses of similar chemotherapy. Intraperitoneal chemotherapy or high-dose chemotherapy with bone marrow transplantation is under study. Radiation therapy is used infrequently. Even if chemotherapy results in a complete clinical response (i.e. normal physical examination, normal serum CA-125 and negative CT scan of the abdomen and pelvis), about 50% of such patients with stage III or IV cancer will have residual tumour. Of patients with persistent elevation of CA-125, 90–95% have residual tumour.

Ovarian stimulation with oocyte or embryo freezing has been reported in patients with low-grade tumours (grade IA/B) who wish to preserve fertility but the effect of this on the underlying disease is as yet unknown and it must therefore be carried out with caution.

Transplantation

LEARNING OBJECTIVES

To understand and appreciate:

- The immunological basis of allograft rejection
- The principles of immunosuppressive therapy
- The side effects of non-specific immunosuppression
- The major issues concerning organ donation
- The main indications for organ transplantation
- The surgical principles of organ implantation
- The causes of graft dysfunction
- The likely outcomes after transplantation
- The potential future developments in transplantation

HISTORICAL PERSPECTIVE

Since early times the idea of tissue and organ transplantation has captured the imagination of successive generations and, over the centuries, numerous fanciful descriptions of successful transplants have been recorded. One of the most widely cited early examples is that of the Christian Arab Saints Cosmas and Damian who, around 300 AD, were reputed to have successfully replaced the diseased leg of a patient with that from another man who had recently died (Fig. 77.1).

Figure 77.1 Depiction of Saints Cosmas and Damian performing a miraculous transplantation of the leg. Oil painting attributed to the Master of Los Balbases (courtesy of Wellcome Institute Library, London).

The modern era of transplantation began in the 1950s (Table 77.1) and relied on surgical techniques for anastomosing blood vessels that had been developed at the beginning of the twentieth century by Jaboulay and Carrel. The first successful kidney transplant was a living donor transplant performed in 1954 between identical twins by Murray and colleagues at the Brigham Hospital in Boston. This, and other kidney transplants between identical twins, demonstrated the technical feasibility of kidney transplantation, but attempts to perform renal transplantation when the donor and recipient were not genetically identical failed because no effective immunosuppression was available (Fig. 77.2). Then, in 1959, Schwartz and Dameshek discovered that 6-mercaptopurine had immunosuppressive properties, and Calne showed that azathioprine, a derivative of 6-mercaptopurine, prevented the rejection of canine kidney transplants. From the early 1960s, a combination of azathioprine and corticosteroids was used with moderate success to prevent graft rejection after kidney transplantation. These agents were sometimes supplemented with a polyclonal anti-lymphocyte antibody given at the time of transplantation to initiate immunosuppression or used to treat an episode of graft rejection.

The ciclosporin era began in the late 1970s following the discovery of this new agent by Borel and the demonstration by Calne of its potent immunosuppressive properties in clinical studies. The

Sir Roy Yorke Calne, Emeritus Professor of Surgery, The University of Cambridge, Cambridge, England.

Table 77.1 Milestones in organ transplantation

1954	Murray performed successful kidney transplants between identical twins (Boston, MA, USA)
1962	Calne demonstrated the efficacy of azathioprine in preventing rejection of kidney allografts (Boston, MA, USA)
1963	Starzl performed the first human liver transplant (Denver, CO, USA)
1966	Starzl and colleagues used anti-lymphocyte globulin immunosuppression (Denver, CO, USA)
1966	Lillehei and Kelly performed the first human whole-organ pancreas transplant (along with a kidney transplant) (Minneapolis, MN, USA)
1967	Barnard performed the first human heart transplant (Cape Town, South Africa)
1968	Derom performed the first human lung transplant (Ghent, Belgium)
1969	Collins developed Collins' solution, a new kidney preservation solution
1974	Sutherland and Najarin performed the first human pancreatic islet transplant (Minneapolis, MN, USA)
1978	Calne introduced ciclosporin into clinical practice (Cambridge, UK)
1981	Reitz and Shumway performed the first successful human heart–lung transplant (Stanford, CA, USA)
1981	Cosimi and colleagues reported the first use of a therapeutic monoclonal antibody (OKT3) in transplantation
1987	Belzer and colleagues developed University of Wisconsin (UW) solution, a new liver and pancreas preservation solution (Wisconsin, USA)
1989	Starzl demonstrated the clinical efficacy of FK506 (tacrolimus) (Pittsburgh, PA, USA)
1995	Ratner and colleagues first described laparoscopic living donor nephrectomy (Johns Hopkins University, Baltimore, MD, USA)

**Figure 77.2** One of the early Boston recipients of a kidney transplant from an identical twin, shown here with her twin sister and their children.

introduction of ciclosporin was a major advance and ciclosporin (usually given together with azathioprine and steroids) not only improved the results of renal transplantation but also allowed transplantation of the heart and liver to be undertaken with acceptable results. Organ transplantation is now well established as an effective treatment for selected patients with end-stage organ failure. Kidney, liver, pancreas, heart and lung transplantation are all routine procedures having a good outcome, and transplantation of the small intestine is becoming more widely practised. Transplant activity is limited only by the shortage of cadaveric organs.

Definitions of common terms used in the area of organ transplantation are given in Summary box 77.1.

Summary box 77.1**Definitions**

- **Allograft:** an organ or tissue transplanted from one individual to another
- **Xenograft:** a graft performed between different species
- **Orthotopic graft:** a graft placed in its normal anatomical site
- **Heterotopic graft:** a graft placed in a site different from that where the organ is normally located
- **Alloantigen:** transplant antigen
- **Alloantibody:** transplant antibody
- **HLA:** human leucocyte antigen, the main trigger of graft rejection

GRAFT REJECTION

Allografts provoke a powerful immune response that results in rapid graft rejection unless immunosuppressive therapy is given. The pioneering studies of Medawar in the 1940s and 1950s firmly established that allograft rejection was due to an immune response and not a non-specific inflammatory response and subsequent studies demonstrated that T lymphocytes play an essential role in mediating rejection.

Allografts trigger a graft rejection response because of allelic differences at polymorphic genes that give rise to histocompatibility antigens (transplant antigens), of which ABO blood group antigens and human leucocyte antigens (HLA) are the most important.

ABO blood group antigens

The ABO blood group antigens are expressed not only by red blood cells but also by most other cell types. For all types of organ allograft it is vitally important to ensure that recipients receive a graft that is ABO blood group compatible otherwise naturally occurring anti-A or anti-B antibodies will likely cause hyperacute graft rejection.

Permissible transplants are:

- group O donor to group O, A, B or AB recipient;
- group A donor to group A or AB recipient;
- group B donor to group B or AB recipient;
- group AB donor to group AB recipient.

There is no need to take account of Rhesus antigen compatibility.

Sir Peter Brian Medawar, 1915–1987, a Zoologist and Immunologist and who was Director of The National Institute for Medical Research, London, England. He shared the 1960 Nobel Prize for Physiology or Medicine with Sir (Frank) Macfarlane Burnett for his research into immunological tolerance.

HLA antigens

Allograft rejection (in blood group-compatible grafts) is directed predominantly against HLA – a group of highly polymorphic cell surface molecules. HLA are strong transplant antigens by virtue of their special physiological role as antigen recognition units, which act to display antigens from foreign pathogens for recognition by T lymphocytes. It was through their role in stimulating graft rejection responses that the existence of these molecules was first demonstrated by Dausset in 1958, hence their description as major histocompatibility antigens (Summary box 77.2).

Summary box 77.2

HLA antigens

- Are the most common cause of graft rejection
- Their physiological function is to act as antigen recognition units
- Are highly polymorphic (amino acid sequence differs widely between individuals)
- HLA-A, -B (class I) and -DR (class II) are the most important in organ transplantation
- Anti-HLA antibodies may cause hyperacute rejection

There are two types of HLA molecule: HLA class I and HLA class II (Table 77.2). They are broadly similar in structure (Fig. 77.3) but have different cell expression profiles. HLA class I antigens are present on all nucleated cells, whereas HLA class II antigens have a more restricted distribution and are expressed most strongly on antigen-presenting cells, such as dendritic cells, macrophages and B lymphocytes. T cells recognise HLA molecules via their T-cell receptors but full T-cell activation also requires an additional or second signal delivered by the interaction of co-stimulatory

Table 77.2 Human leucocyte antigen (HLA) class I and class II molecules

	Class I	Class II
HLA loci	HLA-A, -B and -C	HLA-DR, -DP and -DQ
Structure	Heavy chain and β_2 -microglobulin	α - and β -chain
Distribution	All nucleated cells	B cells, dendritic cells, macrophages

molecules on the surfaces of the antigen-presenting cell and T cell (Fig. 77.4).

Effector mechanisms of rejection

HLA antigens expressed by graft cells activate T cells and stimulate them to proliferate in response to interleukin-2 (IL-2) and other T-cell growth factors. Activated CD4 T cells, through the release of cytokines, play a central role in orchestrating the various effector mechanisms that are responsible for graft rejection (Fig. 77.5). The cellular effectors of graft rejection include cytotoxic CD8 T cells, which recognise donor HLA class I antigens expressed by the graft and cause target cell death by releasing lytic molecules such as perforin and granzyme. Graft-infiltrating CD4 T cells, which recognise donor HLA class II antigens, mediate direct target cell damage and are also able, by releasing cytokines such as interferon- γ , to recruit and activate macrophages that act as non-specific effector cells. Finally, CD4 T cells provide essential T-cell help for B lymphocytes that differentiate into plasma cells and produce alloantibodies which bind to graft antigen and induce target cell injury directly or through antibody-dependent, cell-mediated cytotoxicity.

(a) HLA-Aw68 (class I)

(b) HLA-DR1 (class II)

Figure 77.3 The three-dimensional structure of the extracellular domains of human leucocyte antigen (HLA) class I and class II. The α_1 and α_2 domains of class I and the α_1 and β_1 domains of class II form a cleft that is floored by a β -pleated sheet and walled by two α -helices. The cleft binds an antigenic peptide and displays it on the cell surface for recognition by a T lymphocyte. (Redrawn with permission from Stern, L.J. and Wiley, D.C. (1994) Antigenic peptide binding by class I and class II histocompatibility proteins. *Structure* 2: 245–51. Copyright Elsevier.).

Jean Dausset, B. 1916, a French Immunologist who was Professor of Experimental Medicine at The College of France, Paris, France. He shared the 1980 Nobel Prize for Physiology or Medicine with George Snell and Baruj Benacerraf for his discovery of the HLA antigens.

Figure 77.4 Molecular events involved in T-cell activation by an antigen-presenting cell. T-cell activation requires the delivery of two distinct signals to the T cell. The first signal is delivered by ligation of the T-cell receptor (TCR/CD3) complex with the major histocompatibility complex (MHC/peptide) complex. The second signal is delivered following the interaction between pairs of co-stimulatory molecules such as CD28/B7 and CD40L/CD40.

Types of allograft rejection

Allograft rejection can be divided into three types:

- hyperacute (occurs immediately);
- acute (usually occurs in the first 6 months);
- chronic (occurs months and years after transplantation).

Allograft rejection manifests as functional failure of the transplant and is confirmed histologically. Biopsy material is obtained from renal and pancreatic grafts by needle biopsy and from hepatic grafts by percutaneous or transjugular liver biopsy. Cardiac grafts are biopsied by transjugular endomyocardial biopsy and lung grafts by transbronchial biopsy. After small intestinal transplantation, mucosal biopsies are obtained from the graft stoma or more proximally by endoscopy. A standardised histological grading system, the Banff classification (named after the Canadian town where the initial scientific workshop was held), defines the

presence and severity of allograft rejection after solid organ transplantation (Summary box 77.3).

Summary box 77.3

Types of graft rejection

Hyperacute

- Immediate graft destruction due to ABO or pre-formed anti-HLA antibodies.
- Characterised by intravascular thrombosis

Acute

- Occurs during the first 6 months
- T-cell dependent, characterised by mononuclear cell infiltration
- Usually reversible

Chronic

- Occurs after the first 6 months
- Most common cause of graft failure
- Non-immune factors may contribute to pathogenesis
- Characterised by myo-intimal proliferation in graft arteries leading to ischaemia and fibrosis

Hyperacute rejection

This is due to the presence in the recipient of pre-formed antibodies against HLA class I antigens expressed by the donor. These arise from a previous blood transfusion, a failed transplant or pregnancy. This type of rejection also occurs if an ABO blood group-incompatible organ graft is performed. After revascularisation of the graft, antibodies bind immediately to the vasculature, activate the complement system and cause extensive intravascular thrombosis and graft destruction within minutes and hours. Kidney transplants are particularly vulnerable to hyperacute graft rejection, whereas heart and liver transplants are relatively resistant. Hyperacute rejection can be avoided by ensuring ABO blood group compatibility and by performing a cross-match test on recipient serum to ensure that there are no antibodies directed against HLA antigens expressed by a prospective kidney donor. If recipient serum contains antibodies to donor HLA class I antigens,

Figure 77.5 The central role of the CD4 T cell in orchestrating the various effector mechanisms responsible for allograft rejection. Banff is in Alberta, Canada.

the cross-match test is positive and transplantation should not proceed. Antibodies directed against HLA class II antigens do not usually cause hyperacute rejection but are associated with an increased likelihood of acute rejection and a poor clinical outcome. Patients waiting for a kidney transplant should be screened for the development of HLA antibodies on a regular basis and especially after potential priming to HLA antigens by blood transfusion.

Patients awaiting heart transplantation are also screened for the presence of HLA antibodies and those with pre-formed antibodies are subjected to a prospective cross-match test. Although heart allografts rarely undergo hyperacute rejection, cardiac transplantation in the presence of a positive cross-match is associated with a high incidence of graft loss from accelerated acute rejection.

Even in the presence of a strongly positive cross-match test, liver transplants rarely undergo hyperacute rejection, although their long-term survival is inferior. It is not clear why the liver is resistant to hyperacute rejection. One factor may be that it is less susceptible to ischaemia than the kidney by virtue of its dual blood supply: 60% of the hepatic blood supply is derived from the portal vein and 40% from the hepatic artery.

Acute rejection

This usually occurs during the first 6 months of transplantation but may occur later. It is mediated predominantly by T lymphocytes but alloantibodies may also play an important role. Acute rejection is characterised by mononuclear cell infiltration of the graft (Fig. 77.6). The mononuclear cell infiltrate is heterogeneous and includes cytotoxic T cells, B cells, natural killer (NK) cells and activated macrophages. Antibody-mediated damage may also be present as evidenced by the deposition of the complement component C4d within the graft microvasculature. All types of organ allograft are susceptible to acute rejection and, although relatively common (occurring in around 20–30% of grafts), most episodes of acute rejection can be reversed by additional immunosuppressive therapy.

Chronic rejection

This usually occurs after the first 6 months. All types of transplant are susceptible and it is the major cause of allograft failure. Interestingly, however, the liver appears to be more resistant than other solid organs to the destructive effects of chronic rejection.

Figure 77.6 Severe acute renal allograft rejection with a heavy mononuclear cell infiltrate and intimal arteritis.

The pathophysiology of chronic rejection is not completely understood. The underlying mechanisms are immunological, and both alloantibodies and cellular effector mechanisms appear to be involved. However, alloantigen-independent factors also play an important role in the pathogenesis. A number of risk factors have been identified for chronic rejection of a kidney transplant. These are:

- previous episodes of acute rejection;
- poor HLA match;
- long cold ischaemia time;
- cytomegalovirus (CMV) infection;
- raised blood lipids;
- inadequate immunosuppression (including poor compliance).

The two most important risk factors for chronic rejection after kidney transplantation are acute rejection with vascular inflammation and recurrent episodes of acute rejection. Because non-immune factors often contribute significantly to the long-term failure of a kidney transplant, the term ‘chronic allograft nephropathy’ is usually used in preference to ‘chronic rejection’.

The histological picture of chronic rejection after organ transplantation is dominated by vascular changes, with the development of myo-intimal proliferation in arteries, which results in ischaemia and fibrosis (Fig. 77.7). In addition to vasculopathy there are organ-specific features of chronic graft rejection. These are:

- *kidney*: glomerular sclerosis and tubular atrophy;
- *pancreas*: acinar loss and islet destruction;
- *heart*: accelerated coronary artery disease (cardiac allograft vasculopathy);
- *liver*: vanishing bile duct syndrome;
- *lungs*: obliterative bronchiolitis.

Chronic rejection causes functional deterioration in the graft, resulting after months or years in graft failure. Unfortunately, currently available immunosuppressive therapy has little effect in preventing chronic rejection.

Graft-versus-host disease

Although the main immunological problem after transplantation is graft rejection, the reciprocal problem of graft-versus-host

Figure 77.7 Chronic renal allograft rejection. The arteriole shows severe myo-intimal proliferation and luminal narrowing, resulting in ischaemic fibrosis.

reaction is occasionally seen following certain types of organ transplantation. The donor liver and small bowel both contain large numbers of immunocompetent lymphocytes and these may react against HLA antigens expressed by recipient tissues leading to graft-versus-host disease (GVHD). When GVHD develops it frequently involves the skin, causing a characteristic rash on the palms and soles. It may also involve the liver (after small bowel transplantation) and the gastrointestinal tract (after liver transplantation). GVHD is a serious and sometimes fatal complication.

HLA MATCHING

HLA molecules are encoded by the major histocompatibility complex (MHC), a cluster of genes situated on the short arm of chromosome 6 (Fig. 77.8). The HLA class I antigens comprise HLA-A, -B and -C, and the HLA class II antigens comprise HLA-DR, -DP and -DQ. The expression of MHC genes is co-dominant, i.e. the genes on both the maternally derived and the paternally derived chromosomes are expressed. Consequently, an individual may express between 6 and 12 different HLA antigens, depending on the degree of homozygosity (shared genes) at individual loci.

The HLA haplotype inherited from each parent is usually inherited as a complete haplotype according to simple mendelian genetics (Fig. 77.9). The HLA or 'tissue type' of an individual is determined by DNA typing techniques.

In deceased donor renal transplantation (but not other types of solid organ transplantation) attempts are usually made to match the donor and recipient for as many of the relevant HLA antigens as possible. In addition to reducing the risk of graft loss from rejection, a well-matched kidney allograft that subsequently fails is less likely to cause sensitisation to the HLA antigens that it expresses. It is particularly important in children and young adults to avoid, whenever possible, grafts that are mismatched for common HLA antigens because if re-transplantation is required subsequently it may be difficult to find an organ donor

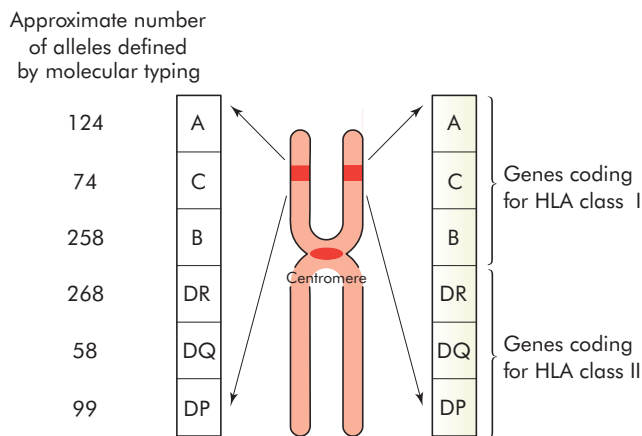

Figure 77.8 The human leucocyte antigen (HLA) system on the short arm of chromosome 6.

Gregor Johann Mendel, 1822–1884, an Austrian monk and naturalist who became Abbot of the Augustinian Monastery at Brunn, The Czech Republic, and discovered the laws of inheritance by studying the edible pea.

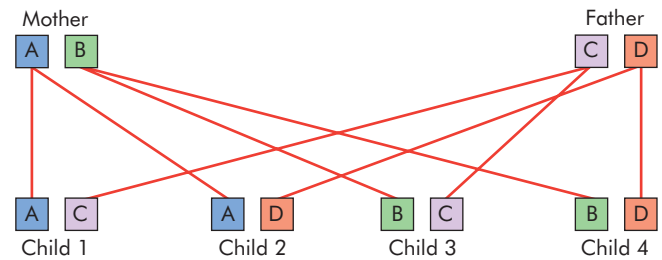

Figure 77.9 Human leucocyte antigen (HLA) inheritance. Children acquire one HLA haplotype (depicted as A–D) from each parent. As shown, child 1 shares one HLA haplotype (haploidentical) with child 2 and child 3, but does not share either haplotype with child 4. The chances that two siblings will share the same parental haplotypes, or that they will share neither HLA haplotype, is one in four. The chance that they will share one HLA haplotype is one in two.

who does not express the antigens to which the recipient has become sensitised. In terms of organ transplantation, HLA-A, -B and -DR are the most important antigens to take into account when matching donor and recipient in an attempt to reduce the risk of graft rejection (Fig. 77.10).

HLA matching has a relatively small but definite beneficial effect on renal allograft survival (HLA-DR > HLA-B > HLA-A). Recipients who receive well-matched renal allografts may require less intensive immunosuppression and also are troubled less by rejection episodes. It is common practice to express the degree of HLA matching between the donor and recipient in terms of whether or not there are mismatches at each locus for HLA-A, -B and -DR. A '000 mismatch' is a 'full house' or complete match, whereas a '012 mismatch' is matched at the HLA-A loci, has one mismatched HLA-B antigen and is mismatched for both HLA-DR antigens. Cadaveric kidneys are allocated in some countries, including the UK, by a points system that optimises HLA matching but also takes into account other factors, such as time on the waiting list, sensitisation to HLA antigens and the age relationship between the donor and recipient. Allocation of organs for transplantation must also take into account the relative size of donor and recipient. This is not an issue in renal transplantation in which adult kidneys can be readily used for paediatric recipients (and vice versa). However, in the case of heart, lung, liver and small bowel transplantation, it is important to consider size compatibility. In the case of liver transplants, HLA matching does not confer an advantage and, although it is beneficial in cardiac transplantation, it is not practicable because of the relatively small size of the recipient pool and the short permissible cold ischaemic time.

IMMUNOSUPPRESSIVE THERAPY

When considering immunosuppressive therapy for organ transplantation the surgeon is faced with an increasing range of agents from which to choose (Table 77.3). The agents used to prevent rejection act predominantly on T cells and the different classes of agent act at different sites during T-cell activation (Fig. 77.11). Most immunosuppressive protocols use a combination of agents. Individual agents can be classified according to their principal mode of action in preventing the T cell-dependent rejection response.

Figure 77.10 Beneficial effect of human leucocyte antigen (HLA) matching (HLA-A, -B and -DR) on first deceased donor renal allograft survival (courtesy of Gerhard Opelz, Collaborative Transplant Study, CTC-K21101, Feb 2007). MM, antigen mismatch.

Table 77.3 Immunosuppressive agents

Agent	Principal mode of action
Corticosteroids	Widespread anti-inflammatory effects
Azathioprine	Prevents lymphocyte proliferation
Mycophenolate mofetil	Prevents lymphocyte proliferation
Ciclosporin	Blocks IL-2 gene transcription
Tacrolimus	Blocks IL-2 gene transcription
Sirolimus/everolimus	Blocks IL-2 receptor signal transduction
OKT3 monoclonal antibody	Depletion and blockade of T cells
ALG/ALS	Depletion and blockade of lymphocytes
Anti-CD25 monoclonal antibody	Targets activated T cells

ALG, anti-lymphocyte globulin; ALS, anti-lymphocyte serum; IL-2, interleukin-2.

Calcineurin blockers (ciclosporin and tacrolimus)

Ciclosporin and tacrolimus are the mainstay of most modern immunosuppressive protocols. Although structurally distinct, they exert their principal immunosuppressive effect through the same intracellular pathway. Each of the two agents binds within the T cell to a particular cytoplasmic protein or immunophilin (ciclosporin binds to cyclophilin and tacrolimus to FK-binding protein). The resulting immunophilin–drug complex then blocks the activity of calcineurin (a phosphatase) within the cytoplasm of the T cell. Calcineurin plays a critical role in facilitating the transcription of IL-2, the main T-cell growth factor, and other cytokines after T-cell activation. By blocking cytokine synthesis, ciclosporin and tacrolimus exert a potent immunosuppressive effect. The agents share a number of side-effects, the most notable of which is nephrotoxicity (Table 77.4). Cosmetic side-effects may be particularly distressing for the patient (Fig. 77.12). The calcineurin blockers have a relatively small therapeutic window. Their immunosuppressive action, as well as their side-effects, are dependent on their blood concentration, and monitoring of whole-blood drug levels is an important guide to optimal therapy. If, after renal transplantation, the graft fails to function immediately because of acute tubular necrosis,

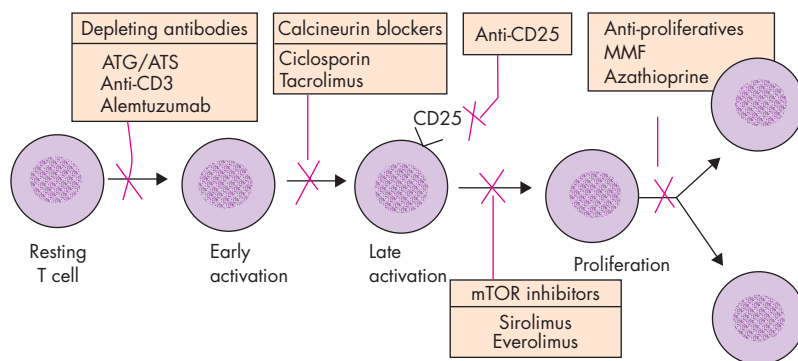

Figure 77.11 Site of action of immunosuppressive agents on the T cell. ATG, anti-thymocyte globulin; ATS, anti-lymphocyte serum; MMF, mycophenolate mofetil; mTOR, mammalian target of rapamycin.

Table 77.4 Side effects of immunosuppressive agents used in organ transplantation

Agent	Side-effect
Corticosteroids	Hypertension, dyslipidaemia, diabetes, osteoporosis, avascular necrosis, cushingoid appearance
Azathioprine	Leucopenia, thrombocytopenia, hepatotoxicity, gastrointestinal symptoms
Mycophenolate mofetil	Leucopenia, thrombocytopenia, gastrointestinal symptoms
Ciclosporin	Nephrotoxicity, hypertension, dyslipidaemia, hirsutism, gingival hyperplasia
Tacrolimus	Nephrotoxicity, hypertension, dyslipidaemia, neurotoxicity, diabetes
Sirolimus/everolimus	Thrombocytopenia, dyslipidaemia, pneumonitis, impaired wound healing
ALG/ALS	Leucopenia, thrombocytopenia
OKT3 monoclonal antibody	Cytokine release syndrome, pulmonary oedema, leucopenia
Anti-CD25 monoclonal antibody	None described

ALG, anti-lymphocyte globulin; ALS, anti-lymphocyte serum.

calcineurin blockers may be reduced temporarily to avoid drug-induced nephrotoxicity. The relative efficacy of ciclosporin and tacrolimus in preventing rejection is broadly similar, and the choice between the two is dependent on the preference of the unit and on individual patient tolerance to the different side-effects.

Figure 77.12 Gingival hyperplasia as a result of ciclosporin treatment.

Anti-proliferative agents (azathioprine and mycophenolate)

Lymphocytes are among the most rapidly proliferating cells in the body, and lymphocyte proliferation and clonal expansion are an integral part of the immune response to an allograft. The antiproliferative agents available for immunoprophylaxis are azathioprine and mycophenolate mofetil (MMF). Azathioprine is converted in the liver to its active metabolite, 6-mercaptopurine, which blocks purine metabolism and thereby inhibits cellular proliferation. Mycophenolate is a newer anti-proliferative agent and has now replaced azathioprine as the agent of choice in many transplant centres. After ingestion, MMF is converted to its active metabolite, mycophenolic acid. It inhibits the enzyme inosine monophosphate dehydrogenase, which is the rate-limiting enzyme in the *de novo* pathway of purine nucleotide synthesis. Because lymphocytes do not have a salvage pathway for purine synthesis, their ability to proliferate is selectively impaired. The main side effects of azathioprine and MMF are bone marrow suppression and gastrointestinal symptoms.

Steroids

Steroids have always been an important component of immunosuppressive regimens. Glucocorticoids are potent anti-inflammatory agents and have wide-ranging effects on the immune response. Because of their numerous and well-known side-effects, some centres attempt to gradually withdraw steroids from patients who have stable graft function after transplantation, but this sometimes precipitates a rejection episode and necessitates continuation of treatment.

Antibody therapies

Monoclonal antibodies directed against the IL-2 receptor on T lymphocytes (CD25) are commonly given at the time of transplantation to temporarily augment the effects of calcineurin blockade during the early post-transplant period. Their effect lasts for a few weeks only and they lack any significant agent-specific side-effects. Polyclonal antibody preparations [anti-lymphocyte globulin (ALG) or anti-lymphocyte serum (ALS)] are also widely used as a more potent and alternative induction agent. They cause a temporary depletion of circulating lymphocytes, which reduces rejection but may lead to an increase in infection and malignancy. In addition to their use as induction agents, polyclonal antibody preparations may be used to treat acute rejection episodes that fail to respond to steroid therapy. Depleting monoclonal antibodies directed against CD3 on T cells are little used now but a newer depleting antibody (alemtuzumab) directed against CD52 (expressed on T cells and dendritic cells) is used by a small but increasing number of units as an induction agent.

mTOR inhibitors (sirolimus and everolimus)

Sirolimus and its structural analogue everolimus are members of a relatively new class of potent immunosuppressive agent. Like tacrolimus, they are macrolides that bind within T lymphocytes to FK-binding protein. However, their mode of action is completely different from that of both ciclosporin and tacrolimus. They act by inhibiting an intracellular kinase called mammalian

de novo is Latin for 'again from the beginning'.

target of rapamycin (mTOR) and thereby interfere with intracellular signalling from the IL-2 receptor and arrest T-cell division in the G1 phase. In contrast to calcineurin blockers they are not nephrotoxic. However, their side-effect profile includes lymphocyte formation, impaired wound healing, an adverse effect on the blood lipid profile, thrombocytopenia and very occasionally a potentially serious pneumonitis. mTOR inhibitors may have anti-tumour activity and the potential value of this effect in transplant patients is under investigation.

Immunosuppressive regimens

When selecting an immunosuppressive regimen, the challenge is to provide levels of immunosuppression that are sufficient to protect the graft from rejection without exposing the recipient to excessive risk from infection and malignancy as a result of non-specific immunosuppression (Summary box 77.4).

Summary box 77.4

Principles of immunosuppression

- Principles are the same for all types of organ transplantation
- The aim is to maximise graft protection and minimise side-effects
- Most regimens are based on calcineurin blockade and include steroids and an anti-proliferative agent
- The need for immunosuppression is highest in the first 3 months but indefinite treatment is needed
- Immunosuppression increases the risk of infection and malignancy

Immunosuppressive therapy is started at the time of transplantation and is continued indefinitely (as maintenance), although the requirement for immunosuppression is highest in the first few weeks after transplantation when the risk of acute rejection is greatest. Immunosuppressive protocols for different types of organ transplant vary somewhat between centres and within centres, but almost all use a combination of immunosuppressive agents acting at different points in the pathway of lymphocyte activation. Nearly all include a calcineurin blocker (cyclosporin or tacrolimus) as the main agent and often this is supplemented with anti-CD25 monoclonal antibody induction therapy. Calcineurin blockers are usually combined with an anti-proliferative agent (most often MMF) and steroids, so called 'triple therapy'. Less often, a calcineurin blocker is used with an anti-proliferative agent alone or with steroids alone (dual therapy). When there is particular concern about acute rejection, polyclonal antibody preparations are administered followed by a calcineurin blocker, an anti-proliferative agent and steroids (quadruple therapy).

The principles of immunoprophylaxis are similar for all types of organ transplantation. However, there is a tendency to use more intensive immunosuppression after thoracic organ transplantation than after kidney transplantation, in part because loss of a heart or lung graft from rejection almost inevitably culminates in death. Interestingly, liver grafts seem to be less susceptible to graft rejection for reasons that are still unclear. The mTOR inhibitors have been shown to be effective immunosuppressive agents for preventing acute rejection following kidney transplantation and they provide a non-nephrotoxic alternative to calcineurin inhibitors for maintenance therapy. They have a

similar safety profile to calcineurin blockers in terms of post-transplant infection but some of their agent-specific side-effects are of potential concern and their clinical niche is still to be determined.

Acute rejection during the first 6 months of transplantation occurs in up to 30% of transplant recipients. Fortunately, the majority of episodes respond to a short course of high-dose steroid therapy. If the response to treatment is inadequate or if acute rejection recurs, rejection can often be treated successfully by anti-lymphocyte antibody therapy.

COMPLICATIONS OF IMMUNOSUPPRESSION

As well as the agent-specific side-effects already mentioned, the immunosuppressive agents used in organ transplantation cause non-specific immunosuppression and increase the risk of both infection and malignancy (Summary box 77.5).

Summary box 77.5

Side effects of non-specific immunosuppression

Infection

- Transplant recipients are at high risk of opportunistic infection, especially by viruses
- Viral infection may result from reactivation of latent virus or from primary infection
- CMV is a major problem
- Bacterial and fungal infections are also common
- Risk of infection is highest during first 6 months after transplantation
- Chemoprophylaxis is important in high-risk patients
- Pre-transplant vaccination against community-acquired infection should be considered

Malignancy

- Recipients are at risk of post-transplant lymphoproliferative disorder
- There is a high risk of squamous cancer of the skin and recipients should be reviewed regularly

Infection

Transplant recipients receiving immunosuppressive therapy are at high risk from opportunistic infection, especially by viruses. This is a potential problem in all recipients but those receiving aggressive immunosuppressive therapy after liver, heart, lung and small bowel transplantation are most at risk. Chemoprophylaxis is important in high-risk recipients, and early recognition followed by prompt and aggressive treatment of infection is essential. Pre-transplant vaccination against community-acquired infections should be considered.

Bacterial infection

The risk of bacterial infection is highest during the first month after transplantation. Recipients are at risk of bacterial infections in the wound, respiratory tract and urinary tract. It is standard practice to give a broad-spectrum antibiotic to cover the perioperative period as prophylaxis against wound infection and possible bacterial contamination of the donor organ. The risk of bacterial infection is greatest in transplant recipients who are critically ill before or after surgery and who are in the intensive care unit with indwelling catheters and lines. After

recovery from surgery the risk of bacterial infection is much reduced. Tuberculosis is a concern in patients who have previously had mycobacterial infection and in patients from the Indian subcontinent. It is usual to give immunoprophylaxis to these individuals for a period of 6–12 months after transplantation.

Viral infection

The risk of viral infection is highest during the first 6 months after transplantation and the most common problem is CMV infection. CMV disease may arise because of reactivation of latent infection or because of primary infection that can be transmitted by an organ from a CMV-positive donor. The recipients at most risk from CMV infection are those who are CMV seronegative (i.e. those who have not been infected previously with CMV) who receive an organ from a CMV-seropositive donor. Matching seronegative donors with seronegative recipients is an effective strategy for reducing the risk of CMV infection but is not practicable. CMV disease typically presents with a high swinging fever, lethargy and leucopenia. The severity of the disease is variable and the clinical picture depends on the organ system most affected. It may present as:

- pneumonia;
- gastrointestinal disease;
- hepatitis;
- retinitis;
- encephalitis.

Severe CMV disease is potentially fatal. Prophylaxis for CMV consists of passive immunisation using hyperimmune immunoglobulin or, more commonly now, the administration of anti-viral agents in the form of aciclovir, valaciclovir, ganciclovir or valganciclovir. A diagnosis of active CMV infection can be confirmed by serology, detection of CMV antigenaemia, CMV culture, detection of viral DNA using the polymerase chain reaction (PCR), and histological examination of biopsy material. Treatment is with anti-viral agents and is more effective when given pre-emptively on the basis of increased viral load as judged, for example, by quantitative PCR analysis of CMV.

Herpes simplex virus (HSV) infection is common after transplantation and is usually due to reactivation of latent infection. It causes mucocutaneous lesions around the mouth and sometimes the genitalia. These usually respond to topical treatment with aciclovir but, in severe cases, systemic anti-viral therapy is needed. Disseminated HSV infection is rare.

Herpes zoster infection, as a result of reactivation of latent varicella zoster virus, occurs more frequently in transplant patients and should be treated with systemic anti-viral therapy. Primary varicella zoster virus infection (chickenpox) is potentially very serious in immunosuppressed patients but is relatively uncommon as most adults have acquired immunity.

Protozoal infection

Pneumocystis carinii is the most important protozoal infection seen after transplantation. It occurs during the first few months post-transplant and presents with respiratory symptoms. The diagnosis is made by examination of bronchoalveolar lavage fluid or lung biopsy material for evidence of parasite infection. Prophylaxis with co-trimoxazole is effective and is continued for up to 6 months after transplantation.

Fungal infection

Invasive fungal infections are uncommon in renal transplant recipients but infection with *Candida* or *Aspergillus* is more common after other types of solid organ transplantation. Fungal infection usually occurs in the first 3 months after transplantation, and early diagnosis and aggressive treatment are essential to avoid fatal infection.

Malignancy

After transplantation there is an increased risk of developing most types of malignancy but the risk is particularly high for those types of tumour in which viral infection plays an aetiological role. The risk is particularly high for skin cancer and a condition called post-transplant lymphoproliferative disorder (PTLD). Most of the skin cancers seen are squamous cell carcinomas, but basal cell carcinoma and malignant melanoma are also more common than in the general population. The risk of skin cancer after transplantation rises with age and with exposure to sunlight, and it has been predicted that 50% of transplant patients will develop a skin malignancy within 20 years of transplantation. Patients must be warned of this risk before they undergo transplantation and advised to take precautions to protect their skin from excessive sunlight. They should undergo a regular review of their skin to detect early malignancy, and when malignant lesions occur they must be treated promptly and aggressively.

PTLD is an abnormal proliferation of B lymphocytes, usually in response to Epstein–Barr virus infection. The condition presents in a variety of ways including as an infectious mononucleosis-type illness, as lymphadenopathy or with involvement of extranodal sites such as the tonsils, gastrointestinal tract, lung, liver or the transplanted organ (Fig. 77.13). PTLD occurs in around 1–3% of kidney and liver transplant recipients and the incidence is considerably higher in children. Patients at most risk are those who have received aggressive immunosuppression. PTLD is a serious condition with a mortality rate of up to 50%. If it is identified at an early stage, reduction or cessation of immunosuppressive therapy may cause disease regression and result in a cure. Chemotherapy is often given and anti-viral therapy, surgery and radiotherapy may also have a role in treating established disease. Disseminated PTLD and central nervous system (CNS) involvement have a poor prognosis.

Transplant patients also have a 300-fold increased risk of developing Kaposi's sarcoma, although this malignancy is still very uncommon after transplantation.

ORGAN DONATION

Most of the organs used for transplantation are obtained from brainstem-dead, heart-beating deceased donors and in the majority of cases multiple organs are procured. However, the number of organs required to satisfy the needs of transplantation far exceeds the number of deceased donor organs available. This has prompted a relaxation in the organ-specific donor selection criteria and in the use of organs from so called 'marginal donors'.

Michael Anthony Epstein, B. 1921, formerly Professor of Pathology, The University of Bristol, Bristol, England.

Yvonne Barr, B. 1931, a Virologist who emigrated to Australia.

Epstein and Barr discovered this virus in 1964.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

Figure 77.13 (a) Intestinal post-transplant lymphoproliferative disease. Note multiple lesions in the terminal ileum and colon. (b) Atypical B lymphocytes stained positive with a probe for Epstein–Barr virus DNA (courtesy of C. Watson, R. Chavez-Cartaya and D. Wight).

In the case of kidney transplantation there is a trend towards increased living donor transplantation and the use of kidneys from non-heart-beating deceased donors (Summary box 77.6).

Summary box 77.6

Overcoming the shortage of organs for transplantation

- Maximising heart-beating deceased donation
- Use of marginal heart-beating deceased donors
- Use of non-heart-beating donors
- Use of split-liver transplantation
- Increased living donor kidney (and liver) transplantation

Determination of brainstem death

Brain death occurs when severe brain injury causes irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity for breathing. In most countries it is accepted that the condition of brain death equates in medical, legal and religious terms with death of the patient. The concept of brain death arose through necessity in the management of

patients with irreversible brain damage on life support when there was no prospect of recovery. It was not in the interests of such patients, their relatives or the hospital in which they were being treated to delay their inevitable demise by continuing with futile life support. Acceptance of the concept of brain death had major implications for organ transplantation as it allowed the possibility of removal of viable organs from brain-dead patients before their circulation failed.

In many countries brain death is defined in terms of permanent functional death of the brainstem as neither consciousness nor spontaneous respiration is possible in the absence of a functional brainstem. A diagnosis of brainstem death should be considered only when certain preconditions have been met. The patient must have suffered major brain damage of known aetiology, be deeply unconscious and require artificial ventilation. Traumatic head injury and sudden intracranial haemorrhage are the most common causes of brainstem death. Particular care must be taken to ensure that muscle relaxant agents and drugs with known CNS depressant effects are not contributing to the clinical picture. Hypothermia, profound hypotension and metabolic or hormonal conditions that may contribute to CNS depression and confound the diagnosis of brainstem death must also be excluded. When the necessary preconditions have been satisfied, formal clinical assessment of the brainstem reflexes can be undertaken (Summary box 77.1). The UK guidelines state that the tests should be performed on two separate occasions by two clinicians experienced in this area. At least one of the two clinicians should be a consultant and neither should be connected with the transplant team. The time that must elapse between the two sets of brainstem tests is not specified in the guidelines and is determined on the basis of clinical judgement. In the UK there is no requirement to perform electrophysiological or brain perfusion studies to aid the diagnosis of brainstem death. Particular care is required in the diagnosis of brainstem death in neonates and infants (Summary box 77.7).

Summary box 77.7

Clinical testing for brainstem death

Absence of cranial nerve reflexes

- Pupillary reflex
- Corneal reflex
- Pharyngeal (gag) and tracheal (cough) reflex
- Oculovestibular (caloric) reflex

Absence of motor response

- The absence of a motor response to painful stimuli applied to the head/face and the absence of a motor response within the cranial nerve distribution to adequate stimulation of any somatic area is an indicator of brainstem death
- The presence of spinal reflexes does not preclude brainstem death

Absence of spontaneous respiration

- After pre-ventilation with 100% oxygen for at least 5 min, the patient is disconnected from the ventilator for 10 min to confirm absence of respiratory effort, during which time the arterial P_{CO_2} level should be > 8 kPa (60 mmHg) to ensure adequate respiratory stimulation.
- To prevent hypoxia during the apnoeic period, oxygen (6 l min^{-1}) is delivered via an endotracheal catheter

Evaluation of the deceased donor

After a brainstem-dead donor has been referred to the transplant team with a view to organ donation, the general suitability of the potential organ donor must be carefully assessed. Particular care must be taken to assess the donor from the point of view of transmissible infectious agents and malignancy. The medical history should be scrutinised and evidence sought of risk factors for human immunodeficiency virus (HIV), such as intravenous drug abuse. The presence of HIV infection and Creutzfeldt–Jakob disease (CJD) are absolute contraindications to organ donation. Hepatitis B (in most countries) and active systemic sepsis are also contraindications to donation. The presence of malignancy within the past 5 years is usually an absolute contraindication with the exception of primary tumours of the CNS, non-melanotic skin tumours and carcinoma *in situ* of the uterine cervix. If there are no general contradictions to organ donation, consideration is then given to organ-specific selection criteria.

Because of the high demand for donors there has been a progressive relaxation of the organ-specific selection criteria. The chronological age of the donor is less important than the physiological function of the organs under consideration for transplantation. As a rough guide, acceptable donor age ranges for each of the commonly transplanted organs are:

- kidney: 2 years to no upper age limit;
- liver: no age limit;
- heart: 1–65 years;
- lung: 5–65 years;
- pancreas: 10–60 years.

The donated organs should be free from primary disease. Potential kidney donors should have a reasonable urine output and relatively normal serum urea and creatinine levels, although acute terminal elevations are acceptable. Liver donors should not have hepatic disease, although impaired liver function tests are common in deceased donors and do not necessarily preclude donation. Heart donors should have a normal electrocardiogram and, in doubtful cases, echocardiography may be necessary. For lung donors the chest radiograph and gas exchange should be satisfactory, and bronchial aspirates should be free from fungal and bacterial infection. Elevations of blood glucose and serum amylase are not uncommon in deceased donors and do not preclude pancreas donation.

Organ procurement

When brainstem death has been confirmed, management of the donor is aimed at preserving the functional integrity of the organs to be procured. Brainstem death produces profound metabolic and neuroendocrine disturbances leading to cardiovascular instability. Careful monitoring and management of fluid balance is essential. Inotropic support is given and there may be a role for the use of tri-iodothyronine (T_3) and argipressin.

Procurement of multiple organs from a cadaveric donor requires cooperation between the thoracic and abdominal surgical teams. A midline abdominal incision and median sternotomy are used to obtain access. After dissection of the organs to be procured they are perfused *in situ*. The heart is perfused with cold cardioplegia solution via a cannula in the ascending aorta and the lungs are perfused via a cannula in the pulmonary artery. The abdominal organs are perfused with chilled organ preservation solution via an aortic and portal cannula. Blood and perfusate are

vented from the left atrial appendage and the inferior vena cava. This produces rapid cooling of the organs, reduces their metabolic activity and preserves their viability. Additional surface cooling of the abdominal organs may be achieved by application of saline ice slush. The heart and lungs are excised followed by the liver and pancreas and then the kidneys, either *en bloc* or separately. The extent to which the abdominal organs are dissected prior to cold flush depends on the preference of the surgical team. Some surgeons perform minimal dissection prior to cold perfusion and complete the dissection of the abdominal organs *in situ* or on the back table after the organs have been removed *en bloc*. During procurement of the liver, care is taken to ensure that if there is an aberrant hepatic artery arising from the superior mesenteric artery it is included in the aortic patch. Similarly, care is taken to ensure that any polar renal arteries are included on an aortic patch with the renal artery (Fig. 77.14). A length of the donor iliac artery is excised for use in reconstructing the arterial supply of the pancreas prior to implantation.

After removal from the donor, the organs may undergo a further flush with chilled preservation solution and are then placed in two sterile bags and stored at 0–4°C by immersion in ice during transportation to the recipient centre. Once the donor organs have been excised, samples of donor spleen and mesenteric lymph nodes are obtained for determination of tissue type and use in the cross-match test.

Various organ preservation solutions are available for flushing organs before simple cold storage. They all contain impermeants to limit cell swelling, buffers to counter acidosis and electrolytes, the composition of which reflects that of intracellular rather than extracellular fluid. Commonly used preservation solutions include University of Wisconsin (UW) solution and Euro-Collins solution, but there are many others. The use of UW solution (Table 77.5) (developed by Belzer and colleagues) is particularly effective for liver grafts and after perfusion with UW solution the liver can be stored safely for up to 24 hours. The amount of time

Figure 77.14 Deceased donor kidney with multiple renal arteries on an aortic patch. The aortic patch has been shortened to limit the length of the anastomosis needed when joining the donor patch to the side of the recipient external iliac artery (courtesy of Medical Photography, Addenbrooke's Hospital).

in situ is Latin for 'in the place'.

en bloc is French for 'in a block'.

for which an organ can be stored before transplantation varies depending on its type (Table 77.6). After arriving at the recipient transplant centre any necessary bench surgery is undertaken prior to implantation.

Non-heart-beating (asystolic) donors

There is an increasing use of kidneys and more recently livers from non-heart-beating (asystolic) donors (NHBD) in an attempt to address the shortage of organs for transplantation. Kidneys may be procured from patients who are dead on arrival at the hospital or who have died after withdrawal of support or following unsuccessful resuscitation.

NHBD can be grouped according to the Maastricht classification as follows:

- category 1: dead on arrival at hospital;
- category 2: unsuccessful resuscitation in hospital;
- category 3: 'awaiting cardiac arrest' after withdrawal of support;
- category 4: cardiac arrest while brain dead.

Maastricht category 1 and 2 donors are sometimes referred to as uncontrolled NHBD. The warm ischaemic time of kidneys from these two categories of donor is usually longer and less predictable than in the case of category 3 (controlled) donors. The majority of NHBD organs used for transplantation are from category 3 donors. To minimise the warm ischaemic time in NHBD, a

Table 77.6 Maximum and optimal cold storage times (approximate)^a

Organ	Optimal storage time (hours)	Safe maximum storage time (hours)
Kidney	< 24	48
Liver	< 12	24
Pancreas	< 10	24
Small intestine	< 4	8
Heart	< 3	6
Lung	< 3	8

double-balloon catheter may be introduced into the aorta via a femoral cut-down and chilled perfusate used to cool the kidneys *in situ*, preferably within 30 min of circulatory arrest (Fig. 77.15). However, it is more common (except in the case of category 1 and 2 donors) to allow a period of 10–15 min to elapse after cessation of heart beat and formal diagnosis of death before the patient is rapidly transferred to the operating room and the abdomen opened to allow cannulation of the aorta and cold perfusion of the kidneys. Kidneys obtained from NHBD invariably suffer a degree of ischaemic damage, and delayed graft function is more common (typically 50% for category 3 NHBD) than for kidneys obtained from heart-beating cadaveric donors. Irreversible ischaemic necrosis occasionally occurs and the graft never functions adequately (primary non-function). However, overall graft survival results for NHBD kidneys appear similar to those of kidneys obtained from heart-beating deceased donors. NHBD are not generally suitable for organs other than the kidney and liver. To minimise additional ischaemic damage it is essential that organs from NHBD are transplanted with the minimum possible cold storage time.

Living kidney donors

Currently, living donor renal transplants account for around 25–30% of the total renal transplant activity in the UK, but in some countries (notably the Scandinavian countries and the USA) this figure is much higher (> 50%). The justification for living donor renal transplantation is based on the shortage of deceased donor transplants and the superior results obtained. Traditionally, most living donor transplants were between genetically related individuals. However, living donor kidney transplants performed between genetically unrelated individuals also fare better than even well-matched deceased donor grafts, and this observation gave rise to a steady increase in living unrelated kidney transplantation activity, usually between partners. In all

Figure 77.15 *In situ* perfusion of kidneys in a non-heart-beating donor (donation after cardiac death DCD). A double-balloon aortic catheter is introduced through a groin incision and 10–15 litres of chilled preservation solution are administered. The perfusate is vented through a Foley catheter introduced into the femoral vein.

cases of living donation it is essential to ensure that the prospective donor is fully informed and is free from coercion to donate and that the risk is small. In the UK, all living donor transplants require prior approval by the Human Tissue Authority (HTA). An independent practitioner approved by the HTA must provide confirmation to the HTA that the donor and recipient understand the implications of the operation and that there is no evidence of coercion or financial inducement.

Live donation should proceed only after the prospective donor has undergone rigorous assessment to ensure that they are suitable. Before the donation it is essential to perform imaging (usually magnetic resonance angiography or computerised tomography-guided angiography) to delineate the anatomy of the arterial supply to the kidneys. If the left kidney has a single renal artery (10% of kidneys have two or more renal arteries) it is usually chosen for transplantation because it has a longer renal vein, which simplifies the transplant operation. The presence of multiple arteries does not necessarily preclude donation although implantation of living donor kidneys with multiple arteries may increase the chances of vascular complications developing after implantation.

Donor nephrectomy was traditionally undertaken either through a loin incision and retroperitoneal approach or through a midline abdominal incision and transperitoneal approach. In many units laparoscopic donor nephrectomy is now undertaken routinely (Fig. 77.16). After removal from the donor the kidney is

Figure 77.16 Laparoscopic living donor nephrectomy. The left kidney has been mobilised on its vascular pedicle ready for staple transection of the renal vessels and removal via a small midline incision.

flushed immediately with chilled organ preservation solution (Fig. 77.17). The mortality rate for live donation is less than 0.05%; around one-half of reported deaths are due to pulmonary emboli so it is essential to ensure prophylaxis. The major complication rate is around 2%. In the long term, a slight elevation in proteinuria and a small rise in blood pressure accompany unilateral nephrectomy.

Around 35% of potential living donor transplant recipients will be ABO blood group incompatible with their intended donor, which until recently precluded transplantation. However, there are now two potential solutions to this problem. The first is 'paired donation' in which incompatible donor/recipient pairs exchange kidneys between pairs to allow ABO compatible transplantation (Fig. 77.18). Recruitment of more than two pairs to facilitate 'pooled donation' increases the likelihood of matching donors with compatible recipients and, although such schemes pose logistic challenges, they are now operating successfully in several countries. An alternative approach is to transiently deplete the recipient of ABO antibodies by passing their blood through special absorption columns, along with administration of pre-transplant immunosuppressive agents. This approach has been successful in Korea and Scandinavia and more recently elsewhere but graft survival is probably worse than for paired donation. Both paired donation and antibody depletion strategies are also potentially applicable to recipients in which HLA antibodies preclude transplantation.

Living liver donors

Living donor liver transplantation is now undertaken in a number of centres worldwide and is relatively common in some countries where deceased donation is not practised for cultural or religious reasons. The concept was first pioneered to allow children to receive the left lobe or lateral segment from an adult donor. In countries where transplantation from a heart-beating cadaveric donor is undertaken, living donor liver transplantation in children has to a large extent been superseded by the techniques of liver reduction or liver splitting. Split-liver transplantation, first performed by Pichlmayr in 1988, allows the liver from a deceased

Figure 77.17 After removal from the donor the kidney is flushed with chilled organ preservation solution and, if necessary, stored briefly on ice until transplanted into the recipient.

Rudolph Pichlmayr, 1932–1997, Surgeon of Hannover, Germany.

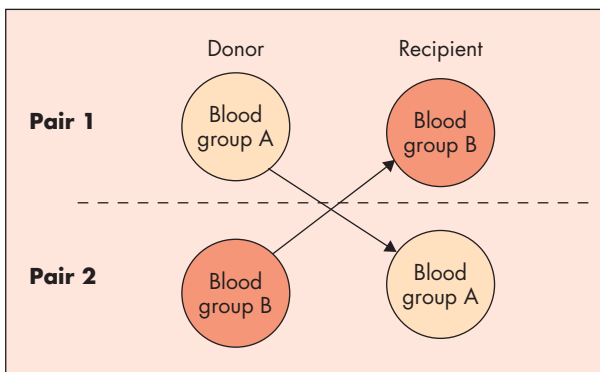

Figure 77.18 Paired living donor kidney transplantation. Paired donation allows patients with willing but blood-group-incompatible donors to be transplanted by pairing them with other incompatible donor–recipient pairs. In the example shown the two willing donors are incompatible with their intended recipients (blood groups A to B and B to A), but by paired donation each recipient can receive an ABO-compatible kidney transplant (blood groups A to A and B to B).

donor to be split in two. The right lobe is used for an adult and the left lobe is usually used for a child, although occasionally a split liver has been used for two adults (Fig. 77.19). In adult-to-adult living donor liver transplantation, the right lobe of the liver is transplanted. The donor procedure has a reported mortality rate of around 0.2% and one of the complications is bile leak.

Living donors: other organs

Occasionally, living donors have provided segments of pancreas, small bowel and lung for transplantation, but this is more controversial. In North America, living donor combined kidney and segmental pancreas transplantation has been undertaken to treat insulin-dependent diabetics with end-stage renal disease. In occasional patients, living donor small bowel transplantation has been performed using a small bowel graft, which comprises a length of around 1.5 m of ileum. Finally, a small number of living donor segmental lung transplants have been performed. To

Figure 77.19 An adult liver may be split (according to Couinaud's segments) so that the left lateral segment (segments II and III) can be transplanted into a child and the right lobe (together with segment IV) can be transplanted into an adult. CHD, common hepatic duct; FL, falxiform ligament; HA, hepatic artery (on aortic patch); IVC, inferior vena cava; LHD, left hepatic duct; LHV, left hepatic vein; LPV, left portal vein; RHA, right hepatic artery; RPV, right portal vein.

provide sufficient pulmonary tissue without compromising the donor it is necessary to use segments from two different donors for each recipient. The ethical issues raised by living donation for extrarenal organs are understandably complex.

Resumption of function following organ transplantation

It is crucial that following heart, lung or liver transplantation the transplanted organ resumes satisfactory function immediately. If primary non-function occurs, the only option is rapid retransplantation. After kidney, pancreas or small bowel transplantation, immediate graft function is desirable but not vital. The factors that determine the functional integrity of a transplanted organ are shown in Summary box 77.8.

Summary box 77.8

Factors determining organ function after transplantation

Donor characteristics

- Extremes of age
- Presence of pre-existing disease in the transplanted organ
- Haemodynamic and metabolic instability

Procurement-related factors

- Warm ischaemic time
- Type of preservation solution
- Cold ischaemic time

Recipient-related factors

- Technical factors relating to implantation
- Haemodynamic and metabolic stability
- Immunological factors
- Presence of drugs that impair transplant function

KIDNEY TRANSPLANTATION

Patient selection

Renal transplantation is the preferred treatment for many patients with end-stage renal disease because it provides a better quality of life than dialysis. Transplantation releases patients from the dietary and fluid restrictions of dialysis and the physical constraints imposed by the need to dialyse. Transplantation is also more cost-effective and probably improves survival.

In the UK, around 80–100 people per million of the population develop end-stage renal disease and the incidence increases with age. The causes of end-stage renal disease are numerous and include:

- glomerulonephritis;
- diabetic nephropathy;
- hypertensive nephrosclerosis;
- renal vascular disease;
- polycystic disease;
- pyelonephritis;
- obstructive uropathy;
- systemic lupus erythematosus;
- analgesic nephropathy;
- metabolic disease (oxalosis, amyloid).

Frequently, the primary cause of end-stage renal disease is uncertain. For renal transplantation, as for other types of organ transplantation, careful patient selection is essential. Before

acceptance as a suitable candidate on the waiting list, all patients should be formally assessed by a transplant surgeon and nephrologist. A significant number are likely to be considered unsuitable because of major comorbidity, especially cardiovascular disease. In the UK, around 30–40% of the dialysis population are on the waiting list for renal transplantation.

The nature of the primary renal disease does not generally affect the decision to proceed to transplantation. Some of the glomerulonephritides [notably immunoglobulin (Ig)A and focal segmental glomerulosclerosis] may subsequently affect a transplanted kidney, but this only occasionally results in failure of the graft in the first 5 years. In the case of primary oxalosis, combined kidney and hepatic transplantation is usually undertaken to eliminate the metabolic defect and thereby prevent early graft failure from the formation of further oxalate stones.

The age of patients with end-stage renal failure accepted for dialysis has gradually risen over the last two decades, and in the UK the mean age of patients starting dialysis is around 70 years. There is no absolute upper age limit to transplantation but, inevitably, older patients (over the age of 65 years) are less likely to be considered because of major comorbidity.

A careful assessment of comorbid disease that might significantly reduce the chances of a successful outcome after transplantation is essential (Summary box 77.9).

Summary box 77.9

Evaluation of potential recipients for organ transplantation

- Evaluation undertaken by appropriate multidisciplinary team including a surgeon and physician
- Determine presence of comorbidity
- Exclude malignancy and systemic sepsis
- Evaluate against organ-specific criteria for transplantation
- Determine probable ability to cope psychologically with transplant and comply with immunosuppression
- Evaluate need for any preparative surgery required to facilitate transplantation
- Optimise recipient condition prior to transplantation

Rigorous evaluation of the cardiovascular system is particularly important. Cardiovascular disease is very common in the dialysis population, especially those with diabetes, and is the major cause of death after transplantation. Before listing patients for transplantation it is important to ensure that their urinary tract is functional and that there is no need for corrective urological surgery. Only when there is intractable renal sepsis or very large polycystic kidneys that intrude into both iliac fossae is native nephrectomy required before transplantation. Finally, the prospective transplant recipient must be deemed able to cope psychologically with transplantation and likely to comply with immunosuppressive therapy.

Immunosuppressive therapy increases the risk of infection and malignancy after transplantation. Consequently, pre-existing malignancy is an absolute contraindication and, even after curative treatment, transplantation should not usually be considered for at least 3 years. Similarly, the presence of active infection is an absolute contraindication.

Technique of renal transplantation

The transplant kidney is placed in the iliac fossa in the retroperitoneal position leaving the native kidneys *in situ*. Using a retroperitoneal approach the donor renal vein is anastomosed end-to-side to the external iliac vein. The donor renal artery on a Carrel patch of donor aorta is anastomosed end-to-side to the external iliac artery (Fig. 77.20a). If the donor renal artery lacks an aortic patch, as in the case of a living donor transplant, it may be preferable to anastomose the donor artery end-to-end to the recipient internal iliac artery (Fig. 77.20 b).

Following completion of the venous and arterial anastomoses, the vascular clamps are removed and the kidney is allowed to reperfuse with blood. The ureter, which is kept reasonably short to avoid the risk of distal ischaemia, is then anastomosed to the bladder (Fig. 77.21). This is most often achieved by direct implantation of the ureter into the dome of the bladder with a mucosa-to-mucosa anastomosis followed by closure of the muscular wall of the bladder over the ureter to create a short tunnel, the Lich–Gregoir technique. A double-J ureteric stent is left *in situ* to reduce the risk of urine leak or early obstruction and removed

Figure 77.20 Implantation of a renal allograft. (a) The renal artery on a Carrel patch is anastomosed to the external iliac artery. (b) The renal artery is anastomosed end-to-end to the internal iliac artery. IVC, inferior vena cava.

Figure 77.21 Ureteric implantation. (a) Lich–Gregoir technique. (b) Leadbetter–Politano technique.

after several weeks during cystoscopy. If the donor ureter is too short to reach the bladder the native ureter can be divided and the distal segment anastomosed to the ureter or renal pelvis of the donor kidney. The proximal segment of the native ureter can usually be ligated and the native kidney left *in situ* without causing a problem. Before closing the transplant wound it is very important to ensure that the kidney is lying in a satisfactory position without kinking or torsion of the renal vessels.

Technical complications

Vascular complications

The incidence of vascular complications after renal transplantation is low. Renal artery thrombosis occurs in approximately 1% of cases. Renal vein thrombosis is more common (up to 5% of cases) and, although sometimes caused by technical error, the aetiology is often uncertain. It presents during the first week after transplantation with sudden pain and swelling at the site of the graft. The diagnosis is confirmed by Doppler ultrasonography. Urgent surgical exploration is indicated and, in most cases, transplant nephrectomy is required. The incidence of renal vein thrombosis can be minimised by giving low-dose heparin or aspirin prophylaxis. Renal artery stenosis usually presents late (often years) after transplantation with increasing hypertension and decreasing renal function. It may occur in up to 10% of grafts and is diagnosed by angiography. Renal artery stenosis is best treated by angioplasty but, if unsuccessful or not technically possible, the condition can be treated by open surgery and vascular reconstruction.

Urological complications

Urological complications occur in around 5% of patients in the early post-transplant period, but their incidence can be reduced markedly by leaving a temporary ureteric stent *in situ*. Urinary leaks result from technical errors at the ureteric anastomosis or because of ureteric ischaemia. They present with discomfort and

leakage of urine from the wound and usually require surgical intervention and reimplantation of the ureter into the bladder or anastomosis of the transplant ureter to the ipsilateral native ureter. Obstruction of the transplant ureter may occur early or late. Causes of obstruction include technical error, external pressure from a haematoma or lymphocele and ischaemic stricture. Ureteric obstruction presents with painless deterioration of graft function and is confirmed by demonstrating hydronephrosis and ureteric dilatation on ultrasound examination. Initial treatment is by percutaneous antegrade nephrostomy and sometimes insertion of a stent. Some ureteric strictures may be amenable to treatment by balloon dilatation but most are best treated by surgical intervention, reimplanting the donor ureter into the bladder or anastomosing it to the native ureter.

Lymphocele

Peri-transplant lymphoceles are usually asymptomatic but occasionally they become large enough to cause ureteric obstruction or oedema of the ipsilateral leg. Initial treatment is usually by ultrasound-guided percutaneous drainage. In the case of large or recurrent lymphoceles, the repeated instillation of povidone-iodine into the lymphocele cavity by a percutaneous drain may lead to resolution. Surgical intervention may be needed to drain a persistent lymphocele into the peritoneal cavity, and this can often be achieved by an ultrasound-guided laparoscopic approach.

Investigation of graft dysfunction

Graft dysfunction during the early postoperative period is a common problem (Summary box 77.10).

Summary box 77.10

Causes of allograft dysfunction

Early

- Primary non-function (irreversible ischaemic damage)
- Delayed function (reversible ischaemic injury)
- Hyperacute and acute rejection
- Arterial or venous thrombosis of the graft vessels
- Drug toxicity (e.g. calcineurin toxicity)
- Infection (e.g. CMV disease in the graft)
- Mechanical obstruction (ureter/common bile duct)

Late

- Chronic rejection
- Arterial stenosis
- Recurrence of original disease in the graft (glomerulonephritis, hepatitis C)
- Mechanical obstruction (ureter, common bile duct)

Delayed graft function (defined as the need for dialysis post-transplantation) as a result of acute tubular necrosis occurs in up to 30% of heart-beating deceased donors and up to 50% of NHBD kidney transplants, but is uncommon (< 5%) following living donor transplantation. Often, recipients produce significant volumes of urine from their native kidneys, making the diagnosis of delayed function more difficult. The incidence of delayed function can be minimised by optimising donor management before kidney procurement and reducing the cold ischaemia time by avoiding unnecessary delay before implantation. As a first step in the management of early graft dysfunction, the urinary catheter should be irrigated in case it is occluded by a blood clot.

Guy W. Leadbetter, a Urologist of Cambridge, VT, USA.
Victor A. Politano, a Urologist who was at The Massachusetts General Hospital, Boston, MA, and is now at the University of Florida, FL, USA.

Hypovolaemia, if present, should be corrected with the aid of central venous pressure (CVP) monitoring. A Doppler ultrasound examination of the graft is the single most important investigation as it allows exclusion of vascular thrombosis and urinary obstruction as causes of graft dysfunction. Renal radionuclide scanning provides information on renal perfusion and excretion and may be helpful. If graft dysfunction is still present after several days, it is usual to perform an ultrasound-guided needle biopsy of the kidney to ensure that graft rejection is not present and to repeat the investigation every week until graft function occurs. To avoid the risk of nephrotoxicity, calcineurin blockers are often withheld or given in reduced doses until graft function is established. If calcineurin blockers are not withheld it is important to monitor their blood levels carefully to avoid nephrotoxicity. Acute tubular necrosis usually resolves within the first 4 weeks of transplantation but a small number of grafts (< 5%) suffer primary non-function (i.e. never function).

Allograft dysfunction developing late (> 1 month after transplant) may be a result of:

- acute/chronic rejection;
- drug toxicity;
- ureteric obstruction (lymphocele/ureteric stricture);
- recurrent disease;
- urinary tract infection.

Blood levels of ciclosporin or tacrolimus are assessed to ensure that they are not elevated, and ultrasound examination of the graft is performed to determine whether ureteric obstruction is present. If obstruction is detected, it is further investigated by percutaneous antegrade pyelography and treated as above. If there is uncertainty about the cause of graft dysfunction, transplant biopsy should be performed to establish if allograft rejection is present.

Outcome after transplantation

The results of organ transplantation are generally defined in terms of patient and graft survival (Summary box 77.11).

Summary box 77.11

Outcome after transplantation

- Transplantation improves the quality and duration of life in most recipients
- Transplant outcome has improved progressively over the last two decades and continues to improve
- Improved outcome is due to better immunosuppression, organ preservation, chemoprophylaxis and technical advances
- Graft survival after kidney, liver and heart transplantation is around 90% at 1 year and 80% at 5 years
- The results of lung and small bowel transplantation are less impressive
- Chronic rejection is the most common cause of graft failure after all types of solid-organ transplant
- Recurrence of the original disease necessitating transplantation may also lead to graft failure
- Death from cardiovascular disease with a functioning transplant is relatively common
- Up-to-date transplant outcomes for different organs can be found in the online national and international transplant databases (see end of chapter for website addresses)

Patient survival after deceased donor renal transplantation is > 90% at 1 year and > 80% at 5 years. Graft survival is around 90% at 1 year and 75% at 5 years. Graft survival after a second transplant is only marginally worse than after a first graft. After living-related kidney transplantation, overall graft survival is around 95% at 1 year and 85% at 5 years. Graft survival after transplantation can also be expressed in terms of the half-life of the graft. The half-life of grafts obtained from living donors is longer than that of cadaveric grafts:

- deceased donor grafts: 13 years;
- living unrelated grafts: 14 years;
- living haploidentical grafts: 15 years;
- living identical sibling grafts: 27 years.

If a kidney transplant fails late after transplantation the graft can often be left *in situ*, but transplant nephrectomy may be indicated if the graft is causing symptoms. The operation is undertaken via the original wound, but the kidney is dissected free from the renal capsule and delivered into the wound. The renal vessels are then ligated and divided, leaving behind the original vascular anastomosis.

In addition to graft survival it is important to consider the extent to which transplantation improves the physical and mental well-being of the patient and allows him or her to lead a satisfactory social life. In the case of the kidney, as in other types of solid organ transplant, successful transplantation undoubtedly leads to a substantial improvement in quality of life. However, although some recipients return to a normal or near-normal life, others fare less well and, for the group overall, the quality of life after transplantation falls short of that seen in normal healthy individuals. Renal transplantation is best regarded, therefore, as an effective form of therapy rather than a complete cure.

PANCREAS TRANSPLANTATION

Successful pancreas transplantation restores the normal control of glucose metabolism and obviates the need for insulin therapy in patients with diabetes mellitus. Improved control of blood glucose levels undoubtedly reduces the progression of secondary complications such as retinopathy, peripheral vascular disease and nephropathy. However, in considering the indications for pancreas transplantation, these advantages have to be weighed carefully against the risks of both the transplant procedure itself and the immunosuppressive therapy. For most patients with diabetes these risks are such that the operation can be justified only when kidney transplantation for diabetic nephropathy is also being undertaken. The only additional risks of pancreas transplantation in such patients relate to the transplant operation itself. In the USA, around one-half of all diabetic patients undergoing kidney transplantation also receive a pancreas transplant. In most cases, the kidney and pancreas are obtained from the same donor, so-called simultaneous pancreas and kidney transplantation (SPKT). Pancreas transplantation is sometimes performed in patients who have already undergone successful kidney transplantation; this is called pancreas after kidney transplantation (PAKT). Occasionally, pancreas transplantation alone (PTA) can be justified to treat life-threatening diabetic complications such as hypoglycaemic unawareness.

Careful patient selection is essential to avoid excessive mortality and morbidity. The procedure is usually reserved for those patients with type I diabetes who are relatively young (under the

age of 55 years) and who do not have advanced coronary artery disease or peripheral vascular disease. Investigation of the heart's response to stress, either using echocardiography or nuclear medicine imaging, is mandatory.

Surgical technique

Most centres now perform transplantation of the whole pancreas together with a segment of duodenum, essentially as pioneered by Lillehei in 1966. Segmental pancreas transplantation is still performed occasionally. SPKT is usually performed through a midline incision (Fig. 77.22). The pancreas graft is placed intraperitoneally in the pelvis, usually on the right, and the kidney graft is placed on the left. The donor vessels of the pancreas graft are anastomosed to the recipient iliac vessels and the exocrine secretions are most commonly dealt with by anastomosing the graft duodenum to the small bowel (enteric drainage), often via a Roux-en-Y loop. The duodenum may also sometimes be anastomosed to the bladder (urinary drainage). The pancreas graft functions immediately after revascularisation, although supplementary insulin may be required for a few days. Technical complications usually occur early and include vascular thrombosis of the graft (5%) and anastomotic leaks. Wound infection occurs in up to 10% of cases and intra-abdominal infection is relatively common. The specific complications of enteric drainage include intra-abdominal sepsis and adhesive small-intestinal obstruction. Bladder drainage of the exocrine pancreas may result in the following complications:

- bladder/duodenal anastomotic leaks;
- cystitis (because of the effect of pancreatic enzymes);
- urethritis/urethral stricture;
- reflux pancreatitis;
- urinary tract infection;

Figure 77.22 Pancreas transplant operation with enteric drainage of the exocrine secretion via a duodenoenterostomy. A 'Y' graft using the donor iliac artery is usually used to reconstruct the divided splenic and superior mesenteric arteries of the graft prior to implantation.

Richard Lillehei, Surgeon, The University of Minnesota, Minneapolis, MI, USA.
Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.

- haematuria;
- metabolic acidosis (caused by loss of bicarbonate in the urine).

Urinary drainage of the pancreas has the advantage that urinary amylase levels can be used to monitor graft rejection. However, urinary complications are common after bladder drainage and in around 20% of cases they are severe enough to require conversion to enteric drainage. Most centres now prefer primary enteric drainage after SPKT.

Acute rejection after SPKT is relatively common (10–20% of cases) and, if detected early, responds to steroids. Because it usually involves both the kidney and pancreas grafts, serum creatinine can be used as a surrogate marker for pancreas graft rejection. Serum lipase and amylase levels are useful indicators of pancreas graft inflammation, of which acute rejection is one cause. Urinary drainage has the advantage after PTA and PAKT of allowing pancreas graft rejection to be monitored by serial measurements of urinary amylase. A fall in urinary amylase is indicative of acute rejection. Elevation of the blood glucose level is a late feature of acute rejection and often indicates the process is beyond reversal.

Results of pancreas transplantation

The principal aim of pancreas transplantation is to prolong life in diabetic patients who otherwise have high mortality rates at 10 years after receiving a kidney transplant alone. It also provides freedom from insulin treatment and improves quality of life.

The results of pancreas transplantation have improved significantly over the last decade. After SPKT, the 1-year patient survival rate is > 95% and the 1-year graft survival rates for pancreas and kidney grafts are 85% and 95% respectively. Most deaths are due to cardiovascular complications or overwhelming infection. Patient and kidney graft survival after SPKT in patients with diabetic nephropathy is at least as good as after kidney transplant alone in this group. The results of PTA are not as good as after SPKT (1-year pancreas graft survival 70%) because acute rejection is more difficult to monitor in the absence of a kidney allograft.

Transplantation of isolated pancreatic islets

Treatment of diabetes by transplantation of isolated islets of Langerhans is a more attractive concept than vascularised pancreas transplantation because major surgery and the potential complications of transplanting exocrine pancreas are avoided. Pancreatic islets for transplantation are obtained by mechanically disrupting the pancreas after injection of collagenase into the pancreatic duct. The islets are then purified from the dispersed tissue by density-gradient centrifugation and can be delivered into the recipient liver (the preferred site for transplantation) by injection into the portal vein. Until recently, human islet transplantation had been performed intermittently and with very disappointing results. Although some degree of islet cell function often occurred initially, this was rarely sustained. However, in 2000, Shapiro and colleagues in Edmonton, Canada, reported success with islet transplantation in seven patients with type I diabetes. Sequential islet transplantation from two or three donor

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiburg, Germany.
Andrew Mark James Shapiro, Chairman of Clinical Research in Transplantation, CIHR/Wyeth Canada, Edmonton, Alberta, Canada.

pancreas glands was required to produce insulin independence and, although the long-term success was less than initially hoped for, some patients remained free from exogenous insulin.

As an alternative to preventing islet cell rejection through immunosuppressive therapy, attempts have been made to protect isolated islet cells from rejection by encapsulating them inside semi-permeable membranes. The protective membranes are designed with a pore size that allows insulin to pass through but prevents antibodies and leucocytes from reaching the islets, thereby avoiding the need for immunosuppressive therapy. A major attraction of this approach is that islets isolated from animals can be used and bioartificial pancreas grafts containing xenogeneic islets are currently under evaluation.

LIVER TRANSPLANTATION

Starzl first attempted liver transplantation in 1963 and, by 1967, had achieved prolonged survival rates. The first liver transplant performed outside the USA was performed in Cambridge in 1968 by Calne. Throughout the 1970s, liver transplantation remained hazardous and frequently failed. However, since then, the results have progressively improved as a result of better patient selection, improved immunosuppression and chemoprophylaxis, better organ preservation, refinements in the operative technique, and advances in pre- and postoperative management. Liver transplantation is now a routine operation in specialist centres.

Indications and patient selection

The indications for liver transplantation fall into four groups:

- cirrhosis;
- acute fulminant liver failure;
- metabolic liver disease;
- primary hepatic malignancy.

The most common indication for transplantation is chronic liver failure. In adults the most common causes are alcoholic liver disease, viral liver disease (hepatitis C in Europe and the USA and hepatitis B in some other countries), primary biliary cirrhosis and sclerosing cholangitis. In children, who account for around 10–15% of all liver transplants, biliary atresia is the most common indication. Acute fulminant liver failure requiring transplantation on an urgent basis accounts for approximately 10% of activity and is usually viral or drug induced (e.g. paracetamol overdose in the UK). There are a variety of metabolic diseases for which transplantation offers the prospect of cure. These include Wilson's disease, oxalosis and alpha-1-antitrypsin deficiency. Primary hepatic malignancy is more common in patients with cirrhosis, especially virally induced disease, and may be best treated by transplantation because tumour resection may leave insufficient functional liver tissue behind. Cholangiocarcinoma has a high recurrence rate and is seldom an indication for transplantation.

Technique of liver transplantation

A transverse abdominal incision with a midline extension is made and the diseased liver is mobilised (Fig. 77.23). Because of portal hypertension, the recipient hepatectomy is often the most difficult

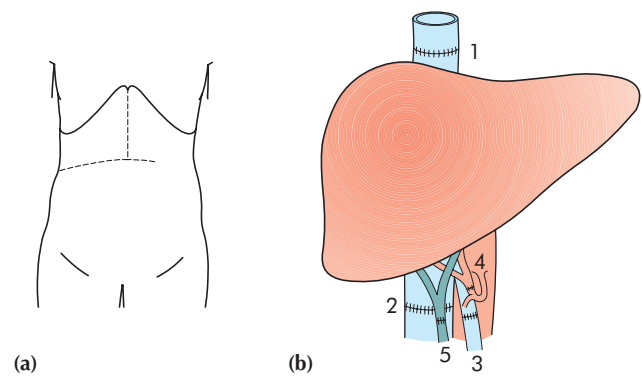

Figure 77.23 (a) Incision used for liver transplantation. (b) Completed implantation. The anastomoses, in order of performance, are: (1) suprahepatic vena cava; (2) infrahepatic vena cava; (3) portal vein; (4) hepatic artery; (5) bile duct.

part of the operation, especially if there has been previous surgery. The common bile duct is divided, as is the hepatic artery. The inferior vena cava is clamped and divided above and below the liver, and the portal vein is clamped and divided, allowing the recipient liver to be removed. Occlusion of the vena cava and portal vein results in a reduction in cardiac output and may necessitate the use of veno-venous bypass. The bypass circuit delivers blood from the portal vein and inferior vena cava back to the heart via a cannula inserted into the axillary vein or the internal jugular veins. After placing the donor liver in position, the supra- and infrahepatic caval anastomoses are performed. The portal vein and the hepatic arterial anastomoses are then completed and the graft is reperfused. Finally, biliary drainage is re-established, usually by a duct-to-duct anastomosis (without the use of a T-tube). It may be necessary, for example in recipients with biliary atresia or sclerosing cholangitis, to reconstruct the biliary drainage by a bile duct to Roux loop anastomosis. An alternative 'piggyback' technique of liver transplantation is sometimes preferred in which the diseased native liver is dissected from the intact inferior vena cava and the suprahepatic vena cava of the donor is anastomosed end-to-side to the anterior wall of the recipient vena cava.

Many patients undergoing liver transplantation are extremely ill and the surgery involved can be very demanding. Optimal perioperative management is crucial for success and presents a major challenge. Blood loss during and after the transplant procedure can be very considerable and management of coagulopathy is particularly important. Coagulation is assessed repeatedly throughout the transplant period and corrected appropriately with fresh frozen plasma, cryoprecipitate and platelets as necessary.

Technical complications

Haemorrhage

Meticulous haemostasis during the transplant operation is essential. It may be necessary, occasionally, to pack the peri-transplant area for 2–3 days to achieve adequate haemostasis when there is diffuse oozing despite correction of coagulopathy. Evacuation of extensive perihepatic haematoma may be required to avoid secondary infection.

Vascular complications

Hepatic artery thrombosis may occur spontaneously or as a result of acute rejection and is more common in children. It may

Thomas Earl Starzl, Professor of Surgery, Pittsburgh, PA, USA.
Samuel Alexander Kinnier Wilson, 1878–1936, Professor of Neurology, King's College Hospital, London, England, described this condition in 1912.

present as a rise in serum transaminase levels, unexplained fever or bile leak. Doppler ultrasonography or angiography is used to confirm the diagnosis and urgent re-transplantation is usually required. Portal vein thrombosis presents more insidiously and does not usually require re-transplantation.

Biliary complications

Biliary leaks are now relatively uncommon and biliary stenosis is the more common problem. It usually occurs late and is managed by endoscopic dilatation and stenting; less often it is managed by surgical correction.

Paediatric liver transplantation

Until recently, the major factor limiting paediatric liver transplantation was the lack of donor livers of suitable size. However, as noted earlier, the development of techniques for using adult livers that have been reduced in size by cut-down techniques has greatly alleviated the problem. For small children the lateral segment of the left lobe is often used but the entire left lobe or the right lobe may also be used.

Outcome after liver transplantation

The outcome after liver transplantation depends on the underlying disease; the best results are seen in patients with chronic liver disease (Fig. 77.24). Patients undergoing transplantation as a result of acute liver failure have a higher mortality rate in the early post-transplant period because of multi-organ failure, but those who recover have very good long-term liver allograft survival. Conversely, patients transplanted for tumour have a very good early outcome but ultimately fare less well because of recurrence. Patients receiving a liver transplantation following hepatitis B or C infection may develop graft failure as a result of recurrent viral disease but the availability of improved anti-viral therapy has helped reduce this problem.

SMALL BOWEL TRANSPLANTATION

Progress in small bowel transplantation has lagged behind that of other types of solid organ transplantation but it is now a well-established therapy for highly selected recipients. Intestinal transplants stimulate a particularly strong graft rejection response, probably because the small intestine contains large amounts of

lymphoid tissue. Moreover, ischaemia and rejection increase intestinal permeability and allow translocation of bacteria from the lumen of the bowel. Added to this, the operation is often complex and is made technically difficult because of repeated previous abdominal surgery. Consequently, graft rejection and infection remain major problems and the results obtained are inferior to those obtained after other types of organ transplantation. Small bowel transplantation is a treatment option for patients with intestinal failure as defined by the loss of intestinal function to the extent that long-term parenteral nutrition is required. Intestinal failure may result from short bowel syndrome after resection of the intestine or from intestinal dysfunction. Indications for transplant include the following:

- intestinal atresia;
- necrotising enterocolitis;
- volvulus;
- disorders of motility;
- mesenteric infarction;
- Crohn's disease;
- trauma;
- desmoid tumours.

Because of the substantial risks associated with small bowel transplantation, the procedure should be considered only for those patients in whom long-term total parenteral nutrition (TPN) has failed, usually because venous access has become impracticable or because of frequent life-threatening line sepsis. The need for small bowel transplantation is estimated at around 0.5–1.0 patient per million of the population and around 50% of cases are children.

Small bowel transplantation may be carried out as an isolated procedure, performed together with a liver transplant or undertaken as a component of a multivisceral transplant. When possible, isolated small bowel transplantation is undertaken because patient survival is higher.

A small bowel transplant from a deceased donor comprises the entire small bowel, but it is no longer considered advisable to include the ascending colon in the graft. The superior mesenteric artery of the graft (with an aortic patch) is anastomosed to the recipient aorta, and the superior mesenteric vein is anastomosed to the inferior vena cava or to the side of the portal vein. The proximal end of the small bowel graft is anastomosed to the

Figure 77.24 Outcome after liver transplantation according to the initial liver disease. Patients transplanted for acute liver disease have a higher early mortality but good long-term outcome. Patients transplanted because of liver tumour have a good initial outcome but survival continues to decline progressively (data obtained from the European Liver Transplant Registry, 2007).

recipient jejunum or duodenum. The distal end of the graft is anastomosed to the side of the colon (with a loop ileostomy) or is fashioned as an end-ileostomy. A gastrostomy tube (to overcome delayed gastric emptying) and a feeding jejunostomy tube are inserted.

About one-half of all patients who require small bowel transplantation have cholestatic liver disease secondary to TPN and require combined liver and small bowel transplantation. Cholestatic liver disease due to TPN is especially common in children. When combined liver and small bowel transplantation is carried out, the two grafts are transplanted *en bloc*. The donor aorta is fashioned into a conduit including the superior mesenteric and coeliac arteries and anastomosed to the recipient aorta. The portal vein anastomosis is as for isolated liver transplantation.

Multivisceral or 'cluster' transplants may be necessary in the case of large desmoid tumours when excision of both the small bowel and adjacent organs is required, when there has been extensive thrombosis of the splanchnic vessels and for generalised disorders of gastrointestinal motility.

The 1-year graft survival rate after small bowel transplantation is about 65% for both isolated small bowel transplantation and for combined liver and small bowel transplantation. After 3 years, the graft survival rate is around 45%. As already noted, however, patient survival is better after isolated small bowel transplantation than after combined liver and small bowel transplantation, when loss of the graft usually equates with death of the recipient. Most of the mortality after small bowel transplantation is due to sepsis and multi-organ failure. The risk of infection after small bowel transplantation is heightened by the additional requirements for immunosuppression to control graft rejection. This accounts for the relatively high incidence of lymphoproliferative disease (around 10%) observed in patients who have undergone small bowel transplantation. Because of the large amount of donor lymphoid tissue transplanted, GVHD may be an added complication. However, despite the hazards, small bowel transplantation offers patients with intestinal failure a chance to lead an active life, free from the constraints of long-term nutritional support.

THORACIC ORGAN TRANSPLANTATION

Heart transplantation

Barnard performed the first human heart transplant in Cape Town, South Africa, in 1967. The operation was based on the experimental work of Lower and Shumway at Stanford, and Shumway subsequently went on to pioneer successful cardiac transplantation in the clinic. Heart transplantation is now considered an effective treatment for selected patients with end-stage cardiac failure. The most common indications are ischaemic heart disease and idiopathic cardiomyopathy, but other indications include valvular heart disease, myocarditis and congenital heart disease.

Transplantation is considered only in patients with end-stage heart disease that has failed to respond to all other conventional

therapy and when predicted survival without transplantation is only 6–12 months. Transplantation is usually limited to patients under the age of 65 years who do not have irreversible damage to other organ systems. The preoperative assessment is rigorous and measurement of pulmonary vascular resistance is mandatory because, when it is raised, perioperative mortality is high.

Technique of heart transplantation

A median sternotomy is performed and the patient is given systemic heparin, placed on cardiopulmonary bypass and cooled to 29°C. After cross-clamping the aorta, the recipient heart is excised at the mid-atrial level. The donor heart is then prepared and the left atrium is opened by making incisions (Fig. 77.25) in the posterior wall between the orifices of the pulmonary veins to create an atrial cuff. The left and then right atrial anastomoses are performed and the pulmonary and aortic arterial anastomoses are then completed (Fig. 77.26). The patient is then rewarmed and weaned from cardiopulmonary bypass. Occasionally, heterotopic cardiac transplantation is undertaken, when the donor heart is placed adjacent to and augments the recipient's own heart.

Heart–lung, single-lung and double-lung transplantation

Pulmonary transplantation became a clinical reality when Reitz performed the first successful combined heart–lung transplant in 1981. Combined heart–lung transplantation is still sometimes performed, usually in patients with pulmonary vascular disease in

Figure 77.25 Recipient cardiectomy. After median sternotomy, the recipient is placed on cardiopulmonary bypass. Venous cannulae for bypass are sited in the superior vena cava (SVC) and inferior vena cava (IVC) via punctures in the right atrium (RA), and oxygenated blood is returned via a cannula in the ascending aorta (Ao). The diseased recipient heart is excised, leaving behind cuffs of right and left atria. IPV/SPV, inferior/superior pulmonary veins; LA, left atrium; PA, pulmonary artery (courtesy of J. Dunning).

Christiaan Neethling Barnard, 1922–2001, Professor of Cardiac Surgery, The University of Cape Town, Cape Town, The Republic of South Africa.
Richard Rowland Lower, Contemporary, Thoracic Surgeon, Richmond, VA, USA.

Bruce Arnold Reitz, Thoracic Surgeon, Stanford University School of Medicine, Palo Alto, CA, USA.

Figure 77.26 Implantation of the donor heart. The donor left atrium is opened by an incision connecting the four pulmonary veins, excising the central portion. The left atrial anastomosis is performed, starting at the lateral wall of the donor and continuing inferiorly and superiorly, concluding with the inter-atrial septum. The right atrial anastomosis is performed, matching the recipient atrium by an incision towards the donor right atrial appendage (dotted line), which avoids the sinus node at the cavoatrial junction. Finally, the pulmonary artery and aortic anastomosis are completed. Abbreviations as for Fig. 77.25 (courtesy of J. Dunning).

whom there is cardiac dysfunction because of congenital (e.g. Eisenmenger's syndrome, in which the left-to-right shunt is reversed because of pulmonary hypertension) or acquired cardiac dysfunction. For most patients with end-stage pulmonary disease, however, single- or double-lung transplantation has now replaced heart–lung transplantation. Lung transplantation is more economical in terms of organ use although, if heart–lung transplantation is undertaken for isolated respiratory disease, the healthy native heart can be used for transplantation, the so called 'domino procedure'. Heart–lung transplantation is performed through a median sternotomy, taking particular care to avoid injury to the phrenic, vagus and recurrent laryngeal nerves during excision of the recipient heart and lungs. The recipient right atrium and aorta are divided as for orthotopic cardiac transplantation and the donor heart–lung block readied for implantation, incising the right atrium from the divided inferior vena cava. An end-to-end tracheal anastomosis is performed and the right atrial and aortic anastomoses are performed as for cardiac transplantation.

Single- and double-lung transplantation are effective therapies for selected patients with end-stage chronic lung disease, in whom declining lung function limits life expectancy despite optimal medical therapy. Common indications are pulmonary fibrosis, pulmonary hypertension, emphysema and cystic fibrosis. Single-lung transplantation can be performed for pulmonary fibrosis. Single-lung transplantation is performed through a posterolateral thoracotomy and double-lung transplantation through a bilateral thoracotomy or median sternotomy. During lung transplantation, the donor pulmonary veins on a left atrial cuff are anastomosed to the recipient left atrium. Next, the bronchial anastomosis and the pulmonary arterial anastomosis are completed. Cardiopulmonary bypass is usually required if pulmonary hypertension is

present. Dehiscence of the airway anastomosis used to be common after heart–lung and lung transplantation, but improvements in organ preservation and surgical technique have dramatically reduced the incidence of this often fatal complication to < 5%. Late airway stenosis at the bronchial anastomosis because of ischaemia occurs in around 10% of bronchial anastomoses and is treated by dilatation.

Outcome after thoracic organ transplantation

The 1- and 5-year graft survival rates after heart transplantation are around 85% and 70% respectively. The results after heart–lung and lung transplantation are less good, with 1-year graft survival rates of around 75% and 5-year survival rates of around 40%.

FUTURE PROSPECTS

The two major problems in organ transplantation are:

- chronic graft rejection and the side-effects of non-specific immunosuppression;
- the shortage of organs for transplantation.

New immunosuppressive agents that have fewer or different agent-specific side-effects from existing therapies are likely to enter clinical practice and there is continuing research into the development of non-invasive biomarkers (in urine or blood) that will allow early diagnosis of graft rejection. A longstanding goal in organ transplantation has been the development of strategies for inducing specific immunological tolerance. Transplantation tolerance would eliminate the need for long-term non-specific immunosuppressive agents, leaving the immune system intact for defence against infection. It has long been possible to induce transplant tolerance in experimental animals with a variety of preconditioning regimens that often involve pretreatment schedules using donor bone marrow cells or donor antigen. So far, however, there is no clinically applicable strategy for inducing transplant tolerance.

The demand for human organs for transplantation is so great that deceased donors cannot ever satisfy it. Many consider that the solution is to perfect xenotransplantation, and there is general agreement that the pig is the most suitable source of xenogeneic organs. However, all humans have pre-formed antibodies directed against carbohydrate antigens expressed by pig organs and these cause hyperacute rejection. The dominant carbohydrate antigen responsible is gal-1,3- α gal. Progress has been made towards circumventing hyperacute xenograft rejection and pigs that have been genetically engineered not to express the gal-1,3- α gal antigen have been produced. However, organs from genetically modified pigs are still rejected within a few weeks by primates, despite the use of potent immunosuppressive agents. In addition to the complex immunological problems posed by xenotransplantation there is a risk that pig organs may transmit infectious agents, and there is particular concern about the risks posed by porcine endogenous retrovirus (PERV). Lastly, there are unanswered questions regarding the extent to which pig organs are able to fulfil the physiological demands required of them after transplantation into a human.

Finally, looking to the future, there is optimism that human pluripotent stem cells may ultimately provide a source of tissue transplants for treating a wide range of diseases. Attempts are now under way to define the cell signals needed to guide human

embryonic and adult stem cells to differentiate *in vitro* into functional tissue of the desired cell type. These include insulin-producing cells, cardiac myocytes and neuronal tissue. Although cell transplantation is the initial goal, by combining the developments in stem cell medicine with those taking place in tissue engineering and biomaterials it may one day be possible to engineer more complex vascularised grafts for transplantation (Summary box 77.12).

Summary box 77.12

Future developments in transplantation

- Novel immunosuppressive agents
- Development of non-invasive biomarkers for monitoring rejection
- Strategies for inducing donor-specific immunological tolerance
- Xenotransplantation
- Stem cell medicine and tissue engineering

Common instruments on the general tray

This is a list of common instruments on the general tray with some information how they are used and about the people associated with them.

Langenbeck retractor

× 0.21 (approx.)

This small general purpose retractor is useful for holding open wounds, such as in an open appendicectomy. They are often used in pairs (one in each of the assistant's hands). They stay in position best if the handles are lifted slightly so that the tips lock in under the fascia. Bernhard Rudolf Konrad von Langenbeck (1810–1887) was Professor of Surgery successively at Keil and Berlin, Germany. He performed the first internal fixation of a femoral neck fracture in 1850.

Morris retractor

× 0.20 (approx.)

This is a big retractor which is useful for giving maximum exposure in large incisions such as those used in the abdomen. It can be used to improve visibility off to one side of an incision (by pulling firmly in that direction) so is valuable during the initial phase of a laparotomy. Sir Henry Morris (1844–1926) was a surgeon at the Middlesex Hospital, London, UK.

Deaver retractor

× 0.15 (approx.)

This retractor is specifically designed for holding the liver up out of the way during a cholecystectomy. It needs to be used carefully to avoid damaging the liver. Some surgeons protect the liver with an abdominal pack before placing the blade on top. John Blair Deaver (1855–1931) was Professor of Surgery at the University of Pennsylvania Medical School, Philadelphia, USA. He also described a paramedian incision for appendicectomy.

McIndoe scissors

× 0.42 (approx.)

Scissors are used by surgeons to perform dissection respecting anatomical planes. The closed blades are inserted into a fascial plane, and then gently opened. The tissue to be divided can then be seen clearly and divided without risk of damage to vital structures. Sir Archibald Hector McIndoe (1900–1960) was a plastic surgeon at St Bartholomew's Hospital, London, and the Queen Victoria Hospital, East Grinstead, UK. He was born in New Zealand (cousin of Harold Gillies) and became a consultant plastic surgeon to the RAF during WW2. He supervised the rehabilitation of badly disfigured airmen who later formed the Guinea Pig Club.

DeBakey forceps

× 0.21 (approx.)

These forceps allow the surgeon to grasp tissues firmly while minimising damage to the tissue held in the jaws of the forceps. They are useful for holding vessel walls in vascular surgery. Michael Ellis DeBakey (born 1908) was Professor of Surgery at Baylor University College of Medicine, Houston, USA. He was the first to successfully implant an artificial heart, and he also performed the first successful carotid endarterectomy.

Gillies forceps

× 0.29 (approx.)

These forceps have teeth and are ideal for holding tough tissues such as skin. Sir Harold Gillies (1882–1960) was a plastic surgeon at St Bartholomew's Hospital, London, UK. He was born in New Zealand (cousin of Archibald McIndoe) and became one of the founders of British plastic surgery. He originated the tubed pedicle flap.

Adson forceps

× 0.23 (approx.)

These forceps are non-toothed, and so are ideal for holding delicate tissues such as bowel. Alfred Washington Adson (1887–1951) was Professor of Neurosurgery at the Mayo Clinic, Rochester, USA. He was one of the first to use sympathectomy for the treatment of hypertension, and cervical sympathectomy for Raynaud's syndrome.

Allis forceps

× 0.25 (approx.)

These forceps are used to hold soft tissues for a long period while minimising tissue damage. Using the ratchet they can be locked on to tissue such as bowel and can be used to provide gentle traction. Oscar Huntington Allis (1836–1921) was a surgeon at the Presbyterian Hospital, Philadelphia, USA.

Spencer Wells forceps

× 0.20 (approx.)

These were one of the first ratchet forceps ever designed and are still very useful. They are often used in pairs for clamping an artery before dividing it. The cut ends of the artery are then tied off, and the forceps removed (carefully!). Sir Thomas Spencer Wells (1818–1897) was a surgeon at the Samaritan Free Hospital for Women and Children, London, UK. He was one of the earliest surgeons to make use of anaesthetics in operation.

 von Recklinghausen, Friedrich Daniel, 474,
 597, 732, 801
 von Recklinghausen's disease
 (neurofibromatosis type 1), 95t, 597,
 631
 phaeochromocytoma, 813
 primary hyperparathyroidism, 801
 von Recklinghausen syndrome, 732
 intradural spinal tumours, 474
 von Rosen, Sophus, 569
 von Volkmann, Richard, 450, 563
 von Willebrand, Erik Adolf, 679, 1157
 von Willebrand's disease, angiodysplasia,
 1157
 V to Y advancement flaps, 403f, 404
 Wada, John A, 639
 Waddell's sign, spine examination, 469
 Waldeyer-Hartz, Heinrich Wilhelm
 Gottfried, 702, 735, 1219
 Waldeyer's ring, 702–703, 702f
 Wallace, David Mitchell, 1339
 Waller, Augustus Volney, 25
 Wallerian degeneration, nerve injury, 25
 Walsh, Patrick C, 1358
 Walsham, William Johnson, 333
 Wangensteen, Own Harding, 1195
 warfare injuries *see* blast injuries; disaster
 surgery
 warfarin
 cessation, endoscopy, 154–155
 deep vein thrombosis, 938
 preoperative preparation, 190
 Warren, John Collins, 194
 Warren, J Robin, 1051
 Warthin, Aldred Scott, 176, 762
 water-hammer pulse, aortic regurgitation,
 866
 Waterhouse, Rupert, 812
 Waterhouse–Friderichsen syndrome, 812
 water intoxication, prostatectomy, 1352
 Watkinson, John Carmel, 796
 Watson, James Dewey, 90
 Watson fundoplication, GORD, 1021
 Weber, Frederick Parkes, 618, 941, 950
 Weber-Liel, Friedrich E, 688
 Weber tuning fork test, ear examination,
 688
 web space, hand/wrist infections, 508
 wedge fracture(s), 356f
 subaxial cervical spine trauma, 319
 wedge resection, typhoid perforation, 69,
 69f
 Wegener, Friedrich, 678, 765
 Wegener's granulomatosis, nasal septal
 perforation, 679
 weight *see* body weight
 Weil, Adolph, 1105
 Weinburg, Robert A, 90
